sulfisoxazole (Gantrisin)	PO: Loading dose: 2–4 g Maintenance dose: 1–2 g qid (max: 12 g/day)	
trimethoprim (Primsol)	PO: 100–200 mg daily	
trimethoprim-sulfamethoxazole (TMP-SMZ) (Bactrim, Septra)	PO: 160 mg TMP/800 mg SMZ bid IV: 8–10 mg/kg/day TMP, q6–12h infused over 60–90 min	
Urinary Antiseptics and Miscellaneous Drugs		
fosfomycin (Monurol)	PO: 3-g sachet dissolved in 3–4 oz of water as a single dose	*Nausea, diarrhea, back pain, headache* Anaphylaxis, superinfections
meropenem and vaborbactam (Vabomere)	IV: 2 g meropenem and 2 g vaborbactam tid	*Headache, phlebitis, infusion site reactions, diarrhea* Anaphylaxis, seizures
methenamine hippurate (Hiprex) or mandelate (Mandelamine)	PO: 1 g bid (hippurate) or 1 g qid (mandelate)	*Nausea, vomiting, diarrhea, increased urinary urgency* Anaphylaxis, crystalluria
nitrofurantoin (Furadantin) and nitrofurantoin macrocrystals (Macrobid, Macrodantin)	PO: 50–100 mg qid (max: 7 mg/kg/day)	*Nausea, vomiting, anorexia, dark urine, rash* Anaphylaxis, superinfections, hepatic necrosis, interstitial pneumonitis, SJS, hemolytic anemia

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

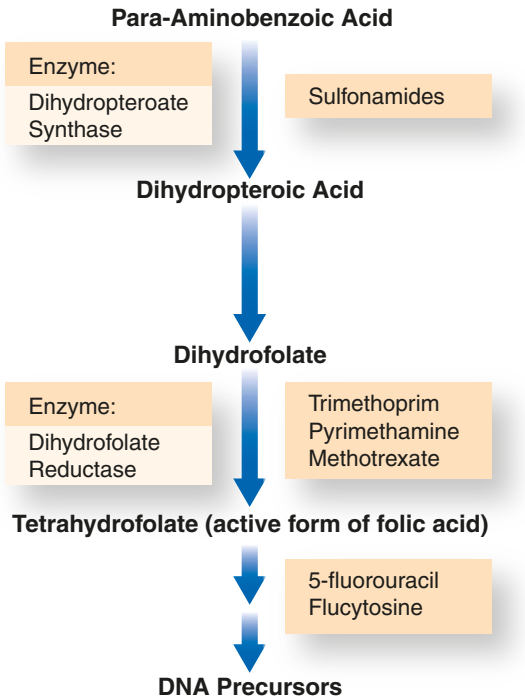

Figure 50.1 Drug inhibition of folic acid metabolism. Drugs inhibit multiple steps in the metabolic pathway leading to folic acid.

drug trimethoprim inhibits the enzyme in step 3. Note how closely the sulfonamides resemble the precursor molecule, **para-aminobenzoic acid (PABA)**, in Figure 50.2. It is easy

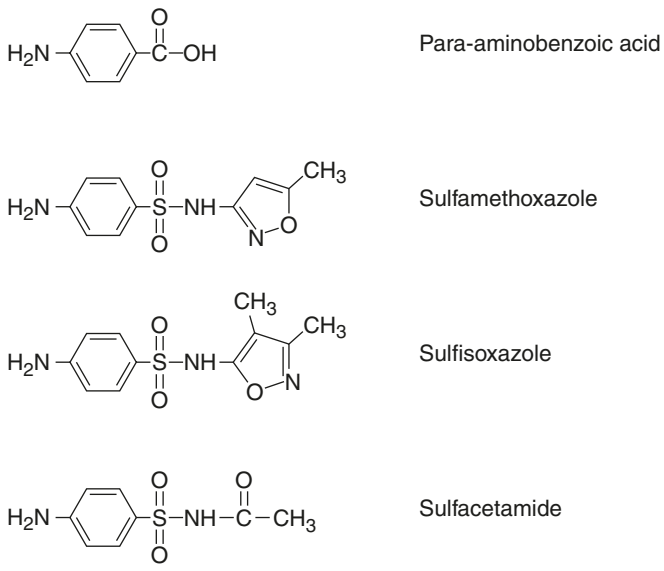

Figure 50.2 Chemical similarities between para-aminobenzoic acid and sulfonamides.

to see how an enzyme could confuse the two similar molecules. Once the enzyme binds to the sulfonamide, however, folic acid synthesis stops, and bacterial growth slows. This explains why these drugs are bacteriostatic; they slow bacterial growth rather than kill the cells.

The widespread use of sulfonamides for over 60 years resulted in a substantial number of resistant strains. The

mechanism of acquired resistance to sulfonamides is likely a mutation in the enzyme performing step 1 of folic acid synthesis. Mutant enzymes can still bind to PABA but can no longer bind to sulfonamides. Resistance to one sulfonamide often confers resistance to all members of this class.

In addition to resistance, several other factors have led to a significant decline in the use of sulfonamides. The development of the penicillins, cephalosporins, and macrolides gave practitioners larger choices of drugs, some of which exhibited an improved safety profile over the sulfonamides. Approval of the combination antibiotic TMP-SMZ marked resurgence in the use of sulfonamides in treating UTIs. Decades of widespread use, however, have now resulted in a large number of strains resistant to TMP-SMZ. In communities with high resistance rates, TMP-SMZ is no longer a first-line drug, unless C&S testing determines it to be the most effective drug for the specific uropathogen.

Sulfonamides are classified by their absorption and excretion characteristics. These subclasses include:

- Oral (PO) drugs that are readily absorbed
- PO drugs that are not absorbed
- Topical drugs.

Medications that are readily absorbed after a PO dose include sulfisoxazole (Gantrisin), sulfadiazine, and TMP-SMZ. These sulfonamides are distributed to most tissues in the body, and the amount of plasma protein binding may be significant. Once hepatic enzymes convert these drugs to inactive metabolites, the drugs are excreted rapidly by the kidney. Sulfadoxine is an exception, with an exceptionally long half-life of 7 to 9 days. For malarial prophylaxis, it is combined with pyrimethamine and marketed as Fansidar.

One sulfonamide comprises the second subclass: drugs that are given PO but undergo no significant absorption. Sulfasalazine (Azulfidine) remains unabsorbed in the alimentary canal, where it is used to treat intestinal infections and mild to moderate ulcerative colitis. Some systemic toxicity may be observed with this drug, because one of its metabolic products is absorbed from the intestine and enters the systemic circulation.

The third subclass includes topical sulfonamides. Silver sulfadiazine (Silvadene, Thermazene) is used for the prophylaxis and treatment of topical infections resulting from wounds or burns. Mafenide (Sulfamylon) is another drug in this class applied topically over burn wounds. Topical sulfonamides may be absorbed across denuded skin, resulting in significant plasma drug levels.

Sulfacetamide (Cetamide) is available as a solution or ointment to treat conjunctivitis and other external eye infections. Blephamide is a combination drug with sulfacetamide and prednisolone indicated for ocular infections that have inflammation as a significant component.

CONNECTIONS: Patient Safety

Trimethoprim-Sulfamethoxazole (Bactrim, Septra)

The nurse is preparing to administer TMP-SMZ (Bactrim, Septra) to a patient with a UTI. Before giving the medication, the nurse reviews the patient's chart. The nurse notices that the patient is afebrile with a normal pulse, blood pressure, and respiratory rate. The most recent culture indicates a decline in the number of bacteria present in the urine. Other information found in the medical record indicates that the patient routinely takes medication for hypertension and arthritis. The patient has also reported allergies to chocolate and thiazide diuretics. Should the nurse give the medication as prescribed?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Adverse Effects

In general, the sulfonamides are safe drugs; however, some adverse effects may be serious. Of most concern are adverse effects on the urinary tract, hypersensitivity reactions, and blood abnormalities. Nausea, vomiting, and anorexia may also occur.

Drugs in this class must be used with caution in patients with chronic kidney disease (CKD). Sulfonamides have a low solubility, which may cause **crystalluria**, crystals that form in the urine and potentially obstruct the kidneys or ureters. The risk is higher in dehydrated patients and when urine pH is abnormally low. To decrease the possibility of crystalluria, fluids in amounts up to 3000 mL/day should be encouraged to achieve a urinary output of 1500 mL in 24 hours.

Although not common, sulfonamides can cause potentially fatal blood abnormalities such as aplastic anemia, acute hemolytic anemia, and agranulocytosis. Baseline and periodic blood laboratory values should be assessed to prevent the development of anemia or other hematologic disorders. Patients with preexisting myelosuppression should be monitored carefully during therapy, because this increases the risks associated with drug-induced bone marrow depression.

Hypersensitivity to sulfa drugs is well documented. These drugs cause a number of dermal reactions ranging from urticaria to photosensitivity and exfoliative dermatitis. Patients may develop fever and malaise. Cross sensitivity exists with diuretics, such as acetazolamide (Diamox) and the thiazides, and with sulfonylurea antidiabetic drugs. These medications should be avoided in patients with a history of hypersensitivity to sulfonamides because this can induce Stevens–Johnson syndrome (SJS). At the first signs of rash, patients should be instructed to stop taking the drug and contact their healthcare provider.

Most sulfonamides readily cross the placenta and may reach sufficiently high levels to cause adverse effects

in the fetus. Sulfonamides are contraindicated during lactation, because they enter breast milk. They are contraindicated for infants less than 2 months of age and for pregnant patients near term, because sulfonamides displace bilirubin from plasma proteins. The displaced, free bilirubin is toxic to the brain and causes kernicterus, a serious type of jaundice.

PROTOTYPE DRUG **Trimethoprim-Sulfamethoxazole (Bactrim, Septra)**

Classification **Therapeutic:** Antibacterial
Pharmacologic: Folic acid inhibitor, sulfonamide

Therapeutic Effects and Uses: Approved in 1973, TMP-SMZ is a folic acid inhibitor containing a fixed-dose combination of trimethoprim (TMP) and sulfamethoxazole (SMZ), a sulfonamide. The drug is commonly used for UTI prophylaxis and in the pharmacotherapy of complicated and uncomplicated UTI, depending on the sensitivity of the specific uropathogen. It is also approved for the treatment and prophylaxis of *P. jiroveci* pneumonia, *Shigella* infections of the small bowel, traveler's diarrhea due to *E. coli*, and for acute exacerbations of chronic bronchitis due to *Streptococcus pneumoniae* or *H. influenzae*. The drug is used off-label for many other indications, depending on the sensitivity of the microbe. PO and IV formulations are available.

Mechanism of Action: Both SMZ and TMP are inhibitors of the bacterial metabolism of folic acid. Each drug inhibits a separate enzyme in the metabolic pathway, creating a synergistic combination: A greater bacterial kill is achieved by the fixed combination than would be achieved with either drug used separately. Because humans obtain folate in their diets, these medications are selective toward bacterial folate metabolism.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Readily absorbed
Distribution	Widely distributed to all body fluids, including cerebrospinal fluid (CSF); crosses the placenta; secreted in breast milk; protein binding is 70% (SMZ) and 44% (TMP)
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	PO: 1–4 h
Duration of action	Half-life: 8–10 h (TMP) and 10–13 h (SMZ)

Adverse Effects: Nausea and vomiting are the most common adverse effects of TMP-SMZ therapy. These normally diminish with time but may require treatment or cause discontinuation of therapy. Hypersensitivity is relatively common and usually manifests as skin rash, pruritus, and fever. Severe hypersensitivity reactions such as anaphylaxis, SJS, epidermal necrolysis, agranulocytosis, aplastic anemia, and allergic myocarditis have been reported. The drug should be discontinued at the first appearance of a skin rash. To prevent crystalluria and potential damage to tubular cells, it is important to maintain dilute urine during therapy to reduce the concentration of the drugs as they travel through the renal tubule. Due to the potential for photosensitivity, the patient should avoid direct sunlight during therapy.

Contraindications/Precautions: An allergy history should be taken prior to administration, because TMP-SMZ is contraindicated in patients with hypersensitivity to sulfites, sulfonamides, or chemically related drugs such as thiazide diuretics. TMP-SMZ is contraindicated in patients with folate-deficiency anemia, since a folic acid inhibitor would worsen this condition. This medication is contraindicated in patients with severe CKD because this is the primary route of drug excretion and the drug may accumulate to toxic levels in these patients. It should be used with caution in patients with hepatic impairment because the liver metabolizes TMP-SMZ. Trimethoprim decreases potassium excretion and is contraindicated in patients with hyperkalemia. Caution must be used when treating patients with acquired immunodeficiency syndrome (AIDS) because these patients have a greater incidence of serious adverse effects than others.

Drug Interactions: TMP and SMZ may enhance the effects of oral anticoagulants. Since methotrexate also interferes with folate metabolism, concurrent use with TMP-SMZ increases the risk of toxicity. TMP-SMZ exerts a potassium-sparing effect on the nephron and should be used with caution with diuretics such as spironolactone (Aldactone) to prevent hyperkalemia. TMP-SMZ may increase the hypoglycemic response to sulfonylureas due to displacement from protein-binding sites or inhibition of metabolism. **Herbal/Food:** Potassium supplements should not be taken during therapy, unless directed by the healthcare provider.

Pregnancy: Category C.

Treatment of Overdose: Acidification of the urine will increase the renal elimination of trimethoprim. If signs of bone marrow depression occur during high-dose therapy, 5 to 15 mg of leucovorin should be given daily.

Nursing Responsibilities: Key nursing implications for patients receiving TMP-SMZ are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Urinary Tract Infection.

Drugs Similar to Trimethoprim-Sulfamethoxazole (Bactrim, Septra)

Other orally absorbed sulfonamides include sulfadiazine, sulfisoxazole, and trimethoprim. Sulfadoxine-pyrimethamine (Fansidar) is used exclusively for treating malaria and is discussed in Chapter 53.

Sulfadiazine: Approved in 1941, sulfadiazine is a short-acting, oral sulfonamide that is given every 4 to 6 hours. It has a broad spectrum and is used for diverse infections, including UTI, nocardiosis, meningococcal meningitis, cerebral toxoplasmosis (in combination with pyrimethamine), and resistant malaria. Sulfadiazine is usually prescribed only when other, safer anti-infectives have failed to produce a therapeutic effect and C&S testing has determined the organism to be sensitive to the drug. Like other sulfonamides, hypersensitivity may be a major clinical limitation to therapy. Sulfadiazine is poorly soluble in urine and causes more crystalluria than other sulfonamides. Adequate fluid intake and frequent urinary testing are essential to avoid nephrotoxicity. Sulfadiazine carries a black box warning that it should be discontinued at the first sign of a skin rash due to the possibility for SJS. Sulfadiazine is pregnancy category C.

Silver sulfadiazine (Silvadene, Thermazene) is a topical cream indicated as an adjunct for the prevention and treatment of wound sepsis in patients with second- and third-degree burns. Adverse effects are rare when the cream is applied over small areas. However, when the drug is applied over large denuded areas, some of the topical medication is absorbed and systemic adverse effects may occur. Silver sulfadiazine is pregnancy category B.

Sulfisoxazole (Gantrisin): Like sulfadiazine, this drug is short acting and must be taken PO every 4 to 6 hours. Approved in 1948, indications include UTI, acute otitis media due to *H. influenzae*, nocardiosis, and malaria, in combination with other antimalarial drugs. It is sometimes preferred over other sulfonamides for UTI because it causes less crystalluria. Hypersensitivity is a common adverse effect. An ophthalmic formulation is available for the treatment of chlamydial conjunctivitis. A fixed-dose suspension of sulfisoxazole with erythromycin is available for the treatment of acute otitis media in penicillin-allergic patients. This drug is pregnancy category C.

Trimethoprim (Primsol): In addition to being part of the TMP-SMZ combination, trimethoprim is also available as monotherapy. Trimethoprim is approved to treat uncomplicated UTI and acute otitis media in children due to *S. pneumoniae* or *H. influenzae*. It has been used off-label for the treatment of traveler's diarrhea and for *Pneumocystis* pneumonia, in combination with either sulfamethoxazole or dapsone. Rash and pruritus are common adverse effects, and these may appear 1 to 2 weeks after therapy has begun. Some patients experience nausea, vomiting, and diarrhea. Trimethoprim is combined with polymyxin B in an ophthalmic solution for ocular infections. This drug is pregnancy category C.

Urinary Antiseptics

50.5 Urinary antiseptics are anti-infective drugs used exclusively for urinary tract infections.

As has been noted throughout this textbook, most medications are totally or partially excreted by the kidneys. The majority of drugs and their metabolites travel through the urinary system, producing little or no effect on the renal tubular cells or the other parts of the kidney. For the small class of drugs known as the urinary antiseptics, however, the urinary system is their target tissue. Being able to reach the urinary tract in high concentrations is essential to their therapeutic success.

Urinary antiseptics are given by the PO route for their antibacterial action in the urinary tract. While they do not reach high enough levels in the blood to be effective for systemic infections, the kidney concentrates the drugs; thus, their actions are specific to the urinary system. Urinary antiseptics reach therapeutic levels in the kidney tubules, and their anti-infective action continues as they travel to the urinary bladder.

The advantage of the urinary antiseptics is that they are able to treat local infections in the urinary tract without reaching high levels in the blood that might produce systemic toxicity. Although not considered first-line drugs for UTI, they serve important roles as secondary medications, especially in patients who present with infections resistant to TMP-SMZ or the fluoroquinolones.

PROTOTYPE DRUG **Nitrofurantoin (Furadantin) and Nitrofurantoin Macrocrystals (Macrobid, Macrodantin)**

Classification **Therapeutic:** Antibacterial
Pharmacologic: Urinary tract antiseptic

Therapeutic Effects and Uses: Nitrofurantoin is an older drug that is indicated for the treatment of uncomplicated acute cystitis, most commonly for the prophylaxis of recurrent UTI. Nitrofurantoin is active against the *E. coli*, *S. saprophyticus*, and many other strains of gram-positive and gram-negative aerobes. It is not effective against the *Pseudomonas*, *Proteus*, or *Serratia* species. It is not indicated for the treatment of pyelonephritis.

Nitrofurantoin is available in three formulations: a microcrystalline form (Furadantin), a regular release macrocrystalline form (Macrodantin), and a sustained release macrocrystalline form (Macrobid). The macrocrystalline form is more slowly absorbed than the microcrystalline form and produces fewer GI-related adverse effects.

CONNECTIONS: Complementary and Alternative Therapies

Cranberry

Description

Cranberry shrubs grow in diverse climates ranging from bogs to forests. The ripe berry is used for its potential medicinal effects.

History and Claims

Native Americans used the berries to treat wounds and to cure anorexia and other digestive complaints. In the early 1900s, it was noted that the acidity of urine increases after eating cranberries; thus began the belief that cranberry juice is a natural cure for UTIs.

Standardization

The herb is taken as juice or dried extract. Doses generally range from 120 to 4000 mL of juice or 400 to 500 mg of the extract daily.

Evidence

Cranberry contains a significant amount of vitamin C and other antioxidants that can promote health. A meta-analysis of the clinical research involving over 1600 patients concluded that cranberry products are indeed effective for preventing UTIs (Wang et al., 2012). Previously, it was thought that cranberry juice changed the pH of urine to become more acidic, discouraging bacteria growth. Recently, specific chemicals found in cranberry juice (e.g., proanthocyanidins) have demonstrated the ability to prevent the bacteria from sticking to the walls of the bladder. This makes it more difficult for the bacteria to colonize and reproduce. The juice should be 100% cranberry and not cocktail juice because that contains sugar, which enhances bacterial growth and may be contraindicated in patients with diabetes. Some individuals may prefer to take cranberry capsules, which are available at most drug stores. Studies assessing the effectiveness of cranberry capsules in preventing UTIs in vulnerable older adults living in long-term care facilities showed that the use of cranberry extract capsules during the postoperative period reduced the rate of UTIs by half (Foxman, Cronenwett, Spino, Berger, & Morgan, 2015).

Cranberry should be used cautiously by people who take anticoagulants such as warfarin (National Center for Complementary and Integrative Health, 2016). GI intolerance and weight gain from extra caloric intake from the juice seem to be the dominant reasons for discontinuing the cranberry product.

Despite being approved by the FDA in 1953, development of resistance has not been a significant problem. The broad-based mechanism of action may explain the relative lack of acquired bacterial resistance to nitrofurantoin. Multiple mutations at diverse locations of the bacterial chromosome would be necessary for a bacterium to acquire such resistance. Cross resistance with other antibiotics is very rare, if it occurs at all.

Mechanism of Action: Nitrofurantoin acts by several unique mechanisms. When bacteria break down nitrofurantoin, the drug is converted to highly reactive intermediates. These intermediates attack bacterial ribosomal proteins. The drug inhibits bacterial protein synthesis, aerobic energy metabolism, DNA synthesis, RNA synthesis, and formation of the cell wall. Nitrofurantoin is bactericidal in the urine at therapeutic doses.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed
Distribution	Widely distributed to body fluids; crosses the placenta; secreted in breast milk; 60% bound to plasma proteins
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	30 min
Duration of action	Half-life: 20 min

Adverse Effects: Nitrofurantoin has the potential to produce many adverse effects. The most frequent include hypersensitivity reactions, anorexia, headache, rash, nausea, and vomiting. Pulmonary toxicity is a serious adverse effect and may include interstitial pneumonitis, persistent cough, and pulmonary fibrosis. Chronic pulmonary toxicity may not appear until months or years after therapy has been completed. Hepatotoxicity is rare, though potentially fatal, and may include cholestatic jaundice, hepatic necrosis, or hepatitis.

Contraindications/Precautions: Because nitrofurantoin is excreted by the kidneys, significant renal impairment (creatinine clearance under 60 mL/min or significant elevated serum creatinine) is a contraindication. Successful treatment depends on achieving high amounts of drug in the urine, which will not occur in patients with oliguria or anuria. Because of the possibility of hemolytic anemia due to immature erythrocyte enzyme systems, the drug is contraindicated in pregnant patients or in neonates less than 1 month of age.

This drug should be used with caution in patients with preexisting pulmonary disease, and pulmonary function should be closely monitored throughout therapy. Although rare, reports have cited diffuse interstitial pneumonitis or pulmonary fibrosis as causes of death in patients receiving nitrofurantoin.

Nitrofurantoin should be used with caution in patients with preexisting hepatic disease. The drug should be

discontinued immediately if changes are noted in liver function tests.

Drug Interactions: Nitrofurantoin should not be given with antacids containing magnesium because absorption will be decreased. Concurrent administration with fluoroquinolones may result in antagonism and a decreased drug effect. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Adequate fluid intake should be provided to ensure renal excretion of the drug. In extreme cases, dialysis may be of value in removing nitrofurantoin.

Nursing Responsibilities: Key nursing implications for patients receiving nitrofurantoin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Urinary Tract Infection.

Drugs Similar to Nitrofurantoin (Furadantin) and Nitrofurantoin Macrocrystals (Macrobid, Macrodantin)

Other urinary antiseptics include fosfomycin and methenamine.

Fosfomycin (Monurol): Approved in 1996, fosfomycin is used for the treatment of uncomplicated UTI caused by susceptible strains of *E. coli* and *E. faecalis*. Technically classified as a cell wall inhibitor (see Chapter 47), it reaches high concentrations in the urine and bladder. Thus, it is sometimes called a bladder antiseptic. It is administered as a single PO dose. The most frequent adverse effects are diarrhea, headache, vaginitis, nausea, rhinitis, and pain. This drug is pregnancy category B.

Methenamine (Hiprex, Urex): Methenamine is an older drug approved in 1939 that is available as hippurate (Hiprex) or mandelate (Urex) salts. In the very acidic environment of urine, methenamine hippurate is metabolized to formaldehyde, a breakdown product toxic to microorganisms. The hippurate salt becomes an acid in the urine, thus providing an even greater environment (lower pH) for the generation of formaldehyde. At therapeutic doses, methenamine is a safe drug, although higher doses can result in dysuria, nausea, vomiting, and hematuria.

The only clinical application of methenamine is for prophylactic treatment of recurrent UTI, especially those with neurogenic bladder. Preventive therapy with methenamine is instituted after eradication of the infection by other appropriate anti-infectives. It is effective against most bacteria typically responsible for UTI. Urease-positive bacteria such as *Proteus* are resistant because they produce ammonia in the urine, which prevents the formation of formaldehyde. Concurrent therapy of methenamine with sulfamethoxazole is contraindicated because the combination promotes crystalluria. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Urinary Tract Infection

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic or renal disease, diabetes, AIDS, folic acid–deficiency anemia, and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of current infection, noting location, characteristics, presence or absence of urinary tract symptoms or of fever.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], C&S, urinalysis, and hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection and fever).
- Continue periodic monitoring of CBC, C&S, urinalysis, and hepatic and renal function as ordered.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, headache, or dizziness. Severe diarrhea, especially containing mucus, blood, or pus, or decreased urine output should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, or signs and symptoms of infection should begin to diminish after taking the first dose and continue to improve.)	• Teach the patient to complete the entire course of the antibacterial; do not share doses with other family members with similar symptoms; and return to the provider if symptoms have not resolved after an entire course of therapy. • Teach the patient to notify the provider if fever and signs and symptoms of infection increase after 3 days.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature, if fever is present. Immediately report undiminished fever, changes in level of consciousness (LOC), or febrile seizures to the healthcare provider. (Continued fever may be a sign of worsening infection, adverse drug effects, or antibiotic resistance.)	• Teach the patient to report a fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider. Immediately report febrile seizures, changes in behavior, or changes in LOC to the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor periodic laboratory work: renal function tests, CBC, urinalysis, and C&S as ordered. (Sulfonamides may be nephrotoxic. Periodic C&S tests may be ordered if infections are severe or are slow to resolve to confirm appropriate therapy.)	• Instruct the patient on the need for periodic laboratory work.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of the drug, and in patients with a history of allergy to thiazide diuretics. Continue to monitor the patient for up to 2 weeks after completing the antibacterial therapy. (Anaphylactic reactions are possible, particularly with the first dose of an antibacterial. Post-use, residual drug levels, dependent on the length of half-life, may cause delayed reactions.)	• Teach the patient to immediately report any itching, rashes, swelling, particularly of the face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing. • Instruct the patient with known antibacterial allergies to carry a wallet identification card or wear medical identification jewelry indicating the allergy.
• Continue to monitor for nephrotoxicity, e.g., diminished urine output, edema, or weight gain greater than 1 kg (2 lb) in 24 h. (Sulfonamides may require frequent monitoring to prevent adverse effects. Increasing fluid intake will help prevent drug accumulation in the kidneys and the development of urine crystals. **Lifespan:** Age-related physiologic differences may place the young child or older adult at greater risk for nephrotoxicity.)	• Teach the patient to immediately report any diminished urine output, visible swelling of feet or ankles, or weight gain greater than 1 kg (2 lb) in 24 h. • Advise the patient to increase fluid intake to 2–3 L/day.
• Monitor for development of superinfections, e.g., CDAD or PMC, fungal, or yeast infections. (Superinfections with opportunistic organisms may occur when normal host flora are diminished or killed by the antibacterial drug and no longer hold pathogens in check. Severe diarrhea may indicate the presence of CDAD or PMC, superinfections caused by *C. difficile*.)	• Instruct the patient to report any diarrhea that increases in frequency, amount, or contains mucus, blood, or pus. • Instruct the patient to consult the healthcare provider before taking any antidiarrheal drugs, which cause the retention of harmful bacteria. • Teach the patient to observe for changes in stool, white patches in mouth, whitish thick vaginal discharge, itching in the genital area, blistering itchy rash, and to immediately report severe diarrhea. • Teach the patient infection control measures such as frequent hand hygiene, adequate drying after showering or bathing, and to increase intake of live-culture dairy foods.
• Continue to monitor for dermatologic effects including red or purplish skin rash, blisters, or sunburn. Immediately report severe rashes, especially any associated with blistering. (Sulfonamides may cause significant dermatologic effects including SJS. Sunscreen and protective clothing should be used to prevent photosensitivity and photoallergic reactions.)	• Teach the patient to wear sunscreen and protective clothing for sun exposure and to avoid tanning beds. Immediately report any severe sunburn or rashes.
• Monitor for systemic effects in patients requiring topical sulfonamide creams for burns or infected wounds. (Large areas of treatment may result in excessive absorption of the drug, resulting in systemic effects. Stinging or burning may occur on application of the cream but does not indicate a systemic effect.)	• Teach the patient to report nausea, vomiting, abdominal cramping, diarrhea, headache, or dizziness while using the topical drug because these may indicate systemic absorption. • Instruct the patient in the appropriate application of the topical cream, applying a thin layer to the affected area, covered by a dry dressing.
• Monitor for anticoagulation effects if the patient is on warfarin. (Sulfonamides may increase the effects of warfarin, resulting in an increased risk of bleeding.)	• Teach the patient on warfarin to report any increase in bruising or bleeding. More frequent laboratory work may be needed.
• Monitor glucose levels more frequently in patients with diabetes on PO medication with sulfonylureas. Monitor potassium levels more frequently in the patient taking K-sparing diuretics or angiotensin-converting enzyme (ACE) inhibitors. (Sulfonamides exert a K-sparing effect on the kidney and may cause hyperkalemia in patients taking K-sparing diuretics or ACE inhibitors. The drugs also increase the hypoglycemic effect of sulfonylureas.)	• Instruct patients taking potassium-sparing diuretics (e.g., spironolactone [Aldactone]) or ACE inhibitors (e.g., lisinopril [Prinivil, Zestril]) to avoid foods high in potassium, e.g., fresh fruits such as strawberries and bananas; dried fruits such as apricots and prunes; vegetables and legumes such as tomatoes, beets, and dried beans; juices such as orange, grapefruit, or prune; and fresh meats; to avoid the use of salt substitutes (which often contain potassium salts); and to consult with a healthcare provider before taking vitamin and mineral supplements or specialized sports beverages. • Instruct patients with diabetes who rely on PO medication with sulfonylureas (e.g., glyburide [DiaBeta, Micronase]) to monitor their blood sugar more frequently and to be aware of subtle signs of possible hypoglycemia (e.g., nervousness, irritability). Any consistent changes in their blood sugar levels while on a sulfonamide antibiotic should be reported to the healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Do not share with other family members, and do not stop taking the medicine when starting to feel better.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking the antibacterial drug.
	  • Discard outdated medications or those no longer in use. Review the medicine cabinet twice a year for old medications (e.g., at the beginning and end of daylight saving time).

Understanding Chapter 50

Key Concepts Summary

50.1 Infections can occur in any portion of the urinary tract.

50.2 Choice of pharmacotherapy for acute urinary tract infection depends on the severity of the infection and the presence of comorbid conditions.

50.3 Infants, children, pregnant women, older adults, and those with recurring urinary tract infections require modifications to standard pharmacotherapy.

50.4 Sulfonamides are the traditional preferred drugs for urinary tract infections, but resistance limits their usefulness.

50.5 Urinary antiseptics are anti-infective drugs used exclusively for urinary tract infections.

CASE STUDY: Making the Patient Connection

Remember the patient "Amoya Deboissiere" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Amoya Deboissiere is a 32-year-old woman who has experienced frequent UTIs. Amoya is married with two children and works as a branch manager in a local bank.

In the clinic, Amoya's physical examination reveals the following findings: temperature, 38.4°C (101.2°F); pulse, 106 beats/min; respiratory rate, 18 breaths/min; and blood pressure 112/74 mmHg. She reports having a fever, chills, dysuria, frequency, urinary urgency, and suprapubic pain. Amoya also reports seeing a small amount of blood in the urine and the sensation of incomplete bladder emptying. She states that recently her urine has become cloudy and smells bad.

As you continue your interview with the patient, she states, "I can't believe I have another UTI. I had one just last month." The urinalysis reveals microscopic bacteriuria (greater than 10^5/mL). A urine culture is also collected during this visit, and the results will be reported within 48 hours. The patient's preliminary diagnosis is recurrent UTI, and she receives a prescription for trimethoprim-sulfamethoxazole (TMP-SMZ) (Bactrim, Septra).

Critical Thinking Questions

1. How should you respond to the patient's statements about the recurrent infections?
2. What health teaching regarding antibiotic therapy should you stress to this patient?
3. What information should you give patients about saving medications?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Dorothy Janes is an 80-year-old woman admitted to your unit for hypertension and a history of stroke with residual right-sided weakness. She is alert and oriented to person, time, and place but requires assistance with ambulation due to a history of falls. Her healthcare provider ordered Dorothy to be restricted to bedrest with bathroom privileges with assistance. When the patient's daughter comes to visit, she tells you that sometimes her mother has urinary incontinence due to her inability to walk to the bathroom by herself when the urge to urinate occurs. She wants to know if her mother can have a urinary catheter inserted to prevent accidents.

1. How would you respond to the daughter's request for her mother to have a urinary catheter inserted?
2. Brainstorm nursing actions that you could implement to avoid urinary incontinence for this patient.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. An older patient is prescribed sulfisoxazole (Gantrisin). Knowing that one of the major adverse effects of this drug is crystalluria, what should the nurse instruct the patient to do?
    1. Limit intake of foods high in calcium such as milk, cheese, and yogurt.
    2. Avoid changing positions (lying down, sitting, or standing) rapidly.
    3. Increase fluid intake to 2 to 3 L per day.
    4. Avoid consuming alcoholic beverages while taking this medication.

2. The nurse understands that which of the following is the main purpose of nitrofurantoin (Furadantin)?
    1. Prevent recurrent urinary tract infections.
    2. Relieve the pain associated with urinary tract infections.
    3. Promote effective urinary elimination and prevent stasis.
    4. Reduce pathogenic microorganisms specific to pyelonephritis.

3. The nurse is collecting health data from a patient with diabetes who has a urinary tract infection before starting an order for trimethoprim-sulfamethoxazole (Bactrim, Septra). Which questions asked by the nurse would be most important? (Select all that apply.)
    1. "Have you ever had migraine headaches?"
    2. "Are you allergic to any sulfa drugs?"
    3. "Do you empty your bladder before and after sexual intercourse?"
    4. "When was your last menstrual period?"
    5. "What drugs do you use to manage your diabetes?"

4. The nurse is providing the patient with discharge instructions concerning silver sulfadiazine (Silvadene) cream, which has been ordered to treat a significant skin infection. Which statement by the patient indicates to the nurse that the teaching session was effective?
    1. "I should use this cream on noninfected surfaces surrounding the infection to prevent additional infection."
    2. "If I experience stinging or burning, I should stop the drug and report that to my doctor immediately as a drug allergy."
    3. "If I experience any nausea that continues for more than 24 hours, I will contact my doctor."
    4. "I must avoid foods high in potassium."

5. The patient is to receive nitrofurantoin (Furadantin) for a urinary tract infection. A nurse should question the order for the patient with which condition?
    1. Pulmonary disease
    2. Diabetes
    3. Rheumatoid arthritis
    4. Angina and hypertension

6. A patient taking trimethoprim-sulfamethoxazole (Bactrim, Septra) develops a reddish-purplish papular rash surrounded by areas of erythema. The rash should be evaluated by the provider because it may indicate which skin condition?
    1. A fungal superinfection
    2. Viral skin eruptions
    3. Dermatologic toxicity including Stevens–Johnson syndrome
    4. Nonadherence with drug therapy

"A few years ago I lost my job and was unable to pay my rent. Since then, you could say that I'm homeless. I try to spend my nights at the shelter, but it is sometimes too crowded and I sleep on the street. About a month ago, I started feeling sick with a cough and fever. I'm exhausted and I have no energy."

Patient "Sam Myers"

Chapter 51
Pharmacotherapy of Mycobacterial Infections

Chapter Outline

- Types of Mycobacterial Infections
- Pathogenesis and Diagnosis of Tuberculosis
- Pharmacotherapy of Tuberculosis

  Antituberculosis Drugs

  PROTOTYPE *Isoniazid (INH), p. 922*
- Drugs for Leprosy

  PROTOTYPE *Dapsone (DDS), p. 929*
- Drugs For *Mycobacterium avium* Complex Infections

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the types of infections caused by mycobacteria.
2. Explain the pathogenesis of tuberculosis.
3. Describe how the pharmacotherapy of tuberculosis differs from that of bacterial infections.
4. Identify the most common drug regimens for treating tuberculosis.
5. Describe the pathogenesis and treatment of leprosy.
6. Describe the pathogenesis and treatment of infections caused by *Mycobacterium avium* complex.
7. Explain significant patient variables that must be considered for effective pharmacotherapy with antimycobacterial drugs.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients receiving pharmacotherapy for mycobacterial infections.

Key Terms

acetylation, 922
atypical mycobacterial infections (AMIs), 916
leprosy, 928
***Mycobacterium avium* complex (MAC), 916**
mycolic acid, 916
purified protein derivative (PPD), 918
rifamycin derivatives, 925
tubercles, 917
tuberculosis (TB), 916

Mycobacterial infections have been responsible for considerable human suffering and death throughout history. Mycobacterial disease was once called *consumption*, because of its ability to cause the body to waste away if left untreated. Although these infections usually respond to modern antiinfectives, therapy is prolonged, and resistant organisms have emerged as major clinical challenges. Despite the effective treatments available for the disease, tuberculosis (TB) still claims about 1.8 million lives each year worldwide. This chapter examines the pharmacotherapy of the three primary infections caused by mycobacteria.

PharmFACT

More than 9500 new cases of tuberculosis are reported each year in the United States. The incidence has decreased every year since 1992 (Centers for Disease Control and Prevention [CDC], 2016).

Types of Mycobacterial Infections

51.1 Several species of mycobacteria are important human pathogens.

The genus *Mycobacterium* consists of over 150 species of aerobic organisms that have in common a unique and complex lipid, **mycolic acid**, which covers their cell surfaces. This waxy coating, comprising up to 40% of the cell's weight, protects the mycobacterium, making it resistant to many disinfectants, including chlorinated water. About 10 are potential human pathogens.

The most common human mycobacterial pathogen is *Mycobacterium tuberculosis*. *M. tuberculosis* was identified as being the cause of TB by Robert Koch, a pioneering microbiologist, in 1882.

Nontuberculosis diseases caused by mycobacteria are known as **atypical mycobacterial infections (AMIs)**. These are considered opportunistic infections because they most often appear in people with compromised immune defenses. As the occurrences of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) rose during the 1980s and 1990s, the once-rare AMIs began to increase in frequency. In addition to HIV-AIDS, AMIs sometimes occur in patients with leukemia, or those who are undergoing antineoplastic or immunosuppressive therapy.

Mycobacterium leprae is an AMI that was identified as the causative agent of leprosy by G. A. Hansen in 1873. Leprosy is still sometimes called Hansen's disease, after its discoverer. The pharmacotherapy of leprosy is presented in Section 51.6.

Unlike *M. tuberculosis* and *M. leprae*, which have been described since antiquity, the characterization of ***Mycobacterium avium* complex (MAC)** infection is relatively recent. MAC usually arises as a secondary infection due to the immunosuppression caused by HIV-AIDS. MAC consists of two predominant species, *M. avium* and *Mycobacterium intracellulare*. The pharmacotherapy of MAC is discussed in Section 51.7.

Several other mycobacteria species can cause AMIs in humans, but their incidence is rare. *Mycobacterium kansasii* is the second most common cause of AMI in patients with HIV-AIDS. *Mycobacterium bovis* is usually acquired from the ingestion of raw, unpasteurized milk. Infections by *M. kansasii* or *M. bovis* cause respiratory symptoms that are almost identical to those of TB.

Mycobacterium scrofulaceum usually affects children 1 to 3 years of age. The target for this pathogen is the lymph nodes, and infants have mild symptoms, such as low-grade fever. Infections by *Mycobacterium chelonae* and *Mycobacterium abscessus* can cause a variety of clinical syndromes including respiratory disease, local skin disease, osteomyelitis, joint infections, and ocular disease. Surgical-site infections due to *M. chelonae* are well documented.

Pathogenesis and Diagnosis of Tuberculosis

51.2 Tuberculosis is a respiratory infection that exhibits both active and latent stages.

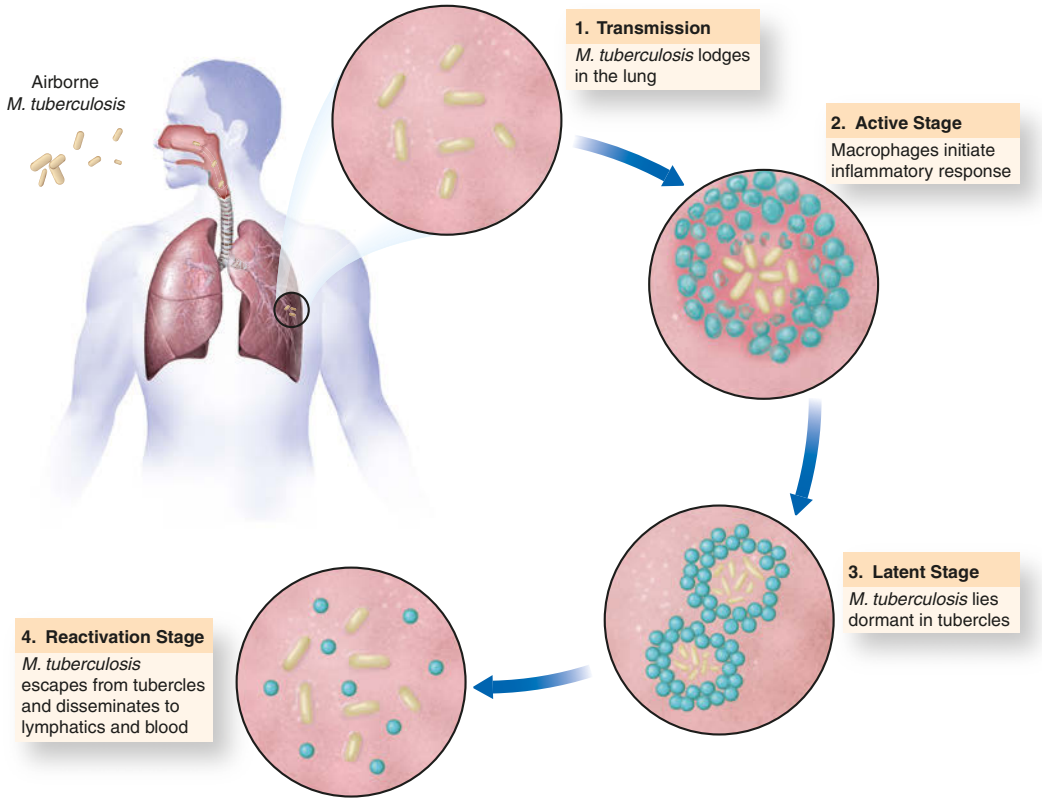
Tuberculosis (TB) is a highly contagious infection caused by the organism *M. tuberculosis*. Although TB has been a major killer throughout human history, its incidence declined in the United States during most of the 20th century. With the appearance of HIV-AIDS, however, the incidence of TB greatly increased from 1985 to 1992. As many as 20% of all patients with AIDS may develop active TB. High immigration rates from areas of the world where TB

is endemic also contributed to increases in this disease in the United States during this period.

Patients acquire *M. tuberculosis* by inhaling infected droplets through sneezing, coughing, and even talking. The organism can remain alive in these droplets for several hours outside the body. Unlike most species of mycobacteria, however, *M. tuberculosis* is not an environmental pathogen. It must reside in a living host to survive and reproduce. Left untreated, it is estimated that each infected individual will spread the disease by close contact to 10 to 15 other people over the course of a year (World Health Organization [WHO], 2017).

TB infections may be classified as primary or postprimary. A *primary* TB infection occurs when the patient inhales mycobacteria from an individual with an active TB infection. The slow-growing mycobacteria activate cells of the immune response, which isolate the microorganisms by creating a wall of macrophages around them. In an attempt to neutralize the mycobacteria, the macrophages ingest them. The pathogens, however, can grow *inside* the macrophages, despite the presence of an ongoing immune response. An acute respiratory infection develops, with symptoms presenting as pneumonia. In those with healthy immune systems, the primary infection lasts a few weeks and then subsides.

Although the macrophages are eventually successful in isolating the pathogen, granulomatous lesions called **tubercles** are formed in the lung. Tissue within the tubercles undergoes necrosis, causing cavities within the lung, which can be identified on chest radiographs. The mycobacteria often become dormant, lying inside the tubercles for an extended time. Indeed, people can retain latent, inactive mycobacteria in tubercles for an entire lifetime.



If the immune system becomes suppressed later in life, the dormant mycobacteria may enter a *postprimary* or *reactivation* stage. Once reactivated, *M. tuberculosis* can be disseminated throughout the body via the blood or lymphatic system. Lymph nodes and organs of the genitourinary system are the most common nonrespiratory sites, although infections of the bone marrow and liver are possible. Reactivation frequently occurs in patients with HIV-AIDS, those with poor nutritional status, and those who have terminal or debilitating diseases. The pathogenesis of TB is illustrated in Pharmacotherapy Illustrated 51.1.

PharmFACT

It is estimated that one-third of the world's population has latent TB. About 10% of the people with latent TB will develop symptoms during their lifetime (WHO, 2017).

Pharmacotherapy Illustrated 51.1

The Pathogenesis of Tuberculosis

Many patients remain asymptomatic following a primary TB infection. Indeed, only about 30% of those experiencing a primary TB infection will develop a latent infection and only 5% to 10% of these patients will progress to the reactivation stage (Bibbins-Domingo et al., 2016). In others, the disease progresses so gradually that the individual may not seek medical interventions until it becomes advanced. Symptoms of reactivation are nonspecific and include anorexia, weight loss, night sweats, fatigue, and low-grade fever. Cough becomes progressively worse, producing infectious sputum.

TB is diagnosed by several different means. Each of the following tests has advantages and drawbacks:

- **Tuberculin skin test (purified protein derivative [PPD]).** A positive PPD indicates the presence of memory T cells to *M. tuberculosis* but cannot determine whether the disease is active or latent. Once a positive PPD occurs, the test will always be positive due to the presence of these memory T cells, and the patient should never have subsequent PPDs because skin damage may result. Although inexpensive, the PPD test requires that the patient return to have the results examined.
- **Sputum culture.** Sputum is obtained to culture and identify *M. tuberculosis*. Unfortunately, samples may be negative even when the patient has confirmed TB. Because *M. tuberculosis* grows very slowly on cultured media, results may take 2 to 8 weeks to produce results.
- **Chest radiography.** Both active and chronic TB infections produce changes in the lung that can be identified on chest radiographs. X-ray evidence is not always specific to TB, however, and other diagnostic evidence is needed to confirm the disease. Annual chest x-rays are often used to exclude active TB in patients who exhibit positive PPDs.
- **Nucleic acid amplification tests.** Diagnostic laboratory tests such as the Amplified *Mycobacterium Tuberculosis* Direct Test can identify the presence of *M. tuberculosis* RNA in a sample in 2 to 4 hours. Because these tests are rapid, they allow for earlier treatment of infected patients.
- **Interferon gamma release assay (IGRA).** The IGRA is a newer TB screening procedure that measures the response of the immune system to a sample of the patient's blood. Large amounts of interferon released by the immune cells during the IGRA test suggest a TB infection. Test results are ready in about 24 hours.

CONNECTION Checkpoint 51.1

From what you learned in Chapter 42, identify immunosuppressant drugs that may cause TB to enter the reactivation stage in a patient who is receiving pharmacotherapy with these drugs. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Tuberculosis

51.3 The pharmacotherapy of tuberculosis requires special dosing regimens and schedules.

The primary goal of TB pharmacotherapy is to eliminate all tubercle mycobacteria, while avoiding the emergence of resistant strains. This involves an initial or induction phase of therapy during which the actively dividing microbes are killed, and a continuation phase in which the remaining dormant mycobacteria are eliminated. Special pharmacotherapeutic strategies are required to successfully eradicate this persistent pathogen.

The pharmacotherapy of TB differs from that of other bacterial infections because the thick mycolic acid layer surrounding the mycobacterium is resistant to penetration by anti-infectives. For the drugs to reach the mycobacteria isolated in tubercles and inside macrophages, pharmacotherapy must continue for 6 to 12 months. Although the patient is not infectious this entire time and, indeed, may have no symptoms, it is critical that therapy be continued for the entire period. Patients who develop multidrug-resistant infections may require therapy for as long as 2 years.

A second difference in the therapy of TB is that a minimum of two—and sometimes as many as seven—antimycobacterial drugs may be necessary. During the long treatment period, different combinations of drugs are used. Combination drug therapy is necessary because mycobacteria grow slowly and often develop resistance during the course of treatment. The incidence of multidrug-resistant TB is increasing. In some communities, as many as 10% of patients have infections resistant to at least one antituberculosis medication. The use of multiple drugs that kill mycobacteria by different mechanisms lowers the potential for resistance and increases pharmacotherapeutic success. Figure 51.1 illustrates the use of combination therapy during tuberculosis therapy. Doses for the antimycobacterial drugs are listed in Table 51.1.

A third difference in therapy is that antimycobacterial drugs are used extensively for *preventing* the disease, in addition to treating active infections. Because of the acute infectious nature of TB, prophylactic therapy is indicated for close contacts or family members of recently diagnosed patients. Therapy of infected patients and all close contacts begins immediately after a positive diagnosis has been established. Patients with compromised immune function, such as those with HIV-AIDS or those who are receiving immunosuppressant drugs, may also receive preventive treatment with antimycobacterials. A short-term therapy of 2 months, consisting of combination therapy with isoniazid (INH) and pyrazinamide, is approved for TB prophylaxis in patients who are HIV positive.

A major concern with TB pharmacotherapy is ensuring that patients fully adhere to the prescribed regimen.

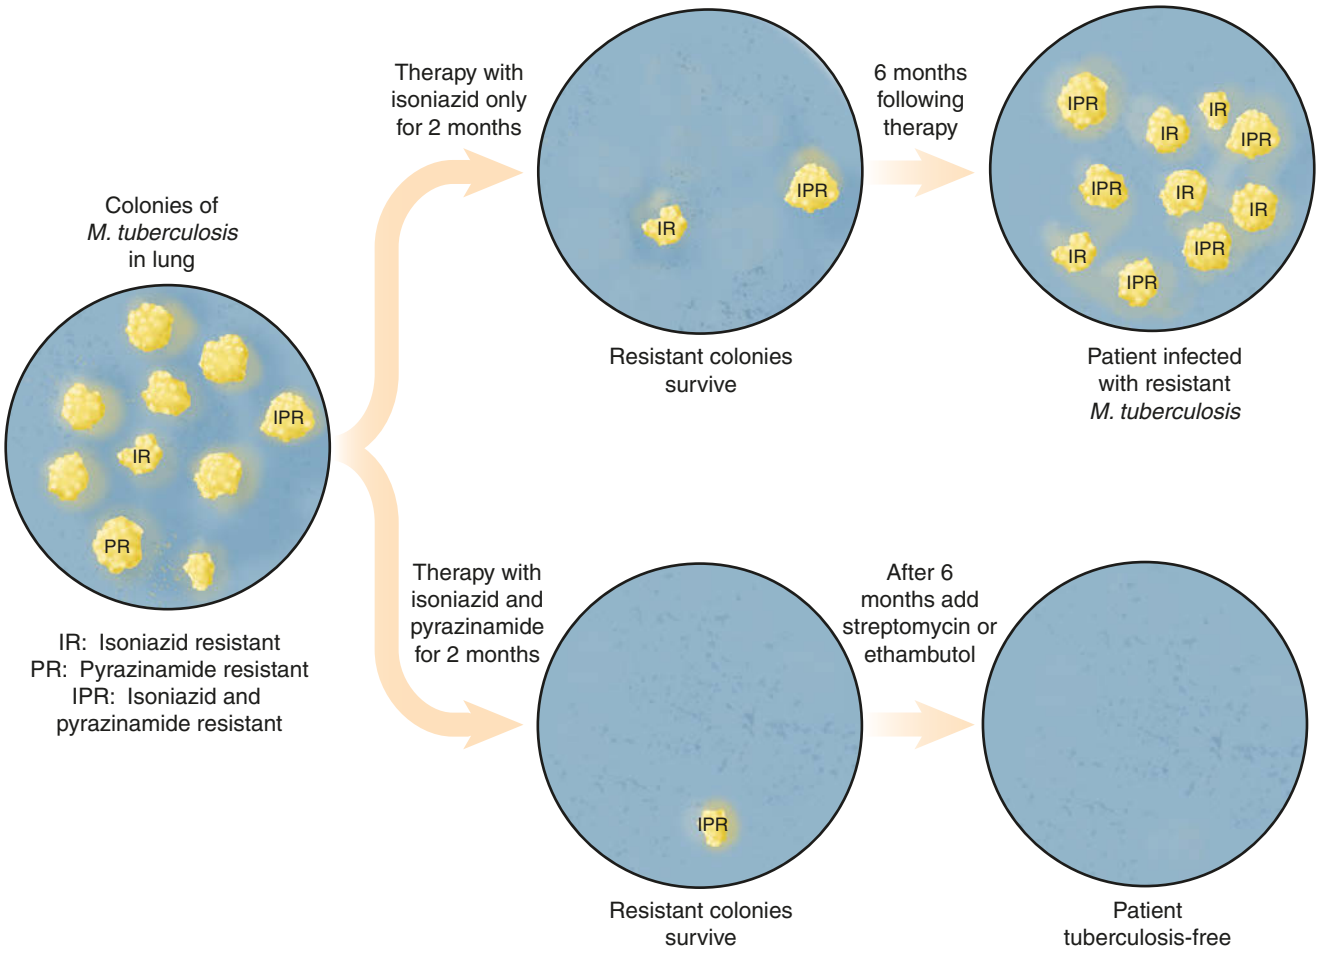


Figure 51.1 Use of combination therapy during tuberculosis therapy to avoid resistance.

Nonadherence to pharmacotherapy is the most common cause of treatment failure in patients with TB. In high-risk patients, directly observed therapy (DOT) is necessary. DOT requires that a healthcare provider directly observe the patient swallowing the pills, whether it is in the hospital, office, or home care setting. Nurses serve essential roles in providing education about this disorder to their patients and stressing the importance of adherence.

CONNECTION Checkpoint 51.2

From what you learned in Chapter 6, identify at least three major factors that might explain why a patient may choose to stop taking antimycobacterials. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

51.4 First-line or primary antituberculosis drugs are the most efficacious and safest drugs for treating *M. tuberculosis* infections.

Medications for TB are placed into two categories. The safer and more effective medications are called *first-line drugs*. A second group of medications, which exhibit greater toxicity, is less effective and prescribed when resistance develops to the first-line drugs. The *second-line drugs* are discussed in Section 51.5.

The pharmacotherapy regimen for TB depends on drug sensitivity, disease stage, and the patient's immune status. Ideally, results of culture and sensitivity (C&S) testing should be obtained prior to treatment because of the possibility of drug-resistant strains. Definitive C&S results may take several weeks, however, and treatment must begin immediately. Therefore, the initial selection of pharmacotherapy is based on the experience of the prescriber and later adjusted when laboratory results become available.

Standard Regimen

The standard regimen is for patients who have a positive diagnosis of TB, or who have symptomology strongly suspicious of this infection. This therapy is recommended by the American Thoracic Society, the CDC, and the Infectious Diseases Society of America (Nahid et al., 2016). The regimen for patients with TB not caused by drug-resistant organisms includes the following:

- **Intensive phase.** Two months of daily therapy with isoniazid (INH), rifampin (Rifadin, Rimactane),

Table 51.1 Antimycobacterial Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
First-Line Drugs		
ethambutol (Myambutol)	PO: 15–25 mg/kg/day (max: 1600 mg for daily therapy)	*Nausea, vomiting, headache, dizziness* Anaphylaxis, optic neuritis (decreased acuity, color blindness, or visual defects)
isoniazid (INH)	Latent TB: PO: 300 mg/day or 900 mg twice weekly for 6–9 months Active TB: PO: Daily therapy: 5 mg/kg/day or 300 mg/day; if given by DOT: 15 mg/kg or 900 mg twice weekly	*Nausea, vomiting, diarrhea, epigastric pain* Anaphylaxis, peripheral neuropathy, optic neuritis, hepatotoxicity, blood dyscrasias
pyrazinamide (PZA)	PO: 5–15 mg/kg tid–qid (max: 2 g/day)	*Nongouty polyarthralgia, increase in serum uric acid, rash* Anaphylaxis, hepatotoxicity, fatal hemoptysis, hemolytic anemia
rifabutin (Mycobutin)	TB prophylaxis: PO: 300 mg once daily (max: 600 mg/day) Active TB: 1st phase PO: 5 mg/kg/day 2nd phase PO: 5 mg/kg/day or twice weekly (max: 300 mg/day)	*Nausea, vomiting, epigastric pain, anorexia, diarrhea, orange discoloration of the urine, sweat, and tears, pyuria, hematuria, urinary tract infection, proteinuria, hypoglycemia* Pseudomembranous colitis (PMC), acute renal failure, hepatotoxicity, hyperuricemia, lymphopenia, neutropenia, anemia
rifampin (Rifadin, Rimactane)	Latent TB: PO: 600 mg/day or 900 mg twice weekly for 4 months Active TB: PO: 10 mg/kg/day or 600 mg/day IV and PO are same dose, but IV needs to be given over 30 min to 3 h and the final concentration should not exceed 6 mg/mL	
rifapentine (Priftin)	PO: 600 mg (four 150-mg tablets) given twice a week for 2 months with an interval of no less than 72 h between doses, then once a week for 4 months	
Second-Line Drugs		
amikacin (Amikin)	Intramuscular (IM): 10–15 mg/kg daily for 2 wk in a large muscle	Pain or inflammation at injection site, rash, fever, nausea, diarrhea, dizziness, tinnitus Anaphylaxis, nephrotoxicity, PMC, ototoxicity
aminosalicylic acid (Paser)	PO: 150 mg/kg/day in three to four equally divided doses (max: 8 g/day)	*GI intolerance, anorexia, diarrhea, fever, leukopenia* Hypersensitivity, inhibition of vitamin B_{12} absorption, hepatotoxicity
bedaquiline (Sirturo)	PO: 400 mg once daily for 2 wk then 200 mg 3 times/wk for 22 wk	*Nausea, arthralgia, headache* QT prolongation, increased risk of death, hepatotoxicity
capreomycin (Capastat)	IM: 1 g/day (max: 20 mg/kg/day) for 60–120 days, then 1 g 2–3 times/wk	*Rash, pain and inflammation at injection site, tinnitus* Blood dyscrasias, nephrotoxicity, ototoxicity, increase in urination, thirst
ciprofloxacin (Cipro)	PO: 250–750 mg bid	*Nausea, diarrhea, vomiting, rash, restlessness, pain and inflammation at injection site, local burning, stinging and corneal irritation (ophthalmic)* Anaphylaxis, tendon rupture, superinfections, photosensitivity, PMC, seizure, peripheral neuropathy, hepatotoxicity
cycloserine (Seromycin)	PO: 250 mg every 12 h for 2 wk; may increase to 500 mg every 12 h (max: 1 g/day)	*Drowsiness, headache, lethargy* Convulsions, psychosis, confusion
ethionamide (Trecator-SC)	PO: 750 mg/day (max: 1 g given in three to four divided doses)	*Nausea, vomiting, epigastric pain, diarrhea* Convulsions, hallucinations, mental depression, hepatotoxicity
kanamycin (Kantrex)	IM: 5–7.5 mg/kg bid–tid	(See amikacin.)
ofloxacin (Floxin)	PO: 200–400 mg bid	(See ciprofloxacin.)
streptomycin	IM: 15–30 mg/kg (max: 1–2 g/day) DOT: twice weekly IM: 25–30 mg/kg (max: 1.5 g) DOT: 3 times/wk IM: 25–30 mg/kg	*Nausea, vomiting, pain at injection site, drowsiness, headache* Anaphylaxis, ototoxicity, profound CNS depression in infants, respiratory depression, exfoliative dermatitis, nephrotoxicity, teratogenicity

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

pyrazinamide (PZA), and ethambutol (Myambutol). If C&S results show that the strain is sensitive to isoniazid and rifampin, ethambutol is dropped from the regimen.

- **Continuation phase.** Four months of therapy with isoniazid and rifampin, 2 to 3 times per week.

The above regimen cures more than 95% of these patients. However, many variations are used, based on patient variables. In regions where the incidence of isoniazid resistance is 4% or higher, ethambutol (Myambutol) or streptomycin is included as part of the initial therapeutic regimen. Three months of additional therapy may be indicated, depending on whether the sputum cultures have turned negative during therapy. Nine months of therapy is recommended for patients with evidence of nonrespiratory TB.

Patients Who Are HIV Positive

Coinfection with both TB and HIV can have mortal consequences: Worldwide, about 35% of patients with HIV die of TB infection (WHO, 2017). Patients who are HIV positive often respond to the standard 6-month regimen. Because nonadherence has been frequently reported, DOT is recommended for patients who are HIV positive. In addition, patients taking numerous antiretroviral drugs are at greater risk for drug–drug interactions and must be monitored carefully. For example, rifampin and rifabutin are considered essential to TB elimination in this population, yet they can increase the metabolism of some antiretrovirals and decrease their effectiveness against HIV. Certain drug combinations, such as rifampin with single protease inhibitors, should be avoided to the extent possible or dosages adjusted accordingly. Nurses treating patients with HIV infection who also have TB should regularly consult recent pharmacology sources to identify the many drug–drug interactions because serious adverse effects can compromise the success of pharmacotherapy.

Pregnant Patients

Pregnant women with TB are at risk because drug choices are fewer. The safety of pyrazinamide during pregnancy has not been established; thus, it is usually avoided. Although ethambutol has been used successfully without adverse fetal effects, high doses in laboratory animals produced a low incidence of birth defects; therefore, it is used in pregnancy only if C&S testing shows it to be effective. Streptomycin is contraindicated during pregnancy because it can cause hearing impairment in the newborn. Fortunately, these drugs have not been shown to have adverse effects on the breastfeeding neonate; thus, therapy can continue during lactation. Pregnant patients should receive isoniazid therapy supplemented with pyridoxine (vitamin B_6), which has been shown to prevent peripheral neuropathy.

Chemoprophylaxis Patients

Treatment of latent TB reduces the risk that the infection will progress to its reactivation stage, thereby helping to prevent transmission of the disease. Although it would seem prudent to treat everyone suspected of having latent TB, pharmacotherapy is expensive and carries the risk of adverse drug reactions. Furthermore, not everyone with latent TB will progress to active disease. Patients with a possible latent TB infection are screened and treated only if they fall into a high-risk category. High-risk categories include patients who are HIV positive, those receiving immunosuppressive drugs, employees and residents of nursing homes, those living in residential facilities for patients with AIDS, those living in prisons, people born in countries where TB is endemic, and those who have been

CONNECTIONS: Using Research in Practice

Support for Patients with Multidrug-Resistant TB

Multidrug-resistant TB (MDR-TB) is a growing public health concern. The length of drug therapy required and the cost and stigma associated with TB infections lead to a lack of patient adherence to the regimen. This exacerbates the problem and allows drug-resistant strains to develop.

To identify and document the problems experienced by people receiving care for MDR-TB and how these people cope, Baral, Aryal, Bhattrai, King, and Newell (2014) examined barriers to the completion of MDR-TB regimens for people starting treatment in Kathmandu Valley, Nepal, during January to December 2008. The researchers found that MDR-TB treatment caused extreme social, financial, and employment hardship, and they wanted to develop strategies to help people cope. They identified two strategies that appeared to improve treatment outcomes: counseling alone, and joint counseling and financial support. Cure rates for those receiving counseling, both counseling and financial support, and no support were 85%, 76%, and 67%, respectively.

The study reinforced that worldwide, patients with MDR-TB are extremely vulnerable to social stigma and extreme financial hardship, and that patients' adherence and cure rates could be improved with both counseling and financial support. National TB programs should consider incorporating financial support and counseling into MDR-TB care because the costs are low relative to the benefits obtained by treating this difficult disease.

in close contact with patients with active TB. Pharmacotherapy of latent TB normally includes one of the following regimens:

- Nine months of therapy with isoniazid. This is considered the most effective treatment. Depending on anticipated patient adherence, the dose may be daily (300 mg) or twice weekly (15 mg/kg).
- Isoniazid and rifapentine 12-dose regimen. This regimen is given once weekly and efficacy appears to be equal to that of the 9-month isoniazid regimen. Recommended for otherwise healthy people who have had recent contact with a TB-infected individual or someone with a positive tuberculin skin test.
- Four months of therapy with rifampin. This monotherapy is used for patients who are unable to take isoniazid or pyrazinamide, or who have infections caused by organisms that are resistant to these drugs.

The pharmacotherapy of latent TB is modified for certain patients. Close contacts of HIV-infected patients with TB should be treated for at least 12 months. Contacts of patients with confirmed multidrug-resistant TB should receive at least two drugs known to be effective against the resistant *M. tuberculosis* strain. These patients usually require follow-up for 2 years to be certain the resistant strains have been killed.

PROTOTYPE DRUG Isoniazid (INH)

Classification **Therapeutic:** Antituberculosis drug, antimycobacterial
Pharmacologic: Mycolic acid inhibitor

Therapeutic Effects and Uses: Although a patient may take many different drugs during the long treatment period for TB, isoniazid is considered the prototype antituberculosis drug. Approved by the U.S. Food and Drug Administration (FDA) in 1952, it remains a first-line drug for the treatment of *M. tuberculosis* infections because decades of experience have shown it to have a superior safety profile and to be the most effective, single drug for the disease. Isoniazid is used exclusively for the treatment and prophylaxis of mycobacterial infections. Isoniazid may be used alone for chemoprophylaxis, or in combination with other antituberculosis drugs for treating active disease. When used for prophylaxis, therapy may continue for as long as a year. While resistance to isoniazid can develop during therapy, the incidence is only about 10%. Treatment of active disease requires multidrug therapy.

The main route of metabolism of isoniazid is through enzymatic acetylation in the liver. **Acetylation** is a general biochemical process that adds a two-carbon chain to a drug molecule, which usually renders the medication less effective or allows it to be excreted more easily. Not all people are able to acetylate isoniazid at the same rate because of genetic differences in the activity of acetyltransferase, the hepatic enzyme that performs this action. Those of Japanese and Inuit descent often have increased enzyme activity and are known as *fast acetylators*. Those with decreased activity—*slow acetylators*—are most commonly of Scandinavian, North African Caucasian, or Jewish descent. The half-life of isoniazid ranges from 70 minutes in fast acetylators to 2 to 5 hours in slow acetylators. Fortunately, isoniazid is safe across a wide range of doses, and these variations do not generally result in toxicity. For optimal therapy, however, doses should be lowered in slow acetylators to avoid adverse effects, and increased in fast acetylators to keep plasma levels consistently in the therapeutic range. Dosage reductions should also occur in any patient with significant hepatic impairment because of diminished acetylation. The acetylation of isoniazid is illustrated in Figure 51.2.

Mechanism of Action: Isoniazid acts by inhibiting the synthesis of mycolic acid, an essential cell wall component of mycobacteria. Because mycolic acids are unique to mycobacteria, isoniazid has no activity for other microbial species. It is bactericidal for rapidly dividing organisms but bacteriostatic for dormant mycobacteria.

Pharmacokinetics:

Route(s)	Oral (PO) and IM (only if PO is unavailable)
Absorption	Readily absorbed
Distribution	Widely distributed (can even enter the necrotic lung tubercles that are characteristic of TB); crosses the placenta, and enters the central nervous system (CNS); secreted in breast milk; about 15% bound to plasma protein
Primary metabolism	Metabolized by acetylation in the liver
Primary excretion	Renal (75%)
Onset of action	Rapid
Duration of action	Half-life: 1–4 h

Adverse Effects: Isoniazid exhibits few serious adverse effects, which is a major reason why it is a preferred drug for mycobacterial infections. Common adverse effects of isoniazid are rash and fever. Neurotoxicity is a concern during therapy, and patients may exhibit paresthesia of the feet and hands, convulsions, optic neuritis, dizziness, coma, memory loss, and various psychoses. A major factor responsible for the neurotoxicity of isoniazid is the ability of the drug to cause a deficiency of activated pyridoxine (vitamin B_6), which is required for synthesis of the neurotransmitter gamma-aminobutyric

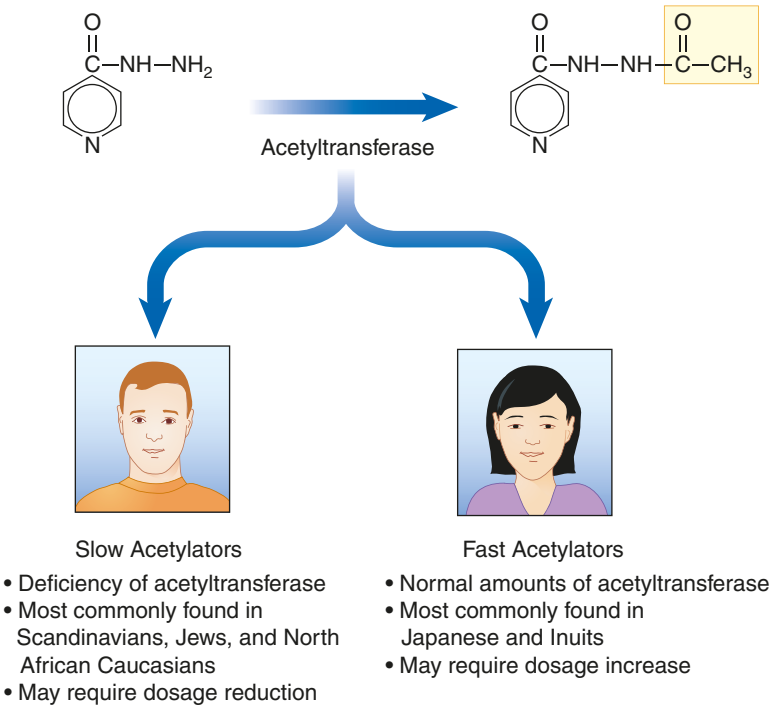

Figure 51.2 Ethnic variation in the acetylation of isoniazid.

acid (GABA). Many practitioners routinely prescribe pyridoxine during isoniazid therapy to prevent the development of peripheral neuropathy. Pyridoxine is considered the antidote for reversing acute nervous system effects of isoniazid overdose. Blood dyscrasias such as agranulocytosis and aplastic anemia may occur, although they are uncommon. **Black Box Warning:** Although rare, hepatotoxicity is a potentially fatal adverse effect; thus, the patient should be monitored carefully for jaundice, fatigue, elevated hepatic enzymes, or loss of appetite. Liver enzyme tests are usually performed monthly during therapy to identify early hepatotoxicity. Hepatotoxicity usually appears in the first 1 to 3 months of therapy but may occur at any time during treatment. Older adults and those with daily alcohol consumption are at greater risk of developing hepatotoxicity.

Contraindications/Precautions: Isoniazid has no absolute contraindications other than previous allergy to the drug. Pharmacotherapy must be monitored carefully in patients with a history of chronic hepatic disease because the liver metabolizes the drug and fatal hepatitis has been reported. Serum aspartate aminotransferase (AST) levels should be monitored regularly during therapy in high-risk patients. If AST levels rise to 3 times baseline levels, liver damage is likely, and isoniazid should be discontinued. Patients with significant chronic kidney disease (CKD) usually require lower doses because the kidneys excrete the drug. Patients with seizure disorders should be carefully monitored because isoniazid can increase the incidence of seizures. Patients with a history of seizures often receive pyridoxine supplementation to prevent seizures during isoniazid therapy.

Drug Interactions: Isoniazid is a potent inhibitor of hepatic metabolic enzymes (CYP2C19 and CYP3A4) and is associated with numerous drug–drug interactions. Before adding a new drug to the regimen, the nurse should consult a drug guide for potential interactions. Aluminum-containing antacids should not be administered concurrently because they can decrease the absorption of isoniazid. Azole antifungals should not be used concurrently with isoniazid because this results in decreased levels of antifungals. Alcohol use should be avoided because it can increase the risk of hepatotoxicity. Isoniazid inhibits the metabolic breakdown of phenytoin, which may cause the anticonvulsant to build to toxic levels, an effect that occurs more often in slow acetylators. Isoniazid can increase serum levels of carbamazepine and cause carbamazepine toxicity. **Herbal/Food:** Food decreases the absorption of isoniazid.

Pregnancy: Category C.

Treatment of Overdose: Isoniazid overdose may be fatal and treatment is mostly symptomatic. Pyridoxine may be infused in a dose equal to that of the isoniazid overdose to prevent seizures and to correct metabolic acidosis. The dose may be repeated several times until the patient regains consciousness.

Nursing Responsibilities: Key nursing implications for patients receiving isoniazid are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Tuberculosis.

Drugs Similar to Isoniazid (INH)

Other first-line antituberculosis drugs include ethambutol, pyrazinamide, rifabutin, rifampin, and rifapentine.

Ethambutol (Myambutol): Approved in 1967, ethambutol is included in multidrug regimens for TB because it is sometimes active against organisms that are resistant to other first-line drugs. It is also effective against atypical mycobacteria such as *M. kansasii*. The mechanism of action of ethambutol is not well understood, although its bacteriostatic effect is thought to be due to the inhibition of cell wall synthesis and RNA synthesis. It is always given with other antimycobacterials because resistance develops rapidly if the drug is given as monotherapy. It is rapidly absorbed, distributed to most tissues, and excreted by both renal and fecal routes. Ethambutol has a short half-life of 1 to 4 hours; therefore, it must be taken daily.

CONNECTIONS: Community-Oriented Practice

Travel and Tuberculosis Risk

The ability nowadays for people to travel to all areas of the world increases the opportunity for acquisition, transmission, and spread of infectious diseases. A rare and exotic disease may be "only one plane flight away" from countries that have never encountered the disease before. But what about a disease such as TB, which is present throughout the world?

After a well-publicized case in the early 2000s about an individual with extensive drug-resistant TB (XDR-TB) who chose to travel by plane after being advised not to, the WHO provided guidelines for preventing or managing a potential TB exposure during air travel (WHO, 2008). Per these guidelines, people with infectious or potentially infectious TB should postpone travel until they became noninfectious, with "noninfectious" being determined by negative sputum cultures. While those guidelines still stand, it is recognized that the risk of TB transmission during air travel is very low (Kotila, Payne Hallström, Jansen, Heibling, & Abubakar, 2016).

Healthcare providers, public health officials, and airlines should inform patients who are infectious or potentially infectious that they should not travel or should deny boarding to these patients. In addition, public health authorities should be alerted to any potential exposure to TB aboard a flight for follow-up screening and investigation. Airlines were given guidance for ventilation systems and the use of HEPA filters, disinfectant procedures, medical emergency procedures, and national public health requirements for postexposure follow-up. Although actual rates of exposure to and transmission of TB are difficult to assess, following WHO guidelines may limit the risk. A detailed individual risk travel evaluation is necessary and it is important for all practitioners giving travel advice to understand and have up-to-date information regarding local conditions (Denholm & Thevarajan, 2016).

Ethambutol has a unique adverse effect of optic neuritis that affects visual acuity and the ability to distinguish red from green. This effect is dose related, may be unilateral or bilateral, and is usually reversible when therapy is discontinued. A baseline ophthalmic examination should be conducted prior to therapy. Ethambutol may decrease the excretion of uric acid, causing hyperuricemia; patients with a history of gout should be closely monitored. This drug has few other significant adverse effects. Ethambutol is pregnancy category C.

Pyrazinamide (PZA): Pyrazinamide is an older drug approved in 1955 that may be used for the initial therapy of active or advanced TB in combination with other antimycobacterials. It is usually taken in combination with rifampin, ethambutol, and INH. If used alone, resistance develops rapidly. Like isoniazid, it acts by inhibiting the synthesis of mycolic acid in *M. tuberculosis*. Given PO, it is distributed to all body fluids and is excreted by the kidneys.

Pyrazinamide causes some degree of dose-related hepatotoxicity in as many as 15% of patients. Caution should be observed when giving pyrazinamide to patients with preexisting hepatic disease, and frequent laboratory monitoring of liver enzymes must be performed. Frequent use of ethanol increases the risk of hepatotoxicity. Hyperuricemia may occur because the drug slows the excretion of uric acid. Uric acid levels should be monitored and the nurse should assess for signs of gout or arthralgia, which can occur in up to 40% of the patients taking this drug. This drug is pregnancy category C.

Rifampin (Rifadin, Rimactane): Rifampin is widely used in combination with other drugs in the first-line treatment of TB: It is rarely given as monotherapy for the short-course therapy of latent *M. tuberculosis* infections. Rifampin exerts its bactericidal effects by inhibiting RNA synthesis. In addition to treating TB, rifampin is a broad-spectrum antibiotic approved for the short-term treatment of meningococci from the nasopharynx of asymptomatic carriers of *Neisseria meningitidis*. When given to meningococcal carriers, the length of therapy is only 2 days. Off-label uses include chemoprophylaxis of contacts of patients with *Haemophilus influenzae* type B and the treatment of Legionnaire's disease. It is also used to treat leprosy, in combination with dapsone. The drug should be used only when the infectious microbe has been demonstrated to be susceptible to the effects of the medication.

Rifampin is administered by either the PO or intravenous (IV) routes. Hypersensitivity reactions cause flulike symptoms in as many as 50% of the patients taking rifampin. Rash and urticaria are relatively common. Rifampin can be hepatotoxic and caution must be used when administering the drug to patients with preexisting liver disease or who are taking other hepatotoxic antituberculosis drugs such as isoniazid and pyrazinamide. Rifampin is a potent inducer of cytochrome P450 (CYP450) enzymes. Thus, it has the potential to increase the metabolism of other drugs metabolized by the liver, such as some antiretrovirals for HIV-AIDS, warfarin, and oral contraceptives. Because resistance develops rapidly, rifampin is almost always given in combination with other drugs. This drug is pregnancy category C.

Rifabutin (Mycobutin) and Rifapentine (Priftin): These two PO drugs are closely related to rifampin, act by the same mechanism, and cause the same adverse effects, including induction of CYP450 enzymes and potential

hepatotoxicity. There is a high level of cross resistance among rifampin, rifabutin, and rifapentine, which, collectively, are called **rifamycin derivatives**. They are always used in combination with other antituberculosis medications.

Approved in 1998, rifapentine is used only for the pharmacotherapy of TB and has a longer half-life than rifampin, thus offering the advantage of twice-a-week dosing. Rifabutin was approved in 1992 for the prophylaxis of MAC in patients infected with HIV. It offers little advantage over rifampin, other than it is thought to have less effect on hepatic enzymes. Rifapentine is pregnancy category C; rifabutin is category B.

Combination drugs: Rifamate and IsonaRif are combination medications that contain isoniazid and rifampin. Rifater is a tablet containing isoniazid, rifampin, and pyrazinamide. Combining multiple drugs into a single capsule or pill increases their ease of use and promotes patient adherence to therapy.

51.5 Second-line antituberculosis drugs are used when resistance develops to the first-line drugs.

If a patient develops multidrug-resistant strains of *M. tuberculosis* during the course of therapy, second-line antibiotics are added to the regimen. These medications are either more toxic or less effective than the first-line drugs. Some of them are occasionally included as part of the initial course of therapy if C&S testing demonstrates their effectiveness. As a general rule, a single antituberculosis drug should never be added to a regimen that has failed to control the mycobacterial infection. At least two, and preferably three, new medications to which the organism is likely to be susceptible should be added.

Aminoglycosides: Amikacin (Amikin), kanamycin (Kantrex), and streptomycin are aminoglycosides used as both antibacterials and antituberculosis drugs. Like other second-line drugs, they are used for multidrug-resistant TB and always in combination with other antimycobacterials. They are administered parenterally because they are not absorbed when given by the PO route.

Approved in 1945, streptomycin has the distinction of being the first clinically effective drug used to treat TB. It was soon noticed, however, that resistance developed quickly when streptomycin was used as monotherapy. Streptomycin use has declined such that it is now a second-line TB drug. This is mostly because of the emergence of numerous streptomycin-resistant strains of *M. tuberculosis* and the need to administer the drug by the IM route. Other indications for streptomycin include tularemia, plague, brucellosis, and subacute bacterial endocarditis.

Streptomycin has a black box warning that renal function tests must be regularly assessed because the drug can accumulate to toxic levels in patients with CKD. Additionally, the warning states that concurrent use with nephrotoxic or neurotoxic drugs should be avoided. IM injection of the drug is painful and can produce sterile abscesses at the site of injection. Also of serious concern is ototoxicity, which can cause tinnitus, deafness, and vertigo. This drug is pregnancy category D.

Amikacin and kanamycin are closely related structurally and have similar spectrums of activity, actions, and adverse effects. Like other aminoglycosides, these drugs are nephrotoxic, and kidney function must be monitored regularly during therapy. They are also ototoxic and can cause deafness and balance abnormalities. The risk of ototoxicity is greater in patients with impaired renal function. Amikacin appears to be less ototoxic than kanamycin and causes less pain when administered IM. Resistance of mycobacteria to either kanamycin or amikacin sometimes confers resistance to the other.

CONNECTION Checkpoint 51.3

From what you learned in Chapter 48, are aminoglycosides bacteriostatic or bactericidal? What is the mechanism of action of aminoglycosides? Are they most effective against gram-positive or gram-negative organisms? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Aminosalicylic acid (Paser): Aminosalicylic acid (or para-aminosalicylic acid) was widely used to treat TB until more effective and safer drugs were discovered. It is structurally similar to para-aminobenzoic acid and is thought to have a similar mechanism of action as the sulfonamides. Aminosalicylic acid is given PO, but it has a half-life of only 1 hour. The drug is available as delayed-release granules that are taken several times a day.

The use of aminosalicylic acid is limited to the treatment of multidrug-resistant strains of *M. tuberculosis*. Higher doses can inhibit the acetylation of isoniazid, especially in patients who are rapid acetylators. Concurrent therapy of aminosalicylic acid with isoniazid, however, does not affect the serum level, half-life, or excretion of isoniazid.

Aminosalicylic acid has many adverse effects, the most common of which are gastrointestinal (GI) related and include nausea, vomiting, diarrhea, and abdominal pain. Taking the drug with food can diminish these types of adverse effects. Hypersensitivity is observed in 10% to 15% of patients and may begin with a rapid onset of high fever, lethargy, and joint pain. Aminosalicylic acid reduces the absorption of vitamin B_{12} by as much as 50%; thus, vitamin B_{12} supplements are indicated during long-term therapy. This is a pregnancy category C drug.

CONNECTION Checkpoint 51.4

From what you learned in Chapter 50, the synthesis of what essential vitamin is inhibited by the sulfonamides? What is the primary indication for sulfonamide pharmacotherapy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Bedaquiline (Sirturo): Bedaquiline was approved in 2013 for the treatment of multidrug-resistant TB. Bedaquiline is always used in combination with at least three other antituberculosis drugs. It should not be used to treat TB strains that are sensitive to first-line drugs, for latent TB, or for nontuberculous mycobacterial infections. It is generally well tolerated, with nausea, headache, and joint pain being the most common side effects. However, the drug carries a black box warning because patients receiving the drug appear to have an increased risk of mortality. In addition, bedaquiline prolongs the QT interval, which is associated with dysrhythmias in some patients. This drug is pregnancy category B.

Capreomycin (Capastat): Approved in 1971, the only indication for capreomycin is the pharmacotherapy of multidrug-resistant strains of *M. tuberculosis*. Capreomycin is always given with other antimycobacterials because resistance quickly develops if it is administered alone. It is given only by IM injection. Because it is usually administered daily for the first 120 days of therapy, care must be taken to inject the drug deep into a large muscle mass and to rotate injection sites.

Capreomycin has a black box warning that the drug exhibits both neurotoxicity and nephrotoxicity. The drug is ototoxic, causing tinnitus and high-frequency hearing loss in up to 9% of patients. Auditory and vestibular function should be assessed prior to starting therapy and retested at least every other month during therapy. Nephrotoxicity is more common with capreomycin than with streptomycin. Older adults are generally more susceptible to the nephrotoxic effects of capreomycin, and the maximal daily dosage should be reduced. Other nephrotoxic drugs such as aminoglycosides should be avoided during capreomycin pharmacotherapy. Renal function tests should be monitored regularly and the drug discontinued if blood urea nitrogen levels exceed 30 mg/dL. Because of these adverse effects, capreomycin is sometimes referred to as a last-line drug for TB. This is a pregnancy category C drug.

Cycloserine (Seromycin): Approved over 50 years ago, cycloserine is a PO drug used in the pharmacotherapy of multidrug-resistant strains of *M. tuberculosis*. The drug, which resembles the common amino acid D-alanine, acts by blocking mycobacterial cell wall synthesis. In addition to being an antimycobacterial, cycloserine is also effective against certain gram-negative and gram-positive bacteria and may be used to treat urinary tract infections that are unresponsive to safer antibiotics. It is taken PO, usually twice daily.

Cycloserine use is limited because the difference between a toxic dose and an effective dose is small. Of most concern is neurotoxicity, which can manifest as different symptoms, including headache, lethargy, convulsions, psychotic states with suicidal ideation, depression, confusion, tremor, and paranoid reactions. Concurrent administration of isoniazid and ethionamide can increase the risk of neurotoxicity. The drug is contraindicated in patients with preexisting psychoses or epilepsy because it may worsen these disorders. Because of its toxicity, serum levels of cycloserine are measured frequently during therapy, with normal levels ranging from 25 to 35 mcg/mL. Patients with serious CKD should not receive this drug because the primary route of excretion of this drug is via the kidneys. This is a pregnancy category C drug.

Ethionamide (Trecator-SC): Approved in 1962, ethionamide is a PO drug used as a second-line drug in the pharmacotherapy of multidrug-resistant TB or when patients are unable to tolerate first-line drugs. Ethionamide is always used in combination with other antituberculosis drugs because resistance develops rapidly if given alone. It is thought to act by inhibiting mycobacterial protein synthesis. The drug has only a 3-hour half-life and therefore must be administered several times daily.

The most common and limiting adverse effects of ethionamide are GI related and include nausea, vomiting, diarrhea, abdominal pain, excessive salivation, metallic taste, anorexia, and weight loss. GI effects may be diminished by decreasing dosage, by taking the drug with food, or by the concurrent administration of an antiemetic. Concomitant administration of pyridoxine is recommended to decrease the incidence of peripheral neuropathy. Depression and drowsiness are common, and seizures have been reported with ethionamide. Hepatic function should be monitored regularly because hepatitis occurs in about 5% of patients taking the drug. Alcohol use should be discouraged during ethionamide therapy because of additive harmful effects on the liver. Ethionamide is a pregnancy category C drug.

Fluoroquinolones: Ciprofloxacin (Cipro) and ofloxacin (Floxin) have undergone considerable testing for use as antituberculosis drugs. Many multidrug-resistant strains of *M. tuberculosis* are sensitive to the actions of the fluoroquinolones. Because this class of antibiotics is widely used in the pharmacotherapy of bacterial infections, there is concern in the medical community that use of these drugs for TB could produce resistant strains of other pathogens in addition to *M. tuberculosis*. Although they are sometimes given for multidrug-resistant TB, they have not been approved by the FDA for this indication. They are the safest of the second-line drugs available for this infection.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Tuberculosis

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, GI, hepatic, or renal disease, and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and over-the-counter drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess for signs and symptoms of current infection, noting symptoms, duration, or any recent changes. Assess for concurrent infections, particularly HIV.
- Evaluate appropriate laboratory and diagnostic findings (e.g., complete blood count [CBC], C&S, hepatic and renal function studies, uric acid levels, visual acuity, and red-green color vision tests).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection, fever, night sweating, increasing ease of breathing, decreased sputum production, radiographic evidence of improving infection).
- Continue periodic monitoring of CBC and hepatic and renal function.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, drowsiness, dizziness, paresthesias, tinnitus, vertigo, blurred vision, changes in visual color sense, increasing fatigue. Eye pain, acute blurring of vision or loss of color sense, sudden or increasing numbness or tingling in extremities, decreased hearing or significant tinnitus, or increase in bruising or bleeding should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished fever, cough, sputum, and other signs and symptoms of infection should be noted.) • Recognize that TB treatment requires long-term adherence and many reasons exist for nonadherence, e.g., cost, adverse effects, concerns for family members with similar symptoms. (Nonadherence may increase risk to the patient's health and family and community health and lead to development of resistant organisms.)	• Teach the patient to complete the prescribed course of therapy; do not share doses with other family members with similar symptoms; and return to the provider if adverse effects develop to ensure that drug therapy is maintained. • Discuss concerns about cost, family members who have similar symptoms or may need prophylactic treatment, and how to manage adverse effects with the patient to help encourage adherence. In cases of significant nonadherence, DOT may be required.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present, breath sounds, and sputum production and quality. Immediately report undiminished fever, increases in sputum production, hemoptysis, or increase in adventitious breath sounds to the healthcare provider. (Increasing signs of infection may signify drug resistance or significant nonadherence to the drug regimen.)	• Teach the patient to report fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider, continued symptoms of disease (e.g., night sweats, fatigue), or increased sputum production to the healthcare provider promptly.
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBCs, sputum culture for acid-fast bacilli (AFB) testing. (Antituberculosis drugs are hepatic and nephrotoxic. **Lifespan:** Monitor the older adult more frequently because age-related physiologic changes may affect the drug's metabolism or excretion. Periodic C&S tests may be ordered if infections are severe or are slow to resolve to confirm appropriate therapy. Levels of drugs with known severe adverse effects will be monitored. **Diverse Patients:** Because some drugs such as isoniazid metabolize through the CYP450 system pathway, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Instruct the patient on the need for periodic laboratory work.
• Continue to monitor for hepatic, renal, and ototoxicity, e.g., jaundice, right upper quadrant pain, darkened urine, diminished urine output, tinnitus, or vertigo. (Antituberculosis drugs that are hepatic, renal, or ototoxic require frequent monitoring to prevent adverse effects. Increasing fluid intake will help prevent drug accumulation in the kidneys.)	• Teach the patient to report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light or clay-colored stools, diminished urine output, darkening of urine, ringing, humming, or buzzing in ears, dizziness, or vertigo immediately. • Advise the patient to increase fluid intake to 2–3 L/day and to eliminate alcohol use.
• Monitor for signs and symptoms of neurotoxicity, particularly peripheral and optic neuropathy, e.g., dizziness, drowsiness, headache, changes in visual acuity, blurred vision, loss of color sense, or paresthesia. (Neurotoxicity and peripheral and optic neuritis are adverse effects of antituberculosis drugs. **Lifespan:** Be particularly cautious with the older adult who is at greater risk for falls. Vitamin B_6 may be ordered to decrease the risk of peripheral neuropathy, especially that associated with isoniazid use. Monitor visual acuity and color vision sense in patients taking ethambutol.)	• Instruct the patient to report drowsiness, dizziness, numbness or tingling in peripheral extremities, blurred vision, changes in visual color sense, or changes in visual acuity. Eye pain, acute blurring of vision or loss of color sense, sudden or increasing numbness or tingling in extremities should be reported immediately. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Encourage the patient to increase intake of vitamin B_6–rich foods (e.g., fortified cereals, baked potato with skin on, bananas, lean meats, garbanzo beans) and discuss vitamin B_6 supplements with the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor blood glucose levels in patients taking isoniazid. (Isoniazid may increase glucose levels. Patients with diabetes may require a change in their antidiabetic drug routine.)	• Teach patients with diabetes to test their glucose levels more frequently, reporting any consistent elevations to the healthcare provider.
• Monitor uric acid levels and for signs and symptoms of gout in patients taking ethambutol and pyrazinamide. (These drugs decrease the renal excretion of uric acid, and hyperuricemia may result.)	• Teach the patient to report signs and symptoms of gout such as inflammation and pain around joints, redness, or swelling, particularly of toes or fingers. • Teach the patient to increase fluid intake to 2–4 L/day, taken throughout the day. • Teach the patient to avoid foods high in purine, eliminate alcohol consumption, and avoid increased vitamin C intake or supplementation. Provide dietitian consult as needed.
• Monitor dietary routine in patients taking isoniazid. (Foods high in tyramine can interact with the drug and cause palpitations, flushing, and hypertension.)	• Advise patients taking isoniazid to avoid foods containing tyramine, such as aged cheese, smoked and pickled fish, beer, red wine, bananas, and chocolate, and to immediately report headache, palpitations, tachycardia, or fever.
• Patients taking rifampin should be cautioned that the drug may turn body fluids (tears, sweat, saliva, urine) reddish-orange. (The effect is harmless but may stain soft, hydrophilic contact lenses or clothing.)	• Teach the patient to consult with an eye provider before using hydrophilic contact lenses. Consider wearing nonwhite clothing or use undergarments if sweating is excessive.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. The duration of the required therapy may be quite lengthy but it is necessary to prevent active infection. Do not stop taking the medicine when starting to feel better.
	  • Do not share the medicine with other family members. If there is reason to believe they need medication, they should be assessed by a healthcare provider.
	  • Eliminate alcohol while on these medications. These drugs cause significant reactions when taken with alcohol.
	  • Take the drug with food or milk but avoid acidic beverages. If instructed to take the drug on an empty stomach, take with a full glass of water.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking these drugs.

Drugs for Leprosy

51.6 Leprosy is caused by a mycobacterium and is treated by a multidrug regimen.

Leprosy is a chronic infection caused by *M. leprae.* Leprosy has been known for thousands of years, but the term *leper* has been used by different cultures to designate someone sinful or unclean, not necessarily someone with the disease we now call leprosy.

Although rare in the United States, it is estimated that 6 million people worldwide have leprosy. Patients with leprosy present with large, macular skin lesions. The organism invades peripheral nervous tissue, resulting in loss of sensation or paresthesia. If left untreated, the infection causes extreme disfigurement and bone resorption, resulting in loss of digits.

Leprosy may be infectious or noninfectious, depending on the stage of the disease and the progress of pharmacotherapy. Although the mode of transmission is not clear, *M. leprae* is likely spread by the respiratory route. The disease may have a very long incubation period extending from several months to years.

PharmFACT

Fewer than 200 cases of leprosy are reported in the United States each year. Most cases are diagnosed in immigrants from countries where leprosy is endemic; however, some patients acquire the disease from armadillos, which are a reservoir for the disease (Smith, 2016).

There are two types of leprosy, and pharmacotherapy differs for each. *Lepromatous* leprosy occurs in patients with defective cell-mediated immunity and is characterized by a slow, progressive development of nodular skin lesions and nerve involvement. Because the patient has an impaired immune system, the mycobacteria may

disseminate throughout the body and cause death. *Tuberculoid* leprosy is less progressive and may have long periods of remission followed by reactivation with more severe nerve involvement. These patients have an intact cell-mediated immune response; thus, the disease is more benign and less often fatal.

Like tuberculosis, leprosy is treated with prolonged combination pharmacotherapy because monotherapy causes rapid development of resistant strains. Although improvement in skin lesions may occur within a few months, therapy must continue during the entire treatment period to eliminate all the mycobacteria. Follow-up may continue for 3 years or longer after the completion of pharmacotherapy. A typical regimen includes the following:

- **Lepromatous leprosy.** Initial three-drug regimen that includes dapsone, clofazimine (Lamprene), and rifampin (Rifadin) given for 2 to 5 years.
- **Tuberculoid leprosy.** Initial two-drug regimen with dapsone and rifampin for 6 to 12 months, followed by dapsone alone for 2 to 3 years.

Other drugs may be substituted when the patient cannot tolerate the standard regimen. Ofloxacin (Floxin), clarithromycin (Biaxin), and minocycline (Minocin) are antibacterials that have activity against *M. leprae* and may be used during the long course of leprosy pharmacotherapy.

During the first year of pharmacotherapy, skin lesions may actually worsen because of activation of the cell-mediated immune response. Skin edema may occur and new lesions may appear on normal skin. Most of these reactions occur because immune cells are attacking antigens released by the mycobacteria. If this occurs, corticosteroids such as prednisone are added to the regimen to reduce the severe inflammation.

PROTOTYPE DRUG Dapsone (DDS)

Classification **Therapeutic:** Antileprosy drug, antimycobacterial, antiacne drug
Pharmacologic: Folic acid inhibitor

Therapeutic Effects and Uses: Approved in 1955, dapsone is a first-line drug for the treatment of *M. leprae* infections, usually in combination with other antileprosy drugs. It has several off-label uses that include the chemoprophylaxis of malaria in combination with pyrimethamine. In combination with trimethoprim, dapsone is used for the prophylaxis and treatment of *Pneumocystis jiroveci* pneumonia in patients with AIDS. It may take 3 to 6 months of dapsone therapy before symptoms begin to improve. Pharmacotherapy for the prophylaxis of toxoplasmosis combines dapsone, pyrimethamine, and leucovorin. Dapsone 5% gel (Aczone) is approved as topical therapy for acne vulgaris.

Dapsone is the primary therapy for dermatitis herpetiformis and for autoimmune disease characterized by severe blistering skin lesions. Although its name implies herpes simplex virus as a causative agent, the etiology of the disorder is sensitivity to gluten in the diet. Gluten is a protein found in wheat products.

Mechanism of Action: The mechanism of action of dapsone is incompletely understood but is thought to be the same as that of the sulfonamides: inhibition of folic acid metabolism.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; up to 90% protein bound
Primary metabolism	Hepatic, through acetylation by CYP2E1 and CYP3A4
Primary excretion	Renal, with small amounts in the feces
Onset of action	4–8 h
Duration of action	Half-life: 20–30 h

Adverse Effects: The most frequent adverse effects of oral dapsone relate to the hematologic system: dose-related hemolysis and methemoglobinemia with cyanosis. Aplastic anemia and agranulocytosis are rare, though potentially severe, adverse effects. Toxic hepatitis has been reported. The drug concentrates in the skin, causing dermatologic reactions that include photosensitivity and toxic epidermal necrolysis. When administered topically, the most frequent side effects are erythema and skin dryness.

Contraindications/Precautions: Contraindications include hypersensitivity to dapsone or related drugs, such as sulfonamides. Because of its adverse effects on the hematologic system, caution should be used in treating patients with preexisting blood disorders. Frequent blood assessments are conducted during therapy to avoid serious adverse effects. Frequent liver enzyme testing should be conducted to monitor for hepatotoxicity, especially in patients with preexisting liver impairment.

Drug Interactions: Some patients receiving pyrimethamine and dapsone concurrently developed agranulocytosis during the second and third month of therapy; therefore, concurrent administration of these drugs must be carefully monitored. Increased dapsone levels have been reported in patients receiving trimethoprim, and patients receiving this combination may be at increased risk for dapsone toxicity. Rifampin may significantly reduce serum levels of dapsone. The H_2-receptor blockers such as ranitidine will decrease gastric pH and lower

the effectiveness of dapsone. **Herbal/Food:** Dapsone levels may be decreased by St. John's wort.

Pregnancy: Category C.

Treatment of Overdose: Acute overdose may result in cyanosis, which is treated by the slow IV administration of 1–2 mg/kg of methylene blue.

Nursing Responsibilities:

- Monitor periodic laboratory tests including white blood cell (WBC) count with differential, serum electrolytes, serum albumin, and liver function.
- Monitor for serious adverse effects such as GI bleeding, bone and joint pain, or diminished vision. Although reactions are usually reversible, they may require months or years to diminish. Other symptoms include colicky abdominal pain, nausea, and vomiting.
- Assess for any reddish-brown discoloration of the skin, cornea, conjunctiva, and body fluids. This adverse effect occurs in 75% to 90% of patients within a few weeks of treatment.
- Assess for tender, erythematous nodules with lymphadenopathy, joint swelling, epistaxis, and iritis, which can suggest a type 2 leprosy reactional state.

Lifespan and Diversity Considerations:

- Monitor hepatic function laboratory values more frequently in the older adult because normal physiologic changes related to aging may affect the drug's metabolism and excretion.
- Because dapsone is metabolized through acetylation, monitor ethnically diverse populations more frequently to ensure optimal therapeutic effects and minimize adverse effects.

Patient and Family Education:

- Maintain strict adherence to the established drug regimen and do not change the drug dosage without the approval of the healthcare provider.
- Do not drive or perform other hazardous activities until the effects of the drug are known because this drug may cause drowsiness or dizziness.
- Minimize the use of soap and rinse thoroughly, especially if the skin is dry.
- Keep all appointments for follow-up care because drug resistance and relapse may occur.
- Immediately report any of the following to the healthcare provider: changes in vision or hearing, dark urine, unusual fatigue, unusual bruising or bleeding, bluish fingernails, or yellowing of the eyes or skin.

Drugs Similar to Dapsone (DDS)

Other primary antimycobacterial drugs for leprosy include clofazimine and rifampin. Rifampin is also used for TB and is discussed in Section 51.4.

Clofazimine (Lamprene): Clofazimine is a drug that exhibits selective activity toward mycobacteria. Although its only approved indication is leprosy, clofazimine is sometimes used in the pharmacotherapy of MAC. Given only by the PO route, the drug has a 70-day half-life—one of the longest of any drug. It may take up to 50 days before it exerts a bactericidal effect. The drug has anti-inflammatory and immunosuppressive properties. Clofazimine, a bright-red dye, can cause a reddish-brown discoloration of the skin, conjunctiva, and body fluids that may take years to disappear after discontinuing therapy. Therapy of dapsone-resistant infections may require daily administration of clofazimine for several years. This drug is pregnancy category C.

Drugs for *Mycobacterium avium* Complex Infections

51.7 *Mycobacterium avium* complex infections are common in patients with impaired immune function.

MAC is the most common cause of lung disease due to atypical mycobacterial infections. Although rare in healthy people, MAC is a frequent cause of infection among those with impaired immune systems and is an expected complication in many patients with AIDS. It is also found in higher incidence in patients with chronic obstructive pulmonary disease. The infection is caused by *M. avium*, *M. intracellulare*, or a combination of atypical mycobacteria.

Unlike TB, MAC infections are not believed to be contagious or spread by human-to-human contact. The mode of transmission is not understood, although the organisms are widely distributed in soil and water and these may be the primary sources of infection. Once inside the body, MAC resides in the lungs like *M. tuberculosis*, and the initial respiratory symptoms are identical. The pathogen may travel through the lymphatics and bloodstream to infect any organ. The frequency of disseminated MAC disease has been markedly reduced in patients with AIDS because of successes in the pharmacotherapy of HIV-AIDS.

Treatment of MAC should include at least two drugs (and often three or four) because monotherapy has been shown to promote the emergence of resistant strains. Treatment is continued for at least 1 year, and relapse rates for treating pulmonary MAC are high. Primary drugs for this infection include the following:

- **Macrolide antibiotics.** Clarithromycin (Biaxin) and azithromycin (Zithromax) are relatively safe and effective against MAC and are included in most regimens.

High doses of clarithromycin (1000 mg bid) are associated with increased mortality rates.

- **Ethambutol (Myambutol).** Usually used for TB, this drug may be combined with clarithromycin in the pharmacotherapy of MAC.
- **Rifabutin (Mycobutin).** If a third drug is needed, rifabutin is often effective. Rifabutin, however, can cause many drug interactions, and high doses (600 mg/day) are associated with greater risk of serious uveitis with eye pain. Rifabutin is approved only for the prophylaxis of MAC in patients with HIV infection, although it is also used off-label to treat active infections.
- **Aminoglycosides.** Streptomycin and amikacin are indicated for severe MAC lung disease, especially in patients with AIDS.

Understanding Chapter 51

Key Concepts Summary

51.1 Several species of mycobacteria are important human pathogens.

51.2 Tuberculosis is a respiratory infection that exhibits both active and latent stages.

51.3 The pharmacotherapy of tuberculosis requires special dosing regimens and schedules.

51.4 First-line or primary antituberculosis drugs are the most efficacious and safest drugs for treating *M. tuberculosis* infections.

51.5 Second-line antituberculosis drugs are used when resistance develops to the first-line drugs.

51.6 Leprosy is caused by a mycobacterium and is treated by a multidrug regimen.

51.7 *Mycobacterium avium* complex infections are common in patients with impaired immune function.

CASE STUDY: Making the Patient Connection

Remember the patient "Sam Myers" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Sam Myers is a 58-year-old man who is homeless and spends some nights in shelters and some nights on the street. For the past 6 weeks, he has experienced anorexia, weight loss, and low-grade fever. He comes to the local church health center and presents with a productive cough that has progressively worsened.

A history and physical examination is completed with an evaluation for TB. The physical examination reveals the following findings: The patient's height is 1.9 m (6′1″) and his weight is 56.2 kg (124 lb). He is emaciated and obviously malnourished. His vital signs are blood pressure, 112/82 mmHg; heart rate, 102 beats/min; respiratory rate, 26 breaths/min; and body temperature, 38.2°C (100.9°F). On auscultation, crackles are heard in the upper lung fields. The patient is experiencing moderate dyspnea. Sam's chest x-ray reveals multiple calcifications and two cavitary masses in the apical posterior segments of the upper lobes of the lungs with lymphadenopathy also present. Sam admits to drinking alcohol almost every day and smoking at least one pack of cigarettes per day. He is admitted to a local acute care hospital for treatment of pulmonary TB.

Critical Thinking Questions

1. Describe the mechanism of transmission for *M. tuberculosis.*
2. Discuss how Sam's living conditions predispose him to pulmonary TB.
3. Why is Sam at high risk for hepatic-related adverse drug effects?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Georgia Sully has been diagnosed with an active TB infection after several months of increasing fevers, night sweats, productive cough, and weight loss. She is prescribed isoniazid (INH), ethambutol (Myambutol), rifampin (Rifadin), and pyrazinamide (PZA) for 6 months. She is also given instructions to take a daily dose of pyridoxine (vitamin B_6). She lives in a state that requires DOT for all patients receiving treatment for active TB.

1. Georgia is worried and questions the nurse about why she is receiving four different drugs for her tuberculosis. How would you respond?
2. Discuss why Georgia is receiving vitamin B_6 supplements.
3. Georgia asks what "directly observed therapy" is and why she needs it. What would you explain about DOT?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient who is receiving isoniazid (INH) reports tingling and numbness of the fingers and toes. The nurse knows that these symptoms are most likely due to the drug's ability to:
   1. Increase the sensitivity of nerve endings.
   2. Decrease the activity of pyridoxine (vitamin B_6).
   3. Accelerate the excretion of neurotransmitters.
   4. Enhance skin receptors for ascorbic acid (vitamin C).

2. Ethambutol (Myambutol) has been included as part of a multidrug regimen to treat a patient with active tuberculosis. Prior to starting this drug, which screening tests should the patient have? (Select all that apply.)
   1. Coagulation studies
   2. Sputum cultures
   3. Uric acid level
   4. Hepatic function tests
   5. Vision acuity and vision color sense screening

3. A patient is identified by ethnic background as a possible slow acetylator and will be closely followed after beginning isoniazid therapy for latent tuberculosis. To ensure that this patient does not experience adverse effects related to the acetylation process, both _____ and _____ will be monitored frequently.

4. A patient with HIV infection who also has a *Mycobacterium avium* complex infection is started on clarithromycin (Biaxin) and ethambutol (Myambutol). What appropriate teaching should the nurse give this patient?
   1. You will remain contagious until drug treatment is completed.
   2. These drugs will be required only for a short period of time, approximately 2 to 3 weeks.
   3. Drug therapy will be stopped if CD4 counts drop below 50 cells/mL.
   4. It will be necessary to continue these drugs for a prolonged period of time to adequately treat the infection.

5. The patient is diagnosed with *Mycobacterium leprae* (leprosy) and is being treated with dapsone (DDS). Which nursing assessment findings would indicate that the patient is experiencing adverse effects from this therapy?
   1. Discoloration of skin, cornea, and conjunctiva
   2. Chronic constipation, chills, and dehydration
   3. Hypoglycemia, impaired memory, and impotence
   4. Memory loss, nervousness, and pruritus

6. Patients with diabetes who take isoniazid (INH) may require more frequent monitoring of blood glucose levels. What effect does isoniazid have on glucose levels?
   1. It may decrease glucose levels.
   2. It has no known effects on glucose levels.
   3. It may increase glucose levels.
   4. It causes rapid rises and falls of glucose levels.

Chapter 52
Pharmacotherapy of Fungal Infections

Chapter Outline

- Characteristics of Fungi and Fungal Infections
- Drugs for Systemic Fungal Infections

  PROTOTYPE *Amphotericin B Deoxycholate (Fungizone), p. 939*
- Drugs for Both Systemic and Superficial Fungal Infections

  PROTOTYPE *Fluconazole (Diflucan), p. 941*
- Drugs for Superficial Fungal Infections

  PROTOTYPE *Nystatin (Nystop), p. 946*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the pharmacotherapy of fungal and bacterial infections.
2. Classify mycoses based on the location of the infection and the causative organism.
3. Compare and contrast the pharmacotherapy of systemic and superficial fungal infections.
4. Identify the types of patients at greatest risk of acquiring serious fungal infections.
5. Describe the nurse's role in the pharmacologic management of fungal infections.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy for fungal infections.

Key Terms

azole, 941
β-glucan, 936
dermatomycoses, 943
ergosterol, 936
fungi, 935
mycoses, 936
onychomycosis, 945

The past few decades have seen a dramatic rise in the incidence of fungal infections due to acquired immunodeficiency syndrome (AIDS), aggressive cancer chemotherapy, the widespread use of indwelling intravenous (IV) catheters, and the use of broad-spectrum antibiotics. Fungi are much more complex than bacteria and require a different approach to pharmacotherapy. Because of these structural and functional differences, most antibacterial drugs are ineffective against fungi. Although there are fewer drugs to treat fungal infections, the available medications are usually effective.

Characteristics of Fungi and Fungal Infections

52.1 Serious fungal infections are uncommon in people with healthy immune defenses.

Fungi are single-celled or multicellular organisms that serve essential roles on the planet as decomposers of dead plants and animals, returning their elements to the soil for recycling. Fungi include mushrooms, yeasts, and molds. Although 100,000 to 200,000 species of fungi exist in soil, air, and water, only about 50 species are associated with disease in humans. A few species of fungi survive as part of the normal host flora on the skin, mouth, and urogenital tract.

Unlike bacteria, which produce toxins or grow rapidly to overwhelm hosts' defenses, some fungi grow slowly and infections may progress for many months before symptoms develop. With a few exceptions (such as athlete's foot), fungal infections are not easily transmitted through casual contact. In addition to causing infections, fungal antigens may trigger hypersensitivity responses in susceptible patients, resulting in allergies to mold or mildew. A few fungi, such as *Aspergillus flavus*, secrete toxins that can cause illness in humans through ingestion of contaminated grains or other foods.

The human body is remarkably resistant to infection by these organisms and patients with healthy immune defenses experience few serious fungal diseases. However, patients with a suppressed immune system (immunocompromised), especially those infected with human immunodeficiency virus (HIV), may experience frequent fungal infections and require aggressive pharmacotherapy. A systemic fungal infection in an immunocompromised patient may be rapidly fatal.

The species of pathogenic fungi that attack hosts with healthy immune defenses are often distinct from those that infect immunocompromised patients. Patients with intact immune defenses are afflicted with community-acquired infections such as sporotrichosis, blastomycosis, histoplasmosis, and coccidioidomycosis. Opportunistic fungal infections acquired in a hospital setting are more likely to be candidiasis, aspergillosis, cryptococcosis, and mucormycosis. Thus, assessing the immune status of a patient may help in diagnosing the specific infection and in determining the course of pharmacotherapy. Table 52.1 lists the species of fungi that most commonly cause disease in humans.

Table 52.1 Fungal Pathogens

Name of Fungus	Description
Systemic	
Aspergillus fumigatus and other species	Aspergillosis: Opportunistic; most commonly affects the lungs but can spread to other organs
Blastomyces dermatitides	Blastomycosis: Begins in the lungs and spreads to other organs
Candida albicans and other species	Candidiasis: Most common opportunistic fungal infection; may affect nearly any organ
Coccidioides immitis	Coccidioidomycosis: Begins in the lungs and spreads to other organs
Cryptococcus neoformans	Cryptococcosis: Opportunistic; begins in the lungs but is the most common cause of meningitis in patients with AIDS
Histoplasma capsulatum	Histoplasmosis: Begins in the lungs and spreads to other organs
Mucorales species	Mucormycosis: Opportunistic; affects blood vessels, causes sinus infections, stomach ulcers, and other disorders
Pneumocystis jirovecii	*Pneumocystis* pneumonia: Opportunistic; primarily pneumonia of the lung but can spread to other organs
Superficial	
Candida albicans and other species	Candidiasis: Affects the skin, nails, oral cavity (thrush), vagina
Epidermophyton floccosum	Athlete's foot (tinea pedis), jock itch (tinea cruris), and other skin infections
Microsporum species	Ringworm of the scalp (tinea capitis)
Trichophyton species	Affects the scalp, skin, and nails
Subcutaneous and Cutaneous	
Sporothrix schenckii	Sporotrichosis: Primarily affects the skin and superficial lymph nodes
Mixed species	Chromoblastomycosis: Chronic skin mycosis found in tropical and subtropical climates

PharmFACT

Certain medications can weaken the immune system and increase the risk of a fungal infection. Patients taking antineoplastics, corticosteroids, and tumor necrosis factor (TNF) inhibitors such as adalimumab (Humira) should be monitored for mycoses during therapy (Centers for Disease Control and Prevention [CDC], 2017)

52.2 Mycoses are classified as superficial, subcutaneous, or systemic.

Fungal infections are called **mycoses** (singular, *mycosis*). A simple and useful method of classifying fungal infections is to consider them as superficial, subcutaneous, or systemic.

Superficial mycoses affect the scalp, skin, nails, and mucous membranes such as the oral cavity and vagina. Only the surface layers of these regions are affected. Mycoses of this type are often treated with topical drugs, because these medications can penetrate into the keratin layer of the skin while producing few systemic adverse effects.

Subcutaneous and cutaneous mycoses are infections that affect deeper skin layers, including the dermis and subcutaneous layers. Often, the organisms that cause subcutaneous and cutaneous infections are different from those that cause superficial infections, as listed in Table 52.1. Because these fungal species often reside in soil, gardeners or people working in occupations involving exposure to soil can acquire these infections through cuts or abrasions on their skin. In addition, these infections occur in greater incidence in regions where the population travels barefoot. Topical antifungal preparations may not penetrate deep enough to reach the pathogen, thus oral (PO) antifungal therapy may be indicated. Some textbooks consider subcutaneous mycoses as subtypes of superficial mycoses.

Systemic mycoses are those that affect internal organs, typically the lungs, brain, and digestive organs. These infections often originate in the lungs, through inhalation of fungal spores. Although less common than superficial or subcutaneous mycoses, systemic fungal infections affect multiple body systems and may be fatal to patients with severely suppressed immune systems. Invasive systemic mycoses require aggressive PO or parenteral medications that produce more adverse effects than the topical drugs.

Historically, antifungal drugs used for superficial infections were clearly distinct from those prescribed for systemic infections. In recent years, this distinction has blurred. Some of the newer antifungals may be used for superficial, subcutaneous, or systemic infections. Furthermore, some superficial infections may be treated with parenteral, oral, or topical drugs. This therapeutic division, however, is still useful because it separates the pharmacotherapy of relatively benign infections (superficial) from those that may be life threatening (systemic).

52.3 Antifungal drugs act by disrupting the fungal cell membrane or wall, affecting fungal enzymes, or disrupting replication.

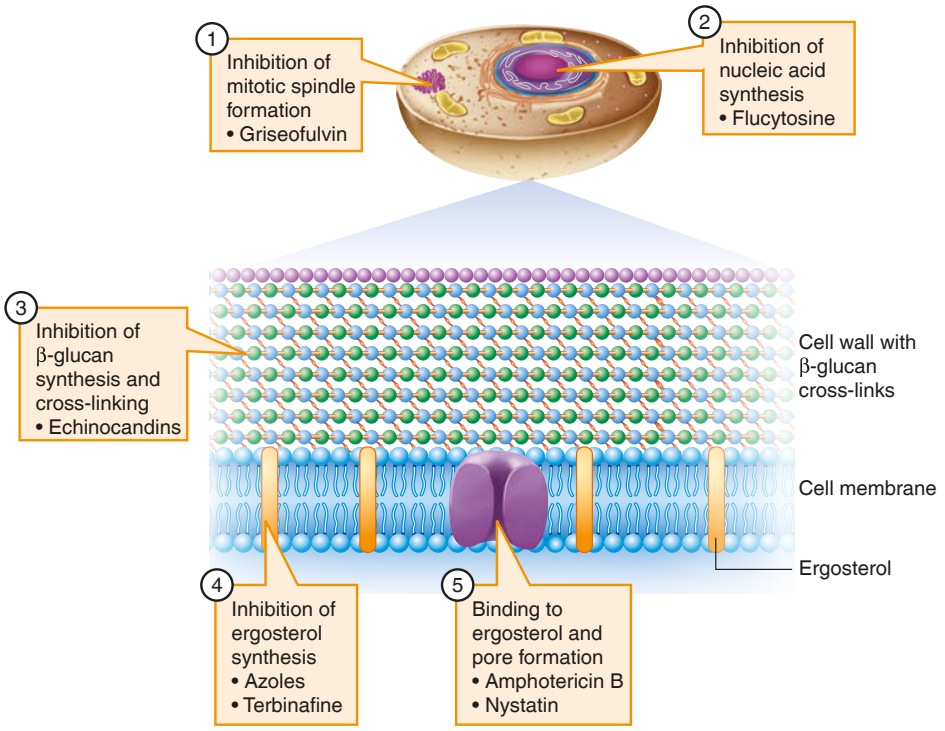
Biologically, fungi are classified as eukaryotes: Their cellular organelles and metabolic pathways are more similar to those of humans than those of bacteria. Antibiotics that are efficacious against bacteria are ineffective in treating mycoses due to these differences in physiology; thus, an entirely different set of drugs is needed to eliminate fungal pathogens.

Like antibacterials, the antifungal drugs may either slow the growth of the organisms (fungistatic) or kill them (fungicidal). The five mechanisms of action of the antifungal drugs are illustrated in Pharmacotherapy Illustrated 52.1.

One important difference between fungal cells and human cells is the specific steroid used in constructing plasma membranes. While cholesterol is essential for animal cell membranes, **ergosterol** is present in fungi. The largest class of antifungals, the azoles, inhibits ergosterol biosynthesis, causing the fungal plasma membrane to become porous or leaky. Amphotericin B (Fungizone), terbinafine (Lamisil), and nystatin also act by this mechanism.

Caspofungin (Cancidas) disrupts fungal cell walls by inhibiting the synthesis of **β-glucan**, an essential component that shapes and strengthens the cell wall. Without sufficient β-glucan, the wall weakens and becomes porous, causing the death of the cell. Chitin is another material in the cell wall of fungi. The polyoxins are fungicides that interfere with chitin synthesis and are widely used in agriculture.

Some antifungals act by mechanisms that take advantage of enzymatic differences between fungi and humans. In fungi, flucytosine (Ancobon) is converted to the potent antimetabolite fluorouracil, which inhibits both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis. Humans do not have the enzyme necessary for this conversion. Fluorouracil itself is a common antineoplastic medication (see Chapter 57).



A final mechanism is used by the drug griseofulvin (Gris-PEG). This drug is incorporated into newly formed keratin where it protects against fungal invasion. Once it has entered the fungal cell, it disrupts the mitotic spindle, preventing replication.

CONNECTION Checkpoint 52.1

From what you learned in Chapter 47, what major classes of antibacterials act by disrupting cell walls? Why are these drugs not effective against fungi? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Asthma and Exposure to Fungal Pathogens

Case

Tyler, a 9-year-old boy, presents to our pediatric pulmonology clinic with severe persistent asthma and atopic dermatitis that he has had since he was 2 years old. He has been hospitalized 3 times for his asthma in the past 18 months. He lives in a major metropolitan city and for several years the family has lived in the same apartment. While taking his health history his mother mentions her concern about the possibility that the visible mold on the windows of the apartment may be making Tyler sick. Results of pulmonary-function tests (PFTs) confirm the asthma diagnosis (he improved after bronchodilator therapy). He has been treated for asthma by his pediatrician in a stepwise fashion, eventually requiring high-dose inhaled corticosteroids, long-acting β agonists, leukotriene receptor antagonists, and antihistamines. Despite these medications, Tyler continues to exhibit daily symptoms that require frequent bursts of high-dose systemic steroids. Because his skin testing was positive for *Aspergillus*, Tyler was started on 100 mg of itraconazole by mouth twice per day. Within 6 weeks, he reported complete resolution of symptoms, and after 6 months on itraconazole, his systemic steroids were weaned and he was maintained on inhaled corticosteroids, long-acting β agonists, and leukotriene receptor antagonists. Throughout the 6-month treatment period, he experienced only one exacerbation. The family will be relocating to a new apartment at the end of their lease in 1 month. Why did the itraconazole help control Tyler's asthma?

Discussion

Asthma is a serious public health problem affecting people of all ages. When uncontrolled, asthma can lead to severe limitation on activities of daily life and may even be fatal. Uncontrolled asthma generally affects only a small percentage of the total asthma population. It is difficult to treat, prone to recurrent exacerbations, and contributes disproportionately to the overall costs of asthma. Exposure to environmental fungal spores has been associated with worsening asthma severity including worsening lung function, increased hospital admissions, and asthma-related deaths (Agarwal & Chakrabarti, 2013).

Preventing exposure to fungal pathogens is the ideal clinical strategy (CDC, 2014):

- Keep humidity levels as low as you can.
- Use exhaust fans that vent outside your home in the kitchen and bathroom.
- Clean and dry out your home thoroughly and quickly after flooding.
- Add mold inhibitors to paints before applying.
- Clean bathrooms with mold-killing products.
- Remove or replace carpets and upholstery that have been soaked and cannot be dried promptly.

Drugs for Systemic Fungal Infections

52.4 Systemic or invasive fungal disease may require intensive pharmacotherapy for extended periods.

Because human body defenses provide a formidable barrier to fungi, systemic mycoses are rarely encountered in individuals with healthy immune systems. The AIDS epidemic, however, resulted in the frequent clinical occurrence of previously rare mycoses, such as cryptococcosis and coccidioidomycosis. The opportunistic disease in patients with AIDS spurred the development of several new drugs for systemic fungal infections. In addition to occurring in patients with AIDS, others who may experience systemic mycoses include those receiving prolonged therapy with corticosteroids, having extensive burns, receiving antineoplastic drugs, having indwelling vascular catheters, or receiving organ transplants. Prophylactic antifungal therapy is sometimes indicated for these high-risk patients.

Pharmacotherapy of systemic mycoses is often continued for many months to ensure that the fungus is eliminated. Unlike the superficial antifungal medications, systemic drugs have the potential to cause serious adverse effects and therapy must be carefully monitored. The systemic antifungal drugs are listed in Table 52.2.

Pharmacologic options for serious systemic mycoses are limited. Amphotericin B (Fungizone) has been the traditional preferred drug for systemic fungal infections since the 1960s. Azole drugs such as itraconazole, however, are considerably safer and have become preferred drugs for less severe infections. Although rarely used as a monotherapy, flucytosine (Ancobon) is sometimes used in combination with amphotericin B in the pharmacotherapy of severe *Candida* infections. Voriconazole (Vfend) has become the preferred drug for treating invasive aspergillosis, a rare though particularly lethal mycosis with a high mortality

Table 52.2 Drugs for Systemic Mycoses

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
amphotericin B (Abelcet, AmBisome, Amphotec, Fungizone)	IV: 0.3–1.5 mg/kg/day, infused over 2–4 h (max: 1.5 mg/kg/day)	*Hypokalemia, hypomagnesemia, rash, fever and chills, nausea, vomiting, anorexia, headache* Nephrotoxicity, liver failure, anaphylaxis, cardiac arrest, thrombocytopenia, leukopenia, agranulocytosis, anemia
anidulafungin (Eraxis)	Candidemia: IV: 200 mg on day 1, then 100 mg/day for 14 days Esophageal candidiasis: IV: 100 mg on day 1, then 50 mg/day for 7–14 days Infusion rate should not exceed 1.1 mg/min	*Diarrhea, nausea, vomiting, mild allergic reactions, hypokalemia* Neutropenia, dysrhythmias, hepatic impairment, anaphylaxis
caspofungin (Cancidas)	IV: 70 mg on day 1, then 50 mg/day infused over 1 h for 14 days	*Fever, chills, diarrhea, increased serum alkaline phosphatase, hypokalemia* Anaphylaxis, hepatic impairment
flucytosine (Ancobon)	PO: 25 mg/kg every 6 h to reach a peak concentration of 50–100 mcg/mL	*Nausea, vomiting, headache* Blood dyscrasias, cardiac toxicity, renal failure, psychosis
micafungin (Mycamine)	IV: 150 mg/day over 1 h for active *Candida* infection; 50 mg/day over 1 h for *Candida* prophylaxis	*Headache, fever, nausea, vomiting, diarrhea, rash* Thrombocytopenia, hemolytic anemia, anaphylaxis, hepatic and renal failure
Azoles		
fluconazole (Diflucan)	PO/IV: 200–400 mg on day 1, then 100–200 mg/day for 2–4 wk PO (for vaginal candidiasis): 150 mg single dose	*Fever, chills, rash, dizziness, drowsiness, nausea, vomiting, diarrhea* Hepatotoxicity, anaphylaxis, blood dyscrasias, visual disturbances (voriconazole), dysrhythmias (posaconazole, voriconazole)
isavuconazonium (Cresemba)	PO/IV: 372 mg daily	
itraconazole (Sporanox)	PO: 200 mg/day (max: 400 mg/day)	
ketoconazole (Nizoral)	PO: 200–400 mg/day	
posaconazole (Noxafil)	PO (delayed release tablet): 100–300 mg daily (max: 400 mg/day)	
voriconazole (Vfend)	IV: 6 mg/kg on day 1, then 4 mg/kg q12h PO (maintenance dose): 200 mg q12h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

rate. In 2015, isavuconazonium (Cresemba) was approved by the U.S. Food and Drug Administration (FDA) as an alternative option for treating invasive aspergillosis.

PROTOTYPE DRUG **Amphotericin B Deoxycholate (Fungizone)**

Classification **Therapeutic:** Antifungal (systemic type)
Pharmacologic: Polyene

Therapeutic Effects and Uses: Approved in 1957, amphotericin B has a broad spectrum of activity that includes most fungi that are pathogenic to humans. It has been the traditional preferred drug for treating severe systemic mycoses and may also be indicated as prophylactic antifungal therapy for patients with severe immunosuppression. Because it is not absorbed from the gastrointestinal (GI) tract, it is normally given by IV infusion. Topical preparations are available for superficial mycoses that do not respond favorably to safer antifungals. Several months of pharmacotherapy may be required for a complete cure. Fungal resistance to amphotericin B is not a major clinical problem.

To reduce the toxicity of amphotericin B, the original molecule has been formulated with several different types of lipid molecules:

- **Liposomal amphotericin B (AmBisome).** Consists of closed spherical vesicles. Amphotericin B is integrated into the membrane, as illustrated in Figure 52.1.
- **Amphotericin B lipid complex (Abelcet).** Contains amphotericin B complexed with two phospholipids in a 1:1 ratio.
- **Amphotericin B cholesteryl sulfate complex (Amphotec).** Consists of a colloidal suspension of amphotericin B in a 1:1 ratio with the lipid cholesteryl sulfate in microscopic disk-shaped particles.

The principal advantage of the lipid formulations is reduced nephrotoxicity and less infusion-related fever and chills. The reduced toxicity is believed to be due to the decreased plasma levels of the drug. Macrophages ingest the lipid formulations and deliver the medication to its fungal targets before it can accumulate to high serum levels that cause toxicity. Because of their expense, however, the lipid preparations are not considered first-line drugs and are generally used only after therapy with other antifungals has failed. A single treatment with the lipid formulations of amphotericin B can cost several thousand dollars.

Mechanism of Action: Amphotericin B acts by binding to ergosterol in fungal cell membranes, causing them to become permeable.

Pharmacokinetics:

Route(s)	IV, topical
Absorption	Not absorbed topically
Distribution	Widely distributed; very little enters the cerebrospinal fluid (CSF) or amniotic fluid; about 90% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	IV: immediate
Duration of action	Half-life: 24–48 h; drug may persist several weeks after therapy is discontinued

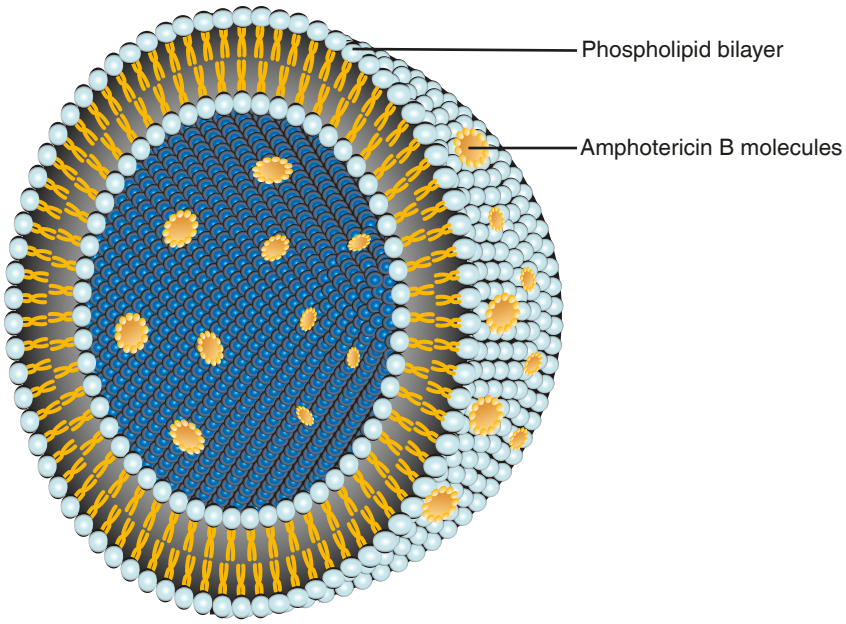

Figure 52.1 Liposomal amphotericin B: Drug molecules are embedded in the phospholipid bilayer.

Adverse Effects: Amphotericin B can produce frequent and sometimes serious adverse effects. At the onset of therapy, as many as 50% of patients experience acute, infusion-related fever and chills, vomiting, anorexia, and headache. These symptoms usually subside as treatment continues. Phlebitis is also common during IV therapy, and alternate-day dosing is sometimes needed to reduce this adverse effect. Amphotericin B can cause ototoxicity, potentially affecting both branches, cochlear and vestibular, of cranial nerve VIII.

The most toxic effects of amphotericin B are related to its effects on the kidney. Some degree of nephrotoxicity is observed in 80% of patients taking amphotericin B; thus laboratory tests of kidney function are regularly performed throughout the treatment period. Electrolyte imbalance, especially

hypokalemia and hypomagnesemia, may develop as a result of renal damage, and place the patient at greater risk of developing life-threatening dysrhythmias and cardiac arrest. Concurrent therapy with other medications that reduce liver or renal function, such as aminoglycosides, is not recommended.

Amphotericin B is occasionally hepatotoxic. Anaphylaxis is possible, and cardiac arrest has been reported. Blood abnormalities, including thrombocytopenia, leukopenia, agranulocytosis, and anemia, are potentially serious adverse effects. **Black Box Warning:** The nonliposomal form of this drug should only be used for patients with a progressive and potentially life-threatening fungal infection. Caution should be exercised to prevent overdosage.

Contraindications/Precautions: Amphotericin B should be infused slowly, over 2 to 6 hours, because hypotension, hypokalemia, and shock may result if the medication is administered too rapidly. The drug should be withheld if blood urea nitrogen (BUN) exceeds 40 mg/dL or if serum creatinine rises above 3 mg/dL.

Drug Interactions: Drug interactions with amphotericin B focus on worsening two of its potentially serious adverse effects: nephrotoxicity and hypokalemia. For example, concurrent therapy with aminoglycosides, cyclosporine, acyclovir, carboplatin, and tacrolimus is not recommended. Corticosteroids, skeletal muscle relaxants, and thiazole may potentiate hypokalemia caused by amphotericin B. Drug-induced hypokalemia will also increase the risk of digoxin toxicity. Because animal studies have indicated an antagonistic effect between amphotericin B and certain azoles (imidazoles), concurrent therapy with this class of antifungals is usually avoided. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Overdose may result in cardiorespiratory arrest. No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving amphotericin B are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antifungals.

Drugs Similar to Amphotericin B Deoxycholate (Fungizone)

Other systemic antifungals include the β-glucan synthesis inhibitors, flucytosine, and certain azole drugs (see Section 52.5).

β-Glucan synthesis inhibitors: Caspofungin (Cancidas), micafungin (Mycamine), and anidulafungin (Eraxis) belong to a class of antifungals called echinocandins or β-glucan synthesis inhibitors. The echinocandins are better tolerated than amphotericin B and do not exhibit significant nephrotoxicity or hepatotoxicity. All three drugs in this class are pregnancy category C.

Caspofungin was approved in 2001 and is particularly effective against invasive *Candida* and *Aspergillus* species. It is effective against some fungal species that have developed resistance to amphotericin B and the azoles. The drug is given by slow IV infusion. Adverse effects with caspofungin include fever, rash, and infusion-related reactions such as phlebitis, diarrhea, headache, and nausea. Caution should be used when administering caspofungin to patients with hepatic impairment.

Micafungin, approved in 2005, is used to treat acute disseminated candidiasis, esophageal candidiasis, and *Candida* infections in patients undergoing bone marrow transplants. It is administered by slow IV infusion. Micafungin causes transient increases in hepatic enzymes, headache, nausea, and vomiting. Although rare, serious cases of renal and hepatic impairment and hematologic toxicity have occurred with micafungin.

Anidulafungin was approved in 2006 for candidemia and other systemic *Candida* infections. Like other drugs in this class, anidulafungin is only administered by slow IV infusion. The drug is generally well tolerated with adverse reactions occurring in 2% or less of patients. These adverse effects are generally not severe and include fever, diarrhea, hypokalemia, and increases in liver function test values.

Flucytosine (Ancobon): Unlike amphotericin B and caspofungin, which must be given parenterally, flucytosine is well absorbed from the GI tract. Approved in 1990, flucytosine is structurally similar to cytosine, a nucleotide used in DNA synthesis. When the fungus attempts to use flucytosine to construct its DNA, cell division is inhibited. It is approved to treat septicemia and pulmonary and urinary tract infections due to *Candida* and *Cryptococcus* species. Unfortunately, resistance to flucytosine is becoming a major clinical problem. The drug is sometimes used in combination with amphotericin B to reduce the potential for treatment failure due to resistance. Combination therapy also permits the use of lower doses of amphotericin B, thus reducing the risk of nephrotoxicity.

Although adverse GI effects are common with flucytosine, they are usually not severe. The drug carries a black box warning that extreme caution should be used in patients with chronic kidney disease (CKD). The warning urges close monitoring of hematologic, renal, and hepatic status during therapy. Flucytosine can cause bone marrow toxicity, leukopenia, agranulocytosis, and thrombocytopenia. Serum concentrations of flucytosine should be less than 100 g/mL to avoid bone marrow suppression. Flucytosine may cause hepatitis and elevate serum levels of hepatic enzymes. This drug is pregnancy category C.

Drugs for Both Systemic and Superficial Fungal Infections

52.5 Azoles are the preferred drugs for many mycoses due to their efficacy and favorable safety profile.

The **azole** class is the largest and most versatile group of antifungals. These drugs have broad spectrums and are used to treat nearly any systemic, subcutaneous, or superficial fungal infection. They have replaced many of the older antifungals because they can be administered PO and have a superior safety profile.

The azoles are sometimes grouped by chemical or therapeutic classes. The azoles form two distinct chemical classes, as follows:

- **Imidazoles:** Butoconazole, clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, sulconazole, and ticonazole
- **Triazoles:** Fluconazole, isavuconazonium, itraconazole, posaconazole, terconazole, and voriconazole

The triazoles are more slowly metabolized and appear to elicit fewer adverse effects than the imidazoles. In clinical practice, imidazoles and azoles exhibit the same spectrum of activity and act by the same mechanism.

A second method of classifying azoles is by their therapeutic utility as either systemic or topical drugs. Fluconazole (Diflucan), itraconazole (Sporanox), ketoconazole (Nizoral), posaconazole (Noxafil), and voriconazole (Vfend) are used for both systemic and topical infections. The remainder of the azoles are prescribed for superficial infections (see Section 52.6).

Azoles interfere with the biosynthesis of ergosterol, which is essential for the construction of fungal cell membranes. By depleting the fungal cells of ergosterol, fungal growth is impaired.

The systemic azoles have a spectrum of activity similar to that of amphotericin B, are less toxic, and have the major advantage that they can be administered PO. Because of these characteristics, some of the azoles have replaced amphotericin B in the pharmacotherapy of less serious systemic fungal infections.

The most common adverse effects of the systemic azoles are nausea and vomiting, which occur in 10% to 20% of patients. Giving the drugs with food or in divided doses may relieve minor GI distress. Severe nausea may require dose reduction or the concurrent administration of an antiemetic. Asymptomatic elevations of serum aminotransferase levels are common during therapy. Anaphylaxis and rash have been reported. Fatal drug-induced hepatitis has occurred with ketoconazole, though the incidence is rare and has not been reported with the other systemic azoles. Because of this, itraconazole has largely replaced ketoconazole in the therapy of systemic mycoses. With all the systemic azoles, liver function tests should be obtained before therapy begins and throughout the course of treatment. Azoles may affect glycemic control, so blood glucose should be monitored regularly in patients with diabetes and those with metabolic syndrome.

Various reproductive abnormalities have been reported with systemic azoles, including menstrual irregularities, gynecomastia in men, and drops in plasma testosterone levels. Decreased libido and temporary sterility in men are other potential adverse effects. Fluconazole is teratogenic in laboratory animals and the safety of the azoles during pregnancy has not been established. The risk–benefit ratio should be carefully weighed before initiating azole therapy in a pregnant patient.

PROTOTYPE DRUG **Fluconazole (Diflucan)**

Classification **Therapeutic:** Antifungal
Pharmacologic: Inhibitor of fungal cell membrane synthesis, triazole (azole)

Therapeutic Effects and Uses: Approved in 1990, fluconazole is available as tablets, oral suspension, and IV injection. It is particularly effective against *Candida albicans* and is used to treat oropharyngeal candidiasis, esophageal candidiasis, vulvovaginal candidiasis, and various systemic infections by this species. It is also effective against cryptococcal meningitis and may be used for mycoses that are resistant to other antifungals. Fluconazole is less effective against non-*albicans Candida* species, which account for a significant percentage of opportunistic fungal infections. The drug is approved for prophylaxis of fungal infections in patients with AIDS, those undergoing bone marrow transplants, and those receiving antineoplastic drugs.

Fluconazole offers several advantages over other systemic antifungals. It is rapidly and completely absorbed when given PO and is also available by the IV route. Compared to itraconazole and ketoconazole, it more easily penetrates body membranes to reach infections in the central nervous system (CNS), bone, eye, urinary tract, and respiratory tract.

Mechanism of Action: Like other azoles, fluconazole acts by interfering with the synthesis of ergosterol.

Pharmacokinetics:

Route(s)	IV, PO
Absorption	Readily absorbed PO
Distribution	Widely distributed, including the CSF; secreted in breast milk; 12% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Peak effect: 1–2 h
Duration of action	Half-life: 20–50 h

Adverse Effects: Fluconazole causes few serious adverse effects. Nausea, vomiting, and diarrhea are reported at high doses. Because the kidneys excrete most of the drug, it should be used cautiously in patients with chronic kidney disease. Hepatotoxicity with fluconazole is less common than with ketoconazole. Stevens–Johnson syndrome has been reported in patients with immunosuppression.

Contraindications/Precautions: The only contraindication to fluconazole is hypersensitivity to the drug or another azole. Fluconazole should be used with caution in patients with hepatic impairment because the drug is metabolized in the liver: Hepatic injury has occurred with this drug. When given by the IV route, fluconazole is usually prepared without added medications because it is incompatible with a number of drugs. Patients with hypokalemia should be treated with caution because fluconazole may worsen this electrolyte imbalance.

Drug Interactions: Fluconazole is a strong inhibitor of CYP2C9, CYP2C19, and CYP3A4; therefore, it has the potential to interact with several drugs. Use with warfarin (Coumadin) may increase prothrombin time and cause increased risk for bleeding. Hypoglycemia may result if fluconazole is administered concurrently with certain oral hypoglycemics, including glyburide. Fluconazole levels may be decreased with concurrent rifampin or cimetidine use. The effects of fentanyl, benzodiazepines, tricyclic antidepressants, or methadone may be prolonged with concurrent administration of fluconazole. Fluconazole increases the serum level of phenytoin; careful monitoring of phenytoin concentrations is recommended to avoid CNS toxicity. Rifampin increases the metabolism of fluconazole; thus, the dose of fluconazole may need to be increased to maintain therapeutic plasma levels. Concurrent use of fluconazole and erythromycin is contraindicated because the combination can increase the level and effect of erythromycin and increase the QT interval. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically. Dialysis can be used to lower serum drug level.

Nursing Responsibilities: Key nursing implications for patients receiving fluconazole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antifungals.

Drugs Similar to Fluconazole (Diflucan)

Other systemic azoles include isavuconazonium, itraconazole, ketoconazole, posaconazole, and voriconazole.

Isavuconazonium (Cresemba): Isavuconazonium is a prodrug that is rapidly converted to its active form, isavuconazole, by enzymes in the blood. Given either PO or IV, it was approved in 2015 to treat invasive aspergillosis and mucormycosis infections. Because isavuconazole is a substrate for CYP450 enzymes 3A4 and 3A5, the drug should not be administered concurrently with CYP3A4 inhibitors such as ketoconazole or carbamazepine. Frequent adverse effects include nausea, vomiting, diarrhea, headache, and elevated hepatic laboratory test results. Serious hepatotoxicity has been reported. Isavuconazonium exhibits embryo and fetal toxicity and should be used in pregnant women only if the benefit to the mother outweighs the risk to the fetus.

Itraconazole (Sporanox): Approved in 1992, itraconazole is available as capsules, PO solution, and IV injection. Its spectrum is similar to that of other azoles, except it may have greater activity against *Aspergillus*. It is metabolized in the liver to hydroxyitraconazole, which also has antifungal activity. Because the drug may take 2 or more weeks to reach therapeutic levels, a loading dose is infused when treating invasive mycoses. The PO capsules should be taken with food to enhance absorption; however, the PO solution should be taken on an empty stomach. Both PO formulations require an acidic stomach environment for absorption and thus should not be taken concurrently with drugs or foods that decrease stomach acidity.

The most common adverse effects of itraconazole are GI related, especially nausea, which occurs in about 10% of patients. Hepatotoxicity is a rare, though potentially serious, adverse effect, which warrants periodic monitoring of liver laboratory tests. Itraconazole carries a black box warning that the drug should be discontinued if any signs of cardiotoxicity or heart failure arise during therapy. The warning also states that care should be taken when administering itraconazole with other medications, since numerous drug–drug interactions have been reported. Concurrent administration of itraconazole with benzodiazepines or statins is contraindicated. This drug is pregnancy category C.

Ketoconazole (Nizoral): Approved in 1981, ketoconazole is available as tablets for systemic mycoses and as a topical preparation for superficial mycoses. The topical drugs are used to treat dandruff and various tinea infections (see Section 52.6). PO ketoconazole requires an acidic stomach environment for absorption and thus should not be taken concurrently with drugs or foods that decrease stomach acidity. As a systemic drug, it is reserved for invasive mycoses, because it is the most hepatotoxic of the azoles. The most common adverse effects are nausea and vomiting, which can affect over 50% of patients taking high doses of the drug.

Ketoconazole carries several black box warnings, and in 2013 the FDA issued a safety alert that the oral form of the drug should be used only when alternative antifungal

therapies have not proven successful. Ketoconazole has been associated with serious hepatotoxicity that can result in death or the need for liver transplantation. Hepatic function must be monitored regularly during therapy and it should not be used in patients with acute or chronic liver disease. Ketoconazole reduces the amount of corticosteroids secreted by the adrenal glands, which can cause symptoms of adrenal insufficiency. Ketoconazole may interact with other medications to cause serious drug–drug interactions; all drugs taken while undergoing ketoconazole treatment must be monitored for potential interactions. Ketoconazole tablets are no longer indicated for fungal infections of the skin and nails. These safety warnings do not apply to the topical forms of the drug. This drug is pregnancy category C.

Posaconazole (Noxafil): Posaconazole is the newest azole, approved in 2013. It is approved in two formulations for different indications. As delayed release tablets, the drug is approved for *prophylaxis* of invasive *Aspergillus* and *Candida* infections, which can be life threatening in patients with severely compromised immune systems. An oral suspension is approved for the treatment of oropharyngeal candidiasis. Caution must be used when treating patients taking calcineurin inhibitors such as tacrolimus or cyclosporine because posaconazole can increase the serum concentrations of these drugs and cause calcineurin toxicity. Posaconazole should also be used with caution in patients with dysrhythmias because the drug can prolong the QT interval. Its use is contraindicated in patients taking sirolimus, statins, and ergot alkaloids. Common adverse effects include fever, diarrhea, and nausea. This drug is pregnancy category C.

Voriconazole (Vfend): Approved in 2002, voriconazole is a second-generation triazole synthesized from fluconazole that is approved to treat invasive *Aspergillus* infections and serious *Candida* infections. It is believed to be safer and more effective than amphotericin B for these indications. It is available by PO and slow IV infusion. Extreme caution should be used when administering voriconazole to patients with severe renal or hepatic impairment, because this can result in toxic accumulation of the drug. The most frequent adverse events affect vision: enhanced brightness, changes in color vision, and blurred vision. Headache, nausea, vomiting, and rash are also common adverse effects. Although visual impairment occurs in 35% to 45% of patients, it is reversible following discontinuation of therapy. Dermatologic toxicity includes photosensitivity and the potential for Stevens–Johnson syndrome. Because it participates in many drug interactions, the nurse should seek information from a current drug guide when administering voriconazole concurrently with other medications. This drug causes teratogenicity in laboratory animals and is rated as pregnancy category D.

CONNECTION Checkpoint 52.2

Antifungal medications are sometimes administered to patients taking calcineurin inhibitors such as tacrolimus. From what you learned in Chapter 42, what is the primary indication for the calcineurin inhibitors? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Drugs for Superficial Fungal Infections

52.6 Drugs for superficial mycoses are safe and effective at eliminating fungi on the skin, nails, or mucous membranes.

Superficial fungal infections of the hair, scalp, nails, and the mucous membranes of the mouth and vagina are rarely medical emergencies. Infections of the nails may be ongoing for months or even years before a patient seeks treatment. Unlike systemic fungal infections, superficial infections may occur in any patient, not just those who have suppressed immune systems. Drugs used to treat superficial mycoses are listed in Table 52.3.

Superficial antifungal drugs are much safer than their systemic counterparts because penetration into the deeper layers of the skin is limited, and only small amounts are absorbed into the circulation. Many are available as over-the-counter (OTC) creams, gels, and ointments. If the infection has grown into the deeper skin layers, PO antifungal drugs are indicated. Extensive superficial or subcutaneous mycoses are sometimes treated with both PO and topical antifungal drugs to ensure that the infection is eliminated from deeper skin layers.

Dermatomycoses: Fungal infections of the skin and hair are called **dermatomycoses**. These infections are named by their Latin terms, beginning with *tinea*. For example, tinea capitis is an infection of the scalp, and tinea pedis is an infection of the feet.

Fungi that cause dermatomycoses grow in the keratin layer of the skin. Because fungi multiply more rapidly in warm, moist areas, dermatomycoses occur more frequently during the summer months and in warmer climates. They tend to favor skin creases that stay moist due to sweat or following bathing. Because relapse rates following pharmacotherapy are high, the patient should be taught proper personal hygiene measures to help eliminate the pathogen. These include frequent bathing with thorough drying of the infected area, the use of separate towels for the groin area, and wearing loose clothing.

Tinea corporis is an infection in which the fungus invades relatively hairless skin. The fungus typically appears as a ring pattern, thus resulting in the name ringworm. Transmission may occur through direct contact with infected animals (especially cats and dogs), infected humans, or

Table 52.3 Selected Drugs for Superficial Mycoses

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
butenafine (Mentax)	Topical: Apply daily for 2–4 wk for tineas	*Drying of skin, stinging sensation at application site, pruritus, urticaria, contact dermatitis* Granulocytopenia (griseofulvin), cholestatic hepatitis (oral terbinafine), neutropenia (oral terbinafine)
ciclopirox cream, gel, shampoo (Loprox), or nail lacquer (Penlac)	Topical: Apply cream bid for 4 wk for tineas Topical: Apply lacquer to nail for 48 wk for onychomycosis	
griseofulvin (Gris-PEG)	PO: 330–375 mg ultramicrosize daily for tineas and onychomycosis	
naftifine (Naftin)	Topical: Apply cream daily or gel bid for 4 wk for tineas	
nystatin topical powder (Nystop); oral suspension, capsule; cream, ointment	Suspension PO: 400,000–600,000 units 4 times/day Topical: Apply bid–tid to the affected area Capsule: PO: 500,000 to 1 million units q6h Vaginal tablets: Insert 1 tablet daily for 2 wk	
tavaborole (Kerydin)	Topical: Apply 5% solution once daily for 48 wk	
terbinafine (Lamisil)	Topical: Apply once daily or bid for 7 wk for tineas PO: 250 mg/day for 6–12 wk for onychomycosis	
tolnaftate (Aftate, Tinactin)	Topical: Apply to the affected area bid for 2 wk for tinea cruris and 4 wk for tinea pedis or corporis	
undecylenic acid (Fungi-Nail, Gordochom, others)	Topical: Apply once daily or bid for tineas for up to 4 wk	
Azoles		
butoconazole (Femstat, Gynazole)	Intravaginal: Femstat: 1 applicator for 3 days Gynazole: 1 applicator as a single dose	*Drying of the skin, stinging sensation at application site, pruritus, urticaria, contact dermatitis* Topical drugs exhibit few serious adverse effects except hypersensitivity
clotrimazole topical cream (Lotrimin AF); intravaginal (Gyne-Lotrimin); troche (Mycelex)	Topical: Apply 1% cream bid for 4 wk Intravaginal: 1 applicator for 7 days; one 100-mg tablet vaginally for 7 days or one 500-mg tablet once Troche: Dissolve one in the mouth over 15–30 min	
econazole (Spectazole)	Topical: Apply 1% cream bid for 4 wk for tineas or cutaneous candidiasis	
efinaconazole (Jublia)	Topical: Apply 10% solution to affected nails once daily for 48 wk	
fluconazole (Diflucan)	PO: 150 mg once, for vulvovaginal candidiasis (VVC)	
itraconazole (Sporanox)	PO: 200 mg daily for 1–2 wk for OPC PO: 200 mg daily for 3 days for VVC PO: 200 mg daily for 3 months for onychomycosis	
ketoconazole (Nizoral)	Topical: Apply 2% cream or shampoo 1–2 times/day to affected area for tineas	
luliconazole (Luzu)	Topical: Apply 1% cream once daily for 2 wk for tineas	
miconazole (Micatin, Monistat-3, Oravig)	Topical (Micatin): Apply 2% cream bid for 2–4 wk Intravaginal (Monistat-3): Insert 1 suppository daily for 3 days for VVC Buccal (Oravig): Apply 1 tablet to the gum region daily for 2 wk for oral candidiasis	
oxiconazole (Oxistat)	Topical: Apply 1% cream daily for 2 months for tineas and cutaneous candidiasis	
sulconazole (Exelderm)	Topical: Apply 1% cream once daily or bid for 2–6 wk for tineas	
terconazole (Terazol)	Intravaginal: 1 applicator for 3–7 days for VVC	
tioconazole (Monistat-1, Vagistat-1)	Intravaginal: 1 applicator as a single dose	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

contaminated furniture or clothing. The most common pathogens are *Trichophyton* and *Microsporum* species. Topical therapies are usually successful in controlling tinea corporis. In cases of inflammatory lesions, oral therapy with griseofulvin (Gris-PEG), terbinafine (Lamisil), itraconazole (Sporanox), or fluconazole (Diflucan) is recommended.

Tinea cruris, commonly called jock itch, is a form of tinea corporis that occurs in the groin, perineum, and perianal region. Topical powders and creams are usually sufficient to cure tinea cruris. PO antifungal drugs such as griseofulvin, terbinafine, itraconazole, or fluconazole may be necessary for severe cases.

Tinea pedis, commonly called athlete's foot, is a type of tinea corporis occurring on the feet, principally between the toes and on the sole. It is associated with the wearing of shoes and contact with infected bath or pool floors. Tinea pedis is the most common dermatomycosis, affecting about 70% of adults at some time during their life. Topical antifungals are effective for noninflammatory tinea pedis. PO therapy is sometimes used to treat more severe infections and areas such as the soles. Typical therapy includes terbinafine (Lamisil) or itraconazole (Sporanox) for 2 to 4 weeks.

Tinea capitis involves the hair of the head, eyebrows, or eyelashes, and primarily affects children between 4 and 14 years of age. *Trichophyton* is responsible for more than 90% of cases. In contrast with other dermatomycoses, tinea capitis is routinely treated with PO drugs. Typical regimens include the following:

- Griseofulvin: 10 mg/kg/day for 8 to 10 weeks
- Itraconazole (Sporanox): 5 mg/kg/day for 1 to 4 weeks
- Terbinafine (Lamisil): 62.5 to 250 mg/day for 4 weeks

Onychomycosis: **Onychomycosis**, or tinea unguium, is the invasion of the nail plate by a fungus. It is a relatively common infection, affecting 2% to 3% of Americans. Rates among men are twice that of women, and infections increase with age. The higher incidence in older patients is believed to be due to reduced peripheral circulation, general inactivity, increased nail trauma, and difficulty (or inability) in maintaining proper nail hygiene. One in four patients with diabetes will acquire onychomycosis, likely due to reduced circulation to the area.

The most common fungal pathogens responsible for onychomycosis are *Trichophyton* and *Epidermophyton* species. Although any part of the nail may be affected, most commonly the infection begins with invasion of the hyponychium, the place where the nail separates from the nail bed. Toenails are more often affected than fingernails. The nail becomes markedly disfigured and distorted.

Although certainly not a life-threatening infection, onychomycosis is one of the most difficult superficial fungal infections to treat. Nails grow slowly and the nail plate is hard, preventing antifungal drugs from penetrating. The traditional medication for onychomycosis has been griseofulvin, but this drug has a narrow spectrum of activity and has been largely replaced by newer drugs. The preferred therapies include terbinafine (Lamisil) and itraconazole (Sporanox). Both of these drugs are absorbed into the nail matrix and remain active for several months. These oral therapies have shorter treatment regimens and higher cure rates than the topical drugs. Terbinafine is administered once daily for 6 to 12 weeks. Itraconazole is taken twice daily for 1 week for fingernails or 12 weeks for toenails.

Topical drugs may be indicated if less than half the nail plate is infected or if the patient is unable to tolerate the oral therapies. Topical and oral medications may be administered concurrently for persistent infections. The preferred topical medications include efinaconazole (Jublia), ciclopirox nail lacquer (Penlac), and tavaborole (Kerydin). These three topical drugs are applied daily for 48 weeks.

PharmFACT

The overall incidence of onychomycosis is highly age dependent. The incidence is 90% in older adults and less than 3% in those under age 18 (Tosti, 2016).

Superficial candidiasis: Although at least 10 species of *Candida* cause disease in humans, *C. albicans* is responsible for nearly 100% of cases of oropharyngeal fungal infections and at least 90% of cases of vulvovaginal candidiasis. A small yeast, *Candida* is often found as part of normal host flora on body surfaces. *Candida* species are the most common pathogens causing fungal disease in patients with compromised immune defenses.

Oropharyngeal candidiasis (OPC) is an oral mycosis, sometimes called thrush. About 50% of people carry *Candida* in the mouth as part of their host flora. Infection occurs when the patient's defenses are weakened; thus the highest incidence of OPC is seen in patients with AIDS, diabetes, or cancer, and in hospitalized patients. Patients taking inhaled corticosteroids are also at greater risk because these drugs cause a local immunosuppression in the oral cavity. Although not life threatening, OPC may predispose a patient to esophageal candidiasis, which is a serious, invasive mycosis.

Several options are available for the pharmacotherapy of OPC. Topical therapy is generally preferred and is often successful for milder, uncomplicated infections. Troches and PO suspensions are the most common formulations for topical therapy. Symptoms generally subside in 2 to 3 days but the nurse should encourage the patient to complete the full 1- to 2-week course of therapy. Preferred treatments for mild OPC include miconazole buccal tablet (Oravig), nystatin PO suspension, or clotrimazole (Mycelex) troche. Moderate to severe OPC is generally treated with oral fluconazole (Diflucan). Alternatives include suspensions of itraconazole (Sporanox) or posaconazole.

CONNECTIONS: Lifespan Considerations

Oropharyngeal Candidiasis in Infants

Oropharyngeal candidiasis (OPC or thrush) is commonly seen in infants. It is often difficult to distinguish from milk and appears as white patches on the tongue, palate, and inner aspects of the cheeks. Frequently, the infant with thrush may refuse to suck or feed because of mouth irritation. Transmission of this fungal infection may occur during a vaginal birth when the infant comes in contact with the mother's normal flora, or during feedings, including breastfeeding. In most cases, thrush is self-limiting and resolves spontaneously. However, it may take as long as 2 months to resolve, during which time it may spread to the larynx, trachea, bronchi, lungs, and GI tract.

The condition is treated with good hygiene, application of a fungicide, and correction of any underlying causes. Because the mother is often the source of the infection, she should also be treated to prevent reinfections. Fluconazole (Diflucan) and nystatin are commonly used, including for topical treatment of the nipple area of the mother if the thrush continues.

Antifungal medications should be administered to the infant after feedings. When possible, sips of water may be useful to rinse away milk sugars and proteins after the feeding. Using an applicator or syringe, the medication should be distributed over the entire surface of the oral mucosa and tongue. After swabbing the area, the remainder of the dose is then deposited in the infant's mouth to be swallowed to treat any more extensive infection.

Candida species are part of the normal vaginal flora in about 50% of healthy women. Because vulvovaginal candidiasis (VVC) occurs in both healthy and immunosuppressed women, it is not considered an opportunistic infection. The biggest risk factors for VVC are sexual activity, pregnancy, diabetes mellitus, the use of oral contraceptives with high estrogen content, and broad-spectrum antibiotics. *Candida* may be transmitted to male sexual partners. Its highest incidence occurs between the ages of 30 and 40. *C. albicans* is by far the most common species, although *Candida glabrata* is an emerging pathogen for VVC.

Several effective topical drugs for VVC are available without a prescription. The various topical regimens have equal effectiveness in treating VVC, with response rates of 80% to 90%. Many women prefer PO therapies because of their convenience. Oral therapy has the same efficacy as topical treatment.

Regimens for VVC are classified by their duration of therapy. The most popular therapies are 1-day PO regimens, due to their ease of use. Although 1-day treatments are effective for most women with VVC, this brief therapy has limitations. Because 1-day treatments may take up to 48 hours to produce relief, faster acting topical drugs may be more beneficial for patients with severe symptoms. In addition, patients with complicated, persistent, or severe infections require 10 to 14 days of therapy for successful elimination of the pathogen, regardless of the route of administration. Typical therapies for VVC include the following:

- Single topical application: ticonazole (Monistat-1, Vagistat-1), 6.5% ointment; butoconazole (Gynazole), 2% cream (sustained release formulation); miconazole, 2% cream
- Single PO dose: fluconazole, one 150-mg tablet; itraconazole, 200 mg bid for 1 day; clotrimazole, one 500-mg tablet for 1 day
- Multiday regimens: butoconazole (Femstat), 2% cream, for 1 to 7 days; clotrimazole (Lotrimin AF), 1% cream or 100-mg tablets for 1 to 7 days; miconazole, 2% cream or 100- to 200-mg suppositories for 1 to 7 days; or nystatin, 100,000-unit vaginal tablet daily for 7 to 14 days

Because recurrent VVC may occur in 5% of patients treated for this infection, cultures may be necessary to identify the specific pathogen. Treatment begins with a 14-day induction phase that uses the same drugs as for nonrecurring infections. A maintenance phase follows, typically with azole antifungals taken once weekly (fluconazole) or once monthly (itraconazole) for 6 months.

PharmFACT

Three of every four women will experience vulvovaginal candidiasis at least once during their lifetime (Hidalgo, 2016).

CONNECTION Checkpoint 52.3

From what you learned in Chapter 46, why might broad-spectrum antibacterial therapy cause a *Candida* infection of the vagina? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Nystatin (Nystop)**

Classification **Therapeutic:** Antifungal, superficial type
Pharmacologic: Polyene

Therapeutic Effects and Uses: Approved in 1954, nystatin belongs to the same chemical class as amphotericin B,

the polyenes. Although it acts by the same mechanism as the polyenes, nystatin has very different indications and is available in a wider variety of formulations, including cream, ointment, powder, tablets, capsules, and oral suspension. Too toxic for parenteral administration, it is usually used topically to treat *Candida* infections of the vagina, skin, and mouth because it is not absorbed in these areas. Although available as vaginal tablets, the azoles have largely replaced nystatin due to their higher efficacy. PO suspensions are available to treat OPC, using a swish-and-swallow technique. It is available as tablets to treat candidiasis of the intestine, since it travels through the GI tract without being absorbed. It is not effective for treating onychomycosis.

Mechanism of Action: Nystatin binds to sterols in the fungal cell membrane, allowing leakage of intracellular contents across the weakened membrane.

Pharmacokinetics:

Route(s)	PO suspension, capsules, troches, topical creams, and vaginal tablets; PO tablets for intestinal infections
Absorption	Poorly absorbed
Distribution	Not distributed
Primary metabolism	Not metabolized
Primary excretion	Excreted unchanged in the feces
Onset of action	Rapid
Duration of action	Half-life: 6–12 h

Adverse Effects: When given topically, nystatin produces few adverse effects other than minor skin irritation and burning at the site of application. There is a high incidence of contact dermatitis, related to the preservatives found in some of the formulations. When given PO, it may cause diarrhea, nausea, and vomiting.

Contraindications/Precautions: The only contraindication to nystatin therapy is hypersensitivity to the drug. Although no teratogenic effects have been reported, safety during pregnancy and lactation has not been established.

Drug Interactions: Unknown.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving nystatin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antifungals.

Drugs Similar to Nystatin (Nystop)

Other superficial antifungals include griseofulvin, terbinafine, topical azoles, and several miscellaneous drugs.

Griseofulvin (Gris-PEG): Approved in 1959, griseofulvin is an inexpensive antifungal that is indicated for the PO therapy of mycoses of the hair, skin, and nails that have not responded to conventional topical preparations. It is not given topically because the drug is unable to penetrate into the deeper skin layers when given by this route. In an attempt to reduce adverse GI effects and increase its bioavailability, griseofulvin is available as ultramicrosize particles (Gris-PEG) that are almost 100% absorbed.

The length of treatment for tinea pedis is 4 to 8 weeks and for tinea unguium, 3 to 6 months. Griseofulvin is deposited in keratin, where it accumulates and inhibits mitosis of the fungal cells. It exhibits few adverse effects, other than headache. Although rare, hepatitis and neutropenia have been reported with prolonged therapy. Griseofulvin has a higher incidence of long-term adverse effects and has a greater relapse rate than some other superficial antifungal drugs. This drug is pregnancy category C.

Terbinafine (Lamisil): Approved in 1993, terbinafine may be administered by the PO or topical route. Terbinafine belongs to a chemical class called allylamines that act by inhibiting ergosterol biosynthesis. The PO form of the drug is available by prescription to treat onychomycosis. The drug rapidly accumulates in nails, although therapy of persistent onychomycosis may require 6 to 12 weeks. The cure rate for onychomycosis is 50% to 70%, which is higher than that for griseofulvin. Oral preparations are well tolerated, with nausea, vomiting, abdominal pain, and diarrhea being the most common adverse effects. Rare, though serious, adverse effects include Stevens–Johnson syndrome, blood dyscrasias, and hepatic failure.

Nonprescription formulations such as Lamisil AT include topical creams and sprays for treating tinea corporis, tinea pedis, and tinea cruris. Adverse effects are rare with topical terbinafine; irritation or urticaria occurs in less than 1% of patients. The drug is not absorbed when administered topically. Both PO and topical forms of terbinafine are pregnancy category B.

Topical Azoles: Eleven azoles are used to treat superficial mycoses. Itraconazole, voriconazole, posaconazole, and fluconazole may be used PO to treat superficial mycoses, whereas the others are for topical use only. Among the topical drugs, all have equal effectiveness and similar adverse effects. Miconazole and clotrimazole are preferred drugs available OTC for vulvovaginal *Candida* infections, although a number of other azoles are available that are equally effective. Transient burning and irritation at the application sites are the most common adverse effects of the topical azoles.

Miscellaneous topical antifungals: Several drugs are less commonly used for superficial fungal infections. These medications are applied topically, for tineas, or intravaginally, for VVC. The doses and indications for these drugs are shown in Table 52.3.

PharmFACT

Oropharyngeal candidiasis in the neonate is most commonly acquired from the infected mucosa of the mother during passage of the infant through the birth canal. Neonatal candidiasis presents 3 to 7 days after birth with oral thrush and diaper dermatitis (Scheinfeld, 2017).

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antifungals

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, and hepatic disease or CKD and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess for signs and symptoms of current infection, noting location, characteristics, presence or absence of drainage, and character of drainage, duration, presence or absence of fever or pain.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, urinalysis, culture and sensitivity [C&S], hepatic and renal function studies).
- Obtain baseline weight and vital signs, especially blood pressure and pulse.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection and fever, surface lesions are improving or cleared).
- Continue periodic monitoring of CBC, electrolytes, C&S, hepatic and renal function.
- Continue to monitor vital signs, especially blood pressure and pulse, in patients on IV antifungal drugs.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, malaise, muscle cramping or pain, chills, drowsiness, dizziness, headache, tinnitus, vertigo, flushing, skin rash, urticaria, seizures, hypotension, electrolyte imbalances (e.g., hypokalemia, hypomagnesemia). Immediately report hypotension, tachycardia, dysrhythmia, changes in level of consciousness, diminished urine output, or seizures.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, or signs and symptoms of infection should diminish and resolve.)	• Teach the patient on PO antifungals that several months of treatment may be required. The entire course of therapy should be completed and the patient should return to the provider if symptoms have not resolved.
Minimizing adverse effects: • Continue frequent monitoring of vital signs, especially blood pressure and pulse, and respiratory rate and depth in patients on IV antifungal drugs. Immediately report dysrhythmias, increasing pulmonary congestion, hypotension, or tachycardia. (Hypotension, tachycardia, dysrhythmias, cardiac collapse, and cardiac arrest are possible adverse effects of antifungal drugs given IV. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension and falls.)	• Instruct the patient on the need for frequent monitoring. Explain the rationale for all monitoring equipment used. • Teach the patient to rise from lying to sitting or standing slowly to avoid dizziness or falls if hypotension is noted. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBC, urinalysis, C&S, electrolyte levels. (Antifungals may be hepatotoxic and nephrotoxic. Antifungals, particularly when given IV, may cause electrolyte imbalances, especially hypokalemia and hypomagnesemia, and electrolyte replacement may be needed.)	• Teach the patient the need for frequent laboratory testing. If prescribed PO antifungals for home use, instruct the patient on the need for periodic laboratory work, depending on the type of drug and the length of therapy.
• Ensure adequate hydration in patients on oral or IV antifungal drugs. Weigh the patient daily and report weight gain of 1 kg (2 lb) or more in a 24-h period. Measure intake or output in a 24-h period and monitor intake and output in the hospitalized patient. (Systemic antifungal drugs may be nephrotoxic. Adequate hydration helps to prevent adverse renal effects. Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Excessive weight gain or edema may indicate renal dysfunction.)	• Teach the patient to increase fluid intake to 2 L/day if on oral antifungal drugs. • Have the patient taking oral antifungal drugs at home weigh self daily, ideally at the same time of day, and record the weight. Have the patient report weight gain of more than 1 kg (2 lb) in a 24-h period.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of an antifungal given IV. Continue to monitor the patient throughout therapy. (Anaphylactic reactions are possible and most common with the first IV infusion. Fever, chills, nausea, and headache are common reactions. A test dose of a small amount given slowly may be given before the main infusion. Premedication, including antipyretics, antihistamines, corticosteroids, and antiemetics, may be required to prevent reactions.)	• Instruct the patient to promptly report any chills, nausea, tremors, palpitations, or headache.
• Continue to monitor for signs of ototoxicity; e.g., tinnitus, dizziness, or vertigo, and report promptly. (Antifungals given systemically may cause ototoxicity and require frequent monitoring to prevent adverse effects.)	• Teach the patient to immediately report any ringing, humming, or buzzing in the ears, dizziness, or vertigo.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor for hepatic toxicity; e.g., jaundice, right upper quadrant pain, darkened urine, diminished urine output, tinnitus, or vertigo in patients on systemic antifungal therapy. (Antifungals may cause hepatic toxicity. **Diverse Patients:** Because fluconazole is metabolized through the CYP450 system pathways, monitor ethnically diverse patients frequently to ensure optimal therapeutic effects and minimize adverse effects.)	• Teach the patient to immediately report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light or clay-colored stools, or darkening of urine.
• Monitor the IV site frequently for any signs of extravasation or thrombophlebitis. (IV antifungal medication is irritating to the vein and the IV site should be monitored frequently. A central line may be used when possible.)	• Instruct the patient to immediately report any pain, burning, or redness at the site of peripheral IV. Explain the rationale for all equipment used.
• Monitor blood glucose levels in patients taking azole antifungal drugs such as fluconazole or ketoconazole. (Azole antifungals may increase glucose levels. Patients with diabetes may require a change in their antidiabetic drug routine.)	• Teach patients with diabetes to test their glucose more frequently, reporting any consistent elevations to the healthcare provider.
• Monitor for significant GI effects, including nausea, vomiting, abdominal pain, or cramping. Give the drug with food or milk to decrease adverse GI effects. (Food or milk may decrease GI effects but an antiemetic may also be required if nausea is severe.)	• Teach the patient to take the drug with food or milk but to avoid acidic foods and beverages or carbonated drinks.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of the medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take oral or topical antifungal medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Several months of oral therapy may be required to adequately treat the infection.
	  • Avoid or eliminate alcohol while on oral antifungals to avoid hepatic complications.
	  • Dissolve oral antifungal lozenges (troches) in the mouth, or rinse with liquids after meals and at bedtime. If dentures are worn, remove them before using the drug and leave them out overnight. Swish the liquid drug around the mouth and hold in the mouth at least 2 min before expectorating. Do not swallow unless instructed to do so by the provider and do not rinse the mouth with water afterward.
	  • Do not use occlusive dressings when topical antifungals are used. Apply a thin, even layer to the affected area.
	  • Allow affected skin areas to air dry when possible, and wear loose-fitting and breathable fabric clothes to allow adequate ventilation. Gently cleanse areas with mild soap and water. Avoid vigorous scrubbing.

Understanding Chapter 52

Key Concepts Summary

52.1 Serious fungal infections are uncommon in people with healthy immune defenses.

52.2 Mycoses are classified as superficial, subcutaneous, or systemic.

52.3 Antifungal drugs act by disrupting the fungal cell membrane or wall, affecting fungal enzymes, or disrupting replication.

52.4 Systemic or invasive fungal disease may require intensive pharmacotherapy for extended periods.

52.5 Azoles are the preferred drugs for many mycoses due to their efficacy and favorable safety profile.

52.6 Drugs for superficial mycoses are safe and effective at eliminating fungi on the skin, nails, or mucous membranes.

CASE STUDY: Making the Patient Connection

Remember the patient "Sarah Williams" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Sarah Williams is a 54-year-old woman with lung cancer who recently finished her second round of chemotherapy. She comes to her appointment at the oncology clinic with concerns about white patches on her tongue and mouth. She states that her mouth is not sore but her throat burns when she swallows. This has made it very difficult for her to eat and drink.

A history and physical examination are completed. She is 5′3″ tall and weighs 52.7 kg (116 lb). The healthcare provider evaluates Sarah for oropharyngeal candidiasis. Sarah was diagnosed with lung cancer several months prior and is taking chemotherapy and corticosteroids. Upon initial assessment, her vital signs are normal, and she has no complaints except her expressed concerns about her mouth and throat. She has worn dentures for about 5 years.

Critical Thinking Questions

1. What are the signs and symptoms that you, as the nurse, look for to determine if Sarah is experiencing oropharyngeal candidiasis?
2. Why do you think that Sarah is at risk for this type of infection?
3. What treatment do you anticipate that Sarah will receive? What patient teaching will she need regarding this treatment?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Sean Seales is a 23-year-old patient with Hodgkin's lymphoma who is undergoing chemotherapy. He has experienced chills and fever with increasing fatigue for the past several days. Sean was assessed by his oncologist and was hospitalized for possible early sepsis. He is neutropenic and will be started on IV antibiotics and fluconazole (Diflucan) IV.

1. Why was Sean started on both IV antibiotics and antifungal medication?
2. What possible adverse effects might Sean experience from the fluconazole (Diflucan)? As his nurse, what will you monitor?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient is admitted to the intensive care unit for systemic fungal infections. Amphotericin B has been ordered and the nurse will administer this drug slowly IV. When administered too rapidly, amphotericin B may cause what significant adverse effects? (Select all that apply.)
    1. Laryngeal spasms
    2. Hypotension
    3. Hypokalemia
    4. Shock
    5. Hypoglycemia

2. A patient with AIDS has been given a prescription for oral fluconazole (Diflucan) to prevent *Candida* infection. Considering the patient's primary diagnosis and the order for fluconazole, what essential teaching will the nurse provide?
    1. Keep a food diary and request antinausea medication if eating becomes problematic.
    2. Maintain regular low-impact exercise daily to avoid loss of muscle mass.
    3. Wear a high-filtration mask if going out in public.
    4. Avoid all fat-based soaps and allow the body to air-dry after bathing.

3. Nystatin suspension has been ordered for treatment of thrush (oropharyngeal *Candida*) in a 6-week-old infant. What instructions should the caregiver receive? (Select all that apply.)
    1. Give the infant a small amount of water after feedings and before the drug to rinse the mouth.
    2. Using an applicator or syringe, distribute the solution around the mouth and tongue, allowing the infant to swallow the remainder.

3. Chill the suspension in the refrigerator before giving for better taste.
4. Give the suspension before feeding the infant to prevent adverse GI effects.
5. Add the suspension to a bottle of formula for easier administration.

4. The nurse is caring for a patient with onychomycosis (nail fungus) who is receiving oral terbinafine (Lamisil) for treatment. The patient questions the need for 3 months' worth of pills. What is the nurse's best response?
   1. "The healthcare provider will evaluate the nails monthly and stop treatment earlier if warranted."
   2. "It is cheaper to buy more pills at one time than on a monthly schedule."
   3. "The extensive prescription avoids the need for shorter term, potentially toxic doses."
   4. "Nails grow slowly and the nail beds must receive adequate length of treatment to eliminate the infection."

5. The nurse knows that pretreatment with corticosteroids, antihistamines, and antipyretics prior to the administration of amphotericin B is given for what effect?
   1. To enhance the effectiveness of amphotericin B
   2. To eliminate toxic by-products of amphotericin B
   3. To reduce the severity of adverse effects associated with amphotericin B
   4. To increase the half-life of amphotericin B

6. A patient with diabetes treated with oral antidiabetic medications is receiving oral fluconazole (Diflucan) for treatment of long-standing tinea cruris (jock itch). The nurse will instruct the patient to monitor blood sugar more frequently while on this drug because of what potential drug effects?
   1. Fluconazole (Diflucan) antagonizes the effects of antidiabetic drugs.
   2. Fluconazole (Diflucan) may increase blood sugar levels.
   3. Fluconazole (Diflucan) may decrease blood sugar levels.
   4. Fluconazole (Diflucan) may enhance the effects of antidiabetic drugs.

Patient "Trevor Skales"

Chapter 53
Pharmacotherapy of Protozoan and Helminthic Infections

Chapter Outline

- Classification and Pathogenesis of Protozoan Infections
- Drugs for Malaria

  PROTOTYPE *Chloroquine (Aralen), p. 956*
- Drugs for Nonmalarial Protozoan Infections

  PROTOTYPE *Metronidazole (Flagyl), p. 960*

  PROTOTYPE *Pyrimethamine (Daraprim), p. 964*
- Classification and Pathogenesis of Helminthic Infections
- Drugs for Helminthic Infections

  PROTOTYPE *Mebendazole (Vermox), p. 968*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify features of protozoa and helminths that distinguish them from bacteria.
2. Identify protozoan and helminthic infections that may benefit from pharmacotherapy.
3. Explain why an understanding of *Plasmodium*'s lifecycle is important to the successful pharmacotherapy of malaria.
4. Explain the etiology, pathogenesis, and pharmacotherapy of amebiasis, giardiasis, cryptosporidiosis, toxoplasmosis, trichomoniasis, trypanosomiasis, and leishmaniasis.
5. Explain the etiology, pathogenesis, and pharmacotherapy of ascariasis, enterobiasis, hookworm, and tapeworm infections.
6. Describe the nurse's role in the pharmacologic management of protozoan and helminthic infections.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy for protozoan and helminthic infections.

Key Terms

cysts, 953
erythrocytic stage, 954
helminths, 965
malaria, 954
merozoites, 954
protozoan, 953
sporozoite, 954
trophozoite, 953
vectors, 954

Protozoa and parasitic worms, or helminths, are more complex than bacteria and cause significant morbidity and mortality worldwide. Pharmacotherapy is complicated by the lifecycles of the organisms, during which they may change form and travel to infect distant organs. Some may remain infectious in contaminated soil or water for months or years. With few exceptions, the anti-infective drugs used to treat these disorders are different from those for bacterial or fungal infections.

Classification and Pathogenesis of Protozoan Infections

53.1 Protozoa are diverse, single-celled organisms that can cause widespread disease.

A **protozoan** is a single-celled organism that inhabits water, soil, and animal hosts. Although only a few of the more than 20,000 species are pathogenic in humans, they cause significant morbidity and mortality in Africa, South America, Central America, and Asia. These parasites thrive in conditions where sanitation and personal hygiene are poor and population density is high. The nurse needs to be familiar with these infections because travelers may acquire protozoan diseases overseas and bring them back to the United States and Canada. In addition, some of the protozoan infections frequently occur in patients with immunosuppression, such as those in the advanced stages of acquired immunodeficiency syndrome (AIDS) or those receiving chemotherapy or immunosuppressants. Selected protozoan infections important to human health are listed in Table 53.1.

Protozoa are an extremely diverse group of organisms, with each class having very different physiologies and survival strategies. Drugs that are effective against one species of protozoan are often not effective against others.

Some pathogenic protozoa have complex lifecycles. The active, growing stage during which the organism feeds, often at the expense of its host, is the **trophozoite** stage. When faced with adverse conditions, some protozoa can form protective capsules called **cysts** that allow the organism to survive in harsh environments in a dormant state for prolonged time periods. Both trophozoite and cyst forms may reside within the human body simultaneously; however, some protozoa enter the cyst stage after they exit the human body through coughing, sneezing, or fecal

Table 53.1 Selected Protozoan Infections

Name of Disease and Protozoan Species	Description	Source of Infection
Amebiasis *Entamoeba histolytica*	Primarily infects the large intestine, causing severe diarrhea; commonly travels to the liver to form liver abscesses; rarely travels to other organs such as the brain, lungs, or kidney	Fecal-contaminated water
Cryptosporidiosis *Cryptosporidium parvum*	Infects the intestines, causing diarrhea; often seen in immunocompromised patients	Fecal-contaminated water; humans and other animals
Giardiasis *Giardia lamblia*	Infects the intestines, causing malabsorption, fatigue, and abdominal pain	Fecal-contaminated water
Leishmaniasis *Leishmania* (various species)	Affects many body systems including the skin, liver, spleen, or blood depending on the species	Bite of sand fly
Malaria *Plasmodium* (various species)	Infects red blood cells to cause fever, chills, and fatigue; some *Plasmodia* invade the liver and other tissues	Bite of female *Anopheles* mosquito
Toxoplasmosis *Toxoplasma gondii*	Can invade any organ; causes a fatal encephalitis in immunocompromised patients	Congenital transmission; cat feces
Trichomoniasis *Trichomonas vaginalis*	Common sexually transmitted infection (STI) that causes vaginitis in women and urethritis in men	Transmission through sexual contact with infected fluids
Trypanosomiasis *Trypanosoma cruzi* (American) *Trypanosoma brucei* (African)	The American form (Chagas' disease) invades cardiac tissue and autonomic ganglia; the African form (sleeping sickness) causes fatigue and central nervous system (CNS) depression	Bite of the kissing bug (American) or the tsetse fly (African)

excretion. Protozoa remain in the cyst form until the organism is able to reinfect another host. When cysts occur inside the host, the parasite is often resistant to drug therapy.

Several of the major protozoan infections are spread by **vectors**, organisms that harbor the pathogen and carry it from one host to another. Some vectors, such as house flies, simply pick up pathogens on their feet and transport them to human food or water. In other cases, the protozoan lives and multiplies inside the insect, which serves as an intermediate host. The protozoan *Plasmodium*, for example, reproduces in the gut of a mosquito and is transmitted to humans during a mosquito bite, causing malaria. The discovery that mites, ticks, or insects could spread infections was a major advance in medicine because researchers then realized that disease outbreaks could be prevented or controlled by eliminating the vectors.

53.2 The female *Anopheles* mosquito is the carrier of several species of *Plasmodium*, the parasite responsible for malaria.

Although rare in the United States and Canada, about 214 million cases of malaria occur annually worldwide. Although malaria was declared eliminated in the United States in the early 1950s, approximately 1500 to 2000 cases are diagnosed each year. Almost all cases occur in infected immigrants or travelers who bring the disease into the United States from regions where the disease is endemic.

PharmFACT

Between 2000 and 2015 the number of worldwide malaria cases declined by 37% and deaths due to the infection declined by 60% (World Health Organization, 2016).

Malaria is caused by four species of the protozoan *Plasmodium*. Each species has a characteristic geographical distribution and pattern of infection, although several species may coexist in the same location. *Plasmodium vivax*, the most common malarial species, occurs predominantly in India, Pakistan, and Central America. *Plasmodium falciparum* occurs with greater incidence in Africa, South America, Haiti, and the Dominican Republic. Although less common, *P. falciparum* causes the most severe symptoms, including a significant number of deaths in endemic areas, and is often more resistant to antimalarial drugs than the other *Plasmodium* species. The other two species, *Plasmodium malariae* and *Plasmodium ovale*, are less common, and current medical sources should be consulted for information on these species.

The carrier of *Plasmodium* is a mosquito. *Plasmodium* resides in the gut of the female *Anopheles* mosquito where it matures to its infective form, called a **sporozoite**. When the mosquito bites a human, some of the sporozoites, contained in mosquito saliva, are injected.

Once inside the human host, the blood carries the sporozoites to the liver, where they multiply and transform into millions of progeny called **merozoites**. There is an incubation period of 1 to 6 weeks following the mosquito bite, during which the patient experiences no ill effects.

After the incubation period, merozoites are released into the blood, where they enter red blood cells (RBCs) and multiply. The infected erythrocytes eventually rupture, releasing more merozoites and causing acute symptoms. This is the **erythrocytic stage** of the infection. The bite of another *Anopheles* mosquito can pick up the merozoites from infected human blood, and the cycle begins anew. *P. vivax* can remain in body tissues for extended periods and cause relapses months, or even years, after the initial infection. Unlike the human host, which can experience severe illness, the mosquito is unaffected by the presence of *Plasmodium*. The lifecycle of *Plasmodium* is shown in Figure 53.1.

Symptoms of *P. vivax* malaria occur in a predictable, cyclic manner every 48 hours. This is because the merozoites grow and rupture erythrocytes on a regular time schedule. The uncomplicated or classic malaria attack lasts 6 to 10 hours and occurs in the following stages:

- **Cold stage:** Intense chills and shivering
- **Hot stage:** Fever, headache, vomiting; possible seizures in young children
- **Sweating stage:** Profuse diaphoresis, followed by return to normal body temperature, and fatigue.

Complicated malaria may involve multiple organ failures and can be fatal. Nervous system involvement, called cerebral malaria, leads to abnormal behaviors, impairment of consciousness, seizures, or coma. Loss of large numbers of erythrocytes can cause severe anemia. Pulmonary edema and renal failure can occur. Complicated symptoms are nearly always indicative of infection by *P. falciparum*; the other three species rarely cause severe manifestations or death.

Drugs for Malaria

53.3 The three goals of malaria pharmacotherapy are chemoprophylaxis, treatment of acute attacks, and prevention of relapses.

Pharmacotherapy of malaria attempts to interrupt the complex lifecycle of *Plasmodium*. Treatment becomes increasingly difficult as the parasite enters different phases of its lifecycle. The goals of antimalarial therapy depend on the stage of the infection. These goals include chemoprophylaxis, treatment of acute attacks, and prevention of relapse. Drugs for malaria are listed in Table 53.2.

Chemoprophylaxis: A rule of thumb to remember about malaria (and many other infectious diseases) is that it is much easier to prevent than to treat. The Centers for Disease

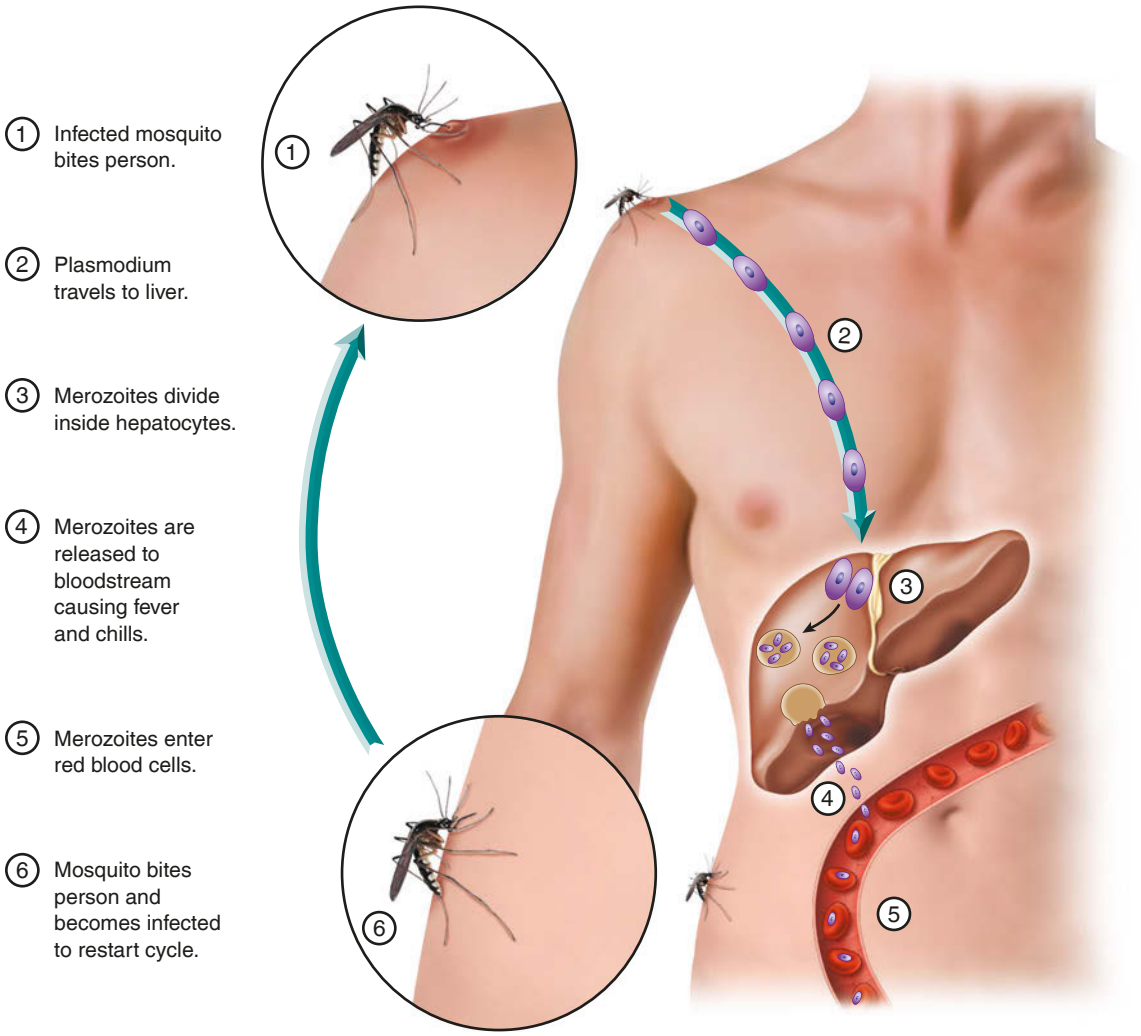

Figure 53.1 Lifecycle of *Plasmodium*.

Control and Prevention (CDC) recommends that travelers to infested areas receive prophylactic antimalarial drugs prior to travel, during their visit, and for at least 1 week after leaving. The recommended drug depends on the specific country or province being visited (CDC, 2016). For many decades, chloroquine (Aralen) was the preferred drug for prophylaxis but many regions now have a high incidence of chloroquine-resistant strains of *Plasmodium*. Chloroquine for chemoprophylaxis has been largely replaced by other effective antimalarials, including atovaquone-proguanil (Malarone), doxycycline, and mefloquine.

Treatment of acute attacks: Once a *Plasmodium* infection has been diagnosed, pharmacotherapy of malaria is most successful when it is begun immediately. Classic malaria symptoms in a patient with a history of recent travel to an endemic region are sufficient evidence to begin antimalarial therapy, without waiting for laboratory confirmation.

Medications are used to interrupt the erythrocytic stage and eliminate the merozoites from RBCs. Elimination will break the lifecycle of the protozoan and stop the acute symptoms. Chloroquine is a preferred antimalarial for treating the acute stage of the disease, if the infection was acquired in a region without chloroquine resistance. Four options are available for treating chloroquine-resistant infections. These include mefloquine, artemether-lumefantrine, atovaquone-proguanil, and quinine sulfate (with an antibiotic such as tetracycline, doxycycline, or clindamycin).

Patients with complicated malaria are treated aggressively with high doses of parenteral antimalarials. Quinidine gluconate infusions are indicated, along with intravenous (IV) tetracycline, doxycycline, or clindamycin.

Prevention of relapse: Patients who acquire an acute malaria infection will almost always experience subsequent attacks unless drugs are given to eliminate dormant *P. vivax* residing in the liver. Primaquine is one of the few drugs able to eliminate hepatic cysts. To achieve a total cure, primaquine is started near the conclusion of acute therapy. Because *P. falciparum* does not invade the liver, relapses are not a problem with this species; thus, prophylactic drug therapy is unnecessary.

Table 53.2 Drugs for Malaria

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
artemether-lumefantrine (Coartem)	For acute infections: PO: 4 tablets as an initial dose followed by 4 tablets 8 h later, then 4 tablets bid for the following 3 days	*Headache, anorexia, dizziness, asthenia, arthralgia, myalgia* QT prolongation, hypersensitivity reactions
atovaquone-proguanil (Malarone)	For acute infections: PO: 4 tablets as a single daily dose for 3 days For prophylaxis: PO: 1 tablet/day starting 1–2 days before travel and continuing 7 days following return	*Nausea, vomiting, abdominal pain, diarrhea, headache, myalgia* Neutropenia, hypotension
chloroquine (Aralen)	For acute infections: PO: 600-mg initial dose, then 300 mg at 6, 24, and 48 h IM: 200 mg q6h prn (max: 800 mg/24 h) For prophylaxis: PO: 300 mg starting 2 wk before travel and continuing 7–14 days following return	*Nausea, vomiting, diarrhea, visual changes, including blurred vision, photophobia, difficulty focusing* Hemolytic anemia in patients with G6PD deficiency; irreversible retinal damage
hydroxychloroquine (Plaquenil)	For acute infections: PO: 620-mg initial dose, then 310 mg at 6, 18, and 28 h For prophylaxis: PO: 310 mg starting 2 wk before travel and continuing 4–6 wk following return	
mefloquine	For acute infections: PO: 1250 mg as a single dose For prophylaxis: PO: 250 mg once a week for 4 wk before travel; continuing 250 mg every other week during travel and 2 doses following return	*Vomiting, nausea, diarrhea, myalgia, dizziness, anorexia, abdominal pain* Atrioventricular block, bradycardia, tachycardia, psychosis
primaquine	For acute infection: PO: 15 mg/day for 2 wk For prophylaxis: PO: 15 mg/day following return for 14 days	*Vomiting, nausea, diarrhea, myalgia, headache, anorexia, abdominal pain* Hemolytic anemia in patients with G6PD deficiency
quinine (Qualaquin)	For acute infections: PO: 650 mg tid for 7 days	*Vomiting, nausea, diarrhea* Cinchonism (tinnitus, ototoxicity, vertigo, fever, visual impairment), hypothermia, coma, cardiovascular collapse, agranulocytosis

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTION Checkpoint 53.1

From what you learned in Chapter 48, what adverse effects of tetracyclines, such as doxycycline, cause these drugs to be used with caution during pregnancy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Chloroquine (Aralen)

Classification **Therapeutic:** Antimalarial drug
Pharmacologic: Heme complexing drug

Therapeutic Effects and Uses: Developed in response to the high incidence of malaria among American soldiers in the Pacific islands during World War II, chloroquine has been the traditional prototype medication for malarial prophylaxis and treatment for over 60 years. Chloroquine is very effective in treating acute symptoms of the erythrocytic stage but has no activity against dormant *P. vivax* or *P. ovale*. It can reduce the high fever of patients in the acute stage in less than 48 hours. It is also effective for the chemoprophylaxis of malaria caused by *P. malariae* and sensitive strains of *P. falciparum*, when taken 2 weeks before entering an endemic area and continuing 4 to 6 weeks after leaving. Chloroquine is used only for patients who acquired malaria in a region without chloroquine resistance.

Mechanism of Action: Chloroquine concentrates in the food vacuoles of *Plasmodia* residing in human RBCs. Once in the vacuole, the drug likely prevents the destruction of heme and other proteins, which then build to toxic levels within the parasite. The anti-inflammatory effects of chloroquine occur because the drug inhibits the actions of histamine and serotonin and inhibits prostaglandin synthesis.

Pharmacokinetics:

Route(s)	Oral (PO), intramuscular (IM)
Absorption	Rapid and completely absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic; two active metabolites
Primary excretion	Renal
Onset of action	Peak effect: 1–2 h
Duration of action	Half-life: 70–120 h

Adverse Effects: Chloroquine exhibits few serious adverse effects at low to moderate doses. Nausea and diarrhea may occur. At higher doses, central nervous system (CNS) and cardiovascular toxicity may be observed. Symptoms include confusion, delirium, convulsions, reduced reflexes, hypotension, and dysrhythmias. Blood dyscrasias are possible. Chloroquine can cause retinal toxicity, including blurred vision, photophobia, and difficulty focusing.

Contraindications/Precautions: Patients with preexisting retinal field changes should not receive chloroquine, because the drug concentrates in this tissue and high doses can cause irreversible retinal damage. Baseline and periodic vision screening should be conducted during therapy. Because this drug can affect heme metabolism, it is contraindicated in patients with porphyria. Patients with known glucose-6-phosphate dehydrogenase (G6PD) deficiency should be treated cautiously, if at all, because chloroquine may cause hemolysis in these patients. Because chloroquine is metabolized in the liver, patients with chronic alcoholism or hepatic impairment should be monitored regularly. It is also contraindicated in patients with chronic kidney disease (CKD) and in those with hypersensitivity to the drug. Patients with preexisting hematologic disease should be treated with caution because chloroquine may cause blood dyscrasias.

Drug Interactions: Antacids and laxatives containing aluminum and magnesium can decrease absorption and must not be given within 4 hours of oral chloroquine administration. Cimetidine may also decrease the absorption of chloroquine. Because chloroquine is associated with an increased risk for QT prolongation and torsades de pointes, it should not be administered concurrently with other drugs known to prolong the QT interval, such as many antidysrhythmics, phenothiazines, and beta-adrenergic agonists. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Chloroquine overdose may be fatal. Symptomatic treatment includes anticonvulsants and vasopressors for shock. Ammonium chloride may be used to acidify the urine to hasten excretion of chloroquine.

Nursing Responsibilities: Key nursing implications for patients receiving chloroquine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections.

Drugs Similar to Chloroquine (Aralen)

Other antimalarials include artemether-lumefantrine, atovaquone-proguanil, hydroxychloroquine, mefloquine, primaquine, and quinine.

Artemether-lumefantrine (Coartem): In 2009, the U.S. Food and Drug Administration (FDA) approved the use of a fixed-dose combination of artemether and lumefantrine to treat acute, uncomplicated malaria. Artemether is prepared from substances obtained from the Chinese herb *Artemisia annua*, which has been known to have antimalarial properties for over a thousand years. Lumefantrine extends the half-life of the combination drug. Coartem is significant because it is very effective and offers an additional option for treating chloroquine-resistant infections. This drug is approved for treatment, not prevention, of malaria. Side effects are generally mild. Because this drug prolongs the QT interval, it should be used with caution in patients with cardiac impairment. This drug is pregnancy category C.

Atovaquone-proguanil (Malarone): The fixed-dose combination drug Malarone was approved in 2000 for the prevention and treatment of malaria. Malarone may be given for prophylaxis or to lessen the severity of acute symptoms. For acute attacks, a 3-day regimen is usually sufficient. For prevention, the drug is begun 1 to 2 days before entering an endemic region and continued for 7 days after returning. The drug combination rarely produces serious adverse effects; rash and gastrointestinal (GI) upset are the two most common complaints. Atovaquone (Mepron) is approved as monotherapy to treat *Pneumocystis jiroveci* pneumonia in patients who are intolerant to trimethoprim-sulfamethoxazole (TMP-SMZ). This drug is pregnancy category C.

Hydroxychloroquine (Plaquenil): As its name implies, hydroxychloroquine is closely related to chloroquine and has essentially the same actions. Approved in 1955, it is indicated for the prevention and treatment of malaria. Like chloroquine, retinal toxicity is a concern. Hydroxychloroquine is also prescribed to treat patients with cutaneous and systemic forms of systemic lupus erythematosus and for rheumatoid arthritis. It is administered by the oral (PO) route and is pregnancy category C.

Mefloquine: Approved in 1989, mefloquine was developed during the Vietnam War to protect American soldiers from multidrug-resistant *P. falciparum* malaria. It is approved for both treatment and prophylaxis. Prophylactic dosing begins 1 week before entering an endemic area and continues for 4 weeks after leaving. Because of the rapid emergence of resistant strains, it is reserved for multidrug-resistant strains of *Plasmodium*. Nausea and vomiting are the most common adverse effects. The primary limitation of mefloquine is nervous system toxicity, including dizziness, nightmares, aggression, and psychoses, which can appear at high doses. Patients with preexisting psychiatric disorders should not take mefloquine. This is a pregnancy category C drug.

Primaquine: Approved in 1951, primaquine is a preferred drug for preventing relapses caused by dormant *P. vivax* in the liver. Because it has no activity against the blood forms of *Plasmodium*, it must always be used in combination with other antimalarials. Standard therapy is for 14 days, although 5-day regimens have proved successful. The drug is well tolerated, even at high doses. The most serious adverse effect is hemolytic anemia in patients who are deficient in G6PD. Unlike some of the other drugs in this class, resistance is not a major clinical problem with primaquine. It is also used to treat *P. jiroveci* pneumonia in combination with clindamycin. This is a pregnancy category C drug.

Quinine (Qualaquin): First described in the 1600s, quinine is the oldest drug used to treat malaria, and it is still obtained

from the bark of the South American cinchona tree. Although safer alternatives have since been discovered, quinine is still used for chloroquine-resistant *Plasmodia*, in combination with other antimalarials. It is approved only for the treatment (not prophylaxis) of uncomplicated malaria caused by *P. falciparum*. For many years, the majority of quinine use in the United States was to treat nighttime leg cramps, an off-label indication. However, in 2010, the FDA issued a black box warning against the off-label use of this drug for leg cramps because of the potential for developing severe and sometimes fatal thrombocytopenia. Cinchonism, a syndrome characterized by tinnitus, deafness, headache, vision abnormalities, and diarrhea, can occur at therapeutic doses. A major limiting factor is cardiotoxicity, which produces quinidine-like dysrhythmias at high doses. This drug is pregnancy category X.

Quinidine gluconate is closely related chemically to quinine. Given by infusion, the drug is used to treat severe, life-threatening malaria. Rarely, it may be used to treat symptomatic atrial dysrhythmias and life-threatening ventricular dysrhythmias when safer and more effective drugs have proven ineffective. Adverse effects are the same as for quinine.

Drugs for Nonmalarial Protozoan Infections

53.4 Amebiasis, giardiasis, and cryptosporidiosis are caused by intestinal parasites and are usually acquired through contaminated water or food.

Although infection by *Plasmodium* is the most significant protozoan disease worldwide, infections caused by other protozoa affect significant numbers of people in endemic areas. Each of the organisms has unique differences in its distribution pattern and physiology.

Many areas of the world do not enjoy the high level of sanitation found in the United States and Canada. In developing countries, drinking water may not be disinfected before consumption and may be contaminated with pathogens from animal waste. In regions with poor sanitation, infectious diseases are endemic and contribute significantly to mortality, especially in children, who are often more susceptible to the pathogens. Amebiasis, giardiasis, and cryptosporidiosis are protozoan infections of the intestines, spread primarily by poor sanitation.

PharmFACT

It is estimated that 50 million cases of amebiasis occur each year worldwide, resulting in 100,000 deaths annually. Worldwide, it is the second leading cause of death due to protozoans (Dhawan, 2016).

Amebiasis: Although not endemic to the United States, as much as 10% of the world's population is infected with this protozoan disease. The infection may be carried to the United States by travelers from regions where the disease is endemic, such as Mexico, India, Western and Southern Africa, and portions of Central and South America. The parasite is spread by ingesting fecally contaminated food or drinking water

Amebiasis begins when an individual ingests cysts of *Entamoeba histolytica*. The trophozoite form of the protozoan invades the colon mucosa, causing ulcerations and considerable abdominal pain, cramping, and bloody diarrhea. Cysts are expelled in the feces. Diagnosis of amebiasis is generally through identification of the trophozoites in the stool; however, serum and stool antigen detection tests specific for *E. histolytica* are available. The lifecycle of *E. histolytica* is illustrated in Figure 53.2.

Although rare, the trophozoite may gain access to the general circulation through colon ulcers and travel to other organs, particularly the liver, where it produces hepatic abscesses. Liver involvement causes high fever and right upper quadrant pain. Other possible sites of infection include the brain, genitalia, and lung.

Regimens for amebiasis include combination therapy with two to three drugs to eliminate the parasites from their many potential sites. The most commonly prescribed medication for both intestinal and hepatic amebiasis is metronidazole, due to its safety and efficacy. In cases of acute disease, IV metronidazole may be administered concurrently with an opioid to control severe diarrhea. Tinidazole (Tindamax) is an option for patients unable to take metronidazole.

If the infection is limited to the intestine, paromomycin (Humatin) and iodoquinol (Yodoxin) are preferred drugs because they are able to reach high concentrations in the intestinal lumen without producing significant systemic toxicity. These drugs are also prescribed to eliminate the protozoan in patients who are asymptomatic carriers of the infection.

Pharmacotherapy for amebiasis is continued until multiple negative stool specimens are obtained. Drugs for amebiasis and other nonmalarial protozoan infections are listed in Table 53.3.

Giardiasis: Giardiasis is an infection caused by the protozoan *Giardia lamblia* that has much in common with amebiasis. They are both endemic to regions with poor sanitation, where the water supply is contaminated with human feces. Both affect the intestine, causing acute cramping pain, severe diarrhea, fatigue, and marked weight loss. Both have a trophozoite and cyst stage, with no intermediate host or vector. Identification of *Giardia* trophozoites or cysts in the stool can help distinguish between the two diseases. Another potential cause of giardiasis in the United States is the unsanitary handling of soiled diapers in daycare centers. It is interesting to note that *Giardia* was the very first protozoan discovered, originally identified by the inventor of the microscope, van Leeuwenhoek, in the 1600s.

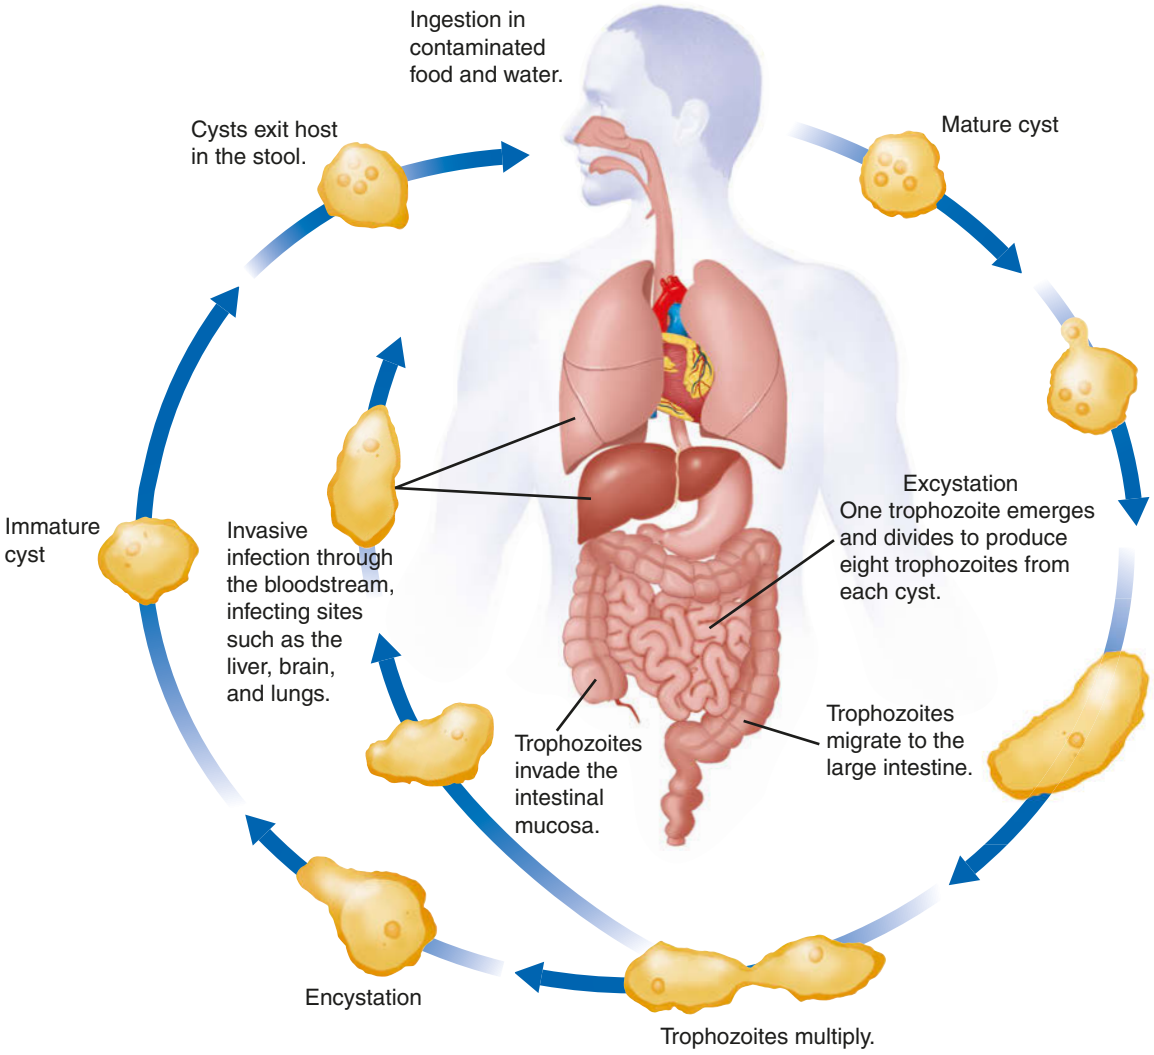

Figure 53.2 Lifecycle of *Entamoeba histolytica.*

More common than amebiasis, giardiasis is the most common intestinal parasite responsible for diarrhea symptoms throughout the world. When contaminated food or water is ingested, the acidic environment of the stomach causes the parasite to transform from the cyst to the trophozoite stage. The incubation period is 1 to 3 weeks, and symptoms last 2 to 6 weeks.

Infections of *G. lamblia* remain localized to the intestine and are often self-limiting. A chronic form of giardiasis, however, can last for months and lead to malabsorption, steatorrhea, weakness, and chronic diarrhea. Although giardiasis is not fatal, it can weaken patients and make them susceptible to infection by opportunistic pathogens. Family members of infected patients, food handlers, and daycare workers who are asymptomatic carriers should receive treatment.

Pharmacotherapy of giardiasis includes metronidazole (Flagyl), tinidazole (Tindamax), and nitazoxanide (Alinia). Diarrhea generally stops within 48 hours after pharmacotherapy is initiated and a typical regimen continues for 3 to 5 days. Follow-up stool specimens are analyzed to confirm that the pharmacotherapy has been successful. For persistent cases, therapy may last 3 to 4 weeks.

PharmFACT

Someone infected with giardiasis may shed as many as 10 billion *Giardia* cysts each day for several months. It is believed that swallowing as few as 10 cysts might cause someone to develop symptoms of giardiasis (CDC, 2015).

Cryptosporidiosis: Cryptosporidiosis is an infection caused by the protozoan *Cryptosporidium parvum* that causes severe diarrhea. Like *E. histolytica* and *G. lamblia, C. parvum* is primarily an intestinal parasite, acquired through the consumption of fecally contaminated food or water. It has also been isolated from recreational water and has even been found in municipal water supplies. Cysts of *C. parvum* survive harsh conditions, including chlorination of water. Although only about 3000 cases of cryptosporidiosis are reported in the United States each year, it is responsible for a significant proportion of infectious diarrhea worldwide.

Table 53.3 Drugs for Nonmalarial Protozoan Infections

Drug	Infection	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
eflornithine (Ornidyl)	African trypanosomiasis	IV: 100 mg/kg injected over at least 45 min q6h for 14 days	*Nausea, vomiting, diarrhea* Blood dyscrasias, seizures, ototoxicity
iodoquinol (Yodoxin)	Intestinal amebiasis	PO: 650 mg tid for 20 days (max: 2 g/day)	*Nausea, vomiting, headache, dizziness* Loss of vision, agranulocytosis, peripheral neuropathy
melarsoprol (Arsobal)	African trypanosomiasis	IV: 2–3.6 mg/kg for 3 days, then repeated on day 7 and days 10–21	*Fever, albuminuria, transient arthralgias, dermatitis* Encephalopathy, increased mental excitement, twitching, confusion, tremor, seizures
metronidazole (Flagyl)	Amebiasis, trichomoniasis, giardiasis, Gardnerella vaginitis	For giardiasis: PO: 500 mg bid for 7 days For amebiasis: PO: 500–750 mg tid for 5–10 days	*Dizziness, headache, anorexia, abdominal pain, metallic taste, nausea* Seizures, peripheral neuropathy
miltefosine (Impavido)	Leishmaniasis	PO: 100–150 mg daily for 28 days	*Skin rash, elevated transaminases and creatinine levels, reduced sperm counts* Stevens–Johnson syndrome, melena, thrombocytopenia, embryo and fetal toxicity
nifurtimox (Lampit)	American trypanosomiasis	PO: 8–10 mg/kg 3–4 times/day for 90–120 days	*Rash, dizziness, headache, nausea, vomiting* Seizures, paresthesia with myalgia, pneumonia
nitazoxanide (Alinia)	Diarrhea caused by cryptosporidiosis or giardiasis in children	PO: 100–200 mg q12h for 3 days	*Abdominal pain, diarrhea, nausea, vomiting, headache* No serious adverse effects
paromomycin (Humatin)	Intestinal amebiasis	PO: 25–35 mg/kg divided in 3 doses for 5–10 days	*Nausea, vomiting, headache, diarrhea, abdominal cramps* Ototoxicity, nephrotoxicity
pentamidine (NebuPent, Pentam)	*Pneumocystis* pneumonia, trypanosomiasis, leishmaniasis	IM/IV: 4 mg/kg/day for 14–21 days Inhaled: 300 mg per nebulizer every 3–4 wk	*Cough, bronchospasm* Hypoglycemia, severe hypotension, kidney failure, pneumothorax
pyrimethamine (Daraprim)	Toxoplasmosis	PO: 50–75 mg for 1–3 wk, then 25–37.5 mg for 4–5 wk	*Nausea, vomiting, diarrhea, rash* Folic acid deficiency, blood dyscrasias
sodium stibogluconate (Pentostam)	Leishmaniasis	IV or IM: 20 mg/kg/day for 20 days	*Nausea, vomiting, diarrhea, anorexia, cough, substernal pain* ECG changes, pneumonia, blood dyscrasias
suramin (Germanin)	African trypanosomiasis	IV: 1 g on days 1, 3, 7, 14, and 21	*Nausea, vomiting, malaise, fatigue, fever, diarrhea, rash* Loss of consciousness, seizures, nephrotoxicity, adrenal insufficiency, blood dyscrasias, hepatotoxicity, severe hypersensitivity reactions
tinidazole (Tindamax)	Amebiasis, giardiasis, trichomoniasis, bacterial vaginosis	For amebiasis: PO: 2 g/day for 3 days For giardiasis or trichomoniasis: PO: 2 g as single dose For vaginosis: PO: 2 g/day for 3 days	*Anorexia, constipation, dyspepsia, dizziness, bitter or metallic taste, nausea, vomiting* Seizures, peripheral neuropathy, angioedema

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

In patients with healthy immune systems, the disease is self-limiting and no antiprotozoan drugs are necessary to remove the parasite. Pharmacotherapy of cryptosporidiosis is targeted at stopping the severe diarrhea through the symptomatic use of antidiarrheal drugs. In addition to opioids, nitazoxanide (Alinia) is approved to treat diarrhea from this parasite.

In immunosuppressed patients, cryptosporidiosis has a high mortality rate. In addition, the disease can spread to other tissues, especially the gallbladder and biliary tree. Antiprotozoan drug therapy is necessary for these patients, with paromomycin (Humatin) being a preferred medication. Other drugs that may be of benefit include azithromycin and nitazoxanide (Alinia). Combination therapy with these drugs may continue for 14 to 28 days, depending on patient response.

PROTOTYPE DRUG Metronidazole (Flagyl)

Classification **Therapeutic:** Anti-infective, antiprotozoan
Pharmacologic: Nitroimidazole drug

Therapeutic Effects and Uses: Approved in 1963, metronidazole is the prototype medication for amebiasis, being effective against both the intestinal and hepatic

phases of the disease. Resistant forms of *E. histolytica* have not yet emerged as a clinical problem with metronidazole. Metronidazole is also a preferred drug for giardiasis (off-label) and trichomoniasis.

In addition to its classification as an antiprotozoan drug, metronidazole has strong activity against anaerobic bacteria and may be given PO or IV to treat a number of serious respiratory, bone, skin, and CNS infections.

Topical forms of metronidazole (MetroGel, MetroCream, MetroLotion) are used to treat rosacea, a chronic, inflammatory condition characterized by skin reddening and hyperplasia of the sebaceous glands, particularly around the nose and face. MetroGel-vaginal is approved to treat susceptible vaginal infections. Helidac (metronidazole, bismuth, and tetracycline) is approved to eradicate *Helicobacter pylori*, an infection associated with peptic ulcer disease. Flagyl-ER is an extended duration form of the drug for treating bacterial vaginosis.

Off-label uses of metronidazole include the pharmacotherapy of pseudomembranous colitis, Crohn's disease, and colitis. When used for intestinal pathogens, metronidazole therapy is sometimes followed by administration of iodoquinol to more effectively eliminate residual parasites harbored in the colon.

Mechanism of Action: Metronidazole enters pathogens and binds to deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and intracellular proteins. Cell death is likely the result of an absence of DNA repair and abnormalities in RNA synthesis.

Pharmacokinetics:

Route(s)	PO, IV, topical
Absorption	Well-absorbed PO (80%)
Distribution	Widely distributed, including the cerebrospinal fluid and abscesses; crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic: 30–60%
Primary excretion	Renal: 77%; feces: 6–15%
Onset of action	PO/IV: rapid; topical: 3 weeks
Duration of action	PO/IV: 6–8 h; topical: 12 h

Adverse Effects: Although adverse effects occur frequently during metronidazole therapy, most are not serious enough to cause discontinuation of the drug. The most common adverse effects are anorexia, nausea, vomiting, diarrhea, abdominal pain, dizziness, and headache. Dryness of the mouth and an unpleasant metallic taste may be experienced. Seizures and peripheral neuropathy have been reported. Patients receiving the drug by the IV route should be monitored for injection-site reactions. Use of the vaginal gel may lead to vaginal candidiasis in more than 10% of patients. **Black Box Warning:** Metronidazole (oral and parenteral) is carcinogenic in laboratory animals and should be used only for approved indications.

Contraindications/Precautions: Although rare, metronidazole can cause bone marrow suppression. Thus, it is contraindicated for patients with blood dyscrasias. Complete blood counts (CBCs) should be monitored during therapy to rule out any developing leukopenia. Metronidazole crosses the blood–brain barrier and is contraindicated in patients with active CNS pathology. Metronidazole should be discontinued if signs of CNS toxicity appear. Liver function tests should be carefully monitored in patients with alcoholism or hepatic impairment, because metronidazole is extensively metabolized in the liver. Doses of metronidazole should be lowered in these patients. The injectable form of metronidazole contains significant amounts of sodium, which can lead to edema in patients with heart failure.

Drug Interactions: Concurrent administration with PO anticoagulants can potentiate hypoprothrombinemia; thus, warfarin doses may require adjustment. Alcohol use may elicit a disulfiram-like reaction. Concurrent use with disulfiram can induce acute psychosis. This includes medications such as cough remedies that contain alcohol. Because metronidazole may elevate lithium levels, doses of lithium may need to be decreased to avoid toxicity. **Herbal/Food:** The extended release form of the drug should be taken on an empty stomach.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy for overdose is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving metronidazole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections.

Drugs Similar to Metronidazole (Flagyl)

Other selected antiprotozoan drugs for amebiasis, giardiasis, or cryptosporidiosis include iodoquinol, nitazoxanide, paromomycin, and tinidazole.

Iodoquinol (Yodoxin): Approved in 1953, iodoquinol is prescribed for amebiasis to treat the trophozoite and cyst forms of *E. histolytica*. The usual regimen lasts for 20 days. Iodoquinol contains iodine; therefore, it should be used with caution in patients with thyroid disease and can influence thyroid function tests for as long as 6 months after discontinuation of therapy. Common adverse effects include diarrhea, nausea, vomiting, and stomach pain. Less common, although more serious, adverse effects include optic neuritis, loss of vision, anaphylaxis, and agranulocytosis. Iodoquinol also has activity against *Trichomonas vaginalis* and certain bacteria and fungi. This drug is pregnancy category C.

Nitazoxanide (Alinia): Approved in 1996, nitazoxanide is approved for the treatment of infectious diarrhea caused by cryptosporidiosis and giardiasis in adults and children. For children, it is formulated as a PO suspension. Off-label uses include diarrhea caused by other agents such as *E. histolytica* and *Clostridium difficile*. A typical regimen is 500 mg bid for 3 days. The drug is well tolerated, with abdominal pain and GI distress being the most common adverse effects. This drug is pregnancy category B.

Paromomycin (Humatin): Approved in 1959, paromomycin is a broad-spectrum aminoglycoside antibiotic with antiprotozoan activity. The drug has activity against most gram-negative bacteria (except *Pseudomonas aeruginosa*), many gram-positive bacteria, some protozoa, and many parasitic worms. Because it is poorly absorbed from the GI tract, PO dosing is used to kill intestinal bacteria, protozoa, and helminths. It is approved for the treatment of intestinal *E. histolytica* infections, with a typical regimen consisting of 10 to 14 days of therapy. The drug has an orphan drug designation for treating multidrug-resistant tuberculosis and *Mycobacterium avium* complex infections. The most common adverse effects are GI related: nausea, vomiting, cramping, and diarrhea. Like other aminoglycosides, the drug may exhibit ototoxicity and nephrotoxicity. This drug is pregnancy category C.

Tinidazole (Tindamax): Approved in 2004, tinidazole is in the same chemical class as metronidazole but has a longer half-life that allows for less frequent dosing intervals. Like metronidazole, tinidazole exhibits both antibacterial and antiprotozoan activity. It is highly active against *E. histolytica*, *T. vaginalis*, *G. lamblia*, and certain anaerobic bacteria. Typical regimens include single PO doses for giardiasis and trichomoniasis and 3-day therapy for amebiasis. In 2007, Tindamax was approved to treat bacterial vaginosis, the most common vaginal infection in the United States. Tinidazole interacts with anticoagulants to increase the risk of bleeding. When taken concurrently with alcohol, a disulfiram-like reaction occurs. Adverse effects are mild and include a bitter or metallic taste and GI distress. Tinidazole carries a black box warning that the drug is carcinogenic in laboratory animals and should be used only for approved indications. Tinidazole is contraindicated during the first trimester of pregnancy (category D) and should be used with caution in the second and third trimesters (category C).

53.5 Other protozoan infections that can cause significant disease include toxoplasmosis, trichomoniasis, trypanosomiasis, and leishmaniasis.

Protozoa can invade nearly any tissue in the body. As discussed earlier in this chapter, *Plasmodia* prefer erythrocytes, *Giardia* the colon, and *Entamoeba* travel to the liver. This section presents less common protozoa that invade additional sites. These infections include toxoplasmosis, trichomoniasis, trypanosomiasis, and leishmaniasis.

Toxoplasmosis: Toxoplasmosis is an infection caused by the protozoan *Toxoplasma gondii*. The domestic cat is an intermediate host to the parasite and serves as a primary means of transmission to humans. The only method of direct human-to-human transmission is from an infected mother to her fetus.

The cycle of *Toxoplasma* infection begins when a cat ingests cysts of *T. gondii*, either through fecally contaminated food or in the flesh of their prey. Once inside the cat, the cysts become trophozoites and invade the small intestine. The cysts are excreted and become infectious after they leave the cat's body. *Toxoplasma* cysts can remain infectious in the environment for up to a year.

Toxoplasmosis can occur if humans are exposed to contaminated cat feces, or if they eat raw or undercooked meat containing the cysts. In healthy people, toxoplasmosis is usually asymptomatic or presents with flu-like symptoms that rarely require treatment. Those who are pregnant or immunosuppressed, however, require pharmacotherapy because the disease can cause significant morbidity in these populations.

Once *T. gondii* enters the body, it can invade nearly any organ. The most common symptom is nonspecific lymphadenopathy. In immunosuppressed patients the brain is sometimes affected, resulting in a variety of CNS symptoms from headache to seizures. The cysts can form necrotic regions in the brain, resulting in focal neurologic abnormalities and changes in mental status. Fatal encephalitis from *Toxoplasma* infection was common in the early years of the AIDS epidemic. Lung infections were also frequent in these patients.

A pregnant patient acquiring *Toxoplasma* during the first two trimesters of pregnancy is at high risk of transmitting the infection to her fetus. The protozoan may cause stillbirth or abortion. Babies may present with ocular toxoplasmosis, a form of the infection that occurs when the cysts are deposited near the retina. Approximately 85% of the newborns who appear normal will develop brain or eye infections from *T. gondii*, sometimes years after birth.

The most effective regimen for acute toxoplasmosis is pyrimethamine (Daraprim) for 4 to 5 weeks. Clarithromycin, azithromycin, or a sulfonamide may be added to the regimen in combination with pyrimethamine or as alternatives. Leucovorin (folinic acid), a form of folic acid, added to the regimen reduces the potential for pyrimethamine-induced bone marrow suppression. Because relapse rates for toxoplasmosis in patients with AIDS approach 100%, lifelong prophylaxis may be necessary.

Trichomoniasis: Trichomoniasis is a parasitic infection caused by the protozoan *T. vaginalis*. It is a common STI,

affecting approximately 15% of women visiting STI clinics in the United States (2.5 to 3 million women).

Because *T. vaginalis* can survive on moist surfaces for several hours, the infection may also be spread by nonsexual means, although this mode of transmission is believed to be uncommon. In addition, there is a small risk of transmission of the infection from mother to baby during childbirth. Thus, trichomoniasis in pregnant patients is usually treated.

Trichomoniasis most commonly presents with malodorous vaginal discharge, accompanied by vulvar pruritus. Intense scratching may cause erythema and secondary infections in surrounding areas. Dysuria and discomfort during intercourse are common. Fifty percent of *Trichomonas* infections are asymptomatic or subclinical. Most infections in men are asymptomatic, or small amounts of urethral discharge may be noted. Because of the nonspecific nature of the symptoms, diagnosis may be difficult. Culturing of the vaginal discharge is conducted in patients who do not respond to standard therapy, and a specific monoclonal antibody test is available.

With pharmacotherapy, cure rates for trichomoniasis are high. A single PO dose of metronidazole (Flagyl) has been demonstrated to be as effective as prolonged therapy, and more effective than topical drugs. However, the higher amount administered as a single dose causes a greater incidence of adverse effects, particularly GI upset. For these patients, 7 days of metronidazole therapy at a lower daily dose is equally effective and produces less GI upset. Therapy should also include the patient's sexual partners, even if they are asymptomatic, to break the cycle of reinfection.

Trypanosomiasis: Trypanosomiasis is actually two distinct parasitic infections: American and African trypanosomiasis. The two infections are caused by different organisms and have different vectors, clinical manifestations, and treatments.

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi*, a parasite found throughout central and northern South America, Central America, and Mexico. The disease is rare in the United States. The vector for Chagas' disease is the "kissing" bug that ingests *T. cruzi* when it feeds on an infected human. The protozoan reproduces in the bug and is transmitted when the vector defecates on the host's skin at the same time that it feeds. *T. cruzi* usually enters the human host by being rubbed into the vector's bite, an open cut, or the mucous membranes of the eye, nose, or mouth. Other carriers are suspected for *T. cruzi*, including dogs, cats, and rodents. It is estimated that 50,000 people die each year from the infection.

Acute Chagas' disease occurs more commonly in children and presents as a granuloma at the entry site, lymphadenopathy, and hepatomegaly. The acute form is not common and is often self-limiting. If pharmacotherapy is initiated, the preferred drugs are benzimidazole and nifurtimox, which are available only from the CDC. Pharmacotherapy for the acute phase is prolonged, at 90 to 100 days.

The chronic stage of Chagas' disease may appear decades after the initial infection. Signs and symptoms include cardiomyopathy and degeneration of autonomic ganglia that can result in megacolon, megaesophagus, and uncoordinated peristalsis. Unfortunately, medications will not cure the chronic phase, which is treated symptomatically.

African trypanosomiasis, commonly known as sleeping sickness, is caused by two subspecies of the protozoan *Trypanosoma brucei*. The infection is transmitted to humans by the bite of a tsetse fly carrying *T. brucei*. African trypanosomiasis is restricted to sub-Saharan Africa, and its incidence ranges from 20,000 to 300,000 new infections annually, with about 50,000 deaths a year due to the infection.

Symptoms of *T. brucei* infection include a chancre at the site of the insect bite, extreme malaise (thus the name "sleeping sickness"), intermittent fever, muscle aches, weight loss, and body rash. The parasitic invasion may reach the CNS, causing personality changes, confusion, encephalitis, coma, and possibly death. The infection also affects the liver, heart, and other organs.

Early stages of *T. brucei* infection may be treated with suramin (Germanin) or pentamidine (Pentam). The standard drug for treating the late CNS manifestations is melarsoprol (Arsobal), a medication that has several toxic adverse effects. Eflornithine (Ornidyl), the first new drug for *T. brucei* in over 50 years, also causes serious adverse effects. There is a need for new, effective drugs for this infection.

Leishmaniasis: Most prevalent in Afghanistan, Bangladesh, Bolivia, Brazil, India, Iran, Peru, Saudi Arabia, Sudan, and Syria, leishmaniasis is an infection caused by about 20 different species of the protozoan *Leishmania*. Worldwide, 350 million people are believed to be afflicted with the disease. Carriers for *Leishmania* include dogs, foxes, squirrels, and rodents. The disease is transmitted to humans by the bite of the sand fly. Two primary forms of leishmaniasis have been identified, based on clinical signs and symptoms:

- **Visceral leishmaniasis.** Begins as a skin lesion but progresses to infect the spleen, liver, bone marrow, and lymph nodes. Visceral leishmaniasis is transmitted by contaminated blood or needlesticks and may occur in patients with advanced AIDS. It is usually fatal if untreated. This type most commonly occurs in Bangladesh, India, and Nepal.
- **Cutaneous leishmaniasis.** Characterized by skin lesions that spontaneously heal in 2 to 10 months. May progress to ulcers of the mucous membranes of the nose, pharynx, or oral cavity. Occurs mostly in Mideastern countries such as Afghanistan, Iran, and Saudi Arabia but also is found in southern Texas, Central America, and South America.

CONNECTIONS: Community-Oriented Practice

Risk of Disease from Consuming Sushi and Sashimi

Eating raw fish and other marine life is common in many areas of the world and has become popular in the United States. Raw fish, squid, oysters, and other animals may carry parasites that infect humans after consuming an infected meal. Tapeworms such as *Diphyllobothriasis nihonkaiense*, nematodes such as *Anisakis simplex* and *Pseudoterranova decipiens*, and more common infections such as *Escherichia coli*, *Vibrio parahaemolyticus,* and *Salmonella* may be ingested during a meal of sushi or sashimi (Hara-Kudo & Kumagai, 2014; Hoel, Mehli, Bruheim, Vadstein, & Jakobsen, 2015; Miguéis, Moura, Saraiva, & Esteves, 2016). Because these parasites are microscopic, consumers do not have a method for determining good sushi from bad sushi when purchasing it.

Ideally, fish and marine life should be cooked before consuming to kill parasites and bacteria. Freezing the flesh until solid at –20°C (–4°F) for at least 7 days will kill many parasites (Seafood Health Facts, 2017), but home freezers do not usually reach below –17.8°C (0°F). However, freezing also noticeably alters the taste and texture. Purchasing sushi and sashimi from trained sushi chefs and reputable restaurants may decrease, but does not eliminate, the risk of infection. Pregnant women, young children, and immunocompromised patients should not consume any raw fish or meat.

The CDC recommends sodium stibogluconate (Pentostam) as the standard treatment for visceral leishmaniasis. This drug is available only through the CDC. Stibogluconate must be administered by the IV or IM routes for 4 to 6 weeks, which makes the treatment of visceral leishmaniasis procedurally difficult in underdeveloped countries where the disease is most prevalent. In addition, resistance is common. Relapse may occur as long as 10 years after the initial exposure. Alternative pharmacotherapy (off-label) for visceral leishmaniasis includes amphotericin B, pentamidine (Pentam), and IM paromomycin (aminosidine).

Cutaneous leishmaniasis generally heals spontaneously in 5 to 12 months in immunocompetent patients and does not require pharmacotherapy. For severe cases, pharmacotherapy includes many of the same drugs used for the visceral form. In 2014, miltefosine (Impavido) became the first FDA-approved drug to treat cutaneous leishmaniasis.

PROTOTYPE DRUG **Pyrimethamine (Daraprim)**

Classification **Therapeutic:** Antiprotozoan
Pharmacologic: Folic acid antagonist

Therapeutic Effects and Uses: Available for over 30 years, pyrimethamine is a preferred PO drug for treating toxoplasmosis. Acute toxoplasmosis is treated for 2 to 4 weeks, whereas chronic stages that exhibit organ involvement may require months of therapy.

Pyrimethamine is primarily effective against the acute phase of *T. gondii* infection and is less effective once the protozoan has entered the cystic phase of its lifecycle. To boost its efficacy, pyrimethamine is sometimes combined with other anti-infectives such as a sulfonamide, clarithromycin, clindamycin, or azithromycin.

Fansidar, a fixed-dose combination drug containing pyrimethamine and sulfadoxine, was once used for the prophylaxis and treatment of malaria. This combination drug has been discontinued in the United States due to the large number of malarial strains that are resistant to it.

Mechanism of Action: Pyrimethamine inhibits the synthesis of folic acid in protozoa, thus inhibiting cell division.

Pharmacokinetics:

Route(s)	PO
Absorption	Pyrimethamine is well absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; over 80% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Kidneys
Onset of action	1 h
Duration of action	Half-life: 100 h

Adverse Effects: Common adverse effects of pyrimethamine include nausea, vomiting, anorexia, abdominal cramping, and rash. Serious adverse effects such as folic acid deficiency, megaloblastic anemia, pancytopenia, thrombocytopenia, and leukopenia may occur.

Contraindications/Precautions: Because pyrimethamine is a folic acid inhibitor, it is contraindicated in patients with preexisting megaloblastic anemia caused by folate deficiency. To prevent the development of anemia during therapy, leucovorin (folinic acid) is administered concurrently. Pyrimethamine can stimulate the CNS and cause seizures. Therefore, it is used with caution in patients with seizure disorders. It should be used with caution in patients with significant chronic kidney disease (CKD) or hepatic impairment and in those with G6PD deficiency.

Drug Interactions: Few significant drug interactions occur with pyrimethamine. Other folic acid antagonists such as TMP-SMZ should not be used concurrently because this will increase the possibility of severe folic acid depletion in the patient. Folic acid supplements should not

be given because they will reduce the effectiveness of pyrimethamine. Pyrimethamine increases the half-life of phenytoin and may cause phenytoin toxicity. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose can cause seizures and serious blood dyscrasias. Parenteral diazepam may be used to control seizures and leucovorin may be administered to prevent folic acid deficiency.

Nursing Responsibilities: Key nursing implications for patients receiving pyrimethamine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections.

Drugs Similar to Pyrimethamine (Daraprim)

Other selected antiprotozoan drugs for toxoplasmosis, trichomoniasis, trypanosomiasis, or leishmaniasis include eflornithine, melarsoprol, nifurtimox, sodium stibogluconate, and suramin.

Eflornithine (Ornidyl): Eflornithine is prescribed for African trypanosomiasis, especially late-occurring CNS disease. It is less toxic than melarsoprol, but it is more expensive and is thus considered for therapy when melarsoprol fails to provide relief. Given by the IV route, therapy is continued for 7 to 14 days. Close medical supervision is required to monitor for the many serious adverse reactions, such as anemia, diarrhea, seizures, and vomiting. Unrelated to its antiprotozoan action, eflornithine cream (Vaniqa) was approved by the FDA in 2000 as the first topical prescription treatment for women with unwanted facial hair. Adverse effects from the topical formulation are mild and transient. Both IV and topical forms are pregnancy category C.

Melarsoprol (Arsobal): Melarsoprol is an older antiprotozoan, approved in 1949, that is used for the late CNS stages of African trypanosomiasis. It is one of only a few antiprotozoan drugs that can cross the blood–brain barrier to reach the parasite in the CNS. Melarsoprol contains arsenic, an element acutely toxic to life-forms. The most common regimen is a series of three IV injections administered with a rest period of 8 to 10 days between each series. Melarsoprol is a toxic drug and severe adverse effects are possible, including fatal encephalopathy, convulsions, coma, thrombophlebitis, and necrosis at the injection site, if the drug is extravasated. Significant drug resistance has developed to melarsoprol. This drug is pregnancy category C.

Nifurtimox (Lampit): Nifurtimox is used for the treatment of American trypanosomiasis. It is given PO for 14 to 21 days. Adverse effects include nausea, vomiting, anorexia, and neurologic disturbances. Only 50% to 70% of patients will respond favorably to nifurtimox therapy, indicating a need for additional drugs for this infection. This drug is pregnancy category D.

Sodium stibogluconate (Pentostam): Sodium stibogluconate is the traditional drug for treating leishmaniasis; however, decades of use have led to near-total resistance in certain strains of *Leishmania*. The drug must be given parenterally for 2 to 3 weeks. The most common adverse effects are pain at the injection site, pancreatitis, muscle and joint pain, and decreases in white blood cell and RBC counts. Treatment failures and relapses are common, indicating a need for more effective drugs for this infection. This drug is pregnancy category C.

Suramin (Germanin): Discovered in 1921, suramin is one of the oldest drugs for African trypanosomiasis. It is used exclusively for pharmacotherapy of the initial phase of the infection, since it is unable to cross the blood–brain barrier to treat the CNS symptoms characteristic of late disease. The usual regimen is one IV injection per week for 5 weeks. Renal toxicity, nausea, and malaise are common during infusions.

CONNECTION Checkpoint 53.2

Sulfonamides have been used as common antibiotics for many decades. From what you learned in Chapter 50, what are the primary indications for sulfonamide pharmacotherapy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Classification and Pathogenesis of Helminthic Infections

53.6 Helminthic infections cause significant intestinal disease, particularly in areas with poor sanitation.

Helminths consist of various species of parasitic worms. Unlike the single-celled protozoa, helminths have many cells, and thus their anatomy, physiology, and lifecycles are more complex. Diseases caused by these pathogens affect more than 2 billion people worldwide and are quite common in areas of the world lacking high standards of sanitation. Helminth infections in the United States and Canada are neither common nor fatal, although drug therapy may be indicated.

Like protozoa, helminths have different stages in their lifecycles, which include both immature and mature forms. Typically, the immature forms enter the body through the skin or the digestive tract. Most attach to the intestinal tract, although some form cysts in skeletal muscle or in organs such as the liver. Helminths are classified as roundworms (nematodes), flukes (trematodes), or tapeworms (cestodes).

Ascariasis: Ascariasis, caused by the roundworm *Ascaris lumbricoides*, is the most common helminth disease

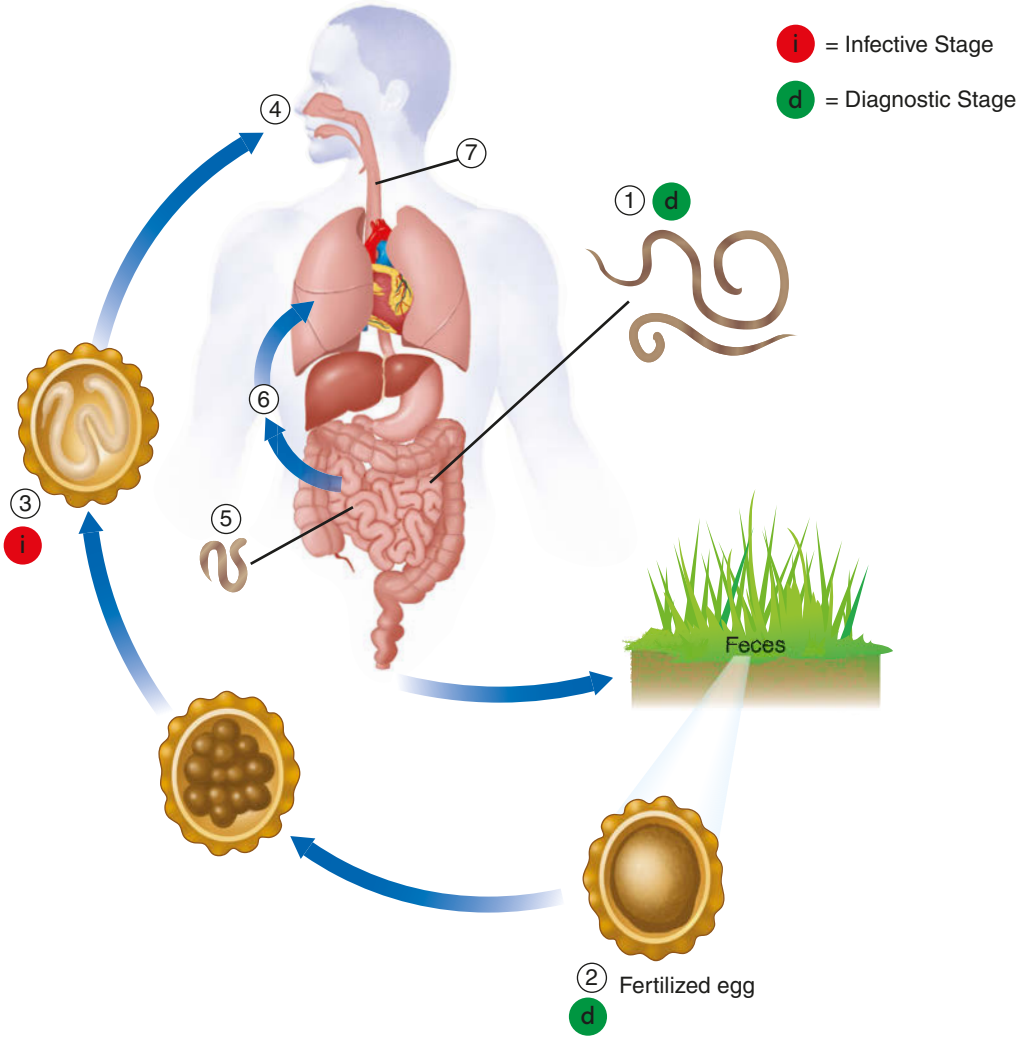

Figure 53.3 Lifecycle of *Ascaris*: Adult worms (1) live in the lumen of the small intestine. A female may produce as many as 240,000 eggs per day, which are passed with the feces (2). Fertile eggs become infective after 18 days to several weeks (3), depending on the environmental conditions (optimal: moist, warm, shaded soil). After infective eggs are swallowed (4), the larvae hatch (5), invade the intestinal mucosa, and are carried via circulation to the lungs (6). The larvae mature further in the lungs (10 to 14 days), ascend the bronchial tree to the throat, and are swallowed (7). Upon reaching the small intestine, they develop into adult worms.

worldwide, affecting more than 1.4 billion people. This parasite is endemic to Latin America and Asia and afflicts 4 million Americans, generally in the warm climates of the southeast. This infection occurs most commonly in children between the ages of 3 and 8 years, because this group is most likely to be exposed to contaminated soil without proper hand hygiene. Although fatalities are rare in the United States, severe infections can lead to complete intestinal obstruction if left untreated. Worldwide, it is estimated that ascariasis causes approximately 60,000 deaths annually, mostly in children.

Transmission of *A. lumbricoides* occurs when an individual unintentionally ingests eggs from the parasite. Once in the stomach, immature worms hatch from the eggs, and larvae attach to the intestinal wall. The larvae can travel through veins and lymphatics and be carried to the lungs, where they burrow through alveolar walls and migrate up the bronchi. Once reaching the throat, the larvae are swallowed and the cycle begins again.

A. lumbricoides develops into adult worms in the intestines. The female adult worm, which can grow to over 40 cm (16 in.) in length, lays as many as 240,000 eggs daily, which enter the feces. Under unsanitary conditions, *Ascaris* eggs reach soil where they may remain infective for years. The lifecycle of *Ascaris* is shown in Figure 53.3.

Ascariasis presents with both pulmonary and intestinal symptoms. As the larvae reach the lungs, the patient experiences cough, dyspnea, and low-grade fever. The intestinal phase is asymptomatic until large masses of worms are present. Vague upper abdominal pain,

distention, and occasional vomiting may be present. Diagnosis is through identification of *Ascaris* eggs or worms in the feces. Occasionally, a worm is observed passing through the anus, mouth, or nose.

Pharmacotherapy for ascariasis is generally successful in eliminating the helminth from the body, without causing significant adverse effects. Oral mebendazole (Vermox) for 3 days is the standard treatment, with albendazole (Albenza) and pyrantel (Antiminth) as alternative medications. Stools are rechecked 2 weeks after therapy is completed to confirm elimination of the roundworms. When possible, pregnant patients are treated after the first trimester to minimize risks to the fetus.

Enterobiasis: Infection by the pinworm *Enterobius vermicularis* is the most common helminth infection in the United States, afflicting as many as 40 million people, mostly children. The disease causes intense perineal itching due to the presence of deposited *Enterobius* eggs or migrating female worms. The itching is worse at night and may cause restlessness, enuresis, and insomnia. Diagnosis is by identification of eggs on the perianal skin or worms in the stool.

Transmission of *Enterobius* is by diapers, toys, hands, or food contaminated with the eggs. After ingestion, eggs hatch in the duodenum within 6 hours and worms mature in 2 weeks. Only 1 cm in size, adult worms infest the terminal ileum and colon. The female worm is either expelled during defecation or migrates to the perineum where 11,000 eggs per day may be released. After leaving the body, *Enterobius* eggs can remain infectious in the environment for up to 3 weeks. If proper hygiene is not observed, eggs deposited under the fingernails during scratching may be placed in the mouth, renewing the infectious cycle. Like ascariasis, enterobiasis is more common in children, due to the inattention to hand hygiene. Enterobiasis, however, does not cause mortality.

Pharmacotherapy of enterobiasis includes mebendazole (Vermox), albendazole (Albenza), or pyrantel (Antiminth). A single dose is usually sufficient to eradicate the pinworms, although the dose may be repeated in 2 weeks to maximize therapeutic success. Antipruritic ointments are available for topical application to the perianal region for symptomatic relief of pruritus. Asymptomatic infestation of other household members is frequent; therefore, it is prudent for all close contacts to receive antihelminthic treatment.

Hookworms: Two human hookworms, *Ancylostoma duodenale* and *Necator americanus*, infect 900 million people each year worldwide, usually in warm subtropical and tropical regions. Only about 1 cm in length, the adult hookworms live in the small intestine of the host. The female produces about 10,000 to 25,000 eggs per day, which are passed in the feces. Five days after exiting the body, hookworm eggs hatch and develop into an infective stage. The parasite is transmitted when an infective larva penetrates the skin, often that of a child walking barefoot through contaminated soil. Diagnosis of infestation is confirmed by identification of hookworm eggs in the feces.

The initial symptom of hookworm infection is an itchy rash called "ground itch" at the site of skin penetration. As larvae migrate through the host's blood, they travel to the lung and up to the throat, where they are swallowed and eventually end up in the small intestine. Pulmonary symptoms include cough, blood-tinged sputum, and low-grade fever. Later symptoms include vague abdominal pain, anorexia, and diarrhea.

The mouthparts of hookworms are modified cutting plates that cause hemorrhage when the worms attach to the intestinal mucosa to suck blood from the host. Children are particularly affected by the loss of blood. Although not directly fatal, hookworm infections can weaken the body by causing anemia and may cause death from infection by opportunistic pathogens.

The larvae of dog and cat hookworms can also infect humans, although they will not mature into adult worms in the human host. Transmitted to humans through contaminated soil or cat litter, these larvae remain in the skin where they migrate for many weeks and cause intense itching. This results in a condition known as *cutaneous larva migrans* or "creeping eruption."

Mebendazole (Vermox), pyrantel (Antiminth), and albendazole (Albenza) are preferred drugs for hookworm infections. Albendazole and pyrantel are given as a single dose; mebendazole therapy is generally for 3 days. Iron supplements and antianemic drugs may be necessary for patients who have lost an extensive amount of blood.

Tapeworms: Taeniasis is a parasitic infection caused by several species of tapeworms. Tapeworms are acquired when consuming raw or undercooked beef, pork, or fish. Some of the tapeworms reach enormous lengths; the beef tapeworm, *Taenia saginata*, grows to 25 meters (82 feet) and the pork tapeworm, *Taenia solum*, is 7 meters (23 feet).

Tapeworm infections may be asymptomatic or produce nonspecific symptoms such as nausea, diarrhea, hunger, fatigue, or abdominal pain. Larval cysts of *T. solium* can infect the brain, resulting in a disease called cysticercosis, which is a major cause of adult-onset seizures in low-income countries. Diagnosis of tapeworm infections is through identification of perianal eggs or by finding tapeworm eggs in a stool specimen.

The treatment of choice for most tapeworm infections is a single dose of praziquantel (Biltricide). For some infections, a laxative is given 2 hours after treatment to remove all parts of the worm and its eggs.

Other helminthic infections: Several other helminths cause significant disease worldwide in areas where sanitation is inadequate and food-handling techniques are poor. Drugs used to treat these infections are either the same as those described above or are only available in other countries. Nurses traveling to these regions should consult medical sources for the most up-to-date pharmacotherapeutic information.

Drugs for Helminthic Infections

53.7 Antihelminthic drugs are usually successful in rapidly eliminating the parasites and have few serious adverse effects.

Drugs used to treat worm infections are called *antihelmintics*. Pharmacotherapy is not indicated for all helminthic infections because some are self-limiting and the adult parasites die without reinfecting the host. When the infestation is severe or if complications occur, however, drug therapy is initiated. Complications caused by extensive infestations may include physical obstruction in the intestine, malabsorption, extensive loss of blood, increased risk for opportunistic bacterial infections, and severe fatigue. Pharmacotherapy is targeted at killing the parasites locally in the intestine, and systemically in the tissues and organs they have invaded. Some antihelminthics have a broad spectrum and are effective against multiple species of worms, while others are indicated for a single species. Resistance is not a clinical problem with antihelminthics. Drugs for helminthic infections are listed in Table 53.4.

Because helminthic infections are often the result of poor sanitation or unhealthy hygiene habits, assessment of the patient's living conditions should be conducted. Often, all family members and close contacts of the patient should be treated in order to prevent reinfestation. Family teaching about ways to prevent reinfestation is essential to break the lifecycle of the parasite.

PROTOTYPE DRUG **Mebendazole (Vermox)**

Classification **Therapeutic:** Antihelminthic
Pharmacologic: Microtubule inhibitor

Therapeutic Effects and Uses: Mebendazole and albendazole belong to the same chemical family, known as the benzimidazoles. Although the two benzimidazoles have similar properties and spectrums of action, mebendazole is the most widely prescribed in the United States.

Approved in 1974, mebendazole is used in the treatment of a wide range of helminthic infections, including those caused by roundworm (ascariasis), pinworm (enterobiasis), and hookworm species. As a broad-spectrum drug it is particularly valuable in mixed helminthic infections, which are common in areas with poor sanitation. It is effective against both the adult and larval stages of these parasites. For pinworm infections, a single dose is taken, followed by a second dose in 2 weeks. Other helminthic infections require 3 consecutive days of therapy. It may be prescribed off-label for tapeworm infections.

Mebendazole is poorly absorbed after PO administration, which allows it to maintain high concentrations in the intestine without causing systemic adverse effects.

Mechanism of Action: Mebendazole kills helminths by several biochemical mechanisms, including inhibition

Table 53.4 Drugs for Helminthic Infections

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
albendazole (Albenza)	PO: 400 mg bid with meals (max: 800 mg/day)	*Abnormal liver function tests, abdominal pain, nausea, vomiting* Agranulocytosis, leukopenia
ivermectin (Stromectol)	PO: 150–200 mcg/kg as a single dose	*Fever, pruritus, dizziness, arthralgia, lymphadenopathy* Acute allergic or inflammatory response
mebendazole (Vermox)	PO: 100 mg as a single dose or 100 mg bid for 3 days	*Abdominal pain, diarrhea, rash* Angioedema, convulsions, agranulocytosis, neutropenia
praziquantel (Biltricide)	PO: 5 mg/kg as a single dose or 25 mg/kg tid	*Headache, dizziness, malaise, fever, abdominal pain* Cerebrospinal reaction syndrome
pyrantel (Antiminth, Pin-X, Others)	PO: 11 mg/kg as a single dose (max: 1 g)	*Nausea, tenesmus, anorexia, diarrhea, fever* No serious adverse effects

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

of glucose transport and uncoupling of energy metabolism in the parasite's mitochondria. The drug binds to β-tubulin and is thought to disrupt the microtubular network in parasitic cells.

Pharmacokinetics:

Route(s)	PO
Absorption	Poorly absorbed
Distribution	Very little reaches the systemic circulation; 95% bound to plasma proteins
Primary metabolism	Hepatic
Primary excretion	Feces
Onset of action	Rapid
Duration of action	Half-life: 3–9 h

Adverse Effects: Because so little of the drug is absorbed, mebendazole does not cause serious systemic adverse effects. As the worms die, some abdominal pain, distention, and diarrhea may be experienced. Rare cases of seizures, agranulocytosis, neutropenia, and angioedema have been reported.

Contraindications/Precautions: Other than hypersensitivity, there are no contraindications for mebendazole. Because it is metabolized by the liver, patients with serious hepatic impairment should be monitored carefully. The drug is a potent teratogen in laboratory animals and should be avoided during pregnancy, especially the first trimester. Use in children under 2 years of age is not advised.

Drug Interactions: Carbamazepine and phenytoin can increase the metabolism of mebendazole, although dosage adjustment is not required because so little mebendazole is absorbed.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving mebendazole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections.

Drugs Similar to Mebendazole (Vermox)

Other selected drugs for helminthic infections include albendazole, ivermectin, praziquantel, and pyrantel. Bithionol (Bitin) is an antihelminthic available from the CDC for treating *Fasciola hepatica* (a liver fluke). Also available only through the CDC, diethylcarbamazine (Hetrazan) is only used to treat helminthic infections known as lymphatic filariasis, which are caused by various species of threadlike worms found in tropical climates.

Albendazole (Albenza): Approved in 1996, albendazole belongs to the same chemical class as mebendazole. It is incompletely absorbed when given PO, although enough of the drug is distributed to kill parasitic cysts in some tissues. It is a first-line drug for larval forms of the beef tapeworm *T. solium* and for hydatid cysts in the liver that form following infection by the dog tapeworm *Echinococcus granulosus*. It is often prescribed off-label for other helminthic infections. Albendazole is well tolerated and exhibits few adverse effects. The most common adverse effect is a transient increase in serum aminotransferase activity caused by its effects on liver function. This is a pregnancy category C drug.

Ivermectin (Stromectol): Approved in 1996, ivermectin has become a mainstay in the pharmacotherapy of several helminthic infections due to its superior safety profile and single-dose efficacy. It is a preferred drug for treating onchocerciasis or "river blindness," an especially debilitating filarial infection in Africa, Latin American, and the Middle East. Annual doses have caused a significant reduction of this disease in endemic areas. It is used (off-label) for the therapy of *cutaneous larva migrans*, or "creeping eruption." Because of its wide spectrum of action, it is of great importance in treating mixed helminthic infections. Adverse effects are minor and include fever, rash, and pruritus resulting from allergic and inflammatory reactions to the death of the parasites. This is a pregnancy category C drug.

Praziquantel (Biltricide): Approved in 1982, praziquantel is a preferred, broad-spectrum antihelminthic for schistosomiasis, a helminthic infection caused by blood flukes that affects 200 million people worldwide. People acquire the parasite by bathing or swimming in fecally contaminated water. Although not found in the United States, the parasite is endemic to tropical regions across the globe, causing chronic ill health. Praziquantel is also approved for Chinese liver fluke infections and is prescribed worldwide for other helminthic infections. It is a safe medication, with dizziness, headache, and abdominal pain being the most common adverse effects. This is a pregnancy category B drug.

Pyrantel (Antiminth, Pin-Rid, others): Approved in 1971, pyrantel is poorly absorbed when given PO; thus, it is effective only against intestinal helminths. As a single dose, it has been a traditional over the counter (OTC) drug for treating enterobiasis, ascariasis, and hookworm infections. Adverse effects are usually minor and include nausea, vomiting, headache, dizziness, and rash. Pyrantel is usually considered an alternative to mebendazole. This is a pregnancy category C drug.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic, or renal disease, hematologic disorders, and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of current infection and assess family members or others living in the home.
- Obtain a travel history, noting dates of travel and when current symptoms started in relation to travel (i.e., before, during, or after travel).
- Evaluate appropriate laboratory and diagnostic test findings (e.g., CBC, culture and sensitivity [C&S], fecal ova and parasites, hepatic and renal function studies, vision screening and retinal examination, electrocardiogram [ECG] as appropriate).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished diarrhea, chills, fever, muscle pain).
- Continue periodic monitoring of CBC, C&S, fecal ova and parasites, hepatic and renal function, vision and retinal examination, ECG as appropriate.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, increasing diarrhea, drowsiness, dizziness, paresthesia, metallic taste, darkened urine, dysrhythmias, palpitations. Immediately report severe diarrhea, especially that containing mucus, blood, or pus; yellowing of the sclera or skin; decreased urine output; numbness of extremities; blurring of vision or difficulty with vision clarity; photophobia; seizures; dysrhythmias; hypotension; and tachycardia.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, diarrhea, or signs and symptoms of infection should begin to diminish soon after taking the first dose and continue to improve.)	• Teach the patient to report a fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider within 3 days, increasing signs and symptoms of infection, or symptoms that remain present after taking the entire course of the drug. • Teach the patient to notify the provider if fever and signs and symptoms of infection increase after 3 days.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Immediately report undiminished fever or changes in level of consciousness (LOC) to the healthcare provider. (Continued fever may be a sign of worsening infection, adverse drug effects, or drug resistance.)	• Teach the patient to report fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider. Immediately report changes in behavior or LOC to the healthcare provider.
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBC, ECG, C&S, fecal ova and parasites, and results of vision and retinal screening. (Hepatic and renal laboratory studies, particularly with IV therapy, should be monitored to prevent adverse effects. Periodic C&S or fecal ova and parasite tests may be ordered if infections are severe or are slow to resolve to confirm appropriate therapy. Periodic vision and retinal screening will be required with chloroquine therapy because the drug can cause irreversible damage to the retina. ECG monitoring may be required with some antimalarial drugs.)	• Instruct the patient on the need for periodic laboratory work. Provide a kit and instructions for home use if fecal specimens are required. • Cultures should be collected before the drug therapy is started or if started in an emergency (e.g., overwhelming infection with significant body-wide symptoms), as soon as feasibly possible, and thereafter as ordered by the provider. • Instruct the patient to immediately contact the provider if blurring, difficulty focusing, or photophobia is severe, continues, or worsens.
• Monitor for hypersensitivity and allergic reactions, especially with the first few doses of any drug treatment. (Anaphylactic reactions are possible, particularly with the first dose. As parasites die, increasing diarrhea, abdominal pain, or chills may occur.)	• Teach the patient to immediately report any itching, rashes, swelling, particularly of the face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing. Report significant increases in abdominal pain, diarrhea, chills, or fever to the healthcare provider.
• Continue to monitor for hepatotoxicity or nephrotoxicity e.g., jaundice, right upper quadrant (RUQ) pain, darkened urine, or diminished urine output. (Increasing fluid intake will prevent drug accumulation in the kidneys. **Lifespan**: Age-related physiologic differences may place older adults at greater risk for hepatotoxicity or nephrotoxicity.)	• Teach the patient to report immediately any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light- or clay-colored stools, diminished urine output, or darkening of urine. • Advise the patient to increase fluid intake to 2–3 L/day. Alcohol use should be avoided or eliminated.
• Monitor for significant GI effects, including nausea, vomiting, abdominal pain, or cramping. Give the drug with food or milk to decrease adverse GI effects. (Food or milk may decrease GI effects, but an antiemetic may be considered if nausea is severe. Alcohol use, especially in patients on metronidazole, may cause a disulfiram-like reaction with excessive nausea, vomiting, and possible hypotension.)	• Teach the patient to take the drug with food or milk but to avoid acidic foods, beverages or carbonated drinks, and alcohol, especially in patients on metronidazole.
• Monitor for signs and symptoms of neurologic effects, e.g., dizziness, drowsiness, or headache, and ensure patient safety. **Lifespan**: Be particularly cautious with the older adult who may be at increased risk for dizziness and falls. (Dizziness or drowsiness increases the risk for falls.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Instruct the hospitalized patient to call for assistance prior to getting out of bed or attempting to walk alone.
• Monitor pulse and ECG as indicated in patients on antimalarial treatment. (Some antimalarials may cause dysrhythmias and hypotension.)	• Teach the patient to report any palpitations, lightheadedness, or dizziness promptly.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for signs and symptoms of bone marrow suppression and blood dyscrasias, e.g., low-grade fevers, bleeding, bruising, significant fatigue. (Bone marrow suppression is an adverse effect and may cause blood dyscrasias with resulting decreases in RBCs, white blood cells [WBCs], or platelets. Periodic monitoring of CBC may be required.)	• Teach the patient to report any low-grade fevers, sore throat, rashes, bruising or increased bleeding, unusual fatigue or shortness of breath, especially after taking drug therapy for a prolonged period.
• Assess the patient's sexual partners for infection and treat current partners to avoid reinfection. (Infection may be reintroduced by an untreated sexual partner.)	• Have the patient notify sexual partners for assessment and treatment.
• Teach general hygiene measures to prevent reinfestation with parasites. (Families with young children should practice scrupulous hand hygiene and proper disposal of diapers, and notify daycare or child care providers of the infection. Assess family pets that may carry infection and also require treatment. International travelers should practice scrupulous hygiene, especially in developing countries.)	• Teach the patient, family, and caregivers appropriate hygiene measures. Encourage veterinary assessment of family pets, even if asymptomatic. • Encourage international travelers to consult the CDC website on "Travelers' Health" to learn the latest information about potential disease risk, preventive and treatment measures, and other valuable travel-related health information before embarking on their trip.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Do not share with other family members and do not stop the medicine when starting to feel better.
	  • Avoid or eliminate alcohol. Some medications (e.g., metronidazole) cause significant reactions when taken with alcohol, and alcohol increases the adverse GI effects of many drugs.
	  • Take the drug with food or milk, but avoid acidic beverages. If instructed to take the drug on an empty stomach, take it with a full glass of water.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking the drug.
	  • Discard outdated medications or those no longer in use. Review the medicine cabinet twice a year for old medications (e.g., at beginning and end of daylight saving time).

Understanding Chapter 53

Key Concepts Summary

53.1 Protozoa are diverse, single-celled organisms that can cause widespread disease.

53.2 The female *Anopheles* mosquito is the carrier of several species of *Plasmodium*, the parasite responsible for malaria.

53.3 The three goals of malaria pharmacotherapy are chemoprophylaxis, treatment of acute attacks, and prevention of relapses.

53.4 Amebiasis, giardiasis, and cryptosporidiosis are caused by intestinal parasites and are usually acquired through contaminated water or food.

53.5 Other protozoan infections that can cause significant disease include toxoplasmosis, trichomoniasis, trypanosomiasis, and leishmaniasis.

53.6 Helminthic infections cause significant intestinal disease, particularly in areas with poor sanitation.

53.7 Antihelminthic drugs are usually successful in rapidly eliminating the parasites and have few serious adverse effects.

CASE STUDY: Making the Patient Connection

Remember the patient "Trevor Skales" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Trevor Skales is a 23-year-old man with an upcoming monthlong eco tour vacation planned to a rain forest in South America. He has been planning and researching this trip since he graduated from college and will be leaving in 3 weeks with two college friends. He knows about the possible endemic diseases in the area including tuberculosis, dengue fever, leishmaniasis, leprosy, and malaria. He discusses the trip with his healthcare provider who determines that malaria carries the biggest threat for transmission during Trevor's vacation.

Trevor has had a complete physical examination and is up to date on all required vaccinations. His provider has also screened for the possibility of a G6PD deficiency, and he has had a thorough eye examination. The provider has ordered chloroquine (Aralen) for Trevor. He is to begin taking it 2 weeks before his trip, every week throughout his trip, and for 1 month after returning home.

Critical Thinking Questions

1. Why was chloroquine (Aralen) ordered for Trevor before he has started his trip?
2. Why are special screening for G6PD deficiency and an eye examination important?
3. Trevor asks why he needs to continue to take the chloroquine (Aralen) after he returns home. As his nurse, what would you teach him about the drug dosing schedule and about symptoms to watch for?
4. What adverse effects are associated with chloroquine (Aralen) therapy?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Mary Porter is a 19-year-old woman who visits the local clinic with malodorous vaginal discharge, accompanied by vulvar pruritus. She also reports dysuria and discomfort during sexual intercourse. Mary is diagnosed with trichomoniasis and started on metronidazole (Flagyl).

1. Why are female patients more likely to contract trichomoniasis?
2. What health teaching would you provide to the patient who is being treated for trichomoniasis?
3. Develop a list of adverse effects this patient may experience while taking metronidazole.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is taking atovaquone-proguanil (Malarone) prophylactically before traveling to a developing country and asks the nurse how long the drug will need to be taken after returning from the trip. Which response from the nurse would be correct? Atovaquone-proguanil (Malarone) is:
    1. Recommended for 7 days after returning from the malaria-infested location.
    2. Not necessary after leaving the location.
    3. Suggested for 3 days after returning from the trip.
    4. Optional unless the patient reports symptoms of malaria.
2. A patient has been started on hydroxychloroquine (Plaquenil) for prevention of malaria on an overseas trip. In addition to the prevention and treatment of malaria, hydroxychloroquine is also indicated for what other conditions? (Select all that apply.)
    1. Systemic lupus erythematosus
    2. Roundworm infections
    3. Urinary tract infections
    4. Rheumatoid arthritis
    5. Leishmaniasis infections

3. A patient is being treated with metronidazole (Flagyl) for *Giardia lamblia* infection. When instructing the patient about this drug, the nurse should caution about the possibility of which adverse reaction?
   1. Flatus and intestinal bloating
   2. Halitosis
   3. Unpleasant metallic taste
   4. Alopecia
4. The patient is diagnosed with toxoplasmosis and will be treated with pyrimethamine (Daraprim). Because of significant adverse effects, what teaching should the nurse give this patient?
   1. Increase intake of fiber-rich foods to prevent constipation.
   2. Report unusual bruising, fatigue, sores that do not heal, or low-grade fever.
   3. Increase fluid intake to 3 L per day.
   4. Schedule eye examinations every 6 months for 2 years after taking this drug.
5. A 6-year-old boy is diagnosed with an *Enterobius vermicularis* (pinworm) infection and has been prescribed mebendazole (Vermox). What appropriate instructions should the nurse give the boy's caregiver?
   1. The drug will be continued for 2 weeks and then a stool sample will be retested.
   2. Because the infection is not easily transmitted, it is not necessary to test or treat family members.
   3. Eliminate all citrus and dairy products while this medication is taken.
   4. Wash all bedding and undergarments thoroughly after the medication is given.
6. A nurse is monitoring a patient receiving metronidazole (Flagyl) for potential adverse effects. Which symptom, if present, would cause the nurse to discontinue the medication and notify the prescriber?
   1. Ataxia and confusion
   2. Nausea and diarrhea
   3. Anorexia and thirst
   4. Weight gain and irritability

Patient "Richard Palmer"

Chapter 54
Pharmacotherapy of Non-HIV Viral Infections

Chapter Outline

- Characteristics of Viruses
- Pharmacotherapy of Non-HIV Viral Infections
- Drugs for Herpesviruses
  Antivirals for Herpesviruses
  PROTOTYPE *Acyclovir (Zovirax), p. 980*
- Drugs for Influenza Viruses
  Antivirals for Influenza Viruses
  Neuraminidase Inhibitors
  PROTOTYPE *Amantadine (Symmetrel), p. 984*
- Drugs for Hepatitis Viruses
  Antivirals for Hepatitis
  PROTOTYPE *Tenofovir (Vemlidy, Viread), p. 989*
  Interferons

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the major structural components of viruses.
2. Identify viral infections that benefit from pharmacotherapy.
3. Explain the five principal stages in the pathogenesis of a viral infection.
4. Explain general principles related to the pharmacotherapy of viral infections.
5. Describe the nurse's role in the pharmacologic management of patients receiving medications for herpesviruses, influenza viruses, and hepatitis viruses.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy for viral infections.

Key Terms

capsid, 976

hepatitis, 985
influenza, 982
intracellular parasites, 976
neuraminidase, 983
provirus, 978
virion, 976
viruses, 976

Viruses are tiny infectious agents capable of causing disease in humans and other organisms. Because they possess only a few simple molecules, viruses use host enzymes and cellular mechanisms to replicate. Although the number of antiviral drugs has increased dramatically in recent years due to research into acquired immunodeficiency syndrome (AIDS), antiviral drugs remain the least effective of all the anti-infective classes. This chapter examines the pharmacotherapy of non-HIV viral infections, including herpesviruses, influenza viruses, and hepatitis viruses. Drugs for human immunodeficiency virus (HIV) infection are presented in Chapter 55.

Characteristics of Viruses

54.1 Viruses are infectious agents with simple structures.

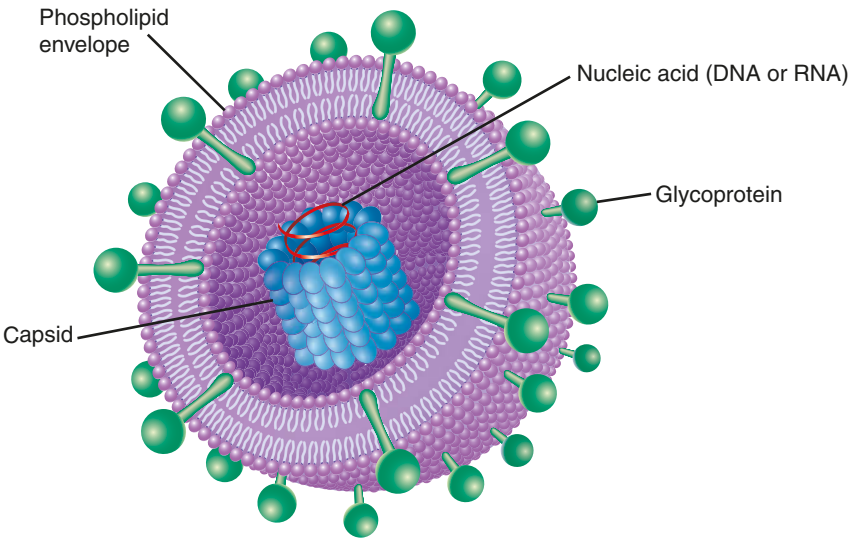
Viruses are nonliving agents that do not contain any of the cellular organelles necessary for self-survival that are present in living organisms. Viruses infect bacteria, plants, and animals by entering a host cell and then using the enzymes inside that cell to replicate. Thus, viruses are **intracellular parasites**: They must be inside a host cell to cause infection. A mature infective virus particle is called a **virion**. Figure 54.1 shows the basic structure of a virus.

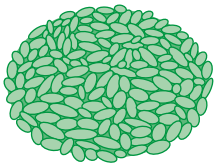
The structure of viruses is quite primitive, compared to even the simplest bacterial cell. The virus is surrounded by a protein coat or **capsid**, which helps to protect it from the surrounding environment. The structural proteins or glycoproteins that comprise the capsid are arranged in distinct, repeating subunits. These proteins help the virus attach to the cell membrane of its host.

All viruses contain genes, which carry the genetic information needed for viral replication, either in the form of ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). Most possess only a few dozen genes.

Some viruses have an envelope surrounding the capsid and genetic material. The viral envelope consists of phospholipids, glycoprotein, and protein "spikes." The phospholipids actually are derived from the host cell membrane as the virus buds off the host cell. The protein spikes are entirely viral in nature. Recognized as foreign by the host's immune system, viral proteins trigger body defenses that attempt to remove the invader.

Although the host cell supplies most of the metabolic machinery needed by the virus, virions contain a few enzymes that serve key roles in the infection process. These enzymes are virus specific and assist the pathogen in entering the host cell, duplicating its genetic material, inserting its genes into the host's chromosome, or assembling newly formed virions. These unique viral enzymes serve as important targets for antiviral drug action.





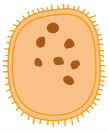


Figure 54.1 General structure of a virus.

54.2 The replication cycle of a virus occurs in five stages.

Despite their simple structures viruses are diverse, each having a distinct spectrum of infection. Although some viruses are lethal, others can coexist with their host and produce no detectable symptoms. Only a handful of viruses cause significant disease in humans. Selected human pathogenic viruses are listed in Table 54.1. Not all viral infections warrant pharmacotherapy. Viruses that may be treated with antiviral medications include herpes simplex, cytomegalovirus, Epstein-Barr, varicella zoster, respiratory syncytial virus, and hepatitis.

Despite their diversity, certain stages are common to most viral infections, as

Table 54.1 Selected Human Viral Diseases

	Virus	Description
DNA viruses	Adenoviruses 	More than 40 species that primarily infect the human upper respiratory tract but can also cause conjunctivitis, gastrointestinal (GI) infections, hemorrhagic cystitis, and serious infections in neonates
	Hepadnaviruses 	Family of viruses that causes hepatitis B by invading hepatocytes; primarily transmitted by injection of infected blood or by use of contaminated needles
	Herpesviruses 	Family of viruses that causes cold sores, genital herpes, infectious mononucleosis, chickenpox, and shingles
	Papovaviruses 	Family of viruses that can cause tumors or warts
	Poxvirus 	Responsible for smallpox, monkeypox, and molluscum contagiosum (a sexually transmitted infection)
RNA viruses	Arenaviruses 	Family of 15 viruses, one of which causes Lassa fever, a severe form of epidemic hemorrhagic fever that is highly fatal
	Coronaviruses 	Family of viruses, some of which cause upper respiratory tract infections with symptoms similar to the common cold
	Myxoviruses and paramyxoviruses 	Family of viruses that includes the influenza virus, respiratory syncytial virus, measles virus, and mumps virus
	Orthomyxoviruses 	Responsible for human influenza and avian (bird) flu
	Picornaviruses 	Large family of viruses that can cause hepatitis A, polio, common cold, meningitis, and myocarditis
	Reoviruses 	Large family of viruses that can cause upper respiratory symptoms and gastroenteritis in infants
	Retroviruses 	Virus family that includes HIV, the virus responsible for AIDS

shown in Figure 54.2. The first stage is attachment of the virus to its host cell. In this stage, the proteins on the surface of the virion fuse with protein receptors on the host cell. This attachment is very specific; the "attachment receptor" may be found only in a single species of plant, bacteria, or animal, or even on a single type of cell within an organism. This specificity is why most viruses infect only one species, although a few viruses can mutate and cross species, as is likely the case for HIV.

The second stage of viral infection is penetration of the viral genes and enzymes into the host cell. For some viruses, the entire virion enters the cell, whereas others simply "inject" their genes and enzymes into the host cell.

The third stage is synthesis of viral nucleic acid and proteins by the host cell. Immediately after penetration, a few viral proteins are constructed, which assist in duplication of the viral DNA or RNA. Following duplication of the viral genetic material, two possible events may occur. The virus may immediately begin replicating itself by making viral capsid proteins and viral enzymes and then assembling more virions. In some cases, however, the viral DNA enters the nucleus of the host cell, where it inserts into the chromosome

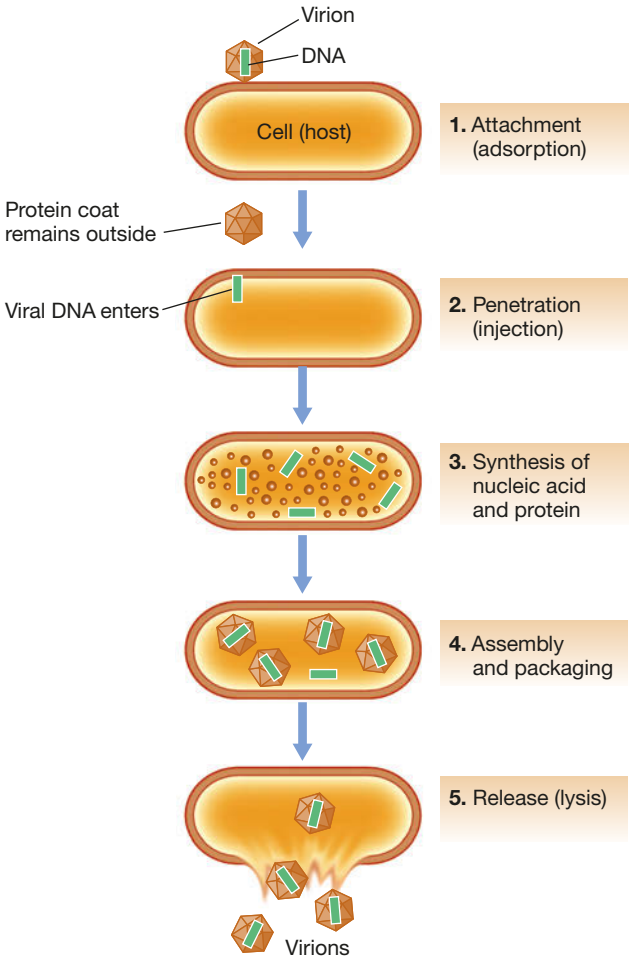

Figure 54.2 The five stages of viral infection.

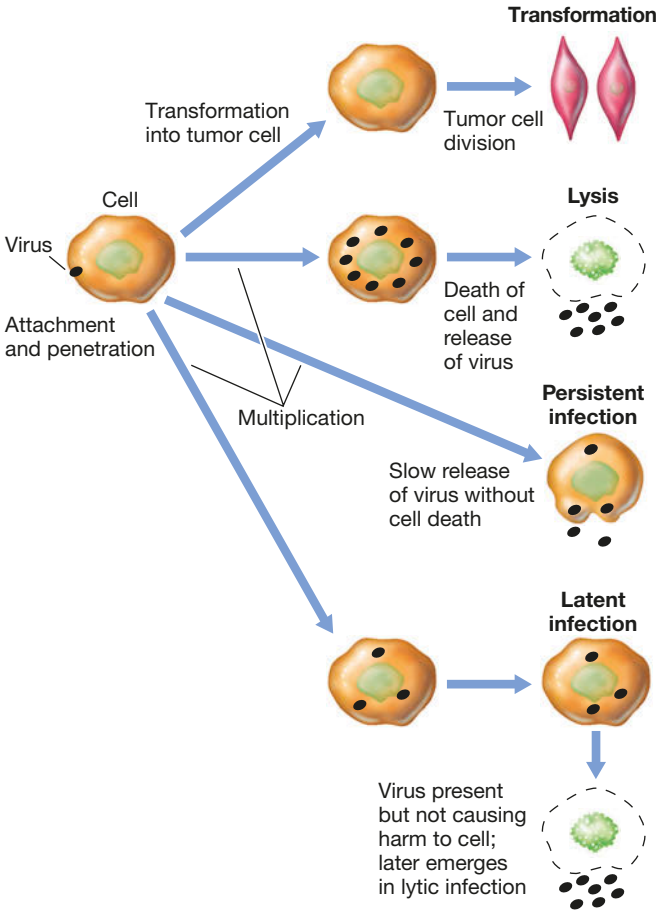

Figure 54.3 Effects of viruses on their host cells.
From *Brock Biology of Microorganisms* (11th ed.), by M. Madigan and J. Martinko, 2006. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, NJ.

and remains for a period of time ranging from weeks to years before it proceeds to the replication stage. Once the viral DNA integrates into the host chromosome, it is called a **provirus**.

Assembly is the fourth stage of viral infection. All the viral components, structural proteins, enzymes, and nucleic acids are packaged and made ready for leaving the cell.

The final stage is the release of virions from the host cell. The number of virions may be so large that the cell bursts, releasing all the infectious particles at one time, killing the cell. In other cases, the virions bud off the host's plasma membrane in a slower, continuous process that does not result in death of the host cell.

Pharmacotherapy of Non-HIV Viral Infections

54.3 Antiviral drugs target a specific viral structure or stage of its replication cycle.

Viruses can produce significant effects on their host cells, as illustrated in Figure 54.3. Some viral infections, such as the common cold, cause acute symptoms but they are self-limiting. While symptoms may be annoying, they resolve in 7 to 10 days and the virus causes no permanent effects if the patient is otherwise healthy. For these viral infections, medication is not warranted due to the expense and the possibility of producing adverse drug effects.

Some viral infections are not self-limiting, and drug therapy can be used to prevent the infection or alleviate symptoms. For example, HIV is uniformly fatal if left untreated. Certain hepatitis viruses can result in permanent liver damage and increase a patient's risk of hepatocellular carcinoma. Although not life threatening in most patients, herpesviruses can cause significant pain and, in the case of ocular herpes, permanent disability. Some viruses may even transform normal cells into tumor cells.

Antiviral therapy is targeted to a specific structure of the virus or an aspect of its replication cycle. For example, antiviral drugs are available that inhibit specific viral enzymes or change the shape of proteins that can prevent attachment to the host cell.

Another approach to treating viral infections is to boost the immune system's response to viral antigens.

CONNECTIONS: Patient Safety

Adverse Reaction to Vaccination

A 62-year-old woman receives a shingles vaccine (Zostavax). Two weeks later, a severe blistering rash develops along the patient's anterior chest wall. The patient also reports having a headache and flulike symptoms, but no fever. On examination, the lesions are confirmed to be herpes zoster and drug therapy with acyclovir (Zovirax) is initiated.

What is a potential cause for the occurrence of herpes zoster after receiving the shingles vaccine? What could the healthcare provider have done differently to prevent such an occurrence?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Prevention of some viral infections can be accomplished through vaccines, which prepare body defenses in advance of the infection (see Chapter 43). Treatment of acute disease may utilize immunomodulators such as interferons (IFNs) that enhance aspects of the immune response. These are of particular value in treating hepatitis (see Section 54.6).

Antiviral pharmacotherapy can be extremely challenging due to the rapid mutation rates of viruses, which can quickly render medications ineffective. Also complicating therapy is the intracellular nature of the virus, which makes it difficult for drugs to find their targets without giving excessively high doses that injure normal cells. Antiviral drugs have narrow spectrums of activity, usually limited to one specific virus. For most of the viral pathogens, pharmacologic cures are not possible; thus, antivirals remain the least effective of all the anti-infective classes.

Drugs for Herpesviruses

54.4 Pharmacotherapy can lessen the severity of acute herpes simplex infections and prolong latency.

Herpes simplex viruses (HSVs) are a family of DNA viruses that cause blister-like lesions on the skin, genitals, and mucous membranes. Herpesviruses are usually acquired through direct physical contact with an infected individual, but they can also be transmitted from infected mothers to their newborns, sometimes resulting in severe central nervous system (CNS) disease. Neonatal herpes infection is estimated to have a mortality rate of 50%. The herpesvirus family includes the following:

- **HSV type 1 (HSV-1).** Primarily infections of the eye, and mouth and lip "cold sores," although it may also cause genital infections
- **HSV type 2 (HSV-2).** Primarily genital infections
- **Cytomegalovirus (CMV).** Affects multiple body systems in immunosuppressed patients
- **Varicella-zoster virus (VZV).** Shingles (zoster) and chickenpox (varicella)
- **Epstein-Barr virus (EBV).** Infectious mononucleosis and a form of cancer known as Burkitt's lymphoma
- **Herpesvirus type 6.** Roseola in children and hepatitis or encephalitis in immunosuppressed patients.

Humans are believed to be the only reservoir for HSV. Following its initial entrance into the human host, HSV may remain in a latent, asymptomatic, nonreplicating state in sensory or autonomic nerve root ganglia for many years. Infection is lifelong. Immunosuppression, physical challenge, or emotional stress can promote active replication of the virus and the reappearance of the characteristic lesions. Complications include secondary infections of nongenital tissues.

The pharmacologic goals for the management of herpes infections are twofold: to relieve acute symptoms and to prevent recurrences. Note that the antiviral drugs used to treat herpesvirus do not cure the patient; the virus remains inside infected neurons for the remainder of the patient's life.

Treatment of acute herpesvirus infection: Pharmacotherapy of initial acute HSV-1 and HSV-2 infections includes 7 to 10 days of oral antiviral therapy. Commonly prescribed antivirals for HSV and VZV include acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex). Topical forms of several antivirals are available for local application to herpes lesions, though they are not as effective as the oral medications. In immunocompromised patients, intravenous (IV) medications may be indicated; however, these drugs have a higher risk of serious adverse effects. Antiviral drugs for HSV infections are listed in Table 54.2.

PharmFACT

In the United States about one out of six people ages 14 to 49 are infected with genital herpes. This rate has remained stable during the past decade (Centers for Disease Control and Prevention [CDC], 2017a).

Because of the severity of neonatal herpes infections, pregnant women with the infection are sometimes treated with antivirals. The most extensive clinical experience during pregnancy has been with acyclovir, which has not been associated with teratogenic effects. The safety and effectiveness of these drugs during pregnancy, however, have not been clearly established. The greatest risk for transmission of HSV occurs when the mother acquires the infection late in the pregnancy.

Herpes of the eye is the most common infectious cause of corneal blindness in the United States. Ocular herpes causes a painful, inflamed lesion on the eyelid or surface of the eye. Prompt treatment with antiviral drugs can stop the

Table 54.2 Drugs for Herpesvirus Infections

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Systemic Drugs		
acyclovir (Zovirax)	Initial episode: PO: 200 mg q4h while awake for 10 days or 400 tid for 5–10 days Mild HSV labialis (cold sore or fever blister), or mild genital or perirectal HSV: PO: 400 tid for 7 days Severe genital or perirectal HSV: IV: 5–10 mg/kg q8h for 7–14 days	*Nausea, vomiting, diarrhea, headache, pain, inflammation at injection sites (parenteral drugs)* Thrombocytopenic purpura or hemolytic uremic syndrome, nephrotoxicity, seizures (foscarnet), electrolyte imbalances (foscarnet), hematologic toxicity or bone marrow suppression (ganciclovir, valganciclovir), neutropenia (cidofovir)
cidofovir (Vistide)	IV: 5 mg/kg once weekly for 2 wk	
famciclovir (Famvir)	PO: 500 mg tid for 7 days (max: 1500 mg/day)	
foscarnet (Foscavir)	IV: 40–60 mg/kg infused over 1–2 h tid (max: 180 mg/kg/day)	
ganciclovir (Cytovene, Zirgan)	IV: 5 mg/kg infused over 1 h bid (max: 6 mg/kg/dose) PO: 1000 mg tid with food (max: 3000 mg/day) Topical (Zirgan): 1 drop in the affected eye 3–5 times/day	
valacyclovir (Valtrex)	PO: 1 g tid (max: 3 g/day)	
valganciclovir (Valcyte)	PO: 900 mg once daily (max: 900 mg/day; 1800 mg/day during CMV retinitis induction therapy)	
Topical Drugs		
docosanol (Abreva)	Topical: 10% cream applied to cold sore up to 5 times/day for 10 days	*Burning, irritation, or stinging at site of application, headache* Photophobia, keratopathy, edema of eyelids (ocular drugs)
penciclovir (Denavir)	Topical: Apply q2h while awake for 4 days	
trifluridine (Viroptic)	Topical: 1 drop in each eye q2h during waking hours (max: 9 drops/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

herpesvirus from multiplying and destroying epithelial cells. Like genital herpes, once patients acquire ocular herpes they often experience recurrences, which may occur years after the initial symptoms. Use of the antiglaucoma medication latanoprost (Xalatan) (see Chapter 74) has been associated with reactivation of latent ocular HSV.

Pharmacotherapy of ocular herpes is through the local application of drops or ointment. The goal of therapy is to prevent permanent visual disability by limiting corneal involvement of the infection. Trifluridine (Viroptic) and ganciclovir (Zirgan) are available in ophthalmic formulations. Oral acyclovir is used in situations where topical drops or ointments are contraindicated. Uncomplicated ocular herpes resolves after 1 to 2 weeks of pharmacotherapy.

Prophylaxis of herpesvirus infection: Due to the expense and potential adverse effects, antiviral drugs are not routinely prescribed for prophylaxis. However, patients who experience particularly severe or frequent recurrences (more than six episodes per year) may receive low doses of prophylactic antivirals. Suppressive therapy may also benefit immunocompromised patients, such as those undergoing antineoplastic therapy or those with AIDS.

CONNECTION Checkpoint 54.1

From what you learned in Chapter 3 about the pharmacokinetics of topical drugs, why are topical medications not as effective as oral drugs in the case of herpes infections? *Answers to Connection Checkpoint questions are available on the faculty resources website. Please consult with your instructor.*

PROTOTYPE DRUG Acyclovir (Zovirax)

Classification **Therapeutic:** Antiviral for herpesviruses
Pharmacologic: Nucleoside (deoxyguanosine) analog

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1982 as one of the first antiviral medications, the activity of acyclovir is limited to the herpesviruses, for which it is a preferred drug. It is most effective against HSV-1 and HSV-2 and effective only at high doses against CMV and VZV. Acyclovir has no activity against HIV. Resistance has developed to the drug, particularly in patients with HIV-AIDS.

Acyclovir decreases the duration and severity of acute herpes symptoms. When given for prophylaxis, it decreases the frequency of herpes recurrences, but it does not cure the patient. It is available in topical form for placing directly on active lesions, in oral (PO) form for prophylaxis, and in an IV form for severe conditions such as herpes simplex encephalitis. Because of its 2.5- to 5-hour half-life, acyclovir is sometimes administered PO up to 5 times a day. PO formulations include capsule, tablet, and oral suspension. A 5% ointment is available for application to cold sores.

Mechanism of Action: Acyclovir is a nucleoside analog that inhibits viral replication by affecting two viral enzymes. First, it enters the host cell where it is activated by a viral enzyme known as thymidine kinase. The activated drug molecule resembles dGTP, one of the building blocks for DNA. As the virus begins to construct its DNA,

it uses acyclovir, rather than dGTP. Once the acyclovir is inserted into the growing DNA chain, viral DNA synthesis is terminated, thus stopping the replication cycle of the virus. Simply stated, acyclovir acts by preventing viral DNA synthesis.

Pharmacokinetics:

Route(s)	PO, IV, topical
Absorption	15–30% is absorbed PO, minimal topical absorption
Distribution	Widely distributed, including the cerebrospinal fluid (CSF); crosses the placenta; secreted in breast milk; 9–33% bound to plasma protein
Primary metabolism	Not metabolized
Primary excretion	Renal excretion, unchanged
Onset of action	Peak effect: 1.5–2 h
Duration of action	4–8 h

Adverse Effects: Acyclovir has few adverse effects when it is administered topically or PO. Nausea, vomiting, anorexia, and elevated hepatic enzymes have been reported. Minor skin irritation, rash, and localized pruritus may occur with the dermatologic formulations.

When given by the IV route, acyclovir is associated with nephrotoxicity, and frequent laboratory tests should be performed to monitor renal function. Ensuring that the infusion is administered slowly and that the patient is properly hydrated can lessen the potential for IV toxicity. Neurotoxicity has also been reported at high doses when acyclovir is given IV, including dizziness, confusion, delirium, and coma.

Contraindications/Precautions: Acyclovir should be used with caution in patients with chronic kidney disease (CKD) because the antiviral is excreted entirely by the kidneys. Doses should be lowered in these patients and proper hydration should be implemented to prevent crystalluria.

Drug Interactions: Acyclovir interacts with only a few drugs. Probenecid decreases acyclovir elimination and can lead to toxic levels of the antiviral. Zidovudine may increase drowsiness and lethargy. Systemic acyclovir may result in additive nephrotoxicity if used with other drugs affecting renal function such as aminoglycosides. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Overdose may result in coma, seizures, and renal failure. No specific therapy is available; hemodialysis may be initiated.

Nursing Responsibilities: Key nursing implications for patients receiving acyclovir are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antivirals for Non-HIV Viral Infections.

Drugs Similar to Acyclovir (Zovirax)

Other antivirals effective for treating herpesvirus infections include cidofovir, docosanol, famciclovir, foscarnet, ganciclovir, penciclovir, trifluridine, valacyclovir, and valganciclovir.

Cidofovir (Vistide): Once activated, cidofovir resembles a natural nucleoside (dCTP) and is incorporated into the viral DNA chain, causing premature termination. Approved in 1996, its use is restricted to the prevention or treatment of CMV retinitis in patients with AIDS, although it has been used off-label to treat HSV, Epstein-Barr, and other viruses. Cidofovir is available only by the IV route. It has an extended intracellular half-life that permits once-weekly dosing, versus foscarnet or ganciclovir, which must be infused daily. Common adverse effects include rash, headache, alopecia, chills, anorexia, and anemia. Cidofovir carries a black box warning that the primary dose-limiting adverse effect is nephrotoxicity. This occurs in a large percentage of patients receiving the drug. Other drugs that cause nephrotoxicity should be avoided during therapy and serum creatinine and urine protein should be monitored within 48 hours of each dose. The black box warning also states that the patient should be monitored for neutropenia during therapy. This is a pregnancy category C drug.

Docosanol (Abreva): Approved in 2000, docosanol is one of the few nonprescription drugs for cold sores and fever blisters. Available as a 10% cream, the drug shortens the healing time and duration of symptoms of the lesions. It acts by blocking the fusion of HSV with its target cells, which is a very different mechanism than other drugs in this class. Docosanol is not absorbed from the skin; thus, no significant systemic adverse effects occur. This is a pregnancy category C drug.

Famciclovir (Famvir): Famciclovir is a nucleoside analog that inhibits viral DNA synthesis in a manner similar to acyclovir, although it has a longer half-life that permits less frequent dosing. Approved in 1994, it is a prodrug, being activated to penciclovir after gastrointestinal (GI) absorption. When used PO for treating acute genital herpes, it reduces the severity of symptoms and shortens the healing time of the lesions. It is also used for prophylaxis of genital herpes and for treatment of acute herpes zoster (shingles). In herpes zoster management, famciclovir shortens healing time from 7 to 5 days and reduces pain. It is well tolerated, with headache, nausea, vomiting, and diarrhea being the most common adverse effects. This is a pregnancy category B drug.

Foscarnet (Foscavir): Approved in 1991, foscarnet is an IV medication that is effective against CMV and herpesviruses. It is indicated for CMV retinitis, acyclovir-resistant infections, and HSV infections in patients with AIDS. Off-label uses include nonocular CMV infections and VZV infections in patients with AIDS. Foscarnet is an expensive drug that exhibits greater toxicity than ganciclovir. Foscarnet has a short half-life that requires daily infusions throughout the therapy period. Headache, nausea, vomiting, and diarrhea are common during therapy. Foscarnet carries a black box warning that nephrotoxicity is a dose-limiting adverse effect that occurs in about 30% of the patients receiving the drug. Serum creatinine must be monitored carefully during therapy. Foscarnet is highly ionized in body fluids and may interfere with mineral and electrolyte metabolism, including serum calcium, phosphate, potassium, and magnesium levels. Electrolyte abnormalities with foscarnet use have been associated with seizures and cardiac abnormalities; thus, regular monitoring of serum electrolytes is essential. This is a pregnancy category C drug.

Ganciclovir (Cytovene, Zirgan): Approved in 1989, ganciclovir is structurally similar to acyclovir and has the same mechanism of action. It is indicated for acute treatment of CMV retinitis and for prophylaxis of CMV infection in immunosuppressed patients. Initial therapy is conducted by IV infusion. Thereafter the patient is switched to PO doses for continued therapy. Ganciclovir has a short half-life and must be administered daily by slow IV infusion during the treatment period. An intraocular implant containing ganciclovir (Vitrasert) is available that releases the drug slowly over 5 to 8 months. Diarrhea, nausea, vomiting, anorexia, abnormal dreams, anxiety, and confusion are frequent adverse effects. A black box warning for ganciclovir states that the principal dose-limiting adverse effect is bone marrow suppression, which can manifest as anemia, neutropenia, thrombocytopenia, or pancytopenia. Complete blood counts (CBCs) and platelet counts must be carefully monitored to assess for leukopenia and thrombocytopenia, because these adverse effects occur in up to 40% of patients taking ganciclovir. Ganciclovir is a known teratogen in laboratory animals. Women of childbearing potential should use effective contraception during treatment. Similarly, men should use barrier contraception for at least 90 days following treatment with ganciclovir. This is a pregnancy category C drug.

Penciclovir (Denavir): Approved in 1996, penciclovir is the active metabolite of famciclovir and acts by the same mechanism. Unlike famciclovir, which is taken PO, penciclovir is available by prescription only as a 1% cream to apply to recurrent cold sores on the lips or face. It should not be applied to lesions on mucous membranes of the nose or mouth. Penciclovir is not absorbed from the skin; thus, no systemic adverse effects occur. To be effective, it should be applied to lesions every 2 hours while awake. This is a pregnancy category B drug.

Trifluridine (Viroptic): Approved in 1980, trifluridine is a 1% ophthalmic solution indicated for primary keratoconjunctivitis and recurrent epithelial keratitis due to HSV types 1 and 2. The drug has no systemic adverse effects and causes only minor eye irritation. This is a pregnancy category C drug.

Valacyclovir (Valtrex): Approved in 1995, valacyclovir is a prodrug that is rapidly transformed into acyclovir after oral absorption. It offers the advantage of greater absorption and higher plasma levels than acyclovir. It has the same mechanism of action, indications, and adverse effects as acyclovir. It was originally approved to treat herpes zoster (shingles), but its indications have since been expanded to include initial and recurrent episodes and prophylaxis of herpes genitalis and herpes labialis. This is a pregnancy category B drug.

Valganciclovir (Valcyte): Approved in 2001, valganciclovir is a prodrug that is rapidly converted to ganciclovir after absorption. Given PO, it has the same mechanism of action, indications (CMV), and adverse effects as ganciclovir. Patients must be monitored carefully for neutropenia and anemia during therapy. Patients may exhibit cross resistance between the two drugs. The black box warnings given for ganciclovir also apply for valganciclovir. This is a pregnancy category C drug.

Drugs for Influenza Viruses

54.5 Pharmacotherapy of influenza viruses includes drugs to prevent infection as well as drugs to treat active infections.

Influenza, or flu, is a viral infection characterized by acute symptoms that include sore throat, sneezing, coughing, fever, and chills. The infectious virions are easily transmitted via airborne droplets or by hand-to-hand contact. In immunosuppressed patients, an influenza infection may be fatal, and flu outbreaks in long-term care facilities can be devastating. In 1919, a worldwide outbreak of influenza killed approximately 20 million people.

Influenza viruses are designated with the letters A, B, or C. Type A is the most common, causes the most severe symptoms, and has been responsible for serious pandemics throughout history. Due to its rapid mutation rate, there are multiple subtypes of influenza A, and each "flu season" is usually caused by a new subtype. Influenza B is much less common, produces milder symptoms, and has no major subtypes. Type C is even less common and produces symptoms similar to those of the common cold. The influenza viruses should not be confused with *Haemophilus influenzae*, a bacterium that causes respiratory symptoms.

PharmFACT

In 2015 in the United States, more than 57,000 people died from pneumonia resulting from influenza infection. Over 80% of the deaths occurred in people ages 65 and older. This is the eighth leading cause of death in the United States (CDC, 2016b).

The influenza viruses contain single-stranded RNA genetic material and have an envelope that contains two types of protein spikes important for pharmacotherapy. One spike contains **hemagglutinin**, an enzyme that facilitates the attachment of the virus to host cells. The other protein spike is composed of an enzyme called **neuraminidase**, which assists the virus in exiting the host cell. Continual mutations to the chemical structures of these spikes create new influenza strains that are able to evade the immune system. New strains are named by the hemagglutinin (H) and neuraminidase (N) proteins. For example, the Spanish flu subtype is H1N1, whereas the avian (bird) flu subtype is H5N1. Attempts to develop vaccines for influenza strains have been challenging because of these many variants.

The best approach to influenza infection is prevention through annual vaccination. Both inactivated (killed) and live (attenuated) influenza vaccines are available. The CDC recommends that all individuals ages 6 and older who are not otherwise contraindicated receive routine annual flu vaccination (Grohskopf et al., 2016). Those who benefit the most from vaccinations include those age 50 or older, residents of long-term care facilities, those with chronic diseases, and women who will be pregnant during the peak flu season. Patients with HIV-AIDS are at increased risk of influenza complications and should be immunized using the inactivated vaccine. Influenza vaccination is also recommended for healthcare workers who deliver direct care to patients at high risk for acquiring influenza, including patients with HIV infection. Adequate immunity is achieved about 2 weeks after vaccination and lasts for several months up to a year.

CONNECTION Checkpoint 54.2

From what you learned in Chapter 43, explain the difference between a live and an attenuated vaccine. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Only a few antiviral drugs are available to treat influenza. Although these antiviral medications may be useful in preventing influenza or decreasing the severity of influenza symptoms, they should not be considered substitutes for vaccination. The drug amantadine (Symmetrel) has been available to prevent and treat influenza A since 1966. Due to a high level of viral resistance to amantadine and rimantadine, the CDC (2017b) no longer recommends that they be used for prophylaxis or treatment of influenza type A. Because of their expense and the possibility of adverse effects, these drugs are prescribed only for patients who are at risk for the severe complications of influenza. Antivirals for influenza are listed in Table 54.3.

The neuraminidase inhibitors are used to treat active influenza infections. Neuraminidase is a viral enzyme that allows newly formed, mature virions to bud from infected cells and disperse throughout the respiratory system. Neuraminidase also promotes the penetration of the virus into respiratory epithelial cells and prevents viral inactivation by respiratory mucus. When viral neuraminidase is inhibited, the virions will cling to the surface of the host cell and be noninfectious.

Given within 48 hours of the onset of symptoms, the neuraminidase inhibitors, oseltamivir (Tamiflu), peramivir (Rapivab), and zanamivir (Relenza), will shorten the normal 7-day duration of influenza symptoms to 5 days.

Table 54.3 Drugs for Influenza Infections

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Influenza Prophylaxis		
amantadine (Symmetrel)	PO: 100 mg q12h continued for at least 10 days after exposure or 2–4 wk after vaccination (max: 400 mg/day)	*Nausea, dizziness, nervousness, difficulty concentrating, insomnia*
rimantadine (Flumadine)	PO: 100 mg bid (max: 200 mg/day)	Leukopenia, hallucinations, orthostatic hypotension, urinary retention, seizures
Influenza Treatment: Neuraminidase Inhibitors		
oseltamivir (Tamiflu)	Treatment: PO: 75 mg q12h for 5 days (must be started within 48 h of symptoms for documented efficacy) Prophylaxis: PO: 75 mg once daily for at least 7 days following close contact, or up to 6 wk during a community outbreak	*Nausea, vomiting, diarrhea, dizziness* Bronchitis, bronchospasm, serious skin hypersensitivity reactions, neuropsychiatric events and abnormal behavior (peramivir), Stevens–Johnson syndrome (peramivir)
peramivir (Rapivab)	Treatment: IV 600 mg once	
zanamivir (Relenza)	Treatment: Two 5-mg inhalations bid for 5 days (must be administered within 2 days of symptom onset) Prophylaxis: One 5-mg inhalation q24h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Oseltamivir is given PO, peramivir is by IV infusion, and zanamivir is inhaled. Oseltamivir is the only antiviral approved to treat both A and B influenza viruses in patients 12 months of age or older. Cross resistance has been reported between the three drugs in this class. Because these drugs are expensive and produce only modest results, prevention through vaccination remains the best alternative.

It is important to remember that these antivirals are not effective against the common cold virus. About 200 different viruses, including rhinoviruses, cause symptoms characteristic of the common cold. Despite considerable attempts to develop a vaccine to prevent this annoying infection, success has not yet been achieved. Some drugs, however, may relieve symptoms of the common cold, and these were presented in Chapter 45.

PROTOTYPE DRUG Amantadine (Symmetrel)

Classification **Therapeutic:** Antiviral for influenza
Pharmacologic: Viral replication inhibitor

Therapeutic Effects and Uses: Amantadine has both therapeutic and prophylactic applications for influenza infections. When given during an active infection, amantadine significantly reduces the duration of influenza symptoms. Amantadine is sometimes used immediately following influenza vaccination to give the patient protection during the 2 weeks it takes for protective antibodies to the vaccine to develop.

Use of amantadine is occasionally prescribed for patients at high risk for influenza exposure. This includes immunocompromised patients, long-term care residents, healthcare workers, and close personal contacts of high-risk patients. Furthermore, the CDC has recommended that the distribution of the drug be further restricted due to the large number of influenza strains becoming resistant to amantadine. This drug should not be used as a substitute for influenza virus vaccination.

Quite by accident, amantadine was found to have anticholinergic effects that can benefit patients with Parkinson's disease. Although approved for this disorder, the effectiveness of amantadine in relieving symptoms of Parkinson's disease is modest and it is not a major drug for this disorder (see Chapter 21).

Mechanism of Action: The precise mechanism of action of amantadine is not known. It is thought to inhibit viral replication by preventing uncoating, although it may also affect assembly of new virions. The antiparkinsonism effects are likely due to the drug's ability to release dopamine and norepinephrine from neuronal storage sites and possibly prevent their reuptake.

Pharmacokinetics:

Route(s)	PO
Absorption	Completely absorbed
Distribution	Widely distributed, including the CSF; crosses the placenta; secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	48 h
Duration of action	Half-life: 20–50 h

Adverse Effects: Up to 33% of patients taking amantadine experience CNS effects that may include insomnia, dizziness, lightheadedness, nervousness, loss of concentration, and mental confusion. These symptoms quickly resolve when treatment is stopped. Amantadine can worsen mental problems in patients with a history of psychiatric disorders or substance abuse and cause or increase suicidal ideation. In patients with CKD, the drug can build to toxic levels, resulting in symptoms such as visual or auditory hallucinations, seizures, coma, or dysrhythmias. Dosage adjustment in these patients is necessary to avoid toxicity. Older adults exhibit a higher incidence of adverse effects and often require reduced dosages.

Contraindications/Precautions: Amantadine should be used cautiously in patients with CNS disease, suicidal ideation, or psychiatric disorders, including seizures or psychoses, because the antiviral may worsen these conditions. Because the drug is excreted almost entirely by the kidneys, patients with CKD must be monitored regularly. Although rare, amantadine has caused peripheral edema and heart failure and therefore should be used with caution in patients with preexisting cardiac disease. The drug should not be abruptly withdrawn in patients with Parkinson's disease because symptoms of parkinsonism may dramatically worsen.

Drug Interactions: Patients should avoid alcohol use while taking amantadine, because the combination can lead to increased CNS toxicity, including dizziness, confusion, and orthostatic hypotension. Anticholinergic drugs will exhibit additive effects with amantadine. Dopamine antagonists such as haloperidol will reduce the antiparkinson effects of amantadine. Coadministration with trimethoprim-sulfamethoxazole may impair renal clearance of amantadine, resulting in higher plasma concentrations of the antiviral. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose of amantadine can result in serious CNS toxicity and death. Physostigmine may be administered by the IV route to control some of the CNS symptoms, and anticonvulsants may be

necessary. Administration of acidic drugs enhances the renal excretion of the drug. Antidysrhythmics and antihypertensives may be administered to manage cardiovascular toxicity.

Nursing Responsibilities: Key nursing implications for patients receiving amantadine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antivirals for Non-HIV Viral Infections.

Drugs Similar to Amantadine (Symmetrel)

Other drugs for treating influenza include oseltamivir, peramivir, rimantadine, and zanamivir.

Oseltamivir (Tamiflu): Oseltamivir is a neuraminidase inhibitor available as a PO suspension or capsule that is indicated for the treatment of influenza A or B in patients over 12 months of age. It is also approved for influenza chemoprophylaxis in patients age 12 months or older. Approved in 1999, the drug must be started within 48 hours of the onset of flu symptoms to be effective. Symptoms in patients infected with influenza resolve 1.3 days (30%) faster if oseltamivir is administered. The drug is well tolerated, with nausea, vomiting, and diarrhea being the most common adverse effects. Oseltamivir should not be administered until 2 weeks after administration of the live attenuated influenza vaccine. This drug is pregnancy category C.

Peramivir (Rapivab): Approved in 2014, peramivir is a neuraminidase inhibitor given by a single IV infusion for the treatment of influenza in patients ages 18 and older. Like other drugs in this class, peramivir must be administered within 48 hours of the onset of flu symptoms to be effective. Although the most common side effect is diarrhea, some patients have experienced neuropsychiatric events such as hallucinations, delirium, and abnormal behavior. This drug is pregnancy category C.

Rimantadine (Flumadine): Approved in 1993, rimantadine is chemically similar to amantadine and acts by a similar mechanism. It is approved for the treatment of influenza A infections in adults and for prophylaxis in children. Formulations include tablets as well as syrup for pediatric use. Like amantadine, it is not effective against influenza B. Rimantadine is less toxic than amantadine, with GI complaints such as nausea, vomiting, and abdominal pain being most commonly reported. Older adults experience more adverse effects to rimantadine; thus, doses in this population should be reduced. Like amantadine, the CDC has recommended that prophylactic use of rimantadine be restricted due to the appearance of resistant viral strains. This drug is pregnancy category C.

Zanamivir (Relenza): Zanamivir is a neuraminidase inhibitor available as an inhaled, powdered formulation. It was initially approved in 1999 for the treatment of active influenza infections in patients age 7 or older and subsequently approved for influenza prophylaxis. Like oseltamivir, the drug must be started within 48 hours of the onset of flu symptoms to be effective. Symptoms in patients infected with influenza resolve 1 to 2 days faster if zanamivir is administered. Zanamivir is well tolerated and devoid of significant adverse effects in most patients. Those with preexisting respiratory disease should use zanamivir with caution, because the drug may initiate bronchospasm in these patients and the use of a bronchodilator may be indicated. Zanamivir should not be administered until 2 weeks after administration of the live attenuated influenza vaccine. This drug is pregnancy category C.

Drugs for Hepatitis Viruses

54.6 The most effective therapies for hepatitis infections are antivirals and drugs that boost the immune system to rid the body of the virus.

Hepatitis, or inflammation of the liver, may be caused by drugs, alcohol, autoimmune disorders, metabolic diseases, or infections. Viral hepatitis is a common infection caused by a number of different viruses. Although each virus has its own unique clinical features, they all invade hepatocytes, producing the same symptoms.

Hepatitis may be acute or chronic. Symptoms of acute hepatitis include fever, chills, fatigue, anorexia, nausea, and vomiting. Chronic hepatitis may result in prolonged fatigue, jaundice, liver cirrhosis, and, ultimately, hepatic failure. Neonates and immunocompromised patients are at higher risk for developing chronic hepatitis. Some patients infected with hepatitis viruses, especially children, are asymptomatic.

The three primary types of viral hepatitis are hepatitis A (HAV), hepatitis B (HBV), and hepatitis C (HCV). These and less common types of hepatitis are summarized in Table 54.4. Drugs used to manage viral hepatitis infections are listed in Table 54.5.

Hepatitis A: Hepatitis A, an RNA virus, is spread by the oral–fecal route and causes epidemics in regions of the world having poor sanitation. Outbreaks in the United States, however, are most often sporadic events caused by contaminated food.

HAV has an incubation period of 4 weeks. During this period, and for 1 to 10 days after symptoms appear, the virus is excreted in the stool and the patient is infectious. Clinical presentation includes an abrupt onset of nausea, anorexia, fatigue, and right upper quadrant (RUQ) pain. Hyperbilirubinemia and very high transaminase values are usually observed.

HAV is the most common cause of acute hepatitis in the United States. Although approximately 20% of patients

Table 54.4 Summary of Viral Hepatitis Types

Type	Transmission	People at Risk	Prevention	Treatment
Hepatitis A	Primarily through food or water contaminated by feces from an infected individual. Rarely, it spreads through contact with infected blood	International travelers; people living in areas where hepatitis A outbreaks are common; people who live with or have sex with an infected individual; and, during outbreaks, daycare children and employees, men who have sex with men, and injection drug users	Hepatitis A vaccine; also, avoiding tap water when traveling internationally, and practicing good hygiene and sanitation	Hepatitis A usually resolves on its own over several weeks
Hepatitis B	Through contact with infected blood, through sex with an infected individual, and from mother to child during childbirth	People who have sex with an infected individual, injection drug users, children of immigrants from disease-endemic areas, infants born to infected mothers, people who live with an infected individual, healthcare workers, hemodialysis patients, people who received a transfusion of blood or blood products before July 1992 or clotting factors made before 1987, and international travelers	Hepatitis B vaccine	Chronic hepatitis B: drug treatment with alpha IFN, peginterferon (pegIFN), lamivudine, or adefovir dipivoxil Acute hepatitis B usually resolves on its own; severe cases can be treated with lamivudine
Hepatitis C	Primarily through contact with infected blood; less commonly, through sexual contact and childbirth	Injection drug users, people who have sex with an infected individual, people who have multiple sex partners, healthcare workers, infants born to infected women, hemodialysis patients, and people who received a transfusion of blood or blood products before July 1992 or clotting factors made before 1987	There is no vaccine for hepatitis C; the only way to prevent the disease is to reduce the risk of exposure to the virus. This means avoiding behaviors like sharing drug needles or sharing personal items like toothbrushes, razors, and nail clippers with an infected individual	Chronic hepatitis C: Drug treatment with pegIFN alone or combination treatment with pegIFN and the drug ribavirin Acute hepatitis C: Treatment is recommended if it does not resolve within 2–3 months
Hepatitis D	Through contact with infected blood; this disease occurs only in people who are already infected with hepatitis B	Anyone infected with hepatitis B; injection drug users who have hepatitis B have the highest risk. People who have hepatitis B are also at risk if they have sex with someone infected with hepatitis D or if they live with an infected individual. Also at risk are people who received a transfusion of blood or blood products before July 1992 or clotting factors made before 1987	Immunization against hepatitis B for those not already infected; also, avoiding exposure to infected blood, contaminated needles, and an infected individual's personal items	Chronic hepatitis D: Drug treatment with alpha IFN
Hepatitis E	Through food or water contaminated by feces from an infected individual; uncommon in the United States	International travelers, people living in areas where hepatitis E outbreaks are common, and people who live or have sex with an infected individual	There is no vaccine for hepatitis E; the only way to prevent the disease is to reduce the risk of exposure to the virus. This means avoiding tap water when traveling internationally and practicing good hygiene and sanitation	Hepatitis E usually resolves on its own over several weeks to months

require some hospitalization for symptoms related to the infection, most recover without treatment and develop lifelong immunity to HAV. Fatalities due to chronic disease are rare, with only a small number of patients developing liver failure. Thus, HAV is normally considered an acute disease, having no significant chronic form. This makes HAV very different from hepatitis B or C.

Like all forms of hepatitis, the best approach for HAV is prevention: No antiviral drugs are available to treat acute HAV infection. Practicing thorough hand hygiene after toileting is the most effective method for preventing the transmission of HAV. When visiting endemic regions, travelers should drink bottled or boiled water and not eat raw food.

HAV vaccine (Havrix, VAQTA) has been available since 1995 and consists of inactivated HAV. It is indicated for all children ages 2 to 18, travelers to countries with high endemic HAV infection rates, people with chronic liver disease, men who have sex with men, and illegal drug users. When a booster is given 6 to 12 months after the initial dose, close to 100% immunity is obtained. The length of protection has been shown to be 5 to 8 years, although it is predicted that antibody levels may provide protection for 20 years or longer. Adverse effects are mild and include pain or swelling

Table 54.5 Drugs for Viral Hepatitis

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Antivirals		
adefovir dipivoxil (Hepsera)	PO: 10 mg once daily	*Headache, nausea, dizziness, fatigue, nasal disturbances (lamivudine), phototoxicity (simeprevir)* Nephrotoxicity, lactic acidosis (adefovir, tenofovir), pancreatitis (lamivudine), hepatomegaly with steatorrhea (lamivudine, entecavir, tenofovir), cardiac arrest (ribavirin), hemolytic anemia (ribavirin), apnea (ribavirin), myopathy (telbivudine), peripheral neuropathy (telbivudine), hepatic decompensation (ombitasvir-paritaprevir-ritonavir)
daclatasvir (Daklinza)	PO: 30–60 mg once daily	
elbasvir-grazoprevir (Zepatier)	PO: 1 tablet (50 mg elbasvir and 100 mg grazoprevir) daily	
entecavir (Baraclude)	PO: 0.5 mg once daily; 1 mg once daily for patients with history of lamivudine resistance	
glecaprevir-pibrentasvir (Mavyret)	PO: 3 tablets once daily (total daily dose: glecaprevir 300 mg and pibrentasvir 120 mg)	
lamivudine (Epivir)	PO: 150 mg bid	
ombitasvir-paritaprevir-ritonavir (Technivie)	PO: 2 tablets once daily	
ribavirin (Copegus)	PO: 800–1200 mg in 2 divided doses	
simeprevir (Olysio)	PO: 150 mg once daily	
sofosbuvir (Sovaldi)	PO: 400 mg once daily	
telbivudine (Tyzeka)	PO: 600 mg/day	
tenofovir alafenamide (Vemlidy)	PO: 25 mg once daily with food	
tenofovir disoproxil (Viread)	PO: 300 mg once daily	
Interferons		
IFN alfa-2b (Intron A)	IM/subcutaneous: 2 million units/m^2 3 times/wk	*Flulike symptoms, myalgia, fatigue, headache, anorexia, diarrhea* Myelosuppression, thrombocytopenia, suicide ideation, anaphylaxis, hepatotoxicity
pegIFN alfa-2a (Pegasys)	Subcutaneous: 180 mcg once weekly for 48 wk	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

at the injection site, headache, fatigue, and anorexia. The availability of the HAV vaccine has led to a dramatic drop in the rate of this infection in the United States.

For someone who has been recently exposed to the HAV, hepatitis A immunoglobulin (HAIg), a concentrated solution of antibodies, may provide some degree of passive immunity. HAV immunoglobulin is administered as prophylaxis for people traveling to endemic areas and to close personal contacts of infected patients to prevent transmission of the virus. A single IM dose of HAIg can provide prophylaxis for about 3 months. If taken within 2 weeks of exposure to the virus, the immunoglobulins are 85% effective at preventing HAV infection. Serious adverse effects to HAV immunoglobulins are rare.

CONNECTION Checkpoint 54.3

From what you learned in Chapter 43, what is an immunoglobulin? Name some other disease or conditions treated with immunoglobulins. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hepatitis B: Hepatitis B is caused by a DNA virus. Although transmission in the United States is primarily through exposure to contaminated blood and body fluids, in endemic regions of the world the infection is widely transmitted by the perinatal route and from child to child.

The incubation period in adults is approximately 4 weeks, whereas in children the asymptomatic period may last decades. Symptoms of HBV infection are indistinguishable from those of other hepatitis viruses and include anorexia, nausea, vomiting, fatigue, and abdominal pain. The acute stage can cause severe jaundice. Treatment of acute HBV infection is symptomatic, because no specific antiviral therapy is available. Although infectious, infants are almost always asymptomatic, which is partly responsible for the spread of the virus from child to child. Ninety percent of acute HBV infections in adults resolve with complete recovery and do not progress to chronic disease. Lifelong immunity to HBV is usually acquired following resolution of the infection.

Chronic HBV infection may be asymptomatic, and it may take as long as 10 years before the chronic stage develops. HBV has a much greater incidence of chronic hepatitis and a greater mortality rate than does HAV. Although adults rarely progress from acute to chronic hepatitis, infants who acquire the infection have a 90% probability of progressing to chronic hepatitis later in life. The final stage of the infection is hepatic cirrhosis. In addition, chronic HBV infections are associated with an increased risk of hepatocellular carcinoma.

Like HAV, the best treatment for HBV infection is prevention through immunization. HBV vaccine (Engerix-B, Recombivax HB) consists of preparations of hepatitis B

Table 54.6 Individuals Who Should Be Vaccinated Against Hepatitis B

• All children, with the first dose beginning at birth
• All children younger than 19 years of age who have not been vaccinated previously
• Susceptible sex partners of individuals who are hepatitis B surface antigen (HBsAg) positive
• Sexually active individuals who are not in a long-term, mutually monogamous relationship (e.g., more than one sex partner during the previous 6 months)
• Individuals seeking evaluation or treatment for a sexually transmitted infection or HIV
• Men who have sex with men
• Injection drug users
• Susceptible household contacts of individuals who are HBsAg positive
• Healthcare and public safety personnel at risk for exposure to blood or blood-contaminated body fluids
• Individuals with end-stage renal disease, including predialysis, hemodialysis, peritoneal dialysis, and home dialysis patients
• Residents and staff of facilities for people with developmental disabilities
• Travelers to regions with intermediate or high rates of HBV infection
• Individuals with chronic liver disease
• Individuals with HIV infection
• Unvaccinated adults with diabetes mellitus ages 19 to 59
• All other individuals seeking protection from HBV infection—acknowledgment of a specific risk factor is not a requirement for vaccination

From *Hepatitis B FAQs for Health Professionals*, CDC, 2016a. Retrieved from http://www.cdc.gov/hepatitis/HBV/HBVfaq.htm

surface antigen (HBsAg), rather than inactivated virus. In recent years, the recommendations regarding populations who should receive the HBV vaccine have expanded to include many diverse groups, as listed in Table 54.6. Hepatitis B vaccine is very safe, with mild reactions such as pain at the injection site and low-grade fever being the most frequent adverse effects. Three doses of the vaccine provide up to 90% of the patients with protection against HBV following exposure to the virus. Combination vaccines that contain HBV vaccine include Comvax (hepatitis B-*Haemophilus influenzae* type b conjugate vaccine), Pediarix (hepatitis B, diphtheria, tetanus, acellular pertussis [DTaP], and inactivated poliovirus vaccine), and Twinrix (HAV and HBV vaccine).

For someone who has been recently exposed to the HBV, therapy with hepatitis B immunoglobulins (HBIg) may be initiated. Indications for HBIg therapy include probable exposure to HBV through the perinatal, sexual, or parenteral routes, or known exposure of an infant to a caregiver with HBV. To be effective, HBIg should be administered within 48 hours after parenteral exposure to HBV, within 2 weeks of sexual contact, or to newborns of HBV-positive mothers 12 hours postpartum.

Once chronic hepatitis B becomes symptomatic, pharmacotherapy is indicated with the drugs listed in Table 54.5. The two basic strategies to eliminate HBV are to stop viral replication (i.e., suppress viral load) with antivirals or to boost body defenses with immunomodulators. Three drugs have demonstrated the greatest effectiveness at reducing viral load and are thus considered first-line drugs for chronic HBV infection:

- **IFN alfa or pegIFN.** Thirty to forty percent of patients respond to 4 months of therapy. Five to ten percent of these patients relapse after completing therapy.
- **Tenofovir disoproxil (Viread).** Following 48 weeks of therapy, about 78% of patients respond to tenofovir. Long-term studies show that resistance to tenofovir is very low.
- **Entecavir (Baraclude).** About 70% of patients respond after 48 weeks of therapy. Long-term studies show that resistance to entecavir is very low.

The remaining medications for HBV infection are considered second-line drugs because they exhibit lower effectiveness, increased adverse effects, or greater resistance than the first-line drugs. The second-line medications such as lamivudine (Epivir) and adefovir dipivoxil (Hepsera) may be useful when resistance to the first-line drugs develops, or when used in combination with those drugs. Clinical guidelines for the treatment of chronic HBV infection continue to evolve as long-term research becomes available.

Because patient symptoms do not reliably indicate the extent of infection, pharmacotherapy is guided by laboratory markers. Hepatic enzymes such as serum alanine transaminase (ALT) and aspartate aminotransferase (AST) are used as indicators of liver damage. Hepatitis B DNA, HBsAg, and hepatitis B e antigen (HBeAg) confirm the presence of the virus. Pharmacotherapy is considered successful when ALT and AST return to normal values, HBV DNA disappears, and HBeAg is eliminated.

PharmFACT

The rate of new acute hepatitis B infections in the United States decreased about 63% from 2000 to 2014. The number of new cases is estimated to be about 19,000 annually (CDC, 2016c).

Hepatitis C and other hepatitis viruses: The hepatitis C, D, E, and G viruses are sometimes referred to as non A–non B viruses. Research is continuing to identify additional hepatitis viruses. Of the non A–non B viruses, hepatitis C has the greatest clinical importance.

Transmitted primarily through exposure to infected blood or body fluids, hepatitis C (HCV) is more common than HBV. About 40% to 50% of all patients with HIV infection are coinfected with HCV. Perinatal transmission rates are very low.

The incubation period for HCV is 50 days. Like other hepatitis infections, HCV symptoms include nausea, vomiting, anorexia, and jaundice. Although acute symptoms

occasionally accompany an HCV infection, the majority of patients are asymptomatic. About 70% of patients infected with HCV proceed to chronic hepatitis, and up to 30% may develop end-stage cirrhosis. HCV is the most common cause of chronic hepatitis and is the most frequent indication for liver transplants.

Unlike HAV and HBV, no vaccine is available for hepatitis C due to the very high mutation rate of the virus. In addition, postexposure prophylaxis of HCV with immunoglobulins is not recommended because its effectiveness has not been demonstrated. At least 6 different viral genotypes (and more than 50 subtypes) have been identified for HCV. HCV genotype 1 accounts for 70% of the infections in the United States. Genotyping is common for chronic HCV because it helps guide the appropriate treatment.

Current pharmacotherapy for chronic HCV infection usually includes combination therapy with two or three antiviral drugs concurrently. Combination therapy has been found to produce a more sustained viral suppression than monotherapy. For example Viekira Pak is a combination of four drugs: ombitasvir, paritaprevir, ritonavir and dasabuvir. In 2017, the FDA approved Vosevi, a fixed-dose combination tablet containing two previously approved drugs—sofosbuvir and velpatasvir—and a new drug, voxilaprevir. Also in 2017, the FDA approved Mavyret as a once-daily treatment regimen containing glecaprevir and pibrentasvir. Mavyret has the advantage of being an 8-week treatment regimen, which is shorter than other treatments requiring 12 weeks or longer.

Interferons (IFNs) are immunomodulatory proteins secreted by macrophages, B lymphocytes, and other body defense cells in response to viral infection. Actions of IFNs include suppression of cell division, inhibition of viral replication, and enhancement of macrophage and T-lymphocyte activity. Only the alpha family of IFNs is used in hepatitis therapy, and each IFN has slightly different applications and indications. Information on IFNs used for other indications may be found in Chapter 42.

PROTOTYPE DRUG Tenofovir (Vemlidy, Viread)

Classification **Therapeutic:** Antiviral
Pharmacologic: Reverse transcriptase inhibitor

Therapeutic Effects and Uses: Originally approved for the treatment of HIV in 2001, tenofovir was approved in 2008 to treat chronic HBV in adults and in children 12 years and older. Tenofovir is given PO, usually in combination with other drugs. When used to treat HIV infection, tenofovir is always combined with at least two other drugs to delay the development of HIV resistance (see Chapter 55). Tenofovir is a preferred drug for treating combined HIV-HBV infections due to its dual effectiveness.

Tenofovir is one of the most effective medications for chronic HBV infection and is considered a first-line therapy. A major advantage of tenofovir over other drugs for chronic HBV infection is that resistance is extremely low during long-term therapy.

Tenofovir is available in two formulations. Tenofovir disoproxil (Viread) was the original salt and has been proven highly effective in clinical practice. Tenofovir alafenamide (Vemlidy) is a newer formulation that has equivalent effectiveness but exhibits less kidney toxicity and fewer effects on bone mineral density. Tenofovir alafenamide is expected to replace tenofovir disoproxil in many fixed-dose combinations.

Mechanism of Action: Resembling a natural nucleoside, tenofovir inhibits viral DNA synthesis by inhibiting the reverse transcriptase enzyme.

Pharmacokinetics:

Route(s)	PO
Absorption	25% absorbed; taking the drug with high-fat meals increases absorption to 40%
Distribution	Distribution to milk and CSF is unknown; minimal protein binding
Primary metabolism	Not metabolized by hepatic CYP450 enzymes
Primary excretion	Renal
Onset of action	Unknown; peak plasma levels reached in 1 h
Duration of action	12 h

Adverse Effects: The most frequent adverse effects include abdominal pain, nausea, insomnia, pruritus, vomiting, dizziness, and pyrexia. Because the drug may cause or worsen kidney disease, renal function should be monitored prior to initiating therapy and periodically during treatment. Decreases in bone mineral density have been recorded, which may cause fractures in patients with osteoporosis. **Black Box Warning:** Tenofovir can cause a type of liver abnormality called lactic acidosis and severe hepatomegaly with steatosis. Although rare, this type of hepatotoxicity has resulted in several deaths. Also part of the warning, tenofovir may cause acute exacerbations of hepatitis B in patients who are coinfected with HBV and HIV and who discontinue this drug abruptly.

Contraindications/Precautions: There are no contraindications to the use of tenofovir. However, patients with CKD should receive a lower dose and be monitored frequently for changes in urinary laboratory values. Hepatic enzyme values should be monitored regularly during therapy. If any signs of lactic acidosis or hepatotoxicity are noted, the drug should be immediately discontinued.

Drug Interactions: Tenofovir should not be used concurrently with Atripla, Complera, Stribild, or Truvada; these are combination drugs for HIV that contain tenofovir as one of their components. **Herbal/Food:** May be taken with or without food, although food increases the rate of drug absorption.

Pregnancy: Category B.

Treatment of Overdose: There is no antidote for tenofovir overdose. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving tenofovir are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antivirals for Non-HIV Viral Infections.

Drugs Similar to Tenofovir (Vemlidy, Viread)

Other antivirals for chronic hepatitis include adefovir dipivoxil, daclatasvir, elbasvir-grazoprevir, entecavir, lamivudine, ombitasvir-paritaprevir-ritonavir, ribavirin, simeprevir, sofosbuvir, and telbivudine. Although structurally different, the IFNs are discussed with this group because they are used to treat hepatitis.

Adefovir dipivoxil (Hepsera): Approved in 2002, adefovir structurally resembles a natural nucleotide and inhibits viral DNA synthesis of HBV. It is active against several species of viruses, although it is approved only for the oral therapy of chronic HBV infection that shows evidence of active viral replication. Adefovir is an antiviral alternative for patients who have developed resistance to first-line antivirals. Other than headache and abdominal pain, the drug is well tolerated at the doses used to treat HBV. Resistance has not been a clinical problem. This drug has a black box warning that in patients with preexisting CKD, urinary laboratory values should be monitored regularly because nephrotoxicity has been reported. Severe exacerbation of hepatitis has been reported in patients who have discontinued therapy with adefovir and some other antivirals. Lactic acidosis and hepatomegaly with steatosis have resulted in several deaths in patients taking adefovir. This drug is pregnancy category C.

Daclatasvir (Daklinza): Approved in 2015, daclatasvir inhibits the viral protein NS5A, which is required for the viral replication cycle. Daclatasvir is used in combination with sofosbuvir (with or without ribavirin) for chronic HCV infection. It is given PO as a once-daily regimen for 12 weeks. The drug is well tolerated, with fatigue and headache being the most common adverse effects. It is contraindicated when the patient is receiving strong inducers of CYP3A such as carbamazepine or St. John's wort. The drug is pregnancy category X when used in combination with ribavirin.

Elbasvir-grazoprevir (Zepatier): Zepatier is a fixed-dose PO combination of elbasvir (an inhibitor of HCV protein 5A) and grazoprevir (an inhibitor of HCV protease) for the treatment of chronic HCV infection. Approved in 2016 for a 12- to 16-week course of therapy, Zepatier may be used in combination with ribavirin. The drug is well tolerated, with the most common adverse effects being fatigue, headache, and nausea. It is contraindicated in patients receiving strong inducers of CYP3A.

Entecavir (Baraclude): Entecavir was approved in 2005 for the treatment of chronic HBV that exhibits evidence of active viral replication. Indications for entecavir were expanded in 2010 to include its use as a pretreatment for chronic HBV in patients with decompensated liver disease. Like lamivudine, entecavir is a reverse transcriptase inhibitor that inhibits viral DNA synthesis. Given PO, the drug is well tolerated and the most common adverse effects include nausea, headache, fatigue, and dizziness. A major advantage of this drug is that viral resistance is very low. Because of its effectiveness and relatively high safety profile, entecavir has become a first-line drug in the pharmacotherapy of HBV infection. A black box warning indicates that fatal lactic acidosis and severe hepatomegaly with steatosis have been reported. Exacerbation of hepatitis may occur following discontinuation of therapy with antivirals. Entecavir is not recommended for patients coinfected with HIV who are not receiving pharmacotherapy for HIV. This drug is pregnancy category C.

Lamivudine (Epivir): Originally approved for HIV infection in combination with other antiviral drugs in 1995, lamivudine was later approved for chronic hepatitis B infections that have evidence of viral replication and active liver inflammation. Lamivudine is given PO, often in combination with other drugs. Compared to tenofovir, patients on lamivudine are more likely to develop resistant strains during long-term therapy. The dose recommended for treating HBV (100 mg/day) is much less than that recommended for treating HIV (300 mg/day). Its use in treating HIV is discussed in Chapter 55.

Most patients tolerate lamivudine well, with the most frequent side effects being nausea, vomiting, abdominal pain, and diarrhea. Ear, nose, and throat infections and fatigue may occur in as many as 25% of patients taking the drug. Lamivudine carries the same black box warning as tenofovir. Both can cause lactic acidosis and severe hepatomegaly with steatosis. In addition, both of these drugs cause severe exacerbations of hepatitis B in patients who are coinfected with HBV and HIV and who discontinue this drug abruptly. Hepatic enzyme values should be monitored regularly during therapy. If any signs of lactic acidosis or hepatotoxicity are noted, the drug should be immediately discontinued. This drug is pregnancy category C.

Ombitasvir-paritaprevir-ritonavir (Technivie): Approved in 2015, Technivie is a fixed-dose combination of ombitasvir (an NS5A inhibitor), paritaprevir (an HCV protease inhibitor), and ritonavir (included to boost the effectiveness

of paritaprevir). This combination is approved with or without ribavirin for chronic HCV infection. The drug is recommended only for HCV genotype 4 in patients without cirrhosis. The most common adverse effects are fatigue, nausea, asthenia, and insomnia. When the combination includes dasabuvir, it is available as Viekira Pak.

Ribavirin (Copegus): Ribavirin resembles a natural nucleoside and inhibits the viral synthesis of both DNA and RNA. Unlike many antivirals, it has a broad spectrum of activity against both RNA and DNA viruses. Ribavirin is given PO when treating HCV, always in combination with alfa IFNs. The inhalation form (Virazole) is approved to treat severe infections from the respiratory syncytial virus. Off-label uses include treatment of influenza, herpes, and other viruses. The drug can affect the heart and should be used with caution in patients with preexisting cardiac disease. According to the black box warning issued for this drug, the most serious adverse effect of ribavirin is hemolytic anemia, and patients must be assessed regularly for changes in laboratory blood values. In addition, ribavirin has produced embryotoxicity and fetal defects in every animal studied; it is pregnancy category X. Indeed, pregnant healthcare workers should not care for patients receiving aerosolized ribavirin due to the risk of incidental exposure.

Simeprevir (Olysio): Simeprevir is one of the newer drugs for the treatment of chronic HCV infection, approved in 2013. The drug acts by inhibiting HCV protease, which is needed for a critical step in the HCV replication cycle. It is approved as combination therapy with pegIFN alfa and ribavirin or with sofosbuvir. It is given once daily by the PO route. The most frequent adverse effects, when used in combination with pegIFN and ribavirin, include rash, photosensitivity, pruritus, and nausea. Sun protection measures should be used when taking this drug. Patients of East Asian descent will exhibit increased risk of adverse effects. The drug is pregnancy category X (due to its combination with ribavirin).

Sofosbuvir (Sovaldi): Sofosbuvir is a first-line drug for chronic HCV due to its effectiveness against several genotypes, its once-daily dosing regimen, and its minimal adverse effects. Sofosbuvir is an inhibitor of viral RNA polymerase, the enzyme required for the virus to make RNA. Approved in 2013 for the treatment of chronic HCV infection, it is used in several combination therapies: with ribavirin, with pegIFN alfa and ribavirin, with daclatasvir, or with daclatasvir and ribavirin. Fatigue and headaches are the most common side effects when used in combination with ribavirin. Several PO fixed-dose combinations are also approved for chronic hepatitis C infection: sofosbuvir with velpatasvir (Epclusa) and sofosbuvir with velpatasvir and voxilaprevir (Vosevi). Sofosbuvir is pregnancy category X when used in combination with ribavirin.

Telbivudine (Tyzeka): Telbivudine was approved in 2006 for the treatment of chronic HBV in patients with evidence of active disease. Like lamivudine, it is an oral drug that inhibits viral DNA synthesis by inhibiting the reverse transcriptase enzyme. Viruses may develop cross resistance between lamivudine and telbivudine. Long-term use of telbivudine with incomplete viral suppression can increase the risk for development of viral resistance. A baseline HBV DNA level should be obtained and subsequent levels determined every 24 weeks to determine if treatment is effective. The most frequent adverse effects include flulike symptoms, upper respiratory tract infection, fatigue, abdominal pain, and diarrhea. According to the black box warning for this drug, fatal lactic acidosis and severe hepatomegaly with steatosis have been reported. Exacerbation of hepatitis may occur following discontinuation of therapy with antivirals. This drug is pregnancy category B.

Interferons: Several IFNs are commercially available as drugs through recombinant DNA technology. All IFNs carry a black box warning that the drug may cause or worsen serious neuropsychiatric, autoimmune, ischemic, and infectious disorders. Additional information on these drugs is presented in Chapter 42.

- **IFN alfa-2b (Intron A).** This drug is approved for chronic HBV infection. After 4 months of pharmacotherapy, approximately one third of patients will experience long-term loss of HBV DNA and HBsAg. In the second or third month of therapy, patients may experience an exacerbation of symptoms, probably due to removal of infected hepatocytes by the immune system. Patients most likely to respond to IFN therapy include those with a low viral load (HBV less than 20 copies/mL) and ALT greater than 100. Although the majority of patients respond to IFN monotherapy with normalization of transaminases and a reduction in liver degeneration, relapse rates are high. IFN alfa-2b is also approved to treat chronic HCV infection. Permanent resolution of chronic HCV occurs in about 10% to 25% of patients. Combination therapy with ribavirin increases the therapeutic success rate. Interferon alfa-2b is also used to treat hairy cell leukemia, follicular lymphoma, malignant melanoma, condylomata acuminata, and Kaposi's sarcoma (see Chapter 42).
- **PegIFN alfa-2a (Pegasys) and pegIFN alfa-2b (PegIntron).** These drugs are pegylated formulations of IFNs that produce a more sustained serum drug level over a longer period of time than the nonpegylated formulations. Pegylation permits the IFN to maintain a consistently high serum level and to be administered less frequently. Whereas standard IFN formulations must be administered 3 times per week, pegylated versions require only one dose per week. The peg molecule is inert and does not influence antiviral activity. Pegasys

and pegIntron are believed to be equivalent in terms of efficacy.

Approved indications for pegIFN alfa-2a include chronic HBV and HCV infections that show evidence that the virus is replicating. PegIFN alfa-2b is indicated for the treatment of chronic hepatitis C in patients 3 years or older with compensated liver disease. PegIFN alfa-2b is usually given in combination with ribavirin over a period of 24 to 48 weeks. Actions and adverse effects are the same as those for IFN alfa-2b.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antivirals for Non-HIV Viral Infections

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including immunizations; respiratory, neurologic, hepatic or renal disease; and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and over-the-counter drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of the current infection, noting onset, duration, characteristics, presence or absence of fever, or pain.
- Evaluate appropriate laboratory findings (e.g., CBC, hepatic and renal function studies, and viral cultures).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished or absence of signs and symptoms of concurrent infections).
- Continue periodic monitoring of CBC and hepatic and renal function.
- Assess for adverse effects: nausea, vomiting, diarrhea, anorexia, fatigue, drowsiness, dizziness, and headache. Decreased urine output or darkened urine, increased bruising or bleeding, increasing fever, or symptoms of infections should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments for therapeutic effects: diminishing signs of original infection, maintenance of normal appetite and fluid intake, and increasing energy level. (Drug therapy effects may not be immediately observable. Gradual improvement should be noted, and the patient should be encouraged to continue taking the medication.)	• Teach the patient to complete the full course of medication. • Encourage adequate nutrition, rest, and activity levels as improvement is noted.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Report increasing fever, dizziness, headache, or diminished urine output to the healthcare provider immediately. (Increasing fever, especially when accompanied by worsening symptoms, may be a sign of worsening infection or adverse drug effects.)	• Teach the patient, family, or caregiver to promptly report a fever that exceeds 38.3°C (101°F) or per parameters set by the healthcare provider, an inability to maintain hydration or nutrition, or dizziness to the healthcare provider.
• Continue to monitor periodic laboratory work: CBC, hepatic and renal function tests, viral cultures. (Antiviral drugs may cause hepatotoxicity or nephrotoxicity. Bone marrow suppression and resulting blood dyscrasias, particularly thrombocytopenia, are also adverse effects.)	• Instruct the patient on the need for periodic laboratory work, correlating any symptoms with the need for possible laboratory tests (e.g., increased bruising or bleeding).
• Continue to monitor for hepatotoxicity and nephrotoxicity; e.g., jaundice, RUQ pain, darkened urine, and diminished urine output. (Hepatotoxicity and nephrotoxicity may occur. **Lifespan:** Age-related physiologic differences may place older adults at greater risk for hepatotoxicity and nephrotoxicity. Increasing fluid intake will prevent drug accumulation in the kidneys.)	• Teach the patient to immediately report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light- or clay-colored stools, diminished urine output, or darkening of urine. • Advise the patient to increase fluid intake to 2–3 L/day.
• Monitor for signs and symptoms of neurotoxicity, particularly in patients on IV acyclovir, e.g., drowsiness, dizziness, tremors, headache, confusion, changes in level of consciousness (LOC), or seizures. Ensure patient safety and have the patient rise slowly from lying or sitting to standing. (Acyclovir, especially when given IV, may be neurotoxic. **Lifespan:** Monitor the older adult patient closely to prevent falls.)	• Instruct the patient, family, or caregiver to report increasing headache, dizziness, drowsiness, tremors, confusion, or changes in LOC immediately. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Caution the patient that drowsiness may occur and to be cautious with driving or other activities requiring mental alertness until the effects of the drug are known.
• Monitor patients on amantadine for changes in behavior, psychiatric symptoms, or suicidal thoughts. (An increased risk of CNS or psychiatric symptoms such as suicidal thoughts have been known to occur with amantadine, especially in patients with preexisting CNS or psychiatric disorders.)	• Have the patient, family, or caregiver immediately report any changes in behavior, confusion, delusion, or expressed thoughts of suicide.
• Monitor for signs and symptoms of blood dyscrasias, e.g., bleeding, bruising, significant fatigue, or increasing signs of infection. (Bone marrow suppression may occur and may cause blood dyscrasias with resulting decreases in red blood cells, white blood cells, or platelets.)	• Teach the patient, family, or caregiver to report any low-grade fevers, sore throat, rashes, bruising or increased bleeding, unusual fatigue, or shortness of breath, especially if on drug therapy for a prolonged period, to the healthcare provider.
• Monitor for, and immediately report, signs and symptoms of lactic acidosis in patients taking lamivudine (Epivir) or several other drugs similar to lamivudine. (Lactic acidosis is a possible life-threatening adverse effect of lamivudine and similar drugs.)	• Teach the patient, family, or caregiver to immediately report symptoms such as abdominal pain, anxiety, fatigue, palpitations, lethargy, rapid breathing and heart rate, weakness, chest pain or tightness, fever, or shortness of breath to the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for significant GI effects, including nausea, vomiting, and diarrhea. Ensure adequate nutrition and caloric intake. (Adverse GI effects are common and the patient may also have disease-related effects, e.g., mouth sores. Maintaining adequate nutrition and fluids is essential to healing. Lamivudine [Epivir] is known to cause or worsen pancreatitis, particularly in children with a history of pancreatitis.)	• Instruct the patient, family, or caregiver to immediately report any severe or increasing abdominal pain to the healthcare provider. • Teach the patient to avoid acidic foods and beverages, carbonated drinks, or excessively hot or cold foods and beverages that may cause mouth irritation. • Encourage the patient to try small, frequent meals, which may be better tolerated than fewer, larger meals. High-caloric foods and supplemental beverages (e.g., Un*Jury*™, Boost™, or Ensure™) may help supply additional calories and fluids. Assist the patient in obtaining a dietary consultation as needed if nausea or diarrhea makes maintaining intake difficult.
• Encourage infection control and good hygiene measures based on the disease condition and follow established protocol in hospitalized patients. (Antiviral drugs decrease the level of infection but do not cure the disease. Excellent hygiene measures will limit the chance for secondary infections in the immunocompromised patient.)	• Teach the patient about adequate infection prevention measures such as frequent hand hygiene, appropriate disposal of dressing material, and adequate nutrition and rest, especially if currently immunocompromised. • The patient may need to be isolated in the hospital or stay at home during peak transmission periods, leading to social isolation. Ascertain if the patient has assistance available if a prolonged period of homebound status is anticipated. • Teach the patient to practice abstinence or always use barrier protection during sexual activity even if genital lesions are not present. Genital HSV infections may be transmitted even in the asymptomatic period. Have the patient consult with the healthcare provider about suppressive therapy.
• Maintain hydration during antiviral therapy, providing preadministration hydration if the drug is given IV. Hydration may be ordered in the immediate pre- and postadministration periods. Monitor intake and output in the hospitalized patient. (Acyclovir and other antiviral drugs may be nephrotoxic and adequate hydration is essential to prevent adverse renal effects.)	• Teach the patient on oral antiviral drugs to increase fluids to 2 L/day throughout therapy.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Suppressive therapy may be used to maintain a symptom-free period. Do not stop the medicine when starting to feel better.
	  • Do not share the medicine with other family members. If there is reason to believe they need medication, they should be assessed by a healthcare provider.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking these drugs.
	  • If using ointments or creams, wash hands well before applying and again after application. If family or caregivers administer the medicine, gloves should be worn.

Understanding Chapter 54

Key Concepts Summary

54.1 Viruses are infectious agents with simple structures.

54.2 The replication cycle of a virus occurs in five stages.

54.3 Antiviral drugs target a specific viral structure or stage of its replication cycle.

54.4 Pharmacotherapy can lessen the severity of acute herpes simplex infections and prolong latency.

54.5 Pharmacotherapy of influenza viruses includes drugs to prevent infection as well as drugs to treat active infections.

54.6 The most effective therapies for hepatitis infections are antivirals and drugs that boost the immune system to rid the body of the virus.

CASE STUDY: Making the Patient Connection

Remember the patient "Richard Palmer" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Richard Palmer, a 19-year-old university student, has come to the health clinic. He states that he gets cold sores at least 6 to 8 times per year. He informs the nurse that the cold sores usually start with lip pain or tingling, often followed by small, painful, fluid-filled blisters on a raised, red, painful area of his lip. The blisters usually last 2 to 3 days, then form yellowish crusts that slough off to reveal pinkish skin.

With his final exams coming up, Richard admits to feeling stressed. He also works part time serving at a local restaurant to help meet the expenses of college. Like other college students his age, Richard eats on the run and seldom sleeps more than 4 to 5 hours per night. His weekends are even more hectic with the job, school, and social activities. Richard requests something to help rid him of the existing cold sore immediately.

Critical Thinking Questions

1. How would you explain the mode of transmission and onset of symptoms for herpes simplex viruses (HSV) to Richard?
2. How would you respond when Richard asks, "Is there any medication that I can take to prevent the cold sores from returning?"
3. Topical acyclovir is prescribed for this patient. What patient education would you provide?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Jeanie Schinkle is a 43-year-old factory worker who has just started a new job. Today, she presents to the employee health services with a fever (temperature: 38.3°C [101.1°F]), headache, myalgia, and cough that developed less than 24 hours ago.

As she is talking to the nurse, she expresses concern that she will lose her job if she is absent from work. "If only I had taken the flu shot, maybe I would not have gotten sick," says Jeanie.

1. Is Jeanie a possible candidate for oseltamivir (Tamiflu)? Why or why not?
2. What health teaching should the nurse provide Jeanie about the flu?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Acyclovir (Zovirax) has been ordered intravenously for a patient with a herpes zoster infection to the upper torso and face. Which nursing intervention will help prevent a common adverse effect?
    1. Administer the drug slowly IV over an hour, and encourage fluid intake throughout the day.
    2. Keep skin areas dry to prevent fungal overgrowth.
    3. Administer antihistamines 1 hour before giving the infusion to prevent itching.
    4. Assess visual acuity periodically and provide for eye comfort such as lubricating eye drops.
2. The patient is receiving elbasvir-grazoprevir (Zepatier) for hepatitis C virus. Which statement by the nurse is correct?
    1. "Neither the topical nor the intravenous form of Zepatier will prevent the spread of hepatitis C virus."
    2. "The patient will receive a 12- to 16-month course of therapy with Zepatier."
    3. "Zepatier may be used in combination with ribavirin."
    4. "The most common adverse effects of Zepatier are fatigue, rash, and dizziness."
3. Which assessment data would be most important for the nurse to monitor frequently in the patient receiving amantadine (Symmetrel)? (Select all that apply.)
    1. White blood cell and platelet counts
    2. Serum creatinine and urine output
    3. Mental status and level of consciousness
    4. Sodium and potassium levels
    5. Lung sounds and signs of peripheral edema

4. The patient has received a prescription for zanamivir (Relenza) for flu symptoms but tells the nurse, "I think I can hold off on starting this, I don't feel that bad yet." What would be the nurse's best response?
   1. "That should be fine and the drug has a stable shelf-life so it can be saved for later infections."
   2. "It can be saved for later but you will also require an additional antibiotic to treat the symptoms at that point."
   3. "It can be started within 2 weeks after the onset of symptoms."
   4. "To be effective, it must be started within 48 hours after the onset of symptoms."
5. A patient with chronic hepatitis B has been prescribed tenofovir (Viread). The nurse will teach the patient to immediately report symptoms of what adverse and potentially life-threatening drug effect?
   1. Systemic yeast infection
   2. Lactic acidosis
   3. Heart failure
   4. Ventricular dysrhythmias
6. The patient is receiving ribavirin (Copegus) for treatment of chronic hepatitis B. Which manifestation, if present in the patient, would the nurse conclude is an adverse effect of this medication?
   1. Neurologic symptoms such as headaches and dizziness
   2. Respiratory symptoms such as dyspnea and congestion
   3. Skin disruptions such as acne and ulcerations
   4. Hematologic symptoms such as excessive fatigue or dizziness

"Yeah, I admit it. I'm scared and practically out of my mind with worry. I've known several people who have died because of AIDS. What if this happens to me?"
Patient "Ryan Orre"

Chapter 55
Pharmacotherapy of HIV Infection and AIDS

Chapter Outline

- Pathogenesis of HIV Infection
- General Principles of HIV Pharmacotherapy
- Classification of Antiretroviral Drugs
- Antiretroviral Drugs

  Nucleoside and Nucleotide Reverse Transcriptase Inhibitors

  PROTOTYPE *Zidovudine (AZT, Retrovir), p. 1004*

  Nonnucleoside Reverse Transcriptase Inhibitors

  PROTOTYPE *Efavirenz (Sustiva), p. 1006*

  Protease Inhibitors

  PROTOTYPE *Lopinavir with Ritonavir (Kaletra), p. 1008*

  Entry Inhibitors and Integrase Inhibitors
- Prophylaxis of HIV Infections

  Vaccines

  Occupational Exposure to HIV

  Perinatal Transmission of HIV
- Pharmacotherapy of Opportunistic Infections Associated with HIV and AIDS

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the primary steps in the pathogenesis of HIV infection.
2. Explain the therapeutic goals for HIV pharmacotherapy.
3. Identify reasons for virologic failure during HIV pharmacotherapy.
4. Describe the advantages of antiretroviral therapy in the pharmacotherapy of HIV infection.
5. Compare and contrast the classes of antiretroviral medications.
6. Describe the difficulties in developing a vaccine to prevent HIV infection.
7. Explain the protocol and rationale for postexposure prophylaxis following occupational exposure to HIV.
8. Explain recent advances in the preexposure prophylaxis of HIV infection.
9. Describe the antiretroviral protocols used for reducing the risk of perinatal transmission and for treating pediatric patients with HIV infection.
10. Identify opportunistic infections commonly acquired by patients with HIV infections and the drugs used to treat them.
11. Describe the nurse's role in the pharmacologic management of patients receiving antiretroviral medications.
12. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
13. Apply the nursing process to care for patients receiving pharmacotherapy for HIV infection or AIDS.

Key Terms

acquired immunodeficiency syndrome (AIDS), 997
acute retroviral syndrome, 999
antiretroviral therapy (ART), 1001
antiretrovirals, 997
CD4 receptor, 997
human immunodeficiency virus (HIV), 997
integrase, 998
lipodystrophy, 1004
mitochondrial toxicity, 1004
pharmacokinetic enhancers, 1003
protease, 998
reverse transcriptase, 997
viral load, 1000
virologic failure, 1000

Recognized by the medical community as a distinct disease in 1981, the first documented case of **acquired immunodeficiency syndrome (AIDS)** has since been traced back to 1959. The syndrome is characterized by profound immunosuppression, leading to opportunistic infections (OIs) and malignancies not commonly acquired by people with intact immune defenses. The **human immunodeficiency virus (HIV)** was quickly identified as the causative agent for AIDS. HIV infection has resulted in a tragic, worldwide epidemic, causing the deaths of millions of people. The infection continues to be a major public health challenge.

PharmFACT

It is estimated that 1.2 million Americans are living with HIV; 13% do not know they are infected (Centers for Disease Control and Prevention [CDC], 2017).

Pathogenesis of HIV Infection

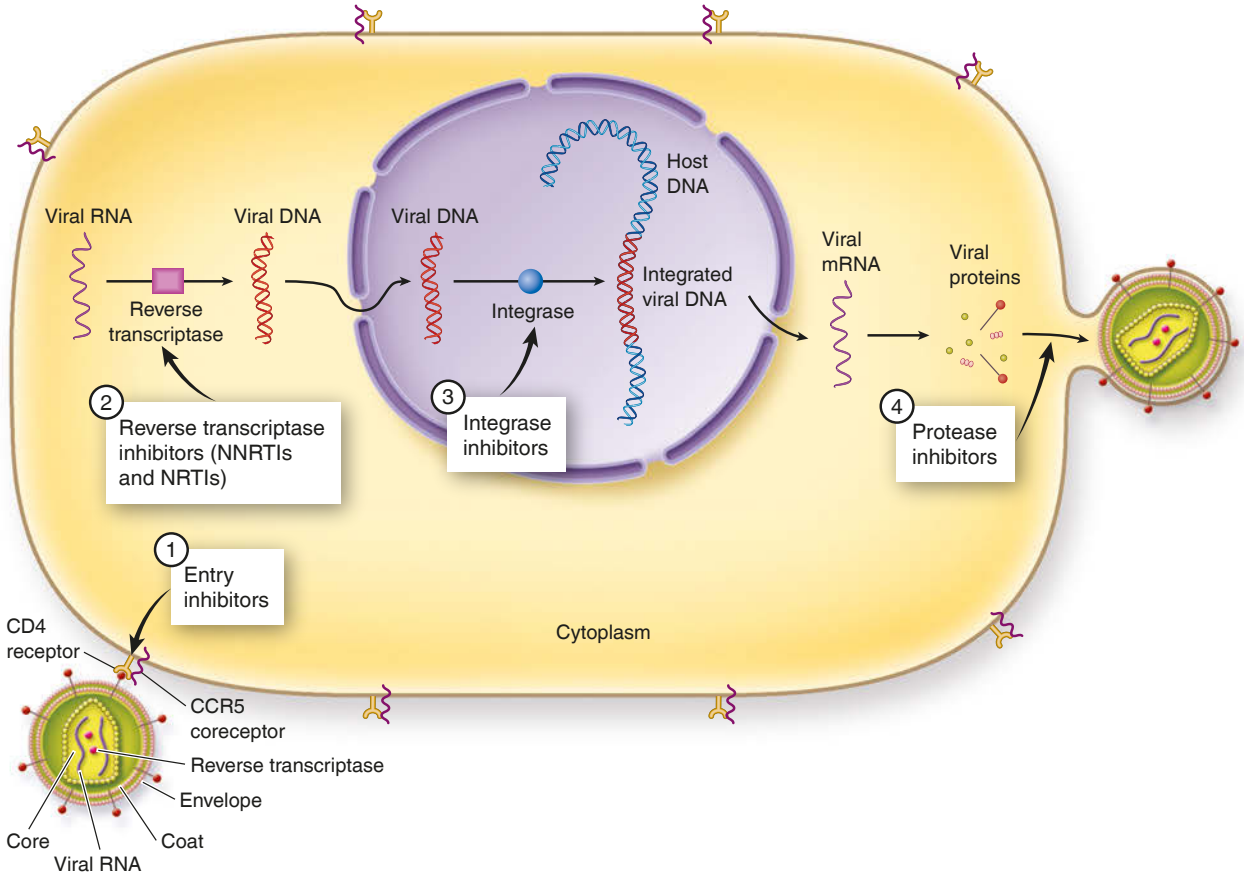
55.1 HIV causes a profound loss of immune function.

The two primary types of HIV are HIV-1 and HIV-2. Because more than 99% of the global AIDS cases are caused by HIV-1, the discussion in this text will apply only to HIV-1. HIV uses the same stages of viral infection described in Chapter 54. There are, however, additional details that are important to understanding the pharmacotherapy of HIV infection.

Transmission: HIV infection occurs by exposure to contaminated body fluids, most commonly blood or semen, because these fluids have the highest concentration of the virus. Transmission may occur through sexual activity or through contact of infected fluids with broken skin, mucous membranes, or needlesticks. Newborns of a mother infected with HIV may acquire the virus during birth or breastfeeding. Although in the United States the majority of patients with HIV infection are men who have sex with other men, heterosexual transmission is significant and is the predominant means of acquiring the infection in developing countries.

PharmFACT

About 39,000 new cases of AIDS are diagnosed each year in the United States. Approximately 60% of these involve male-to-male sexual contact. However, about one in every four people who acquire this disease is a woman who acquired the infection through heterosexual contact (CDC, 2017).



Replication cycle: Like other viruses, HIV must infect a host cell to duplicate its genetic material and assemble more virus particles (virions). Knowledge of the replication cycle of HIV, which is shown in Pharmacotherapy Illustrated 55.1, is critical to understanding the pharmacotherapy of HIV infection.

The first stage of HIV pathogenesis is the attachment of the virus to its preferred target: the **CD4 receptor** on the surface of T4 lymphocytes. (Note that the terms *CD4 cells*, *T4 cells*, and *T4 lymphocytes* are used interchangeably in this text.) During this initial stage, structural proteins on the surface of HIV fuse with the CD4 receptor. Because these receptors are also present on monocytes, macrophages, and dendritic cells, multiple cell types become infected. In addition to the CD4 receptor, coreceptors known as CCR5 and CXCR4 have been discovered that assist HIV in binding to the T4 lymphocyte.

The second stage of pathogenesis is the penetration of HIV into the T4 lymphocyte. The virus uncoats and the single-stranded ribonucleic acid (RNA) genetic material enters the host cell. HIV converts its RNA strands to double-stranded deoxyribonucleic acid (DNA), using the viral enzyme **reverse transcriptase**. Only a few viruses are able to construct DNA from RNA; no bacteria, plants, or animals are able to perform this unique metabolic function. All living organisms make RNA from DNA. Because of their "backward" or reverse DNA synthesis, these viruses are called *retroviruses* and drugs used to treat HIV infections are called **antiretrovirals**. Although unique to HIV, reverse transcriptase is an inefficient enzyme that makes many errors when converting the viral RNA to double-stranded DNA. The enzyme has no "proofreading" ability, which allows errors in the viral genetic code to accumulate. This produces a high mutation rate, making it difficult to develop effective vaccines.

Pharmacotherapy Illustrated 55.1

Replication of HIV

The viral DNA eventually enters the nucleus of the T4 lymphocyte where it becomes incorporated into the host's chromosomes. This action is performed by HIV **integrase**, another enzyme unique to HIV. Once incorporated into human chromosomes, the HIV is called a provirus, and it remains for the lifetime of the cell. It is impossible to recognize the HIV provirus or remove it once it has entered the cell. Indeed, despite the fact that the T4 lymphocyte is infected with a deadly virus, the host's immune system is unable to effectively remove the defective cells.

This *latent phase* of the infection may last only a few weeks, or it may continue for decades. During this phase, patients are asymptomatic and do not realize they are infected. It was once thought that the virus was truly "silent" during the latent phase but continuous HIV replication and immune system damage are occurring.

At some point, the latent provirus becomes activated and produces large amounts of viral messenger RNA, with the first strands producing viral proteins that amplify the replication process. All structural components of HIV are subsequently synthesized, and the cell is ready to assemble more virions.

The individual structural components of HIV migrate to the plasma membrane of the host cell, where they are packaged, and eventually bud from the host cell. The new virions, however, are not yet infectious. As a final step, the viral enzyme **protease** cleaves some of the larger proteins to smaller, functional forms. Once budding occurs, the immune system recognizes that the cell is infected and kills the T4 lymphocyte. Unfortunately, it is too late; it is estimated that a patient infected with HIV may produce as many as 10 billion new virions every day, and the immune system becomes overwhelmed by the infection.

Symptoms: The immune system recognizes invasion by the virus and mounts an immediate defense, resulting in an acute inflammatory response that rids the body of many of the infectious virions. It is estimated that a billion HIV virions are destroyed each day during this early stage. Patients experience sore throat, fever, rash, malaise, and weight loss that may last several weeks. However, because

patients often mistake these vague symptoms for the common cold or flu, they do not realize that HIV infection has occurred and rarely seek medical intervention. Symptoms during this initial phase, which lasts 2 to 4 weeks, are known as the **acute retroviral syndrome**. Although body defenses may suppress the viral invasion, tragically they are unable to eliminate the virus.

Progression to AIDS is characterized by gradual destruction of the immune system, as measured by the steady decline in the number of CD4 lymphocytes. Unfortunately, the CD4 lymphocyte is the primary cell coordinating the immune response for both the humoral and cell-mediated branches of the immune system. When the CD4 cell count falls below a critical level, the patient begins to experience opportunistic bacterial, fungal, and viral diseases and certain malignancies. Left untreated, the patient eventually is unable to mount any immune defense, and death occurs.

CONNECTION Checkpoint 55.1

Patients who are receiving immunosuppressant drugs have low white blood cell counts and, like patients with AIDS, are at risk for contracting OIs. From what you learned in Chapter 42, what are the major indications for immunosuppressant therapy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

General Principles of HIV Pharmacotherapy

55.2 Treatment of HIV infection is difficult due to the latent nature of the virus and the development of resistant strains.

The widespread appearance of HIV infection in 1981 created enormous challenges for public health and an unprecedented need for the development of new antiretroviral drugs. HIV infection is unlike any other viral disease because it is sexually transmitted, uniformly fatal, and demands a continuous supply of new drugs for patient survival. Over 20 new antiretroviral drugs were developed during the past 30 years, but the disease remains essentially incurable. Although the infection can be managed as a chronic disease, stopping antiretroviral therapy always results in a rapid rebound in HIV replication. With HIV mutating extremely rapidly and resistant strains developing so quickly, the creation of new, novel approaches to antiretroviral drug therapy must remain a high priority in treating HIV infection.

While pharmacotherapy for HIV infection has not produced a cure, it has resulted in significant therapeutic successes. For example, many patients with HIV infection are able to live symptom free with their disease for a long time due to medications. Furthermore, the transmission of the virus from a mother infected with HIV to her newborn has been reduced dramatically due to intensive drug therapy of the mother prior to delivery and of the baby immediately following birth. Along with better patient education and prevention, successes in pharmacotherapy have produced a steady decline in the annual death rate due to AIDS in the United States from a high of almost 41,000 in 1985 to around 12,000 now.

The therapeutic goals for the pharmacotherapy of HIV infection include the following:

- Reduce HIV-related morbidity and prolong survival.
- Improve the quality of life.
- Restore and preserve natural functions of the immune system.
- Suppress plasma HIV viral load to the maximum extent possible.
- Prevent HIV transmission.

Initiation of antiretroviral therapy: Once a diagnosis is established, current guidelines recommend that antiretroviral therapy be initiated immediately. Early antiretroviral therapy has been shown to delay the onset of symptoms and the progression to AIDS. OIs can be prevented.

The decision to begin treatment during the asymptomatic stage, however, has certain negative consequences. Medication for treating HIV infection is expensive; the average annual cost is about $23,000, and treatment with some of the newer medications is more than $60,000 per year. These drugs produce uncomfortable and potentially serious adverse effects that can reduce the quality of life. Therapy over many years promotes viral resistance; when the acute stage eventually develops, the medications may be less effective.

Patients receiving their first treatment for HIV infection are called antiretroviral *naïve*. Medication choices for antiretroviral naïve patients are often different from that for antiretroviral experienced patients because drug-resistant strains of HIV develop during therapy.

Monitoring the progress of antiretroviral therapy: Two laboratory tests used to guide pharmacotherapy are absolute CD4 cell count and measurement of HIV RNA in the plasma. Figure 55.1 illustrates the progression of these two values during an untreated HIV infection.

The number of CD4 lymphocytes is an important indicator of immune function that shows the actual degree of immune system damage caused by the virus. It is a good predictor of the likelihood of the patient acquiring an OI. Normal values range from 500 to 1600 cells/m^3. Patients with HIV infection whose CD4 lymphocyte count falls below 200 cells/m^3 are at high risk for OIs. Once treatment succeeds in raising the CD4 cell count above the

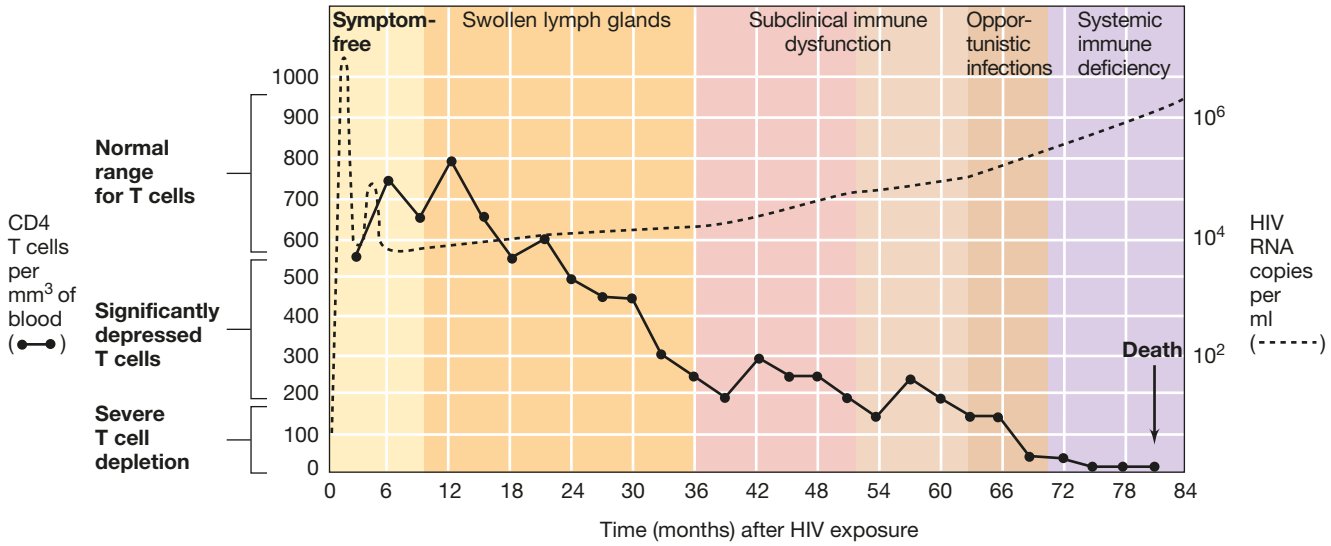


Figure 55.1 Decline of CD4 lymphocyte and progression of untreated HIV infection.
From *Brock Biology of Microorganisms* (15th ed.), by M. T. Madigan, K. S. Bender, D. H. Buckley, W. M. Stately, and D. A. Stahl, 2018. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.

level for OI risk, this laboratory test is conducted every 6 to 12 months.

The **viral load** is determined by measuring the amount of HIV RNA in the blood, which provides an estimate of how rapidly the virus is replicating in the body. Plasma viral load is considered the most reliable indicator of response to drug treatment. HIV RNA levels are determined periodically to assess the effectiveness of antiretroviral therapy. The goal of antiretroviral therapy is to reduce plasma HIV RNA to undetectable levels or less than 50 copies/mL. For most patients, 12 to 24 weeks of HIV pharmacotherapy is required to achieve this level.

Reasons for virologic failure: Antiretroviral therapy does not totally eliminate the virus from the body and many patients experience relapses during therapy. **Virologic failure** is defined as a plasma HIV RNA level that rises above 200 copies/mL during HIV treatment. Factors responsible for virologic failures include emergence of resistant HIV strains, adverse effects of the medications, lack of adherence to drug therapy, and drug interactions (including interactions with food, supplements, and other medications). Analysis of the reason for the failure can be challenging for the healthcare provider.

Drug resistance has become a serious barrier to success in treating HIV infection. When standard therapies fail, viral resistance must always be considered as a potential cause. Baseline HIV drug resistance testing is now recommended when patients enter care. Should virologic failure occur, viral genotypic drug testing is conducted to determine which mutated viral genes are causing the resistance. Ideally, the patient is switched to at least two (preferably three) drugs from chemical classes that will yield full antiretroviral activity. Unless the virologic failure is severe, adding only a single new drug to the regimen may lead to the rapid development of resistance.

Antiretroviral drugs cause many adverse effects, including nausea, diarrhea, rash, lipid abnormalities, hepatotoxicity, neuropathy, and increased risk of cardiovascular events. Patients always take multiple drugs, which often interact with other medications to cause additional adverse effects. Identifying the specific drug interaction causing a toxic effect is challenging. Serious adverse effects often require an immediate change in pharmacotherapy. Other times, a simple adjustment, such as changing the amount per dose or spacing doses further apart, may prevent or eliminate the adverse effect or drug interaction. Adding antinausea or antidiarrheal drugs to the regimen can diminish some of the more common adverse effects.

To be successful, antiretroviral therapy requires strict patient adherence to a complex regimen. Unfortunately, many factors have the potential to affect adherence. Some antiretroviral drugs have inconvenient schedules and must be taken 3 to 4 times per day or be given parenterally. Some are expensive or simply not available to patients in developing countries. Others make the patients feel quite ill; patients may actually feel much better when they are not taking the drugs. Given these complicating factors, and the prospect of a lifetime of drug therapy, it is easy to understand why adherence to the medication regimen is difficult, even for a motivated patient. The nurse is the key to helping develop a rational

daily plan of treatment that best fits the lifestyle of the patient and family.

Why do some patients succumb to HIV infections within months after diagnosis while others survive for decades? Considerable research over 4 decades has focused on genetic factors that have allowed some individuals to live with HIV for a long time without progressing to AIDS. These patients are known as long-term nonprogressors (LTNPs). Scientists have looked for specific antibodies, cytokines, and protective immune responses in these patients with the hope of developing therapies to help other infected patients. While some progress has been made in this area, researchers are far from understanding the protective genetic makeup of these LTNPs. Until knowledge advances, HIV infection will continue to be potentially fatal in every patient who acquires the infection.

Sexual lifestyle adjustments: Patients with HIV infection often face serious mental health challenges because of their illness. Most patients are young and sexually active. Knowing that they will likely die prematurely of the infection and that they could kill others through unsafe sexual practices is difficult to accept. Many patients benefit from psychotherapy, and all benefit from compassionate, nonjudgmental nursing care. Teaching patients with HIV infection or AIDS how to care for themselves and how to protect others from their disease is a major task of the nurse.

Studies have shown that antiretroviral therapy can markedly reduce the amount of HIV viral load in blood and body secretions. Reducing a patient's HIV RNA below the detectable level results in reduced infectiousness. This should not be interpreted, however, to mean that the patient is noninfectious. Patients who are asymptomatic, whether or not they are receiving antiretroviral therapy, are still infectious. Patients must observe abstinence or safe sexual practices for the remainder of their lifetimes to protect others from this lethal viral infection.

Classification of Antiretroviral Drugs

55.3 Five classes of antiretroviral drugs are available to treat HIV infection.

Antiretroviral drugs target specific phases of the HIV replication cycle. The standard pharmacotherapy for HIV infection includes aggressive treatment with multiple drugs concurrently, a regimen called **antiretroviral therapy (ART)**, formerly called highly active antiretroviral therapy (HAART). The goal of ART is to reduce the replication of HIV as much as possible, as measured by a reduction in plasma HIV RNA to its lowest possible (or undetectable) level. The simultaneous use of medications from several classes reduces the probability that HIV will become resistant to treatment.

It is important to understand that eliminating the virus from the blood is not a cure because HIV is harbored in locations other than the blood, such as lymph nodes. In fact, only a small percentage of the total CD4 lymphocytes in the body is circulating in the blood at any given time. Should a patient reach a stage where HIV RNA levels are undetectable, it is important for the nurse to stress that the disease has not been cured and that antiretroviral therapy must be continued for the lifetime of the patient.

Antiretroviral drugs, listed in Table 55.1, are classified into the following groups, based on their mechanism of action:

- Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs and NtRTIs)
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs)
- Protease inhibitors (PIs)
- Entry inhibitors (includes fusion inhibitors and CCR5 antagonists)
- Integrase inhibitors.

Throughout the AIDS epidemic, pharmacotherapeutic regimens for treating the infection have continuously evolved based on ongoing research. Recommendations vary based on comorbid conditions such as hepatitis, tuberculosis, liver disease, or kidney disease. In current clinical practice, the following regimens have been shown to be the most successful choices for the *initial* therapy of HIV infection (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2016):

- **PI-based regimens:**
- darunavir (ritonavir-boosted) plus emtricitabine plus tenofovir (disoproxil or alafenamide)
- **Integrase inhibitor–based regimens:**
- raltegravir plus emtricitabine plus tenofovir (disoproxil or alafenamide)
- dolutegravir plus emtricitabine plus tenofovir (disoproxil or alafenamide)
- elvitegravir plus cobicistat plus emtricitabine plus tenofovir (disoproxil or alafenamide)
- dolutegravir plus abacavir plus lamivudine.

Although the preceding drug combinations are recommended, divergence to other regimens is necessary, especially as resistant strains develop. The pharmacotherapy of HIV infection is evolving, and healthcare providers are still learning what drug combinations are most effective. The nurse should always review the latest medical literature before treating patients with HIV infection.

To improve adherence and to make the regimen more convenient for patients, the pharmaceutical companies

Table 55.1 Antiretroviral Drugs for HIV Infection

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Nucleoside and Nucleotide Reverse Transcriptase Inhibitors (NRTIs, NtRTIs)		
abacavir (Ziagen)	PO: 300 mg bid (max: 600 mg/day)	*Fatigue, generalized weakness, myalgia, nausea, headache, abdominal pain, vomiting, anorexia, rash, sleep disorders* Bone marrow suppression, neutropenia, anemia, granulocytopenia, lactic acidosis with steatorrhea, neurotoxicity, peripheral neuropathy (stavudine), pancreatitis (didanosine, lamivudine), hepatotoxicity (stavudine)
didanosine (ddI, Videx EC)	PO: 200–400 mg once daily on an empty stomach	
emtricitabine (Emtriva)	PO: 200 mg once daily (max: 200 mg/day)	
lamivudine (Epivir, 3TC)	PO: 150 mg bid (max: 300 mg/day)	
stavudine (d4T, Zerit)	PO: 40 mg bid (max: 80 mg/day)	
tenofovir disoproxil (Viread)	PO: 300 mg once daily	
zidovudine (AZT, Retrovir)	PO: 200 mg q4h (1200 mg/day); after 1 month may reduce to 100 mg q4h (600 mg/day) IV: 1–2 mg/kg q4h (1200 mg/day)	
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
delavirdine (Rescriptor)	PO: 400 mg tid (max: 1200 mg/day)	*Rash, fever, nausea, diarrhea, headache, stomatitis* Paresthesia, hepatotoxicity (nevirapine), Stevens–Johnson syndrome (SJS), CNS toxicity (efavirenz), severe depression (rilpivirine)
efavirenz (Sustiva)	PO: 600 mg/day (max: 600 mg/day)	
etravirine (Intelence)	PO: 200 mg bid following a meal (max: 400 mg/day)	
nevirapine (Viramune)	PO: 200 mg/day for 14 days, then increase to bid	
rilpivirine (Edurant)	PO: 25 mg once daily	
Protease Inhibitors (PIs)		
atazanavir (Reyataz)	PO: 300 mg plus 100 mg ritonavir daily with food	*Nausea, vomiting, diarrhea, abdominal pain, headache* Anemia, leukopenia, deep venous thrombosis, pancreatitis, lymphadenopathy, hemorrhagic colitis, nephrolithiasis (indinavir), cardiac arrest (atazanavir), thrombocytopenia (saquinavir), pancytopenia (saquinavir)
darunavir (Prezista)	PO: 600 mg taken with 100 mg ritonavir bid with food	
fosamprenavir (Lexiva)	PO: 700–1400 mg bid in combination with 100 mg ritonavir bid (max: 2800 mg/day)	
indinavir (Crixivan)	PO: 800 mg tid 60 min before a meal	
lopinavir with ritonavir (Kaletra)	PO: 800 lopinavir and 200 mg ritonavir given once or twice daily	
nelfinavir (Viracept)	PO: 750 mg tid with a meal	
ritonavir (Norvir)	PO: 600 mg bid (max: 1200 mg/day)	
saquinavir (Invirase)	PO: 1000 mg bid (max: 2000 mg/day)	
tipranavir (Aptivus)	PO: 500 mg taken with 200 mg ritonavir bid with food (max: 2000 mg/day)	
Entry Inhibitors		
enfuvirtide (Fuzeon)	Subcutaneous: 90 mg bid	*Local injection-site reactions, nausea, diarrhea, fatigue* Hypersensitivity, neutropenia, thrombocytopenia, nephrotoxicity, pneumonia
maraviroc (Selzentry)	PO: 150–600 mg bid (max: 1200 mg/day)	*Respiratory tract infections, cough, pyrexia, rash, dizziness* Hepatotoxicity, myocardial infarction
Integrase Inhibitors		
dolutegravir (Tivicay)	PO: 50 mg once daily	*Insomnia, headache* Severe hypersensitivity reactions, hepatotoxicity
elvitegravir (Vitekta))	PO: 150 mg once daily with food in combination with a ritonavir-boosted PI	*Nausea and diarrhea* Acute renal failure, Fanconi syndrome, decrease in bone mineral density, lactic acidosis, severe hepatomegaly with steatosis
raltegravir (Isentress)	PO: 400 mg bid (max: 800 mg/day)	*Headache, diarrhea, nausea, fatigue, insomnia* Hypersensitivity reaction, myopathy, rhabdomyolysis

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

have created many fixed-dose regimens combined into a single tablet or capsule. Some of these combinations are shown in Table 55.2.

Pharmacokinetic considerations: Pharmacokinetic variables become very important when treating patients with HIV and can, in fact, contribute in a major way to the success or failure of pharmacotherapy. The bioavailability of some antiretrovirals is greatly affected by food in the stomach. The absorption of certain antiretrovirals (e.g., indinavir) is decreased in the presence of food. Some (e.g., lopinavir) have a significantly increased absorption with high-fat meals and others (e.g., nevirapine) are not affected by the presence of food.

Table 55.2 Combination Drugs for HIV Infection

Trade Name	NRTIs and NtRTIs	NNRTIs	PIs	Integrase Inhibitors	Pharmacokinetic Booster
Atripla	emtricitabine, tenofovir disoproxil	efavirenz	—	—	
Combivir	zidovudine, lamivudine	—	—	—	—
Complera	emtricitabine, tenofovir disoproxil	rilpivirine	—	—	—
Descovy	emtricitabine, tenofovir alafenamide	—	—	—	—
Epzicom	abacavir, lamivudine		—	—	—
Evotaz	—	—	atazanavir	—	cobicistat
Genoya	emtricitabine, tenofovir alafenamide	—	—	elvitegravir	cobicistat
Kaletra	—	—	lopinavir	—	ritonavir
Odefsey	emtricitabine, tenofovir alafenamide	rilpivirine	—	—	—
Prezcobix	—	—	darunavir	—	cobicistat
Stribild	emtricitabine, tenofovir disoproxil	—	—	elvitegravir	cobicistat
Triumeq	abacavir, lamivudine		—	dolutegravir	—
Trizivir	abacavir, zidovudine, lamivudine		—	—	—
Truvada	emtricitabine, tenofovir disoproxil	—	—	—	—

In addition to changes in absorption, most antiretrovirals are metabolized by the liver. Several can significantly increase or decrease the hepatic metabolism of other drugs, resulting in large numbers of potential drug–drug interactions. These effects differ, even within the same drug class. For example, nevirapine induces the hepatic CYP450 enzyme system, thus decreasing the levels of other drugs. Delavirdine, an antiretroviral in the same class, inhibits the CYP450 system, thus increasing the levels of other drugs. Predicting and avoiding complex drug interactions in patients with HIV requires truly skilled and dedicated nurses and other healthcare providers who are current on the most recent medical literature.

Two drugs, ritonavir and cobicistat, are given concurrently with antiretrovirals primarily for the purpose of inhibiting liver enzymes that would inactivate the antiretroviral. Ritonavir and cobicistat raise the serum concentration of other antiretrovirals. These drugs are called **pharmacokinetic enhancers** or boosters. For example, giving cobicistat with atazanavir enhances the actions of atazanavir. It also allows for lower doses of atazanavir, which lowers the potential for adverse drug effects. Cobicistat itself has no antiretroviral activity. The other booster, ritonavir, does have some antiretroviral activity of its own.

Antiretroviral Drugs

55.4 Reverse transcriptase inhibitors block the synthesis of viral DNA.

Following entry into a T4 lymphocyte, the single-stranded viral RNA is used as a template to synthesize double-stranded proviral DNA. HIV virions come "prepackaged" with reverse transcriptase, the enzyme necessary to perform this critical step. Because reverse transcriptase is a viral enzyme not found in human cells, researchers have been able to design drugs with the ability to selectively inhibit viral replication.

The synthesizing of proviral DNA requires biochemical building blocks known as nucleosides and nucleotides. Nucleosides and nucleotides form the backbone of the DNA molecule and are composed of the four bases, adenine, guanine, thymine, and cytosine. These same nucleosides and nucleotides are used to make human DNA.

Drugs in the nucleoside and nucleotide reverse transcriptase inhibitor classes (NRTIs and NtRTIs) chemically resemble the natural building blocks of DNA. In essence, reverse transcriptase is "tricked" into inserting these drugs into the proviral DNA strand. When the "fake" nucleosides and nucleotides are used to build DNA, however, the proviral DNA chain is prematurely terminated. Hence, the viral DNA chain is unable to insert into the host chromosome. Reverse transcriptase inhibitors (NRTIs and NtRTIs) have less effect on the progression of the infection if the proviral DNA has already been integrated into the host chromosome.

Of the 25 medications available for HIV infection, tenofovir and emtricitabine are the most effective drugs for reducing viral load and are included in nearly all treatment guidelines for the initial therapy. With the exception of zidovudine, which may occasionally be used as monotherapy to prevent the perinatal transmission of HIV, the NRTIs and NtRTIs are always used in multidrug combinations with drugs from other classes.

The NRTIs are prodrugs. They must first be metabolized to their active, triphosphate form inside their target

cells before they become effective. Unlike many other antiretrovirals, the NRTIs do not interact extensively with other drugs undergoing hepatic metabolism. The NtRTIs are nucleotide inhibitors that are already in their active, triphosphate forms; thus, no metabolic activation is necessary. Tenofovir is the only NtRTI approved for HIV therapy although a second drug in this class, adefovir, is available for treating hepatitis B virus (HBV) infection.

As a class, the NRTIs are well tolerated, although nausea, vomiting, diarrhea, headache, and fatigue are common during the first few weeks of therapy. Some of the serious adverse effects of NRTIs are caused by **mitochondrial toxicity**. NRTIs inhibit a human enzyme called gamma-polymerase, which is responsible for the replication of DNA in mitochondria. This small, obscure DNA molecule encodes subunits for mitochondrial enzymes in the respiratory chain, which generates ATP. All the NRTIs have been associated with a low incidence of an unusual form of mitochondrial toxicity known as lactic acidosis–severe hepatomegaly with steatosis. This syndrome, which occurs more commonly in women and in those with preexisting hepatic impairment, includes lipid deposits in the liver, elevated transaminase values, and possible hepatic failure. Symptoms are often vague and include nausea, right upper quadrant (RUQ) pain, and myalgia. The nurse must carefully monitor liver function tests and assess for hepatic disease, because some fatalities have resulted from this adverse effect.

Another manifestation of mitochondrial toxicity from NRTIs is **lipodystrophy**, a disorder in which fat is redistributed in specific areas of the body. Areas such as the face, arms, and legs tend to lose fat, while the abdomen, breasts, and base of the neck (buffalo hump) develop excess fat. The fat redistribution may be associated with hyperlipidemia and hyperglycemia. In 2010, the U.S. Food and Drug Administration (FDA) approved tesamorelin (Egrifta), a drug similar to growth hormone that is prescribed to reduce the excess abdominal fat in patients with lipodystrophy who are infected with HIV.

PROTOTYPE DRUG Zidovudine (AZT, Retrovir)

Classification **Therapeutic:** Antiretroviral
Pharmacologic: Nucleoside reverse transcriptase inhibitor

Therapeutic Effects and Uses: Zidovudine was first discovered in the 1960s and its antiviral activity was demonstrated prior to the AIDS epidemic. It was approved in 1987 for the treatment of HIV infection in combination with other antiretrovirals, as well as for prevention of the transmission of HIV from mother to fetus or neonate.

Because of its widespread use since the beginning of the AIDS epidemic, HIV strains resistant to zidovudine are common. There is a high degree of cross resistance between zidovudine and other NRTIs. Current treatment guidelines for patients newly diagnosed with HIV infection do not include zidovudine as a first-line drug due to the potential for resistance. Zidovudine is frequently prescribed with other antiretrovirals to lower the viral burden in pregnant patients and for the prophylactic treatment of newborns who may have been exposed to HIV.

Mechanism of Action: Structurally, zidovudine resembles thymidine, one of four nucleoside building blocks of DNA. As the reverse transcriptase enzyme begins to synthesize viral DNA, it mistakenly uses zidovudine instead of thymidine, thus terminating the growing chain and creating a defective proviral DNA strand.

Pharmacokinetics:

Route(s)	Intravenous (IV), oral (PO)
Absorption	Readily absorbed
Distribution	Widely distributed, including the cerebrospinal fluid (CSF); secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Peak effect: 1–2 h
Duration of action	Half-life: 1 h

Adverse Effects: Many patients experience headache, anorexia, nausea, and diarrhea. Patients may report fatigue, myalgia, and generalized weakness. It is often difficult to determine if adverse effects are due to zidovudine, other drugs the patient is taking concurrently, or the progression of the HIV infection. **Black Box Warnings:** Rare cases of fatal lactic acidosis with severe hepatomegaly and steatosis have been reported with zidovudine and other drugs in this class. Bone marrow suppression may result in neutropenia or severe anemia. Myopathy may occur with long-term use.

Contraindications/Precautions: Because zidovudine can suppress bone marrow function after 4 to 6 weeks of therapy, it should be used with caution in patients with preexisting anemia or neutropenia. Blood counts and other laboratory blood tests should be monitored frequently during therapy to prevent hematologic toxicity. Patients with significant chronic kidney disease (CKD) or hepatic impairment require a reduction in dosage, because zidovudine may accumulate to toxic levels in these patients. Breastfeeding should be suspended because both the virus and the drug may be transmitted through breast milk. Discontinuation of therapy should always be conducted under the guidance of a healthcare provider.

Drug Interactions: Zidovudine interacts with many drugs. Concurrent administration with other drugs that depress bone marrow function, such as ganciclovir, interferon-alfa, dapsone, flucytosine, or vincristine, should

be avoided due to cumulative immunosuppression. Ribavirin and doxorubicin compete for intracellular activation sites and will diminish the effects of zidovudine. Probenecid, fluconazole, atovaquone, valproic acid, amphotericin B, and aspirin increase the blood levels of zidovudine and may increase the adverse effects of the antiretroviral. Other antiretroviral drugs may contribute to the lactic acidosis and hepatomegaly caused by zidovudine. **Herbal/Food:** Zidovudine should be used with caution with herbal supplements such as St. John's wort, which may cause a decrease in antiretroviral activity.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving zidovudine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antiretrovirals.

Drugs Similar to Zidovudine (AZT, Retrovir)

Other NRTIs and NtRTIs include abacavir, didanosine, emtricitabine, lamivudine, stavudine, and tenofovir. All of the NRTIs and NtRTIs are used in combination with other antiretrovirals. Fixed-dose combinations with NRTIs and NtRTIs are shown in Table 55.2

All drugs in this class carry a black box warning for lactic acidosis and severe hepatomegaly with steatosis. Some carry additional warnings.

Abacavir (Ziagen): Abacavir chemically resembles the natural nucleoside guanosine and is indicated for the treatment of HIV infection as part of a multidrug regimen. Approved in 1998, it is given PO once or twice daily and is widely distributed throughout the body, including the CSF.

The most common adverse effects are gastrointestinal (GI) and include nausea, vomiting, anorexia, and diarrhea. Alcohol use during abacavir therapy should be avoided, because blood levels of the antiretroviral can increase as much as 40%. Abacavir carries a black box warning regarding the potential for hypersensitivity reactions. This unique hypersensitivity syndrome occurs in 4% to 6% of patients taking the drug. Symptoms, which include fever, rash, dyspnea, cough, or GI distress, occur within the first 6 weeks of treatment. It is essential that these symptoms be monitored and the medication immediately discontinued should allergy be suspected, because deaths have been recorded from this syndrome. This drug is pregnancy category C.

Didanosine (ddI, Videx EC): Approved in 1991, didanosine chemically resembles the naturally occurring nucleoside inosine and is indicated for the treatment of HIV infection as part of a multidrug regimen. Given orally once daily, it should be administered on an empty stomach to enhance absorption. Didanosine is not a preferred drug for treating HIV.

Diarrhea and peripheral neuropathy involving numbness and tingling in the hands and feet are common adverse effects occurring in over 20% of patients taking the drug. This drug has black box warnings that include pancreatitis, which may occur in up to 10% of patients. Patients should be carefully monitored for signs and symptoms that may suggest pancreatitis, such as nausea, vomiting, elevated serum amylase, and increased serum triglycerides, because deaths have occurred due to this disorder. This drug is pregnancy category B.

Emtricitabine (Emtriva): Approved in 2003, emtricitabine is a cytosine analog, also known as FTC, which is approved for the treatment of HIV infection as part of a multidrug regimen. Although chemically similar to lamivudine, it has the advantages of once-daily dosing and fewer adverse effects. The most frequently reported adverse effects are nausea, headache, dizziness, depression, rhinitis, skin rash, and skin discoloration on the palms and soles. Of the NRTIs, emtricitabine is believed to have the least mitochondrial toxicity. Emtricitabine carries a black box warning that it should not be administered to patients coinfected with HBV because severe exacerbations of HBV symptoms may occur after discontinuation of emtricitabine. Emtricitabine is a first-line drug for initial HIV therapy. This drug is pregnancy category B.

Lamivudine (Epivir, 3TC): Also known as 3TC, lamivudine is a chemical analog of cytosine, a naturally occurring nucleoside. Approved in 1995, lamivudine is rapidly absorbed PO and better tolerated than most NRTIs. Minor adverse effects include transient insomnia and headache. Because serious adverse effects from lamivudine are uncommon, it has been a widely used component of ART regimens. This drug is also approved for treatment of HBV (Epivir HBV) (see Chapter 54). An off-label indication is for HIV prophylaxis following perinatal or suspected occupational exposure to HIV. Its primary disadvantage is rapid emergence of resistance. A black box warning states that severe exacerbations of HBV illness may occur when the drug is withdrawn from patients infected with HIV. This drug is pregnancy category C.

Stavudine (d4T, Zerit): Approved in 1994, stavudine is a chemical analog of thymidine, a naturally occurring nucleoside that is approved for the treatment of HIV infection as part of a multidrug regimen. Given orally, the use of stavudine has declined because the drug exhibits greater mitochondrial toxicity than others in this class. Of special concern is a high degree of lipodystrophy, evidenced by excessive loss of fat tissue, which persists long after the drug is discontinued. Headache and peripheral neuropathy occur in 50% or more of patients taking the drug. A black box warning includes serious pancreatitis that may occur if this drug is given concurrently with didanosine. This drug is pregnancy category C.

Tenofovir (Viread): Approved in 2001, tenofovir is an NtRTI that is indicated in combination with other antiretrovirals for the treatment of HIV infection in adults and children 2 years of age and older. Tenofovir is administered PO on an empty stomach to increase absorption. Tenofovir is a preferred drug for the initial treatment of HIV infection and chronic HBV infection, for which it is a prototype drug in Chapter 54.

The most frequently reported adverse effects of tenofovir are nausea, vomiting, depression, and diarrhea. Because tenofovir has less effect on mitochondrial enzymes than other drugs in this class, it is better tolerated. Tenofovir disoproxil can lower bone mineral density, placing the patient at risk for osteopenia or bone fractures. Due to nephrotoxicity, the use of tenofovir disoproxil in patients with CKD should be carefully monitored, and it should be used cautiously in patients receiving other nephrotoxic drugs. A black box warning states that severe exacerbations of HBV illness may occur when tenofovir is withdrawn from patients with HIV infection. This drug is pregnancy category B.

In 2016, a new salt of tenofovir became available. Tenofovir disoproxil is the original salt that has been proven highly effective in clinical practice. The new formulation, tenofovir alafenamide, has equivalent effectiveness but exhibits fewer adverse effects on the kidney and on bone mineral density. Tenofovir alafenamide is available as monotherapy (Vemlidy) for the treatment of chronic hepatitis B infection. To treat HIV infection, the drug is available in several fixed-dose combinations (see Table 55.2).

55.5 The nonnucleoside reverse transcriptase inhibitors inhibit viral DNA replication by binding to reverse transcriptase.

The nonnucleoside reverse transcriptase inhibitors (NNRTIs) act by a mechanism distinct from the NRTIs. Drugs in this class bind in proximity to the active site of reverse transcriptase, causing a change in shape of the enzyme molecule. Because of this structural change, reverse transcriptase is unable to add more nucleotides to the proviral DNA chain, resulting in a direct inhibition of enzyme function.

Because resistance develops rapidly to NNRTIs, they are always used in combination with other antiretrovirals. Resistance to one NNRTI usually confers resistance to all drugs in this class.

The NNRTIs are generally well tolerated and exhibit few serious adverse effects. The adverse effects are different than those of the NRTIs. Rash is common with NNRTIs and rare cases of Stevens–Johnson syndrome (SJS) have been reported. They all affect hepatic metabolism, increasing the risk of drug–drug interactions. Liver function should be regularly assessed, especially in patients with preexisting liver disease.

PROTOTYPE DRUG Efavirenz (Sustiva)

Classification **Therapeutic:** Antiretroviral
Pharmacologic: Nonnucleoside reverse transcriptase inhibitor

Therapeutic Effects and Uses: Approved in 1998, efavirenz is given PO in combination with other antiretrovirals in the treatment of HIV infection. Efavirenz has the advantage of once-daily dosing and penetration into the CSF. In 2013, the indications for efavirenz were extended to include pediatric patients who are 3 months or older and weigh at least 3.5 kg (7.7 lb).

Resistance to NNRTIs can develop rapidly and cross resistance among drugs in this class can occur. High-fat meals increase the absorption by over 20%, which may result in toxicity. Because of this, efavirenz should be taken on an empty stomach.

Mechanism of Action: Efavirenz binds directly to reverse transcriptase, disrupting the shape of the enzyme's active site. This inhibition prevents viral DNA from being synthesized from HIV RNA.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed
Distribution	Widely distributed, including the CSF; unknown if secreted in breast milk; 99% bound to plasma protein
Primary metabolism	Hepatic (CYP3A4 and CYP2B6)
Primary excretion	Renal
Onset of action	Peak effect: 3–5 h
Duration of action	Half-life: 52–76 h

Adverse Effects: Central nervous system (CNS) adverse effects are observed in at least 50% of patients when first initiating therapy, including sleep disorders, nightmares, dizziness, reduced ability to concentrate, and delusions. The CNS adverse effects usually diminish after 3 to 4 weeks of therapy. Like other drugs in this class, rash is common and must be monitored carefully.

Contraindications/Precautions: Efavirenz causes birth defects and should not be given to pregnant patients unless the benefits outweigh the risk to the fetus. Patients in the childbearing years should be advised to use reliable methods of birth control to avoid pregnancy. Contraceptive measures should continue for 12 weeks after the drug is discontinued. Liver function should be monitored during therapy due to the risk for hepatotoxicity. Efavirenz should be used cautiously in patients with a history of seizures.

Drug Interactions: Efavirenz induces CYP3A4 and can interact with drugs that are substrates for, or antagonists of,

this isozyme. Patients who are receiving antiepileptic medications metabolized by the liver, such as carbamazepine, phenytoin, and phenobarbital, may require periodic monitoring of plasma levels because efavirenz may increase the incidence of seizures. Efavirenz can decrease serum levels of the following: statins, methadone, sertraline, and calcium channel blockers. The CNS adverse effects of efavirenz are worsened if the patient takes psychotropic drugs or consumes alcohol. Levels of warfarin may either increase or decrease. **Herbal/Food:** Efavirenz should be used with caution with herbal supplements, such as St. John's wort, which may cause a decrease in antiretroviral activity.

Pregnancy: Category D.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving efavirenz are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antiretrovirals.

Drugs Similar to Efavirenz (Sustiva)

Other NNRTIs include delavirdine, etravirine, nevirapine, and rilpivirine.

Delavirdine (Rescriptor): Approved in 1997, delavirdine is given orally and is very similar to other NNRTIs in actions and adverse effects. It may be administered with or without food. Delavirdine is infrequently prescribed because it must be administered 3 times per day and does not appear to be as effective as nevirapine or efavirenz. Many patients taking this drug develop a skin rash. In most cases, this rash disappears after several weeks of therapy, but it must be monitored carefully because cases of SJS have been reported in patients receiving this drug. GI distress, headache, and fatigue are also common adverse effects. Because delavirdine can decrease hepatic metabolism, many drug–drug interactions are possible, including those listed for efavirenz. This drug is pregnancy category C.

Etravirine (Intelence): Approved in 2008, etravirine is used in combination with other antiretroviral drugs in the pharmacotherapy of HIV infection. It is approved only for treatment-experienced adults. Because the fasting state can increase absorption of the drug significantly and cause potential toxicity, it should always be taken with food. It is excreted primarily in the feces; therefore, no dose adjustment is necessary in patients with CKD. Because etravirine can decrease hepatic metabolism, many drug–drug interactions are possible, including those listed for efavirenz. The drug does not exhibit the hepatotoxicity of nevirapine or the CNS toxicity of efavirenz. The drug is generally well tolerated, with the most frequently reported adverse effect being rash. This drug is pregnancy category B.

Nevirapine (Viramune): Nevirapine was approved in 1996 for the treatment of HIV infection in combination with other antiretroviral drugs. By inducing CYP450 enzymes, nevirapine increases its own breakdown; thus, dosage may need to be increased after several weeks of therapy to maintain its effectiveness. In addition, because the metabolism of protease inhibitors is decreased, dosage adjustments in these antiretrovirals may be necessary. Unlike some other antiretrovirals that negatively impact lipid metabolism, nevirapine may improve the lipid profile by increasing high-density lipoprotein (HDL) levels. Common adverse effects include nausea, diarrhea, fever, fatigue, and rash, which is occasionally severe enough to require discontinuation of therapy. A black box warning states that during the first 18 weeks of therapy, the patient should be carefully monitored for hepatic function due to potentially life-threatening hepatotoxicity. Patients with a history of hepatitis or other liver disease are at greater risk for nevirapine-induced hepatotoxicity. In addition, severe dermal reactions, including SJS, have been reported. Serum transaminase levels should be checked for all patients developing a rash in the first 18 weeks. This drug is pregnancy category C.

Rilpivirine (Edurant): Rilpivirine was approved in 2011 for the treatment of HIV infection in treatment-naïve patients with HIV RNA levels of 100,000 copies/mL or less at the start of therapy. It is a PO drug that offers the convenience of once-daily dosing. The most common adverse effects are depression, insomnia, headache, and rash. Patients should be monitored for possible suicide ideation during therapy. Liver function should be monitored during therapy due to the risk for hepatotoxicity. Because rilpivirine can decrease hepatic CYP metabolism, many drug–drug interactions are possible. This drug is pregnancy category B.

55.6 Protease inhibitors prevent HIV protease from completing the final step in HIV maturation.

Near the end of its replication cycle, HIV has synthesized all the necessary components to create new virions. As the newly formed virions bud from the host cell and are released into the surrounding extracellular fluid, one final step remains before the HIV matures and becomes infectious: A long polypeptide chain must be cleaved to produce the final HIV proteins. The enzyme performing this step is HIV protease.

Drugs in the protease inhibitor (PI) class attach to the active site of HIV protease, thus preventing the final synthesis of HIV proteins. Without this final step in HIV maturation, the virions are noninfectious. When combined with other antiretroviral drug classes in an ART regimen, the PIs are capable of lowering plasma HIV RNA levels to an undetectable range. The PIs are included in most treatment guidelines for the treatment of HIV infection.

PIs are metabolized in the liver and induce hepatic enzymes; thus, they have the potential to interact with

numerous medications. In general, they are well tolerated, with GI complaints being the most common adverse effects. Lipodystrophies have been reported, including elevated cholesterol and triglyceride levels, and abdominal obesity. Some of the PIs are associated with hyperglycemia and can cause diabetes or worsen existing diabetes. Blood glucose levels should be monitored regularly in patients taking PIs.

The available PIs are very similar but there are some noticeable differences in pharmacokinetic properties and adverse effect profiles. Darunavir (boosted with ritonavir) is a first-line drug for the initial therapy of HIV. Cross resistance among the PIs may occur.

The initial choice of a primary PI most often includes low doses of ritonavir, which is classified as a pharmacokinetic booster or enhancer. Addition of small amounts of ritonavir allows longer dosing intervals and increases the plasma concentration of the primary PI.

PROTOTYPE DRUG Lopinavir with Ritonavir (Kaletra)

Classification **Therapeutic:** Antiretroviral
Pharmacologic: Protease inhibitor

Therapeutic Effects and Uses: Approved in 2000, Kaletra is a combination drug containing the protease inhibitors lopinavir and ritonavir. Lopinavir is the active component of the combination. Ritonavir inhibits the hepatic breakdown of lopinavir, thus permitting serum levels of lopinavir to increase by more than 100-fold. Kaletra tablets may be taken with or without food, but the oral solution form must be taken with a meal to enhance absorption. It has an extended half-life that allows for once- or twice-daily dosing.

Mechanism of Action: By effectively inhibiting HIV protease, the final step in the assembly of an infectious HIV virion is prevented.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed (but quickly destroyed through hepatic first-pass metabolism)
Distribution	Widely distributed; 98% bound to plasma proteins
Primary metabolism	Hepatic (lopinavir is metabolized by CYP3A; ritonavir inhibits CYP3A)
Primary excretion	Renal (10%); feces (83%)
Onset of action	Peak effect: 3–4 h
Duration of action	Half-life: 5–6 h

Adverse Effects: Kaletra is well tolerated, with the most frequently reported problem being diarrhea. Headache and GI-related effects are common, including nausea, vomiting, dyspepsia, and abdominal pain. Kaletra may cause or worsen symptoms of diabetes mellitus, and hyperglycemia has been reported. Lipodystrophy syndrome occurs in many patients receiving long-term therapy with PIs and large increases in total cholesterol and triglycerides may occur during therapy. This syndrome is associated with hyperglycemia and fat redistribution. Kaletra should be used with caution in patients with cardiac disease because the drug can prolong the PR interval and cause third-degree heart block. Pancreatitis is a rare, though potentially fatal, adverse event.

Contraindications/Precautions: Because of its extensive hepatic metabolism, patients with liver impairment, especially those with preexisting viral hepatitis, should be carefully monitored. Hepatic enzyme levels should be regularly evaluated in these patients to prevent hepatic failure. Patients with diabetes should be monitored regularly because Kaletra may exacerbate this condition.

Drug Interactions: Lopinavir is extensively metabolized by hepatic CYP3A, and drugs that undergo hepatic metabolism may interact with Kaletra. Drugs that increase hepatic CYP450 enzymes will reduce the effectiveness of the antiretroviral. These include nevirapine, efavirenz, barbiturates, rifampin, rifabutin, phenytoin, and carbamazepine. Conversely, drugs that inhibit the CYP450 enzymes will increase levels of lopinavir, including alfuzosin, ketoconazole, delavirdine, indinavir, and ritonavir. Statins should not be administered with Kaletra due to an increased risk for myopathy. Concurrent use of rifampin may lower the effectiveness of Kaletra. Potentially life-threatening dysrhythmias may occur if Kaletra is used concurrently with cisapride, pimozide, and certain other antidysrhythmic drugs. Kaletra may increase adverse effects associated with selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, and phenothiazines. **Herbal/Food:** St. John's wort should be used with caution, because it may decrease antiretroviral activity.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving lopinavir with ritonavir are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antiretrovirals.

Drugs Similar to Lopinavir with Ritonavir (Kaletra)

Other PIs include atazanavir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, and tipranavir. Amprenavir (Agenerase) has been discontinued in the United States.

Atazanavir (Reyataz): Approved in 2003, atazanavir offers the advantages of once- or twice-daily dosing and fewer adverse

effects on lipid levels than other PIs. Headache, insomnia, dizziness, myalgia, depression, fever, and nausea are common adverse effects. Atazanavir increases bilirubin levels, and cholelithiasis is possible. Liver function should be regularly monitored during therapy. Atazanavir has been shown to prolong the PR interval of the electrocardiogram (ECG) and produce first-degree atrioventricular block and other conduction abnormalities. The drug should be discontinued if rash occurs due to the risk for SJS. Atazanavir may cause hyperglycemia and worsen the symptoms of diabetes. Other adverse effects, contraindications, and drug interactions are similar to those of lopinavir. This drug is pregnancy category B.

Darunavir (Prezista): Approved in 2006, the PI darunavir is indicated for the treatment of HIV infection in adults and in pediatric patients ages 6 years and older. Darunavir must be concurrently administered with ritonavir. Although cross resistance has been reported, darunavir retains some activity against viral strains resistant to other PIs. Because both darunavir and ritonavir decrease hepatic metabolism, numerous drug–drug interactions are possible. Darunavir should be administered with food to increase its absorption. Diarrhea, nausea, vomiting, rash, and headache are the most common adverse effects. Because drug-induced hepatitis has been reported with this drug, hepatic enzymes should be monitored regularly. Severe rashes are possible, and these call for discontinuation of therapy. Other adverse effects, contraindications, and drug interactions are similar to those of lopinavir. This drug is pregnancy category B.

Fosamprenavir (Lexiva): Approved in 2003, fosamprenavir is administered with low doses of ritonavir as a booster. Both tablet and oral solution formulations are available and fosamprenavir may be taken with or without food. Like other PIs, fosamprenavir affects the hepatic metabolism of many drugs, making interactions likely. The drug can cause hyperglycemia and thus should be used cautiously in patients with diabetes. Other adverse effects, contraindications, and drug interactions are similar to those of lopinavir. This drug is pregnancy category C.

Indinavir (Crixivan): Approved in 1996, indinavir is used to treat HIV infection. It is administered PO, usually with a high-fat meal to increase drug absorption. It has a short half-life that requires 3 doses per day. Boosting with low doses of ritonavir is recommended. Like other PIs, indinavir should be used cautiously in patients with diabetes due to the risk of hyperglycemia. The most serious potential adverse effect is the formation of crystals in the urine, causing nephrolithiasis, which is unique among the protease inhibitors. Renal function should be monitored regularly and the patient should be encouraged to consume adequate amounts of fluid to dilute the urine in order to prevent crystalluria. Because indinavir can decrease the hepatic metabolism of drugs, numerous drug–drug interactions are possible. This drug is pregnancy category C.

Nelfinavir (Viracept): Approved in 1997, nelfinavir was one of the most frequently used PIs for many years. Its use has declined because newer PIs offer a lower pill burden and fewer adverse effects. Nelfinavir is given PO, usually with meals, in order to increase drug absorption. Unlike some other antiretrovirals, nelfinavir is 98% bound to plasma proteins and excreted almost entirely in the feces. Because large amounts of the drug and its metabolites reach the colon, severe diarrhea is possible and antidiarrheal medications may be indicated. Patients taking oral contraceptives should be advised to use a second method of birth control, because nelfinavir decreases plasma levels of ethinyl estradiol. Patients with diabetes should be monitored carefully due to the hyperglycemic effect of the antiretroviral. This drug is pregnancy category B.

Ritonavir (Norvir): Approved in 1995, ritonavir is well absorbed orally and is available in both capsule and solution formulations. The use of ritonavir is limited to enhancing the function of other PIs. The drug undergoes extensive hepatic metabolism and is excreted primarily in the feces. Like other PIs, ritonavir inhibits CYP450 hepatic metabolizing enzymes, which reduces the elimination of many drugs. When acting by this mechanism, ritonavir is called a pharmacokinetic enhancer or booster. This is used to advantage in dual PI regimens. Giving low doses of ritonavir to boost serum levels of other PIs permits lower doses of the second PI. Ritonavir increases several other drug-metabolizing enzymes in the liver; therefore, drug–drug interactions are common.

Most of the adverse effects of ritonavir are GI related and may limit therapy. Peripheral and perioral paresthesias are possible. Because ritonavir induces enzymes that increase its own metabolism, its effectiveness will diminish unless doses are increased. This drug is pregnancy category B.

Saquinavir (Invirase): Saquinavir was the original protease inhibitor approved by the FDA in 1995. Boosting with ritonavir increases the serum levels of saquinavir, making the drug more effective. Resistance to saquinavir develops with continued use and may include cross resistance with other PIs. Saquinavir is well tolerated, with the most frequently reported problems being GI related, such as nausea, vomiting, dyspepsia, and diarrhea. Other adverse effects are similar to those of lopinavir. Because of its extensive hepatic metabolism, patients with liver impairment should be carefully monitored. This drug is pregnancy category B.

Tipranavir (Aptivus): Approved in 2005, tipranavir is indicated for the management of HIV infection in treatment-experienced patients and those with strains of HIV that are resistant to more than one PI. To boost antiretroviral activity, it is administered with ritonavir. Tipranavir capsules and solution can be taken without regard to food but the tablets should be taken with a high-fat meal to enhance absorption. The most common adverse effects are diarrhea, nausea, pyrexia, vomiting, fatigue, headache, and abdominal pain.

Tipranavir contains sulfur and should be used with caution in patients with allergies to sulfa drugs. Tipranavir has been associated with the development or worsening of diabetes, elevations in cholesterol and triglycerides, and lipodystrophies. Tipranavir inhibits platelet aggregation and should be used with caution in patients who may be at risk of increased bleeding from trauma, surgery, or other medical conditions or who are receiving anticoagulants or antiplatelet drugs. The drug should be discontinued if a severe skin rash occurs. Black box warnings state that tipranavir has been associated with intracranial hemorrhage. Caution should be used when prescribing it to patients with elevated transaminases or preexisting hepatic impairment. The black box warning also notes that patients coinfected with HBV or hepatitis C (HCV) have a higher risk for hepatotoxicity. This drug is pregnancy category C.

55.7 Entry inhibitors and integrase inhibitors are newer strategies for managing HIV infections.

Because HIV develops resistance to many of the frequently prescribed antiretrovirals, scientists have been looking intensively for unique mechanisms of drug action. In recent years, several such mechanisms have been discovered. The role of these drugs in treating HIV infection is evolving.

Entry inhibitors: Entry inhibitors block the entry of the viral nucleic acid into the T4 lymphocyte. The two drugs in this class block the entry of HIV by different mechanisms.

Approved in 2003, enfuvirtide (Fuzeon) blocks the fusion of the viral membrane with the bilipid layer of the host's plasma membrane, a step required for entry of the virus. Because this mechanism is very different from other antiretrovirals, patients resistant to other drug classes may be sensitive to the effects of enfuvirtide. The use of enfuvirtide is limited because it is expensive to manufacture and it is given by subcutaneous injection twice daily. Its current use is for treating HIV infections in treatment-experienced patients with strains resistant to other antiretrovirals. Almost every patient taking enfuvirtide will experience an injection-site reaction, usually during the first week of therapy. These reactions may involve severe pain, pruritus, erythema, cysts, abscesses, and cellulitis. Nausea, diarrhea, and fatigue are other common adverse effects. Patients should be carefully monitored for lung infections because an increased incidence of pneumonia has been reported in patients taking enfuvirtide. No significant drug interactions have been found with enfuvirtide. This drug is pregnancy category B.

The second entry inhibitor, maraviroc (Selzentry), was developed in 2007 after scientists discovered that HIV needs coreceptors (in addition to the CD4 receptor) to enter human cells. CCR5 is the name of one of the coreceptors required for entry. Maraviroc is the first of a new class of HIV drugs called CCR5 coreceptor antagonists. This drug blocks CCR5 and has the ability to significantly reduce viral load and increase T-cell production. Before treatment is initiated the patient must receive a tropism assay, which is used to determine if the strain of HIV has the CCR5 receptor (CCR5-tropic HIV).

Maraviroc may be administered with or without food. It is approved for combination therapy with other antiretrovirals in treatment-naïve patients. The drug is well tolerated, with the most frequently reported adverse effects being upper respiratory tract infections, cough, pyrexia, rash, and dizziness. Caution should be used when administering this drug to patients with preexisting cardiac disease because the drug may increase the risk for myocardial ischemia or infarction. Maraviroc carries a black box warning regarding the possibility of hepatotoxicity, which may be preceded by signs of a systemic allergic reaction. This drug is pregnancy category B.

Integrase inhibitors: In 2007, the FDA approved the first drug in a class of antiretrovirals called the integrase inhibitors. HIV requires the integrase enzyme to insert its viral DNA strand into the human chromosome. These drugs are sometimes called integrase strand transfer inhibitors (ISTIs). The integrase inhibitors have become first-line antiretrovirals for the therapy of treatment-naïve patients.

Raltegravir (Isentress), the first integrase inhibitor, is indicated for combination therapy with other antiretroviral drugs for the treatment of HIV infection in adult patients. It may be administered with or without food. Insomnia, fatigue, headache, and GI-related symptoms such as diarrhea and nausea are the most frequently reported adverse effects. Caution should be used when administering this drug to patients with myopathy or rhabdomyolysis because raltegravir may worsen these conditions. This drug is pregnancy category C. Other integrase inhibitors include dolutegravir (approved in 2014) and elvitegravir (approved in 2012).

Prophylaxis of HIV Infections

55.8 The development of vaccines to prevent HIV has produced disappointing results.

Early in the history of the AIDS epidemic, scientists were optimistic that vaccines could be quickly developed that would prevent the spread of HIV infection. After all, scientists had totally eradicated the smallpox virus as a human threat and essentially controlled major viral infections such as measles and mumps. Such a vaccine could be given in childhood, offering lifetime protection against the fatal disease.

After decades of research, the FDA has not approved a single effective vaccine. Only a few HIV vaccines are currently in clinical trials, and none is expected to have a major impact on the HIV epidemic. At best, the HIV vaccines produced thus far only boost the immune response; they are unable to prevent the infection. While this may help a patient already infected with the virus to better control the disease, it does not prevent new infections. Why is this the case?

HIV has an extremely rapid replication rate, combined with a high "error" or mutation rate. While creating new viral DNA at a breakneck pace, reverse transcriptase frequently inserts an incorrect nucleotide. It is estimated that, given the size of the HIV genome at 10,000 base pairs, every possible mutation probably occurs at every nucleotide daily in an untreated patient. These errors create huge numbers of genetic variants, or mutant strains, with new and different characteristics from the original. It is not unusual to find dozens of genetic variants of HIV replicating within the same patient. Thus, vaccine development, and indeed antiretroviral therapy, is trying to hit a "moving target" that is changing its genetic makeup literally every minute.

Also challenging is determining the most effective type of vaccine for HIV. The classic type of vaccine uses live, attenuated viruses because this mimics a natural exposure and produces the greatest immunologic response (see Chapter 43). However, given the extreme rate of HIV mutation, scientists are concerned that an attenuated form of HIV could mutate back to a live form and infect the patient. Thus, the approach with HIV has been to take various fragments of the virus, such as envelope protein subunits and portions of HIV genes, and produce a vaccine "cocktail" to administer to the patient. Unfortunately, these mixes have so far proven ineffective at preventing infection.

An additional challenge is to produce a vaccine-mediated immune response that will reach viruses lying latent inside T cells. HIV-infected cells reside in virtually every compartment in the body and serve as reservoirs for the latent virus, protecting it from the immune response produced by the vaccine. How do scientists coax the immune system to recognize these infected cells and dispose of them? Perhaps a better question is: Can a vaccine be designed to prevent the entry of the virus into cells to begin with? And how can this vaccine be ethically tested, since no animal has the same immune system as humans to serve as an experimental model?

Vaccine research has not been a total failure. Scientists have learned an enormous amount about the immune system's response to HIV infection. This has promoted the development of new drugs and advanced our understanding of how to treat and control the infection. It is likely that a preventive vaccine will become available in the future, but not soon enough for the millions already infected.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antiretrovirals

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic, or renal disease, and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Obtain a vaccination history, especially a history of recent vaccinations with live agents. Be alert to possible drug interactions.
- Assess signs and symptoms of current infection, noting onset, duration, characteristics, and presence or absence of fever or pain.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], CD4 count, HIV viral load, culture and sensitivity [C&S] for any concurrent infections, hepatic and renal function studies, lipid levels, serum amylase, and glucose).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., CD4 counts and HIV viral load remain within acceptable limits, able to attend to normal activities of daily living [ADLs], absence of signs and symptoms of concurrent infections).
- Continue periodic monitoring of CBC, CD4 and HIV viral load, hepatic and renal function, lipid levels, serum amylase, and glucose.
- Assess for adverse effects: nausea, vomiting, anorexia, abdominal cramping, diarrhea, fatigue, drowsiness, dizziness, mental changes, insomnia, delusions, chills, fever, muscle or joint pain, paresthesia, hypotension, syncope, hyperglycemia. Severe diarrhea, jaundice, decreased urine output or darkened urine, purplish-red blistering rash on body or oral mucous membranes, acute abdominal pain, increasing mental or behavioral changes, or decreased level of consciousness (LOC) should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects: maintenance of normal or increasing appetite, increasing energy level and ability to maintain ADLs, CD4 counts and HIV viral load within acceptable limits and stabilized, and maintenance of therapeutic regimen. (Drugs will be required long term and have many potential adverse effects, making adherence to the medication regimen difficult.)	• Teach the patient to continue taking the course of medications, to not share doses with others, and to return to the healthcare provider if adverse effects make adherence to the therapeutic regimen difficult to continue. • Teach the patient to notify the provider if fever and signs and symptoms of concurrent infections increase, excessive fatigue is present, or adverse effects place adherence to drug therapy at risk.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Immediately report increasing fever, diarrhea, vomiting, dyspnea, tachycardia, dizziness, syncope, changes in behavior or LOC, or lethargy to the healthcare provider. (Increasing fever, especially when accompanied by worsening symptoms, may be a sign of worsening infection, adverse drug effects, or drug resistance.)	• Teach the patient, family, or caregiver to immediately report a fever that exceeds 33.8°C (101°F) or per parameters set by the healthcare provider, changes in behavior or LOC, shortness of breath, inability to maintain hydration or nutrition, or dizziness and fainting to the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBC, CD4 counts, HIV viral load, lipid levels, serum amylase, glucose, and C&S if concurrent infections are present. (Some drugs used for the treatment of HIV are hepatotoxic and nephrotoxic. Bone marrow suppression and blood dyscrasia, particularly anemia and leukopenia, are also adverse effects and will be monitored by CBC. Lipid levels and serum amylase will be monitored to assess for pancreatitis, and glucose levels checked for hyperglycemia.)	• Instruct the patient on the need for periodic laboratory work, correlating any symptoms with the need for possible laboratory tests (e.g., serum amylase if the patient is having upper abdominal pain). Advise laboratory personnel of HIV status.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of any antiretroviral or protease inhibitor. Continue to monitor the patient as needed based on drug used or patient condition. (Anaphylactic reactions are possible and reactions may not always be predictable.)	• Teach the patient to immediately report any itching, rashes, swelling, particularly of face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing.
• Continue to monitor for hepatic and renal toxicities; e.g., jaundice, RUQ pain, darkened urine, or diminished urine output. (Antiretrovirals and PIs may be hepatotoxic or nephrotoxic. **Lifespan:** Age-related physiologic differences may place older adults at greater risk for hepatotoxicity or nephrotoxicity. **Diverse Patients:** Because zidovudine is metabolized through the CYP450 system pathways, monitor ethnically diverse patients frequently to ensure optimal therapeutic effects and minimize adverse effects. Increasing fluid intake will prevent drug accumulation in the kidneys.)	• Teach the patient to immediately report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light- or clay-colored stools, diminished urine output, or darkening of urine. • Advise the patient to increase fluid intake to 2–3 L/day if permitted.
• Continue to monitor for dermatologic effects such as red or purplish skin rash, blisters, or peeling skin, including oral mucous membranes. Assess oral mucous membranes for signs of stomatitis because drug effects or immunosuppression may result in overgrowth of oral flora. Immediately report severe rashes, especially those associated with blistering. (These drugs may cause significant dermatologic effects including stomatitis, and SJS, a potentially fatal condition.)	• Teach the patient to inspect the oral cavity at least once a day and obtain regular dental examinations. Maintain good oral hygiene and rinse mouth with plain water or solution as prescribed by the healthcare provider after eating. Use protective clothing for sun exposure and immediately report any significant rashes or sunburned appearance.
• Monitor for signs and symptoms of neurotoxicity, e.g., drowsiness, dizziness, mental changes, insomnia, delusions, paresthesia, headache, changes in LOC, or seizures. (Some HIV drugs cause peripheral neuropathy and have neurologic adverse effects. Frequent monitoring is needed to prevent or minimize adverse effects.)	• Instruct the patient, family, or caregiver to immediately report increasing headache, dizziness, drowsiness, worsening insomnia, numbness of hands, feet, or extremities, or changes in behavior or LOC. • Caution the patient that drowsiness may occur and to be cautious with driving or other activities requiring mental alertness until the effects of the drug are known. • Instruct the patient to be cautious when in contact with heat or cold, because numbness from peripheral neuropathy may make sensing accurate temperatures more difficult. • Encourage sleep hygiene measures, e.g., restful routines before bed, and avoiding large meals within 1–2 h of sleep. Have the patient consult with the healthcare provider if insomnia causes daytime sleepiness or continues.
• Monitor for signs and symptoms of blood dyscrasias, e.g., low-grade fevers, bleeding, bruising, or significant fatigue. (Bone marrow suppression may occur and may cause blood dyscrasias with resulting decreases in red and white blood cells or platelets. Periodic monitoring of CBC will be required.)	• Teach the patient to report any low-grade fevers, sore throat, rashes, bruising or increased bleeding, unusual fatigue or shortness of breath, especially after taking drug therapy for a prolonged period.
• Monitor for, and immediately report, signs and symptoms of lactic acidosis. (Some antiretroviral drugs may cause lactic acidosis with hepatomegaly and steatosis. Lactic acidosis is a possible life-threatening adverse effect.)	• Teach the patient to immediately report symptoms such as abdominal pain, anxiety, fatigue, palpitations, lethargy, rapid breathing and heart rate, weakness, chest pain or tightness, fever, or shortness of breath to the provider.
• Monitor for significant GI effects, including nausea, vomiting, abdominal pain or cramping, and diarrhea. Administer drugs per guidelines. Additional pharmacologic treatment may be necessary to limit adverse GI effects. Ensure adequate nutrition and caloric intake. (Adverse GI effects are a common adverse effect of most antiretrovirals and PIs.)	• Teach the patient to take the drug with food or milk if appropriate, or to take the drug on an empty stomach with a full glass of water. Avoid acidic foods and beverages or carbonated drinks that may cause stomach upset. • Assist the patient in obtaining a dietary consultation as needed if nausea or diarrhea makes maintaining intake difficult.
• Monitor for symptoms of pancreatitis including severe abdominal pain, nausea, vomiting, and abdominal distention. (Some antiretroviral drugs may cause pancreatitis. Serum amylase and lipid levels should be monitored periodically.)	• Instruct the patient to immediately report fever, severe abdominal pain, nausea, vomiting, and abdominal distention.
• Monitor blood glucose in patients taking antiretrovirals. (Many antiretroviral drugs may cause hyperglycemia. Patients with diabetes may require a change in their antidiabetic drug routine.)	• Teach the patient with diabetes to test blood glucose level more frequently, reporting any consistent elevations to the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor cholesterol and triglyceride levels. For patients on long-term antiretroviral therapy, assess for fat distribution and effects on patient body image. Provide for counseling and support for body image concerns. (Lipodystrophy syndrome occurs in many patients receiving long-term therapy with many antiretroviral drugs, and large increases in total cholesterol and triglycerides may occur during therapy.)	• Instruct the patient on the need for periodic laboratory work. • Provide emotional empathy and referral to support services as needed (e.g., counseling services, nutritional support) if the patient expresses concerns about body image or overall health while on long-term antiretroviral therapy.
• Women of childbearing age should use an alternative form of birth control to prevent pregnancy. (Some antiretroviral drugs may significantly reduce the effectiveness of oral contraceptives.)	• Teach women of childbearing age on oral contraceptives to consult their healthcare provider about birth control alternatives.
• Provide resources for medical and emotional support. (Treatment requires a multidisciplinary approach.)	• Advise the patient about community resources and support groups. Assist the family or caregiver with respite care as needed.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient or family in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. The duration of the required therapy may be quite lengthy but it is necessary to prevent active infection. Do not stop taking the medicine when starting to feel better.
	  • Do not share the medicine with other family members. If there is reason to believe that family members need medication, they should be assessed by a healthcare provider.
	  • Eliminate alcohol while on these medications. These drugs cause significant reactions when taken with alcohol.
	  • Take the drug with food or milk if instructed to take with food, but avoid acidic beverages. If instructed to take the drug on an empty stomach, take with a full glass of water.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking these drugs.

CONNECTION Checkpoint 55.2

From what you learned in Chapter 43, explain the difference between active immunity and passive immunity. Which type of immunity would an HIV vaccine produce? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

55.9 Postexposure prophylaxis of HIV infection is designed to prevent transmission to healthcare workers.

Since the start of the AIDS epidemic, nurses and other healthcare workers caring for patients with HIV infection or AIDS have been concerned about acquiring the disease from their patients. Fortunately, if proper precautions are observed, the disease is rarely transmitted from patient to healthcare worker. Accidents have occurred, however, in which the healthcare provider has acquired the infection by exposure to the blood or body fluids of patients infected with HIV. Although the risk is small, the question remains: Can HIV transmission be prevented following unintentional occupational exposure to HIV? The answer is a qualified yes.

The success of postexposure prophylaxis (PEP) for occupational HIV exposure is difficult to assess due to the lack of controlled studies and the small numbers of cases. Enough data have accumulated, however, to demonstrate that PEP is successful in certain circumstances. For prevention to be most successful, PEP should be started within 72 hours after exposure to a source individual who is known to be HIV positive. Although the exact interval remains undefined, longer periods allow the infection to progress to stages where prophylaxis would not be successful. The healthcare worker should obtain a baseline HIV viral load as soon as possible after exposure.

If the HIV status of the source individual is unknown, PEP is decided case by case, based on the type of exposure (percutaneous or mucous membrane) and the likelihood the blood contained HIV. In some cases, PEP is initiated for a few days, until the source individual can be tested. PEP should be initiated only if the exposure was sufficiently severe and the source fluid is known, or strongly suspected, to contain HIV. Using PEP outside established guidelines is both expensive and dangerous; the antiretrovirals used for PEP produce adverse effects in most recipients.

Current research has not yet reached consensus on an optimal regimen for PEP. The following are proposed regimens:

- Raltegravir (Isentress) 400 mg PO twice daily plus Truvada (tenofovir disoproxil 300 mg/emtricitabine 200 mg) 1 PO once daily
- Dolutegravir 50 mg/day plus Truvada once daily.

Guidelines have also been established for the nonoccupational postexposure prophylaxis (nPEP) of HIV. These guidelines are largely based on animal studies and analysis of the existing data for occupational exposure. Because nPEP is expensive and may result in adverse drug effects, it is recommended only for specific nonoccupational exposures. First, the individual should have been exposed to the blood or body fluids of someone known to be infected with HIV. Second, the nature of the exposure must be such that there is a substantial risk for transmission. Third, the exposure must have occurred no later than 72 hours before antiretroviral therapy is initiated. The sooner nPEP is initiated, the more successful the outcome. The healthcare provider considers nPEP for exposures outside these guidelines on a case-by-case basis. Therapy recommended by the CDC includes a 28-day regimen with emtricitabine/tenofovir disoproxil plus raltegravir or dolutegravir. HIV status should be reassessed at 4 to 6 weeks, 3 months, and 6 months after exposure.

55.10 Preexposure prophylaxis has been shown to be partially effective in certain groups.

Significant research has been conducted to determine if HIV infection can be prevented by medications. The goal of preventing HIV infection is an important one to consider because prevention is always preferable to treatment. This type of therapy is called preexposure prophylaxis (PrEP).

Research has demonstrated that, if taken continuously on a daily basis, the two-drug combination of emtricitabine and tenofovir disoproxil can prevent HIV infection in men who have sex with men and for heterosexually active men and women at high risk for the infection. Based on this research, the CDC also recommends this regimen for intravenous drug users (CDC, 2013). The effectiveness of PrEP is difficult to determine, but likely ranges between 40% and 90%. It is clear that people should not expect pharmacotherapy alone to prevent this lethal infection, and that other protection measures or lifestyle changes must be implemented.

55.11 The risk of perinatal transmission of HIV can be markedly reduced by specialized drug protocols.

Treatment regimens for HIV infection do not differ between men and women. Because some antiretrovirals have pharmacokinetic interactions with oral contraceptives, a second method of birth control is recommended for HIV-infected patients..

Should pregnancy occur, the therapeutic outcomes focus on aggressively lowering the viral load in the mother while preventing the transmission of HIV to the unborn child. Reducing the viral load in the mother has been shown to reduce the risk of HIV transmission to the fetus. Indeed, women with effective viral suppression during pregnancy have less than a 1% risk of transmitting the virus to the baby.

Current guidelines recommend that antiretroviral therapy begin as early in pregnancy as possible (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2016). Recommended protocols for the pregnant woman include a combination of two NRTIs: zidovudine/lamivudine, abacavir/lamivudine, or tenofovir disoproxil/emtricitabine, with either an NNRTI (nevirapine) or a PI (lopinavir boosted with ritonavir). The specific regimen is adjusted based on resistance testing.

Regardless of the antepartum therapy, it is recommended that the woman receive a continuous infusion of zidovudine during labor. Zidovudine rapidly crosses the placenta. This may provide some protection for the fetus because most perinatal transmission of HIV occurs near to or during labor and delivery.

Therapy of neonates born to mothers infected with HIV should begin immediately after delivery, preferably 6 to 12 hours after delivery (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2016). HIV infection is established in infants by 1 to 2 weeks of age, and beginning antiretroviral therapy more than 48 hours after birth is less effective in preventing the infection. Current recommendations include the following:

- If the mother had been receiving antiretroviral therapy and viral load was suppressed prior to delivery, the infant receives 4 weeks of prophylactic zidovudine.
- If the mother had not been receiving antiretroviral therapy prior to delivery, the infant receives 6 weeks of zidovudine plus 3 doses of nevirapine. Many clinicians support adding a third drug to the regimen (lamivudine).

The CDC advises that mothers with HIV infection not breastfeed their infants, because this is a possible route of HIV transmission, and many antiretrovirals are secreted in breast milk (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2016). On the other hand, the World Health Organization (WHO) advises breastfeeding as long as the mother is taking antiretroviral drugs and there is little or no HIV-RNA in the mother's blood (WHO, 2016).

Although initial HIV antibody tests on the newborn may be positive, these antibodies may be due to maternal infection and not HIV infection in the child. Definitive diagnosis on infants less than 18 months of age requires virologic testing. If diagnostic testing reveals that the infant is not infected before the 6-week prophylactic treatment period is completed, zidovudine therapy is discontinued. On the other hand, if HIV diagnosis is confirmed during this period, the infant is switched to ART.

CONNECTIONS: Community-Oriented Practice

HIV Testing and Counseling

HIV testing and counseling are crucial first steps in the treatment and prevention of HIV. Early diagnosis and treatment can lower viral load, improve outcomes, and reduce the risk of transmitting HIV to others by up to 96% (CDC, 2016a).

Although HIV testing rates have steadily increased, more than half of Americans still have not been tested for HIV in their lifetime (CDC, 2016a). It has been almost a decade since the CDC modified its recommendations to include HIV screening as part of routine medical care in the United States for those ages 13 to 64 years. The proportion of U.S. adults screened for HIV increased from 40.2% in 2006 to 43.5% in 2013 (Van Handel & Branson, 2015). In 2013, the U.S. Preventive Services Task Force issued its own recommendation for routine HIV screening for those ages 15 to 65 years.

The needle continues to move in the right direction with regard to HIV testing; however, reaching the national HIV prevention goal of increasing awareness of HIV has not yet been realized. Doing so will require expanding current efforts to integrate routine testing into existing systems and continuing to support other testing strategies. Nurses should be aware of the changing testing recommendations and should advocate for testing regardless of HIV risk.

Approximately 10 antiretrovirals are approved for pediatric indications. The other antiretrovirals are too toxic for pediatric use, not available in convenient formulations, or the doses remain to be established. Like adults, the specific regimen is chosen based on the experience of the prescriber and resistance patterns of the HIV strain. The possibility that the child may have inherited a strain already resistant to some of the antiretrovirals must be considered when developing the regimen.

Pharmacotherapy of Opportunistic Infections Associated with HIV and AIDS

55.12 Loss of immune function due to HIV often results in opportunistic infections that require anti-infective therapy.

In the early 1980s, all patients with AIDS acquired serious OIs from pathogenic bacteria, viruses, fungi, and protozoans. Profound loss of immune function allowed dormant pathogens to flourish and also lowered the defense barriers for infection by newly acquired organisms. Often, the presentation of an acute OI was the reason the patient first sought medical attention for HIV disease. For example, in the early years of the epidemic, 70% to 80% of all patients with AIDS developed *Pneumocystis* pneumonia, which carried a mortality rate of up to 40% in these patients. Since the advent of ART, *Pneumocystis* pneumonia is now rare.

OIs still occur in patients with HIV infection and AIDS; however, they are less common and mortality is diminished. This is because ART increases the numbers of CD4 lymphocytes, allowing patients with HIV infection to maintain a higher level of immunologic defense. In addition, the anti-infective pharmacotherapy of OIs has evolved due to a better understanding of these diseases. Patients with CD4 counts below 200 cells/mcL may be placed on prophylactic antibiotics because the risk of an OI in these patients is very high. Most other patients with HIV infection are monitored carefully for signs of infectious disease and treated as symptoms indicate.

Drugs used for treating OIs have been presented in previous anti-infective chapters. The CDC publishes detailed, updated recommendations for prevention and treatment of OIs in patients with HIV infection (CDC, 2016b). A selected list of preferred drugs for selected OIs is given in Table 55.3.

Table 55.3 Pharmacotherapy of Selected Opportunistic Infections in Patients with HIV infection and AIDS

Disease	Preferred Drug(s) for Prevention	Comments
Bacterial enteric infections	PO: fluoroquinolone (ciprofloxacin preferred) or ceftriaxone	Most common pathogens are *Salmonella*, *Campylobacter*, and *Shigella*
Bacterial respiratory infections	Pneumococcal vaccine (PCV or PPV); inactivated influenza vaccine	Most common pathogens are *S. pneumoniae* and *H. influenzae*
Candidiasis (mucocutaneous)	PO: fluconazole	Topical azoles may be used for vulvovaginal or oropharyngeal disease
Cryptococcosis	No prevention recommended; treatment is with amphotericin B with flucytosine for 2 wk, followed by fluconazole for 8 wk	Lifelong prophylaxis with fluconazole is indicated in certain patients
Cryptosporidiosis	Antiviral regimen should be optimized	HIV-infected patients should drink only purified water free from possible bacteria
Herpes simplex	PO: famciclovir or acyclovir for 7–14 days	IV therapy is indicated in severe infections
Histoplasmosis (disseminated)	PO: itraconazole daily	Lifelong prophylaxis with itraconazole is indicated in certain patients
Pneumocystis pneumonia (PJP)	PO: trimethoprim-sulfamethoxazole (TMP-SMZ) for 21 days	Lifelong prophylaxis is indicated in certain patients; pentamidine IV may be used for severe cases
Syphilis	IM: benzathine penicillin	If allergic to penicillin, penicillin desensitization is attempted or doxycycline is substituted
Toxoplasma gondii encephalitis	PO: TMP-SMZ	Pyrimethamine and clindamycin are alternative drugs
Tuberculosis	PO: isoniazid plus pyridoxine for 9 months	Serious drug interactions can occur between rifamycins and the NNRTIs and protease inhibitors

Understanding Chapter 55

Key Concepts Summary

55.1 HIV causes a profound loss of immune function.

55.2 Treatment of HIV infection is difficult due to the latent nature of the virus and the development of resistant strains.

55.3 Five classes of antiretroviral drugs are available to treat HIV infection.

55.4 Reverse transcriptase inhibitors block the synthesis of viral DNA.

55.5 The nonnucleoside reverse transcriptase inhibitors inhibit viral DNA replication by binding to reverse transcriptase.

55.6 Protease inhibitors prevent HIV protease from completing the final step in HIV maturation.

55.7 Entry inhibitors and integrase inhibitors are newer strategies for managing HIV infections.

55.8 The development of vaccines to prevent HIV has produced disappointing results.

55.9 Postexposure prophylaxis of HIV infection is designed to prevent transmission to healthcare workers.

55.10 Preexposure prophylaxis has been shown to be partially effective in certain groups.

55.11 The risk of perinatal transmission of HIV can be markedly reduced by specialized drug protocols.

55.12 Loss of immune function due to HIV often results in opportunistic infections that require anti-infective therapy.

CASE STUDY: Making the Patient Connection

Remember the patient "Ryan Orre" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Ryan Orre is a 37-year-old single man who has come to his healthcare provider because of the recent onset of a chronic sore throat and flulike symptoms, including swollen lymph nodes in the neck and armpits, tiredness, fever, and night sweats. During this office visit, Ryan appears extremely anxious and troubled.

When questioned about his apparent nervousness, Ryan states, "You don't understand; I'm gay. But I've always been very careful and practice safe sex. What if I have AIDS? What will I do? I don't want to die." The healthcare provider acknowledges Ryan's fears and spends additional time allowing Ryan to express his concerns. The process of diagnosing HIV infection is discussed with the patient and initiated.

Ryan's medical history reveals that he is allergic to penicillin, which results in rash and pruritus. Although Ryan does not currently take any prescribed medications, he recently started multivitamin and nutritional supplements due to a recent loss of weight. The patient denies any current recreational drug use but admits that he occasionally used IV drugs during his college years. He has not used them in the past 8 years. No past history of medical or psychiatric illness exists. He has never had surgery.

Ryan does not use tobacco products. He reports drinking alcoholic beverages several times weekly but never to excess. Ryan explains that he has had several male sexual partners over the past 10 years but feels that he has been consistent in his use of condoms. He currently lives alone and works as a sales representative with a local computer firm. A series of laboratory diagnostic tests found the following abnormal results: white blood cell (WBC) count of $2950/mm^3$ and CD4 count of $550/mm^3$. Ryan is hospitalized with the preliminary diagnosis of sepsis and to rule out HIV. A test for HIV viral load is ordered.

Critical Thinking Questions

1. You are the nurse caring for Ryan in the hospital. On the first evening, he asks if you think his provider will be prescribing antiretroviral therapy. Given this situation, how would you explain the factors that determine when antiretroviral therapy should be initiated?
2. Ryan's CD4 count is still within low-normal range, but his HIV viral load comes back significantly increased, indicating HIV infection. After talking with the provider, Ryan asks you to explain again the difference between HIV infection and AIDS. How would you explain this?

3. Ryan's provider has decided to start him on antiretroviral therapy and Ryan will begin taking efavirenz (Sustiva), tenofovir disoproxil (Viread), and emtricitabine (Emtriva). What will be the best method of teaching Ryan about these drugs? What other factors should be considered when talking with Ryan?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Alexa Trihan is referred to an HIV clinic after she is diagnosed at the free clinic she goes to for medical care as having the HIV infection, most likely acquired by IV drug use. She is prescribed antiretroviral therapy using an ART regimen. Although the healthcare provider has explained the therapy, Alexa's anxiety results in her inability to comprehend the entire explanation provided. Alexa begins asking you, her nurse, questions about ART.

1. Using simple language, how would you, as Alexa's nurse, explain HIV and ART?
2. Alexa tells you that she may be pregnant. How will this potentially affect her treatment?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Zidovudine (AZT, Retrovir) is prescribed for a patient. Which statement by the patient would indicate that further medication-related teaching is needed?
   1. "Antiretroviral therapy must be continued for the remainder of my life."
   2. "The human immunodeficiency virus vaccine creates only temporary immunity against the disease."
   3. "The medication schedule can be adjusted daily depending on my activities."
   4. "Many individuals infected with the human immunodeficiency virus are able to live symptom free due to the medication."

2. A patient has been taking lopinavir with ritonavir (Kaletra) for the past 8 years and has noticed a redistribution of body fat in the arms, legs, and abdomen (lipodystrophy). In addition to this effect, the nurse knows that this drug may be associated with which additional adverse effects? (Select all that apply.)
   1. Chronic kidney disease
   2. Hyperglycemia
   3. Pancreatitis
   4. Bone marrow suppression
   5. Hepatic failure

3. Emtricitabine (Emtriva) is included as part of an antiretroviral therapy (ART) regimen for a patient newly diagnosed with HIV. While lower in toxicity than other nucleoside reverse transcriptase inhibitors (NRTIs), a potentially fatal adverse effect known to occur is:
   1. Ventricular cardiac dysrhythmias.
   2. Pulmonary fibrosis.
   3. Necrotic bowel syndrome.
   4. Lactic acidosis.

4. Protease inhibitor–based regimens have been shown to be one of the most successful choices for the initial therapy of HIV infection. Which adverse effects are common with this regimen?
   1. Fatigue, generalized weakness, myalgia
   2. Headache, diarrhea, nausea, fatigue, insomnia
   3. Nausea, vomiting, diarrhea, abdominal pain, headache
   4. Respiratory tract infections, cough, pyrexia, rash, dizziness

5. The nurse is planning a teaching session with a patient who will be receiving antiretroviral therapy (ART). Which of the following should be included in the teaching plan? (Select all that apply.)
   1. Avoid crowds and other people with colds, flu, and other infections.
   2. Notify the healthcare provider at the first sign of any rash.
   3. The medications will reduce transmission of the disease.
   4. The drugs will be stopped periodically to give the immune system a chance to respond.
   5. Herbal supplements will not interfere with this therapy.

6. The strategies for managing and treating HIV infection during pregnancy have changed as more is learned about the disease. As the nurse teaching a group of new graduate nursing employees, which of

the following information would you provide? (Select all that apply.)

1. Due to toxicities, HIV therapy will be initiated after delivery and only after confirming the infant's viral load.
2. Mothers with HIV infection are started on HIV as early as possible in pregnancy.
3. Infants born to mothers with HIV infection will start on HIV therapy as soon as possible after delivery.
4. Treatment of an infant born to a mother who was not on antiretroviral therapy during pregnancy will be continued for 6 months.
5. Due to toxicities, newborns should be breastfed only so that any drug therapy the mother is receiving will be passed to the infant through the breast milk.

"When the doctor first told me that I had cancer, I was scared. Now after hearing all of the things that the chemotherapy can do to my body, I'm petrified."
Patient "Cheryl Ogen"

Chapter 56
Basic Principles of Antineoplastic Therapy

Chapter Outline

- Characteristics of Cancer
- Etiology of Cancer
- Detection and Prevention of Cancer
- Goals of Chemotherapy
- Staging and Grading of Cancer
- The Cell Cycle and Growth Fraction
- Cell Kill Hypothesis
- Improving the Success of Chemotherapy
- Toxicity of Antineoplastic Drugs

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the differences between normal cells and cancer cells.
2. Identify etiologic factors associated with an increased incidence of cancer.
3. Construct a table categorizing the major primary and secondary means of cancer prevention.
4. Compare and contrast the following goals of chemotherapy: cure, control, palliation, prophylaxis, adjuvant therapy, and neoadjuvant therapy.
5. Explain the purposes of staging and grading cancers.
6. Explain the significance of growth fraction and the cell cycle to the success of chemotherapy.
7. Assess the ability of antineoplastic drugs to achieve a total cancer cure based on the cell kill hypothesis.
8. Explain how special chemotherapy protocols increase the effectiveness of therapy.
9. Discuss the types of toxicity and adverse effects of chemotherapeutic drugs on the various organ systems.

Cancer is one of the most feared diseases in society for a number of valid reasons. In the United States, cancer accounts for one out of every four deaths. It is often silent, producing no symptoms until it reaches an advanced stage. It sometimes requires painful and disfiguring treatments such as surgery or radiation. Cancer may strike at an early age, even during infancy, to deprive patients of a normal lifespan. Perhaps worst of all, the medical treatment of cancer often cannot offer a cure, and progression to death is sometimes slow and psychologically difficult for patients and their loved ones.

Despite its feared status, many successes have been made in the diagnosis and treatment of cancer. Modern treatment methods result in a cure for nearly two of every three people and the 5-year survival rate has steadily increased for most types of cancer. This chapter examines the basic principles of cancer therapy. Chapter 57 examines the medications used to treat cancer.

PharmFACT

The American Cancer Society (2016a) estimates that more than 1,685,210 new cancer cases occur each year in the United States (not including basal cell or squamous cell skin cancer). More than 595,690 deaths occur annually (about 1630 people each day).

Characteristics of Cancer

56.1 Cancer is characterized by rapid, uncontrolled growth of cells that eventually invade normal tissues and metastasize.

A **tumor** is a swelling, an abnormal enlargement, or a mass. The word **neoplasm** is often used interchangeably with *tumor*. Tumors may be benign or malignant. Whereas benign tumors are usually slow growing, remain localized, and rarely cause death, malignant tumors grow rapidly, are invasive, and will kill the host if left untreated. Malignant tumors are classified as carcinomas or sarcomas. Examples of various types of benign and malignant tumors are listed in Table 56.1.

Cancer or carcinoma is a disease characterized by abnormal, uncontrolled cell division. Cell division is a normal process that occurs extensively in most body tissues from conception to late childhood. At some point in time, whether it occurs during fetal life, childhood, or adulthood, the degree of cell division in every tissue must be controlled.

Each cell in the body has the ability to regulate its growth (proliferation) by turning specific genes on and off. For example, growth-promoting genes can be turned on when it is necessary to replace worn-out cells, as in the case of blood stem cells, skin epithelial cells, and the lining of the digestive tract. Growth suppressor genes are responsible for slowing the duplication rate and can completely

Table 56.1 Classification and Naming of Tumors

Name	Description	Examples
Benign tumor	Slow growing; does not metastasize and rarely requires drug treatment	Adenoma, papilloma, lipoma, osteoma, meningioma
Carcinoma	Cancer of epithelial tissue; most common type of malignant neoplasm; grows rapidly and metastasizes	Malignant melanoma, renal cell carcinoma, adenocarcinoma, hepatocellular carcinoma
Glioma	Cancer of glial (interstitial) cells in the central nervous system	Telangiectatic glioma, brainstem glioma, posterior pituitary gland, or retina
Leukemia	Cancer of the blood-forming cells in bone marrow; may be acute or chronic	Myelocytic leukemia, lymphocytic leukemia
Lymphoma	Cancer of lymphoid tissue	Hodgkin's disease, lymphoblastic lymphoma
Sarcoma	Cancer of connective tissue; grows extremely rapidly and metastasizes early in the progression of the disease	Osteogenic sarcoma, fibrosarcoma, Kaposi's sarcoma, angiosarcoma

shut down replication, as in the case of muscle cells and most neuron cells. If the suppressor genes become damaged or mutated and do not slow down or stop cell growth, the cells will undergo abnormal proliferation. Because of the critical importance of cell growth to life, it is likely that each cell has multiple genes that regulate division, all of which are responsive to various chemical signals or messages originating from both inside and outside the cell.

Cancer is thought to result from damage to the genes controlling cell growth. Once damaged, cells may become unresponsive to the chemical signals that normally check growth. The cancer cells lose their normal functions, dividing rapidly and invading surrounding tissues. Unlike most normal cells, cancerous cells are able to move to other places in the body. The abnormal cells often travel to distant sites where they populate new tumors, a process called **metastasis**. Figure 56.1 illustrates some characteristics of cancer cells.

Each time a cell divides, it loses a small amount of deoxyribonucleic acid (DNA) at the end of each chromosome. These regions of "extra" repetitive DNA, called **telomeres**, serve to protect the vital sequences of DNA from being destroyed. Average reproducing cells are able to undergo mitosis 50 to 60 times before the cell loses the protective telomeres. Certain human stem cells contain the enzyme **telomerase**, which can lengthen the DNA chains and allow continued replication. Interestingly, this enzyme is not produced in mature cells, which dooms the cells to eventual death.

Cancer cells are different from normal cells in that they do not die as quickly and can divide and form new cancer cells indefinitely. One explanation for this difference is that most cancer cells produce large amounts of telomerase, which continues to add pieces to the telomeres so that the cell can continue to divide. It is believed that the cancer cell begins to produce telomerase soon after it has mutated and that this may be an important factor in the progression to cancer.

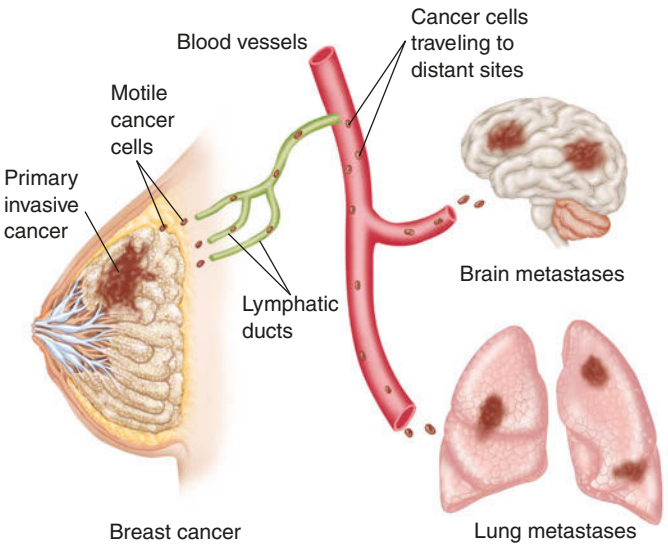

Figure 56.1 Invasion and metastasis by cancer cells.

To divide rapidly (and indefinitely), tumor cells need an adequate supply of nutrients. Solid tumors need to create a new capillary network to "feed" themselves. The process of **angiogenesis**, which is the formation of new blood vessels, is controlled by a cascade of events similar to blood coagulation. Some factors that are secreted by cells promote angiogenesis, whereas others inhibit it. Cancer cells appear to have the ability to control angiogenesis and to establish their own blood supply, which not only brings in nutrients, but also provides an "escape route" during metastasis.

Etiology of Cancer

56.2 The etiology of cancer may be chemical, physical, or biologic.

Numerous factors cause cancer or are associated with a higher risk for acquiring the disease. Agents that cause cancer are called **carcinogens**.

Many chemical carcinogens have been identified. For example, chemicals in tobacco smoke are responsible for about one third of all cancers in the United States. Alcohol ingestion has also been linked to certain cancers, including esophageal, oral, breast, and liver cancers. Chemicals such as asbestos and benzene have been associated with a higher incidence of cancer in the workplace. In some cases, the site of the cancer may be distant from the entry location, as is the case with bladder cancer, which is caused by the inhalation of certain industrial chemicals.

A number of physical factors are also associated with cancer. For example, exposure to large amounts of x-rays is associated with a higher risk of leukemia. Ultraviolet (UV) light from the sun is a common cause of skin cancer.

Viruses and bacteria are estimated to cause 15% to 20% of all human cancers. The common bacterium *Helicobacter pylori* is associated with a higher incidence of gastric cancer. Examples of viruses include hepatitis B and C, Epstein-Barr, human papillomavirus (HPV), and human T-lymphotrophic viruses. If patients remain free from infection with these viruses, their chances of developing certain types of cancer diminish greatly. For example, a vaccine against HPV is available to prevent infection from the two major types of HPV that cause cervical cancer and genital warts. On the other hand, factors that depress immune function, such as the human immunodeficiency virus (HIV) or immunosuppressant drugs given after transplant surgery, may promote the growth of cancer cells.

Some cancers have a strong genetic component. The fact that twins or close relatives may acquire the same type of cancer suggests that certain genes may confer a predisposition to the condition. These abnormal genes interact with chemical, physical, and biologic agents to promote the formation of cancer. Gender can also be considered a risk factor for certain types of cancer. For instance, breast cancer

is more commonly associated with women, whereas bladder cancer is more frequent in men.

Although the development of cancer has a genetic component, it is also greatly influenced by factors in the environment. Maintaining or adopting healthy lifestyle habits may reduce the risk of acquiring cancer. Following proper nutrition, avoiding chemical and physical risks (especially tobacco), and maintaining a regular schedule of health checkups can help prevent cancer from developing into a fatal disease.

Detection and Prevention of Cancer

56.3 The keys to successful cancer treatment are prevention and early detection.

If allowed to grow unchecked and untreated, cancer is fatal in nearly 100% of those who acquire it. The keys to successful cancer treatment are prevention and early detection. Prevention of cancer falls into two categories: primary prevention and secondary prevention.

Primary prevention of cancer includes interventions that keep cancer from ever developing. Interventions for primary prevention are targeted at avoiding known carcinogens and promoting a healthy lifestyle. Examples of primary prevention include the following:

- Health counseling and education delivered by the nurse
- Elimination of tobacco use to prevent lung, oral, and other cancers
- Receiving the HPV vaccination to prevent cervical cancer
- Maintaining a healthy diet low in fat and high in fresh vegetables and fruits
- Maintaining weight within recommended levels
- Decreasing excess stress
- Avoiding chronic or prolonged exposure to direct sunlight or wearing protective clothing or sunscreen.

Secondary prevention includes interventions leading to the discovery and control of cancerous or precancerous lesions while they are small and localized. Examples of secondary prevention include the following:

- Receiving a Papanicolaou (Pap) smear every 3 years, for women between the ages of 21 and 29; every 5 years between the ages of 30 and 65; and testing can be stopped at age 65 if previous tests have been negative
- Receiving a screening colonoscopy, according to the schedule recommended by the healthcare provider
- Receiving mammograms, according to the schedule recommended by the healthcare provider
- Receiving prostate screening, as recommended by the healthcare provider
- Performing regular skin self-examinations to check for abnormal lesions.

The American Cancer Society recommends using the following acronym to help people remember what to look for when self-assessing for cancer:

Caution
C: Change in bowel or bladder habits
A: A sore that does not heal
U: Unusual bleeding or discharge
T: Thickening or lump in the breast or elsewhere
I: Indigestion or difficulty swallowing
O: Obvious change in a wart or mole
N: Nagging cough or hoarseness

CONNECTION Checkpoint 56.1

From what you learned in Chapter 43, describe the recommended immunization schedule for receiving the HPV vaccine. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Goals of Chemotherapy

56.4 The three primary goals of chemotherapy are cure, control, and palliation.

Pharmacotherapy of cancer is sometimes simply referred to as **chemotherapy**. Transported through the blood, drugs have the potential to reach cancer cells in virtually any location. Certain chemotherapeutic drugs are specifically designed to be able to cross the blood–brain barrier to reach brain tumors. Others are instilled directly into body cavities such as the urinary bladder to bring the highest dose possible to the cancer cells without producing systemic adverse effects. Chemotherapy has three general goals: cure, control, and palliation.

When diagnosed with cancer, the primary goal desired by most patients is to achieve a complete cure; that is, permanent removal of all cancer cells from the body. The possibility for cure is much greater if a cancer is identified and treated when the tumor is small and localized to a well-defined region. The 5-year survival rates for nearly all types of cancers have increased in the past two decades due to improved detection and more effective therapies. Examples in which chemotherapy has been used successfully as curative treatment include Hodgkin's lymphoma, certain leukemias, and choriocarcinoma.

PharmFACT

The highest 5-year survival rates are for cancers of the prostate, testis, and thyroid. The lowest survival rates are for pancreatic, liver, and lung cancers (American Cancer Society, 2016a).

When cancer has progressed and cure is not possible, a second goal of chemotherapy is to control or manage the disease. Although the cancer is not eliminated, preventing the

growth and spread of the tumor may extend a patient's life. Essentially, the cancer is managed as a chronic disease, such as hypertension or diabetes.

In its advanced stages, cure or control of the cancer may not be achievable. For these patients, chemotherapy is used as **palliation**. Chemotherapy drugs are administered to reduce the size of the tumor, easing the severity of pain and other tumor symptoms and thus improving the quality of life. Examples of advanced cancers for which palliation is frequently used include osteosarcoma, pancreatic cancer, and Kaposi's sarcoma.

Chemotherapy may be used alone or in combination with other treatment modalities such as surgery or radiation therapy. Surgery is especially useful for removing solid tumors that are localized. Surgery lowers the number of cancer cells in the body so that radiation therapy and pharmacotherapy can be more successful. The process of removing only a portion of a tumor is referred to as *debulking*. Surgery is not an option for tumors of blood cells or when it would not be expected to extend a patient's lifespan or improve the quality of life.

Approximately 50% of patients with cancer receive radiation therapy as part of their treatment. Radiation therapy is most successful and produces the fewest adverse effects for cancers that are localized when high doses of ionizing radiation can be aimed directly at the tumor and be confined to a small area. Radiation treatments are frequently prescribed postoperatively to kill cancer cells that may remain following an operation. Radiation is sometimes given as palliation for inoperable cancers to shrink the size of a tumor that may be pressing on vital organs and to relieve pain, difficulty breathing, or difficulty swallowing.

Adjuvant chemotherapy is the administration of antineoplastic drugs after surgery or radiation therapy. The purpose of adjuvant chemotherapy is to rid the body of any cancerous cells that were not removed during the surgery or to treat any micrometastases that may be developing.

Neoadjuvant chemotherapy is the administration of antineoplastic drugs before surgery or radiation therapy with the goal of shrinking a large tumor to a more manageable size. This may also be done if the tumor has invaded vital tissue around it, such as may happen with brain tumors. Shrinking the tumor preoperatively results in less surgical invasion when removing the tumor.

In a few cases, drugs are given as chemoprophylaxis with the goal of preventing cancer from occurring in patients at high risk for developing tumors. For example, patients with a close family history of breast cancer who have had a primary breast cancer removed may receive tamoxifen, even if there is no evidence of metastases. Tamoxifen has been shown to prevent the recurrence of breast cancer in these patients. Chemoprophylaxis of cancer is uncommon because most of these drugs have potentially serious adverse effects.

CONNECTION Checkpoint 56.2

Corticosteroids are administered to most patients who are receiving tissue or organ transplants. From what you learned in Chapter 42, what is the rationale for administering corticosteroids to these patients? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Staging and Grading of Cancer

56.5 Cancers are described by their stage and grade.

Staging and grading must be done to determine the extent to which a cancer has invaded the body. These processes are performed on the initial diagnosis of cancer to determine the best course of therapy and predict patient outcomes.

Staging is the process of determining where the cancer is located and the extent of its invasion. Staging helps the healthcare provider to more accurately communicate the prognosis of the disease with the patient and helps to determine the best course of treatment.

During the staging of solid tumors, diagnostic testing determines the size of the tumor, whether the tumor has invaded surrounding tissue, the involvement of lymph nodes, and the presence or absence of metastasis (Table 56.2). The patient's disease is assigned numerical values for the tumor (T), node (N), and metastasis (M). Once these are determined, an overall stage is assigned: I, II, III, or IV. Stage I is assigned to cancers that are the least invasive and have the best prognosis. Stage IV is given for cancers that are the most aggressive and have the poorest prognosis.

Once a cancer is staged, the level does not change even if the cancer progresses. For example, if a cancer is a Stage II

Table 56.2 Staging of Cancer*

T Category: Describes the Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T_{is}	Tumor is confined to the primary area
T1–T4	Tumor has invaded areas surrounding the primary tumor (number based on extent and size of the tumor)
N Category: Describes Whether or Not the Cancer Has Spread to Lymph Nodes	
NX	Nearby lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1–N3	Primary tumor has spread to regional lymph nodes
M Category: Describes Whether or Not Distant Metastases Are Present	
MX	Distant metastases cannot be assessed
M0	No distant metastases were found
M1	Distant metastases are present

*The exact staging of a tumor varies somewhat with each specific type of cancer. Most have multiple subcategories to better define the tumor.

cancer on diagnosis, it will always be referred to as a Stage II cancer even if it spreads to other sites. At this point, it may receive a qualifier, such as Stage II *with metastasis* or Stage II *recurrent*. Statistics regarding cancer survival and treatment are based on the initial stage at which the cancer was diagnosed.

Grading is a process that examines potential cancer cells under a microscope and compares their appearance to normal parent cells. Normal cells are highly differentiated: They have developed, become fully mature, look like the parent cell, and carry on the functions of the parent cell. For example, it is very easy to distinguish a liver cell from a muscle cell or a nerve cell microscopically. When a normal cell becomes cancerous, however, it gradually changes and becomes less differentiated in both structure and function. Once fully undifferentiated, the cancer cell will look very different from the parent cell from which it came and will not carry on the functions of the parent cell.

In the grading process, if the biopsy cells appear differentiated and very similar to the parent cells, the tumor is classified as a Grade 1 (G1) and has the best prognosis. G4 cells are grossly abnormal and clearly different from normal cells. Patients with these malignant and aggressive cells have the worst prognosis. The different grades are described in Table 56.3.

Grading has certain limitations. For instance, solid tumors often contain many different types of cells that vary in appearance from near normal to grossly abnormal. One part of the tumor may have cells consistent with G2, whereas other parts of the same tumor may have cells consistent with G4. Unlike staging, grading may change over time as the tumor evolves.

Table 56.3 Grading of Cancer Cells

Grade	Description
GX	Grade cannot be determined
G1	Well differentiated: The cancer cells look like normal cells and are replicating slowly
G2	Moderately differentiated: The cancer cells look somewhat like normal cells and are replicating moderately fast
G3	Poorly differentiated: The cancer cells look clearly different from normal cells and are replicating rapidly
G4	Undifferentiated: The cancer cells do not look anything like normal cells and are replicating aggressively

The Cell Cycle and Growth Fraction

56.6 Many antineoplastic drugs are more effective when given at specific stages of the cell cycle and in tumors with a high growth fraction.

Both normal and cancerous cells go through a sequence of events known as the cell cycle, which is illustrated in Figure 56.2. Knowledge of the cell cycle is important to understanding the effectiveness of anticancer drugs.

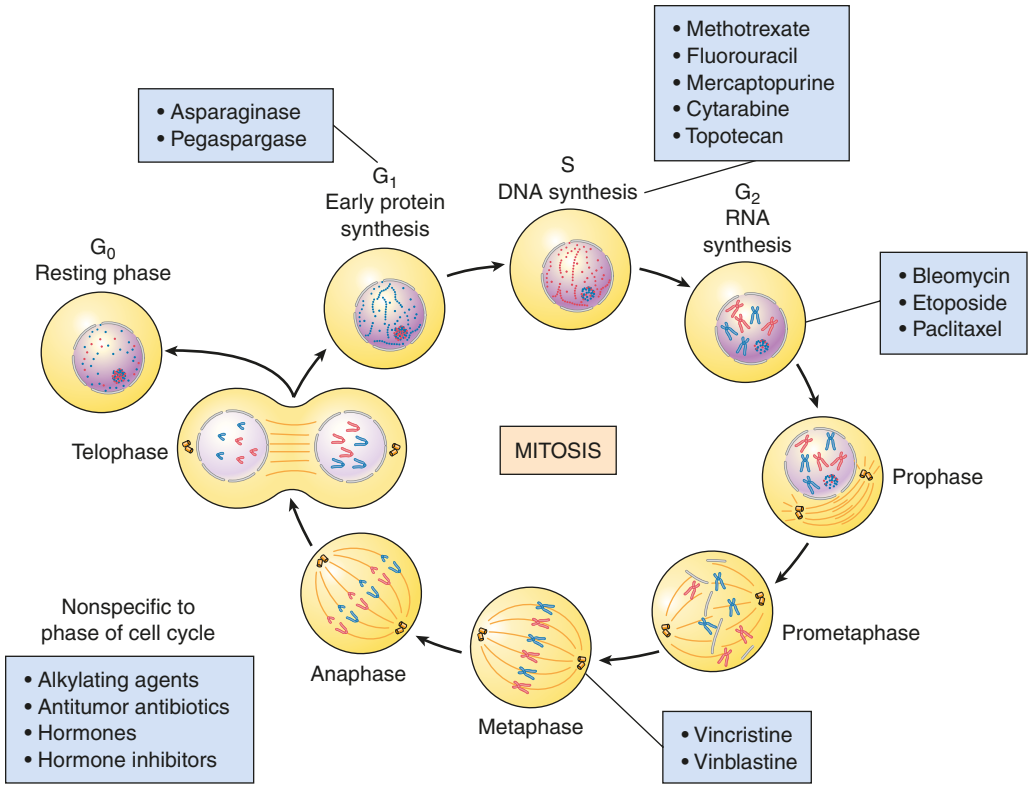

Figure 56.2 Antineoplastic drugs and the cell cycle.

In simplest terms, a cell is either performing its daily functions or it is undergoing cell division. Certain cellular activities occur in between these two basic functions of the cell that allow its lifecycle to be divided into five stages or phases.

Stage G_0: Although sometimes called the resting phase, G_0 is the phase during which cells conduct their everyday activities such as metabolism, impulse conduction, contraction, or secretion. A cell may enter its G_0 phase at any point in the cycle and remain there for extended periods, depending on the specific tissue and surrounding cellular signals. Cells spend most of their lifetime in the G_0 phase.

Stage G_1 (gap 1): If a cell receives a signal to divide, it leaves the G_0 phase and enters the G_1 phase, during which it synthesizes the ribonucleic acid (RNA), proteins, and other components needed to duplicate its DNA.

Stage S (synthesis): During the S phase the cell duplicates its DNA.

Stage G_2 (gap 2): During the G_2 or premitotic phase the cell makes additional proteins and the spindle apparatus that are necessary for cell division or mitosis.

Stage M (mitosis): The cell undergoes mitosis, which includes prophase, metaphase, anaphase, and telophase. Following mitosis in the M phase, the cell has split into two identical cells that will either start the process over at the G_1 phase or enter the G_0 phase depending on the needs of the body. This is the briefest stage of the cell cycle.

The actions of some antineoplastics are specific to certain phases of the cell cycle, whereas others are mostly independent of the cell cycle. Cell cycle specific drugs kill the most cancer cells when they are administered in divided but frequent doses. Cell cycle specific drugs are most effective in treating hematologic malignancies and other cancers that have a relatively large proportion of cells proliferating at any given point in time. Examples include mitotic inhibitors such as vincristine (Oncovin), which affect cells in the M phase, and antimetabolites such as fluorouracil (Adrucil), which are most effective against cells during the S phase. In general, cell cycle specific drugs are not effective against tumors that have a large percentage of resting cells.

Cell cycle nonspecific drugs can kill cancer cells in any stage of the cell cycle, including the G_0 resting phase. Often, these drugs are incorporated into resting cancer cells and have no effects until the cells attempt to divide. These drugs act relatively slowly and are given intermittently to give normal cells an opportunity to recover. The effects of alkylating agents such as cyclophosphamide (Cytoxan), antitumor antibiotics, and hormonal therapies are generally independent of the phases of the cell cycle.

The **growth fraction** is a measure of the number of cells undergoing mitosis in a tissue. It is a ratio of the number of replicating cells to the number of resting cells. Antineoplastic drugs are more toxic to tissues and tumors with high growth fractions. For example, certain leukemias and lymphomas have a high growth fraction and therefore have a greater antineoplastic success rate. Solid tumors such as breast and lung cancer generally have a low growth fraction; therefore, they are less sensitive to antineoplastic drugs. Because certain normal tissues, such as hair follicles, bone marrow, and the gastrointestinal (GI) epithelium, also have high growth fractions, they are sensitive to the effects of the antineoplastics.

CONNECTIONS: Complementary and Alternative Therapies

Acupuncture

Description

Acupuncture involves stimulating anatomic points on the body to treat pain and other health conditions. Based on traditional Chinese medicine, the body is viewed as having a delicate balance between two opposing forces—yin and yang—that, when out of balance, results in symptoms or disease. Acupuncture is an attempt to correct the balance of energy between the two. The body has at least 2000 acupuncture points along pathways known as meridians or channels. It is these meridians or channels that acupuncture seeks to unblock and rebalance so that energy can flow. There are more than 12 primary meridians consisting of many interconnected acupuncture points (American Academy of Medical Acupuncture, n.d.).

History and Claims

Acupuncture has been used as a component of traditional Chinese medicine for thousands of years. Early needles were made of wood, bone, or stone. Metal needles the approximate width of a human hair are currently used. The World Health Organization and the National Institutes of Health recognize acupuncture as a legitimate health option for treating disorders such as asthma, bronchitis, carpal tunnel syndrome, constipation, diarrhea, menopausal symptoms, pain, fibromyalgia, and many others (National Center for Complementary and Integrative Health, 2016).

Evidence

There is growing evidence that acupuncture has a physiologic basis for its efficacy. Clinical trials have indicated that acupuncture may be of benefit for chemotherapy-induced leukopenia (CIL) to prevent bone marrow suppression and increase leukocyte counts after chemotherapy (Fu, Chen, Hong, & Guo, 2015; Nian et al., 2016). Other studies have shown that it may be beneficial in the treatment of xerostomia induced by radiation (Li, Tian, & He, 2016) and hot flashes and night sweats caused by hormonal-based chemotherapy such as tamoxifen (Hervik & Mjåland, 2014).

With large solid tumors, a high percentage of the cells have entered the G_0 phase, causing the tumor to have a lower growth fraction. Chemotherapeutic drugs are not as effective against cells that are in the G_0 phase. To improve the success of chemotherapeutic drugs, the tumor may be debulked. When a tumor is debulked, a portion is removed surgically, causing the remaining cells to move into the active phases of mitosis. Once the cells enter into mitosis, the chemotherapeutic drugs can more effectively kill the cancer cells.

Cell Kill Hypothesis

56.7 The goal of chemotherapy is to kill as many cancer cells as possible while sparing normal cells.

Measurement of the success of chemotherapy is dependent on the therapeutic goal. If the desirable outcome is a total cure, then success is measured by how long the patient remains cancer free following treatment. If the goal is palliation, success is measured by the degree to which the patient's quality of life is improved. Because chemotherapy is often prolonged and physically challenging, it is crucial that the patient understand the goals of treatment and how they will be measured. In cases of palliation, the patient must weigh whether the adverse effects associated with treatment are worth the anticipated increase in the quality of life.

Patients who are undergoing chemotherapy usually receive several rounds of treatment spaced over a designated time, usually several weeks or months. This is because each round of chemotherapy kills a set percentage of cancer cells, usually those that are rapidly dividing at the time of treatment. Subsequent rounds kill additional cells. Another reason is that chemotherapy always damages normal cells and can cause serious adverse effects. Patients need time to recover between treatments. For example, neutrophils are especially sensitive to chemotherapy and a patient's absolute neutrophil count (ANC) will usually plummet after a therapy session. Intervals between treatments allow the body to make more neutrophils so that body defenses are able to fight infections.

The **cell kill hypothesis** is a theoretical model that predicts the ability of antineoplastic drugs to eliminate cancer cells. This hypothesis predicts that a drug will kill a certain percentage, rather than a constant number, of cancer cells. Why is this important?

Theoretically, every single cell in a malignant tumor must be eliminated from the body to cure a patient. Leaving even a single malignant cell could result in regrowth of the tumor. Eliminating every cancer cell with chemotherapy alone, however, is a very difficult task. As an example, consider that a small, 1-cm breast tumor may already contain 1 billion cancer cells before it can be detected during a manual examination. A drug that is able to kill 99% of these cells would be considered a very effective drug indeed. Yet even with this fantastic achievement, 10 million cancer cells would remain, any one of which could potentially cause the tumor to return and kill the patient. The relationship between cell kill and chemotherapy is illustrated in Figure 56.3. It is likely that no antineoplastic drug (or combination of drugs) has the ability to kill 100% of the tumor cells. The large burden of cancer cells, however, may be lowered sufficiently to permit the patient's immune system to control or eliminate the remaining cancer cells. Because the immune system is able to eliminate only a relatively

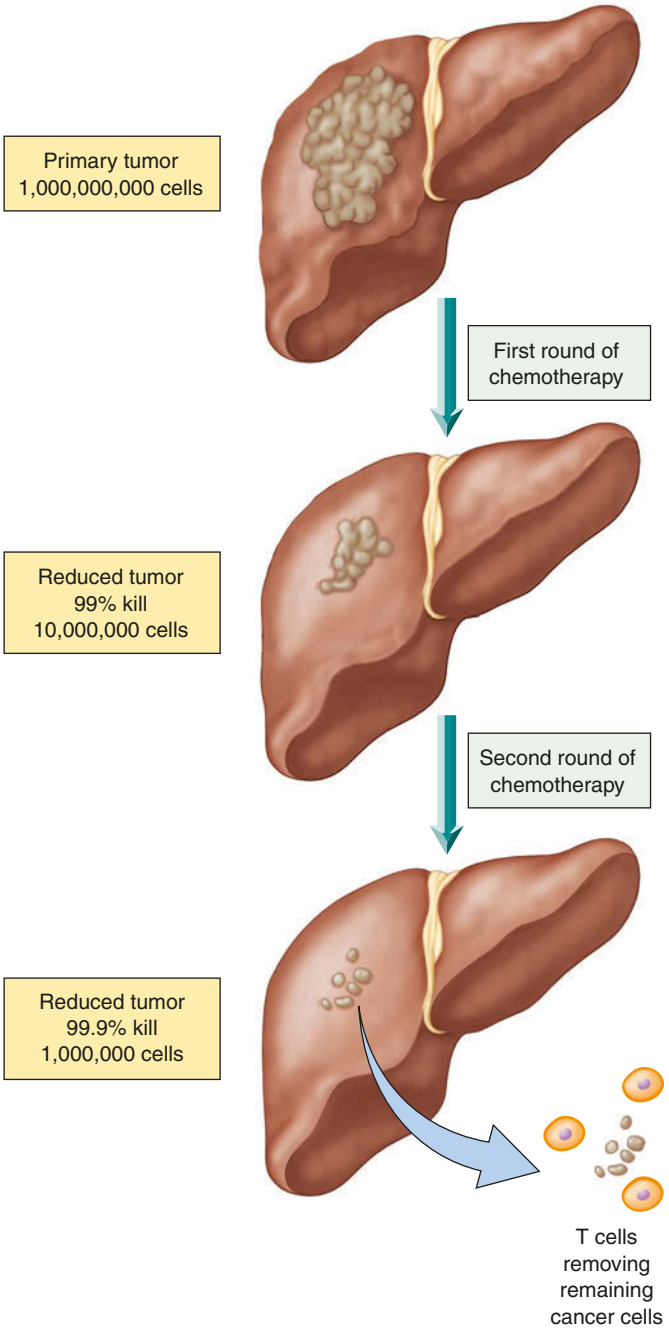

Figure 56.3 Cell kill and chemotherapy.

small number of cancer cells, it is imperative that as many cancerous cells as possible be eliminated during treatment. This example reinforces the need to diagnose and treat tumors at an early stage when the number of cancer cells is smaller.

Because of their rapid cell division, tumor cells express a high mutation rate, which continually changes their genetic structure, resulting in a more heterogenous mass as the tumor grows. Essentially, the tumor becomes a mass of hundreds of different types of cancer cells with different growth rates and physiologic properties. Administration of an antineoplastic drug may kill only a small portion of the tumor, leaving some clones unaffected and able to repopulate the tumor with resistant cells. The appearance of cancer cells that are resistant to antineoplastic drugs complicates the chances for a pharmacologic cure because a therapy that was very successful in reducing the tumor mass at the start of chemotherapy may become less effective over time.

Improving the Success of Chemotherapy

56.8 Use of multiple drugs and intermittent dosing are strategies that allow for greater success of chemotherapy.

As has been seen throughout this text, the majority of pharmacotherapy is conducted with a single drug given in a constant amount over a specified time period. For most indications, the use of multiple drugs increases the expense of treatment and can cause additional adverse effects. Cancer chemotherapy is an important exception: The concurrent use of multiple drugs, combined with intermittent dosing, results in improved patient outcomes.

Combination Chemotherapy

Chemotherapy is conducted using established protocols that are specific to the type of cancer and its stage. A cancer treatment protocol describes the specific combination of antineoplastics that will be given, their doses, and the cycles in which they will be administered. The use of multiple drugs affects the different stages of the cancer cell's lifecycle and attacks the various clones within the tumor via several mechanisms of action, thus increasing the percentage of cell kill. Combination chemotherapy also allows for lower dosages of each individual drug, thereby reducing toxicity and slowing the development of resistance. Examples of established protocols using combination therapy include cyclophosphamide-methotrexate-fluorouracil (CMF) for breast cancer and cyclophosphamide-Adriamycin-vincristine (CAV) for lung cancer. Each type of cancer has its own individual protocol, which was established through clinical trials. These protocols are being refined and revised continually based on current research.

CONNECTION Checkpoint 56.3

From what you learned in Chapters 46 through 55, name two infectious diseases that require several years of therapy with antiinfectives, using multiple drugs. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Dosing Schedules

Most chemotherapeutic medications are administered intermittently using specific dosing schedules that have been determined through research to increase the effectiveness of the antineoplastic drugs. For example, some of the anticancer drugs are given as a single dose or perhaps several doses over a few days. A few weeks may pass before the next series of doses begins. This gives normal cells time to recover from the adverse effects of the drugs and allows tumor cells that may not have been replicating at the time of the first dose to begin dividing and become more sensitive to the next round of chemotherapy. Sometimes the optimal dosing schedule must be delayed until the patient sufficiently recovers from the drug toxicities, especially bone marrow suppression. Delays or reductions in the planned dosages are likely to negatively affect treatment outcomes. The specific dosing schedule chosen depends on the type of tumor, stage of the disease, and overall condition of the patient.

Route of Administration

Antineoplastic drugs are available for administration by virtually any route. Whenever possible, the oral (PO) route is used because it is most acceptable to the patient and eliminates risks associated with intravenous (IV) administration, such as phlebitis or tissue necrosis. Antineoplastics may be given locally by topical application to the lesion or through direct instillation into the tumor region. Regional administration causes less systemic toxicity. The most common route for delivering antineoplastics is via the venous system.

Oral: The PO route is the easiest, most convenient, and least expensive route for chemotherapy administration. Patients can self-administer their PO chemotherapy medications at home. One problem associated with PO administration is the inconsistency of absorption. Chemotherapeutic medications that are administered PO produce many of the same adverse reactions as the injectable drugs, and the patient and caregivers must be aware of these. They must also be taught safe handling and disposal of these drugs. Examples of antineoplastics available as PO preparations include methotrexate, mercaptopurine, cyclophosphamide, and melphalan.

Intravenous: IV is the most common route for delivery of chemotherapy drugs. One advantage to the IV route is that a constant and consistent serum level of the drug can be obtained by fine adjustments to the infusion rate. A disadvantage is that **sclerosing**, or abnormal tissue hardening of the veins, may occur during prolonged administration. Another disadvantage to the patient is that chemotherapy administration is done in a cancer center, healthcare provider's office, or some other place away from the patient's home. This may require many miles of commuting and present a hardship to the patient and family. In addition, traveling out of the home may expose the patient to viruses and other infectious agents, which can be hazardous to those with diminished immune function. In some geographic areas, an oncology nurse will come to the patient's home and administer the chemotherapy.

Administration of chemotherapeutic drugs can be done through a centrally located access device such as a Groshong catheter, which is inserted by being tunneled under the skin on the chest into a major vein for long-term medication instillation, or through a peripheral vein via a **peripherally inserted central catheter (PICC) line**. A PICC line is a central catheter that is threaded into the vena cava for administration of chemotherapy. The advantages of a central line are that it is less likely to infiltrate and it is inserted in a large vein, which is less likely to become irritated during chemotherapy. A disadvantage of a central line is that it increases the patient's risk of acquiring an infection.

Because IV administration requires a free-flowing IV in a large vein, it is imperative for the nurse to constantly assess the insertion site of the IV for signs of infiltration or phlebitis. Some antineoplastics can cause extreme cellular damage if the solution is allowed to enter surrounding tissues. Because of the potential for tissue damage, most antineoplastics are not administered by the intramuscular (IM) or subcutaneous routes. Examples of IV antineoplastics are carmustine, cisplatin, doxorubicin, and mitomycin.

Intrathecal: Some antineoplastic medications may be delivered intrathecally into the subarachnoid space of the spinal cord. In intrathecal administration, the drug bypasses the blood–brain barrier and circulates with the cerebrospinal fluid (CSF) to expose central nervous system (CNS) tumors to high concentrations of the drug. A specially trained individual must conduct the procedure because it requires a lumbar puncture or surgical placement of a reservoir or implanted pump for drug delivery. An advantage to intrathecal administration is that it provides a consistent drug level in the CSF. Potential adverse effects include headaches, confusion, lethargy, seizures, nausea, or vomiting, all of which are signs of increased intracranial pressure.

Intra-arterial: Occasionally the healthcare provider may choose to administer chemotherapeutic medications through an artery. Intra-arterial administration requires a surgical procedure for catheter placement and, often, special x-ray techniques. In most cases, a catheter is passed via the femoral or brachial artery so that its end lies close to the blood supply of the tumor. Injection delivers a high dose of drug directly to the tumor site. Although the drug subsequently distributes via the circulation to other tissues, the tumor area receives the highest dose.

Intraperitoneal: Intraperitoneal administration via a catheter or port is used to deliver antineoplastic drugs directly to intra-abdominal metastases. The drug is slowly absorbed into the systemic circulation, or it may be drained out of the peritoneum via a catheter after a few hours of treatment. A disadvantage of this method is that it requires the placing of a Tenckhoff catheter, which is a specialized catheter. One end is placed into the peritoneum and the other end has an external port, which provides an access area into which medication is instilled.

Intravesicular: The intravesicular route instills high doses of antineoplastics into the urinary bladder via a Foley catheter to treat tumors of the bladder mucosa. Only small amounts of the drugs are absorbed systemically. The patient retains the drug for a specified period, after which it is voided or removed via catheter.

Toxicity of Antineoplastic Drugs

56.9 Serious toxicity limits therapy with most antineoplastic drugs.

Although cancer cells are clearly abnormal in structure and function, much of their physiology is identical to that of normal cells. Because it is difficult to kill cancer cells selectively without profoundly affecting normal cells, all antineoplastic drugs have the potential to cause serious toxicity. These drugs are often pushed to their maximum dosages to obtain the greatest tumor cell kill. These high dosages always result in adverse effects in the patient, some of which are listed in Table 56.4. Because antineoplastic drugs primarily affect cells with a high growth fraction, normal cells that are replicating, such as cells in the hair follicles, GI tract, and hematologic system, are most susceptible to adverse effects.

Hematologic System

Erythrocytes, leukocytes, and platelets have relatively short lifespans and must be continually replaced by hematopoietic stem cells residing in the bone marrow. Stem cells may be destroyed by antineoplastic drugs, resulting in bone marrow suppression (myelosuppression). Myelosuppression is the most common dose-limiting adverse effect of chemotherapy and the one that most often causes

Table 56.4 Examples of Adverse Effects of Anticancer Drugs

Common Expected Adverse Effects	Drug-Specific Adverse Effects	Dose-Limiting Adverse Effects
Alopecia	Cardiotoxicity (daunorubicin, doxorubicin)	Acute renal failure
Anorexia	Fetal malformations (mercaptopurine, methotrexate, pemetrexed)	Bone marrow suppression
Fatigue	Peripheral-sensory neuropathy (cisplatin)	Diarrhea
Immunosuppression	Sterility (mechlorethamine)	Pulmonary fibrosis
Nausea and vomiting		
Stomatitis		

discontinuation or delays of chemotherapy. Severe bone marrow suppression is a contraindication to therapy with most antineoplastic drugs.

Chemotherapy causes erythrocyte, leukocyte, and platelet counts to decrease until they reach their lowest value, known as the **nadir**. Patients are most susceptible to the symptoms, such as anemia, infections, or bleeding, during the nadir. Following the nadir, blood counts begin their recovery back to normal values. The nadir is specific for each drug and for each type of blood cell. For example, antimetabolites produce rapid nadirs for neutrophils in 7 to 14 days after the initiation of chemotherapy, with recovery within 7 to 21 days following the nadir. Other drugs such as the nitrosoureas produce a delayed nadir for neutrophils at 26 to 63 days, with recovery at 35 to 89 days after the nadir.

Neutrophils are the type of white blood cells (WBCs) most affected by chemotherapy. This is primarily because the normal lifespan of a neutrophil is only 7 to 12 hours, and without continual replacement by stem cells the number of circulating neutrophils quickly falls. A patient is diagnosed with neutropenia when the neutrophil count is less than 1500 cells/mL. Patients are very susceptible to infections while they are neutropenic. Many times patients who are neutropenic are placed in reverse isolation to protect them from exposure to any infections from family members or healthcare providers. Even an infection from a mild cold could be fatal to patients with extremely low neutrophil counts. If a patient who is neutropenic and receiving chemotherapy acquires an infection, an increase in WBCs may not be evident. If a patient who is neutropenic does develop a fever, this may be an indication of sepsis, and antibiotics are indicated.

Medications such as colony-stimulating factors (filgrastim [Neupogen] and sargramostim [Leukine]) are sometimes administered to accelerate recovery of suppressed bone marrow cells and to increase the WBC count. The administration of these drugs shortens the time of neutropenia, thus lowering the risk of opportunistic infections and allowing the patient to maintain an optimal chemotherapy dosing schedule. Filgrastim is presented as a prototype drug in Chapter 39.

Because the lifespan of a platelet is only 7 to 8 days, these blood elements require constant replenishment by bone marrow stem cells. A patient is diagnosed with thrombocytopenia when the platelet count is less than 100,000 per milliliter of blood. Chemotherapy is often delayed if this occurs. In patients who are receiving chemotherapy, thrombocytopenia usually occurs concurrently with neutropenia. Thrombocytopenia can cause the patient to exhibit abnormal bleeding, with symptoms ranging from bruising to petechiae to serious hemorrhage. Bleeding precautions must be implemented if the platelet count falls below 50,000 per milliliter of blood. To prevent the platelet count from decreasing to a harmful level, platelet infusions may be necessary. Oprelvekin (Neumega) is a thrombopoietic growth factor that may be administered to increase platelet production. This drug is presented as a prototype hematopoietic agent in Chapter 39.

Because erythrocytes have a longer lifespan (90–120 days) than neutrophils or platelets, reductions in red blood cells (RBCs), or anemia, occur later in the course of chemotherapy. Hemoglobin carries oxygen to all tissues in the body; thus anemia may affect every system in the body. An infusion of RBCs may be required to increase a patient's RBC count and hemoglobin value. A medication that the nurse may administer to help increase the number of RBCs is epoetin alfa (Epogen), which is presented as a prototype in Chapter 39. When assessing for anemia, remember that the etiology may be the result of nonchemotherapy-related causes, such as bleeding, iron deficiency, or kidney damage.

Gastrointestinal Tract

The vomiting center in the medulla is triggered by many antineoplastics. Acute nausea and vomiting often begin within minutes of chemotherapy administration and may last for 24 hours. Delayed nausea and vomiting begin 24 hours after chemotherapy and may continue for up to 6 days. Anticipatory nausea and vomiting may occur before chemotherapy because the patient may be expecting an unpleasant experience. Antineoplastics are sometimes classified by their capacity to induce vomiting or **emetogenic potential**. Before starting therapy with highly emetogenic potential drugs, patients are pretreated with antiemetic medications such as ondansetron (Zofran), prochlorperazine (Compazine), or lorazepam (Ativan). It is not uncommon to administer several different antiemetic medications that have several

modes of action. Antiemetic medications are presented in detail in Chapter 60.

The epithelial lining of the GI tract is very sensitive to the effects of chemotherapeutic drugs. The GI mucosa commonly becomes inflamed, a condition known as **mucositis**. Consequences of mucositis include painful ulcerations in the mouth and esophagus, difficulty eating or swallowing, GI bleeding, intestinal infections, or severe diarrhea. Some research has shown that eating popsicles during chemotherapy infusions can decrease the severity of mucositis. The nurse may also instruct the patient to eat a bland diet and to use a soft toothbrush for oral care. Some healthcare providers may order a "medical cocktail," which may include lidocaine viscous, liquid diphenhydramine, and Carafate to decrease the pain associated with the mucositis. The patient should also be instructed to report any signs of thrush, which is an oral yeast infection.

Most patients receiving antineoplastics experience anorexia, usually due to a combination of nausea, vomiting, and mucositis. At times the patient's appetite is decreased such that tube feedings or parenteral feedings may be indicated. The body needs sufficient nutrients and calories for normal cells to repopulate and for repair of body tissues. When assessing for anorexia, remember that this symptom may be the result of direct effects from the tumor itself or from associated psychologic changes such as depression or anxiety.

The patient may experience constipation or diarrhea depending on the specific drugs administered. Some chemotherapeutic medications damage the intestinal lining, inhibiting the reabsorption of fluids and producing loose stools. Replacement of fluids and electrolytes as well as treatment with an antidiarrheal drug may be indicated. Some chemotherapeutic medications decrease the motility of the GI tract, resulting in greater reabsorption of fluids, which leads to constipation. When assessing for constipation, note that other common reasons for this symptom include therapy with opioid analgesics and inadequate water and fiber intake.

Many patients with cancer experience a general wasting of muscle and other tissues referred to as **cachexia**. Cachexia may be caused by toxic effects from the cancer itself or from its treatment. Chemotherapy symptoms such as anorexia, mucositis, nausea, and vomiting may contribute to cachexia, but other non-GI factors also contribute such as serious chronic pain, depression, and fatigue.

Cardiopulmonary System

Some of the chemotherapeutic medications can be toxic to the heart and lungs. For example, doxorubicin (Adriamycin) is specifically known for its cardiotoxicity and the nurse should monitor the patient for any changes in the electrocardiogram (ECG) and assess for any signs of heart failure. This adverse effect can be serious enough to later cause the patient to need cardiac monitoring or a heart transplant. A cardioprotective drug such as dexrazoxane (Zinecard) is administered just prior to a doxorubicin infusion to prevent permanent heart damage.

Bleomycin (Blenoxane) is specifically known to cause pneumonitis in patients. Nursing care of the patient who is receiving bleomycin should include monitoring the patient's pulse oximeter and respiratory status. Auscultating crackles in the lung fields may be a sign of a developing pneumonitis. Chest x-rays may be necessary two to three times per week to assess for lung changes.

Urinary System

Some of the chemotherapeutic medications can exhibit considerable nephrotoxicity. For example, cisplatin (Platinol) can lead to kidney failure if the dosage limit is exceeded. When administering drugs that are nephrotoxic, the nurse should closely monitor intake and output and urine dipstick results for red cells. The patient should remain well hydrated during the treatment to help prevent renal damage. Diuretics may be administered to help balance the intake and output of the patient. In addition, the drug mesna (Mesnex) is administered to prevent hemorrhagic cystitis during chemotherapy with cyclophosphamide or ifosfamide.

Reproductive System

Some antineoplastics, particularly the alkylating agents, affect the gonads and have been associated with infertility in both men and women. If a woman is pregnant while receiving treatment, the fetus may be severely damaged due to the high growth fraction of the fetus's cells or it may be killed during the treatment. Sexually active male and female patients should be instructed to use reliable contraception while receiving chemotherapy and for 3 to 6 months following treatment.

Antineoplastic medications are more likely to cause permanent sterility in men than in women. Some patients choose to have their sperm or eggs harvested prior to treatment in case the chemotherapy does affect their fertility.

Many hospitals have protocols specifying that female nurses and pharmacists not handle chemotherapeutic drugs if they are pregnant or are trying to become pregnant due to the toxic effects that the chemotherapy may have on the fetus.

Nervous System

Several chemotherapeutic drugs are toxic to the nervous system. For instance, vincristine (Oncovin) may cause muscle weakness and peripheral neuritis. It is important for the nurse to assess the patient's neurologic status

frequently when administering this medication. Patients should also be informed of the potential adverse effects so that they may inform the nurse of any tingling or pain in their extremities or if changes occur in muscle strength.

Cisplatin (Platinol) has been known to cause hearing loss and deafness in some patients. The nurse should assess the patient's hearing throughout the course of treatment and document any changes noted in the patient's ability to hear.

Skin and Soft Tissue

Many antineoplastics are classified as **vesicants**, agents that can cause serious tissue injury if they escape from an artery or vein during an infusion or injection. Extravasation or infiltration from an injection site can produce severe tissue and nerve damage, local infection, and even loss of a limb. If a nurse is concerned that a peripheral IV is no longer working properly, the IV should not be used for chemotherapy administration. Although rare, extravasation can still occur with a central line so the nurse should continue to frequently assess the insertion site of a central line while administering chemotherapy. Rapid treatment of extravasation is necessary to limit tissue damage, and certain antineoplastics have specific antidotes. For example, extravasation of carmustine (BiCNU, Gliadel) is treated with injections of equal parts of sodium bicarbonate and normal saline into the extravasation site. Before administering IV antineoplastic drugs, the nurse should know the emergency treatment for extravasation. Antineoplastics with the strongest vesicant activity include busulfan, carmustine, dacarbazine, dactinomycin, daunorubicin, idarubicin, mechlorethamine, mitomycin, plicamycin, streptozocin, vinblastine, vincristine, and vinorelbine.

Other Effects

Fatigue is a common complaint during chemotherapy. The precise etiology of the fatigue is often difficult to determine. If the patient has anemia, the lack of hemoglobin to carry oxygen to the tissue can cause the patient to feel fatigued. The patient may be experiencing anxiety or depression due to the diagnosis of cancer, which may lead to sleep deprivation. The process of cellular regeneration after chemotherapy treatments may also cause feelings of fatigue. A nutritional consultation may be helpful in determining if the fatigue has a nutritional origin. Coping strategies for dealing with stress and scheduled periods of rest may benefit the patient.

Hair follicles are damaged by many chemotherapeutic drugs, resulting in hair loss, or **alopecia**. Hair loss usually begins within 1 to 2 weeks of the first treatment, and regrowth may take 3 to 5 months after the last chemotherapeutic treatment. The potential for alopecia should be discussed with patients before treatment begins so that they may choose to wear a hat, bandana, wig, or other accessory.

One of the ironies of chemotherapy is that the medications that are given to kill the cancer may cause a secondary cancer to develop elsewhere in the body. This is not a common adverse effect, but it has been clearly demonstrated in patients. The secondary malignancy usually occurs many years after the initial cancer; thus this adverse effect is of most concern to children being treated with chemotherapy. It is estimated that pediatric cancer survivors have a 10 to 20 times greater risk than other children of developing a secondary malignancy. The most common secondary malignancy is nonlymphocytic leukemia.

Hyperuricemia is most frequently associated with chemotherapy for lymphomas and leukemias due to the rapid cell kill. A patient is diagnosed with hyperuricemia when uric acid levels in the blood are elevated, which can lead to renal failure if the uric crystals deposit in the renal tubules. Signs of hyperuricemia are nausea, vomiting, and oliguria. Keeping the patient hydrated helps to preserve renal function by flushing microscopic crystals out of the kidney before they have a chance to form larger crystals. The nurse who is caring for a patient who is suspected of developing or has been diagnosed with hyperuricemia should monitor the patient's intake and output closely.

PharmFACT

The morbidity and mortality rates for most types of cancer remain higher in Black Americans than in Whites. However, the overall disparity has narrowed during the past 20 years, especially in males (American Cancer Society, 2016b).

Understanding Chapter 56

Key Concepts Summary

56.1 Cancer is characterized by rapid, uncontrolled growth of cells that eventually invade normal tissues and metastasize.

56.2 The etiology of cancer may be chemical, physical, or biologic.

56.3 The keys to successful cancer treatment are prevention and early detection.

56.4 The three primary goals of chemotherapy are cure, control, and palliation.

56.5 Cancers are described by their stage and grade.

56.6 Many antineoplastic drugs are more effective when given at specific stages of the cell cycle and in tumors with a high growth fraction.

56.7 The goal of chemotherapy is to kill as many cancer cells as possible while sparing normal cells.

56.8 Use of multiple drugs and intermittent dosing are strategies that allow for greater success of chemotherapy.

56.9 Serious toxicity limits therapy with most antineoplastic drugs.

CASE STUDY: Making the Patient Connection

Remember the patient "Cheryl Ogen" at the beginning of the chapter? Now read the rest of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Cheryl Ogen is a 39-year-old woman who is employed as a kindergarten teacher. She has been married for 15 years and has never had any children. Her medical history confirms that both her mother and maternal grandmother died from breast cancer. Now Cheryl has been diagnosed with breast cancer. She is admitted to the hospital for tumor resection and chemotherapy. Cheryl's breast cancer is Stage T1, N0, M0, and G2. She has undergone a lumpectomy with regional lymph node biopsy and is now about to begin chemotherapy.

Critical Thinking Questions

1. Cheryl would like to know why she is receiving chemotherapy after the surgeon has removed the cancerous tumor. What would you tell her?
2. Why is it important to understand the staging and grading system used with cancer? How would you interpret the staging and grading of Cheryl's cancer?
3. Identify some of the hematologic changes that Cheryl may experience while receiving chemotherapy.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Patient Jonah Cooper has been newly diagnosed with acute lymphocytic leukemia. He is 28 years old and the father of two children ages 9 months and 2 years. Jonah is admitted to the hospital for his initial round of chemotherapy.

1. Will Jonah's children be allowed to visit him during his hospital admission?
2. Why is Jonah receiving more than one type of chemotherapy?
3. Why was Jonah's cancer not staged on diagnosis?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The healthcare provider has written in the patient's chart that the cancer is at Stage I. The nurse knows that the implications for this staging are that the:
    1. Cancer is advanced and the patient has a poor prognosis.
    2. Cancerous cells are only moderately differentiated from the parent cells.
    3. Cancer has been detected at an early stage.
    4. Tumor is large and is invading surrounding tissue.
2. Which of the following statements by a patient who is undergoing chemotherapy would be of concern to the nurse? (Select all that apply.)
    1. "I attended a meeting of a cancer support group this week."
    2. "My husband and I are planning a short trip next week."
    3. "I try to eat six small meals plus two protein shakes each day."

4. "I am taking my 15-month-old granddaughter to the pediatrician next week for her baby shots."
5. "I am going to go shopping at the mall next week."

3. The nurse determines that the patient understands an important principle of chemotherapy when the patient makes which statement?
   1. "The use of multiple chemotherapy drugs affects different stages of the cancer cell's lifecycle."
   2. "Staging describes the process of determining how responsive the cancer is to the prescribed chemotherapy."
   3. "Antineoplastic drugs kill the entire tumor, including the clones, and prevent repopulation."
   4. "Combination chemotherapy requires higher dosages of each individual drug and increases toxicity."

4. Chemotherapy is being initiated for a patient with prostate cancer who is experiencing mucositis. Which health teaching would be most appropriate for this condition?
   1. Use an over-the-counter mouthwash to eliminate bacteria.
   2. Increase intake of citrus-containing foods and beverages.
   3. Eat a bland diet with low roughage and use a soft toothbrush or plain water rinses for oral care.
   4. This adverse effect is expected and will disappear within a few days.

5. The nurse is collaborating with other members of the healthcare team regarding the care of a patient with a brain tumor. The nurse knows that the most common reason that subsequent rounds of chemotherapy may be delayed is due to what condition?
   1. Myelosuppression
   2. Alopecia
   3. Mucositis
   4. Cachexia

6. A patient with cancer is started on a drug that is a known vesicant. The nurse performs which priority activity related to this drug? Monitor the patient's:
   1. Response to antinausea drugs.
   2. Intake of calcium-rich foods.
   3. Respiratory status for cough.
   4. IV port site for redness, swelling, and pain.

Chapter 57
Pharmacotherapy of Neoplasia

Chapter Outline

- Classification of Antineoplastic Drugs
- Antineoplastic Medications
  - Alkylating Agents
    PROTOTYPE *Cyclophosphamide (Cytoxan), p. 1038*
  - Antimetabolites
    PROTOTYPE *Methotrexate (MTX, Rheumatrex, Trexall), p. 1044*
  - Antitumor Antibiotics
    PROTOTYPE *Doxorubicin (Adriamycin), p. 1048*
  - Hormones and Hormone Antagonists
    PROTOTYPE *Tamoxifen, p. 1053*
  - Natural Products
    PROTOTYPE *Vincristine (Marqibo, Oncovin), p. 1057*
  - Biologic Response Modifiers and Targeted Therapies
  - Miscellaneous Antineoplastics
- Drugs for Reducing Adverse Effects
- Preparing and Administering Antineoplastics

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain why it is difficult to accurately classify antineoplastic drugs.
2. Describe the common and dose-limiting toxicities of antineoplastics.
3. Describe how the process of alkylation kills rapidly growing cells.
4. Describe how antimetabolites kill cancer cells.
5. Describe mechanisms by which antitumor antibiotics kill cancer cells.
6. Explain applications of hormones and hormone antagonists to cancer chemotherapy.
7. Identify natural products that have the ability to kill tumor cells.
8. Explain the use of biologic response modifiers and targeted therapies in cancer chemotherapy.
9. Describe the types of drugs prescribed to reduce or prevent the adverse effects of antineoplastic drugs.
10. Discuss ways nurses can protect themselves from exposure to antineoplastics.
11. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
12. Apply the nursing process to care for patients receiving cancer chemotherapy.

Key Terms

alkylating agents, 1037

leucovorin rescue therapy, 1043
oncology nurse, 1069
targeted therapies, 1065

The decision to begin cancer chemotherapy is a collaborative one made by the patient, the family, and the healthcare provider. Although there have been some remarkable successes in treating cancer, patients will experience adverse effects that can challenge their resolve to complete the chemotherapy regimen. Nurses must be prepared to assist patients and their families in dealing with the common adverse effects of the antineoplastics, the more serious adverse reactions, and the psychologic impact of the decision to continue or discontinue treatment. This chapter examines the types of medications used in cancer chemotherapy and their applications to clinical practice.

Classification of Antineoplastic Drugs

57.1 Antineoplastic drugs kill or stop the growth of cancer cells and may be classified in multiple ways.

Drugs used in cancer chemotherapy come from diverse pharmacologic and chemical classes. Antineoplastics have been extracted from plants and bacteria as well as created entirely in the laboratory. Some of the drug classes attack cellular macromolecules in cancer cells, such as deoxyribonucleic acid (DNA) and proteins, whereas others poison vital metabolic pathways of rapidly growing cells. The common theme among all the antineoplastic drugs is their toxicity. They have the ability to kill or stop the growth of cancer cells.

Classification of the antineoplastics is difficult because some of these drugs kill cancer cells by multiple mechanisms and have characteristics from more than one class. For example, paclitaxel (Abraxane, Taxol) can be classified as a natural product (it was derived from a plant), a taxane (its chemical structure), a mitotic inhibitor (its mechanism of action), or a cell cycle inhibitor. Furthermore, the mechanisms by which some antineoplastics act are incompletely understood. A simple method of classifying this complex group of drugs includes the following categories:

- Alkylating agents
- Antimetabolites
- Antitumor antibiotics
- Hormones and hormone antagonists
- Natural products
- Biologic response modifiers and targeted therapies
- Miscellaneous antineoplastic drugs.

PharmFACT

Because approximately 90% of all prostate cancer is diagnosed at the local and regional stages, the cure rate for this cancer is nearly 100% (Prostate Cancer Foundation, n.d.).

Antineoplastic Medications

The antineoplastic medications include alkylating agents, antimetabolites, antitumor antibiotics, hormones and hormone antagonists, natural products, biologic response modifiers, targeted therapies, and miscellaneous antineoplastics.

Alkylating Agents

57.2 Alkylating agents change the shape of the DNA double helix and prevent cancer cells from dividing normally.

Alkylation, which is the transfer of a carbon group (alkyl group) from one molecule to another, is a common biochemical reaction. In the specific case of chemotherapy, alkylation involves covalent bonding of the antineoplastic drug to the DNA of the cancer cell. The drug may form a "bridge" or cross-link between the two DNA strands and markedly affect the function of the DNA.

Alkylating agents kill cancer cells by altering the shape of the DNA double helix and preventing the DNA from duplicating during cell division. Each alkylating agent attaches to DNA in a different manner; however, they all have the effect of inducing cell death or at least slowing the replication of tumor cells. Although the process of alkylation may occur at any time during the cell cycle, the killing action occurs when the affected cell attempts to duplicate the defective DNA strands. The alkylating agents are used against a broad range of malignancies, including certain types of lymphomas, myelomas, leukemias, and pancreatic cancers, and some testicular, ovarian, and breast cancers. They are the oldest classification of antineoplastics, having been available since the 1940s, and are still the most widely used antineoplastic drugs. Alkylating agents are sometimes subdivided into chemical classes, which include the nitrogen mustards, nitrosoureas, and platinum compounds, as listed in Table 57.1. Figure 57.1 illustrates the process of alkylation.

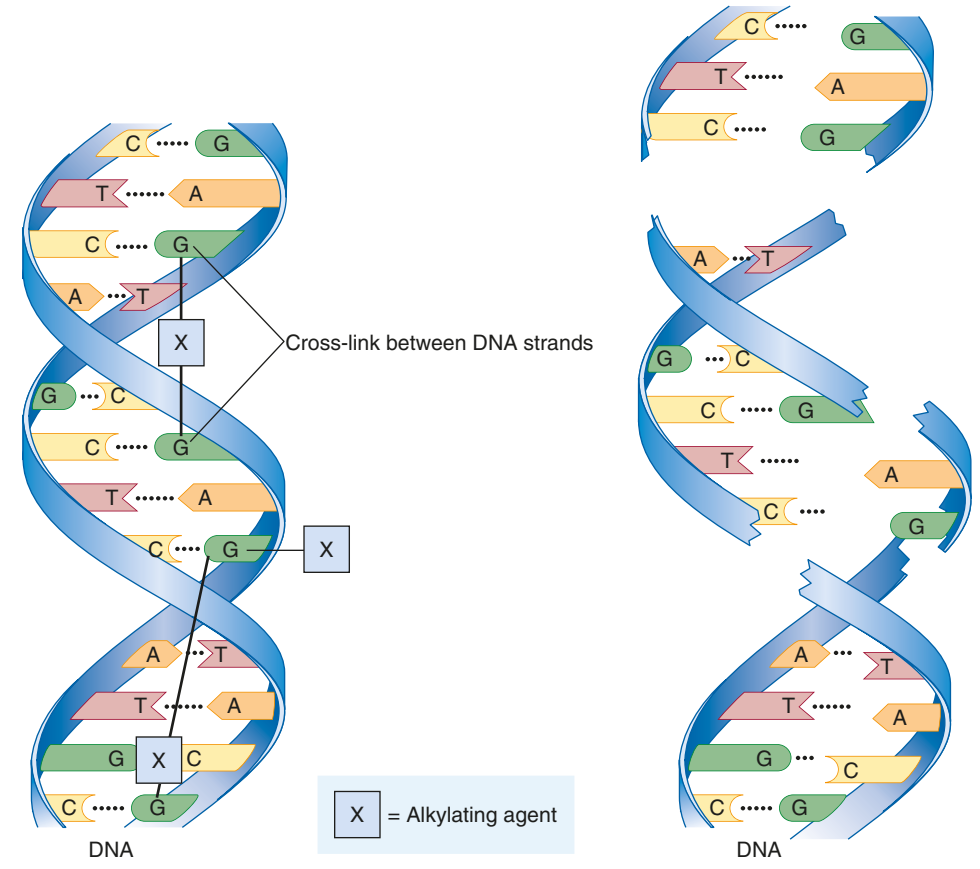
Table 57.1 Alkylating Agents

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Nitrogen Mustards		*Headache, alopecia, nausea, vomiting, stomatitis, anorexia, rash, fluid retention*
bendamustine (Treanda)	IV: 100 mg/m^2 on days 1 and 2 of a 28-day cycle	
chlorambucil (Leukeran)	PO: 0.1–0.2 mg/kg/day for 3–6 wk	
cyclophosphamide (Cytoxan)	PO: 1–5 mg/kg/day	
estramustine (Emcyt)	PO: 14 mg/kg/day in 3–4 divided doses	
ifosfamide (Ifex)	IV: 1.2 g/m^2/day for 5 consecutive days	
mechlorethamine (Mustargen)	IV: 0.4 mg/kg as a single or divided dose	
melphalan (Alkeran)	PO: 6 mg/day for 2–3 wk	
Nitrosoureas		
carmustine (BiCNU, Gliadel)	IV: 200 mg/m^2 once q6wk	
lomustine (CCNU, CeeNU)	PO: 130 mg/m^2 as a single dose, once q6wk	
streptozocin (Zanosar)	IV: 500 mg/m^2 for 5 consecutive days, q6wk	
Platinum Agents		
carboplatin (Paraplatin)	IV: 360 mg/m^2 once q4wk	
cisplatin (Platinol)	IV: 20 mg/m^2/day for 5 days	
oxaliplatin (Eloxatin)	IV: 85 mg/m^2 for 2 h	
Miscellaneous Alkylating Agents		
busulfan (Busulfex, Myleran)	PO: 4–8 mg/day IV: 0.8 mg/kg qid for 4 days	
dacarbazine (DTIC-Dome)	IV: 2–4.5 mg/kg/day for 10 days, repeated q4wk	
procarbazine (Matulane)	PO: 2–4 mg/kg/day in single or divided dose for 1 wk, then 4–6 mg/kg/day	
temozolomide (Temodar)	PO: 75–150 mg/m^2/day	
thiotepa	IV: 0.3–0.4 mg/kg q1–4 wk	
		Myelosuppression, severe nausea, vomiting, diarrhea, Stevens–Johnson syndrome (SJS), hemorrhagic cystitis (ifosfamide), neurotoxicity, ototoxicity (platinum agents), pulmonary toxicity, nephrotoxicity (platinum agents), hepatic necrosis (dacarbazine), anaphylaxis and other hypersensitivity reactions, tissue necrosis (due to extravasation)

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Because blood cells are particularly sensitive to the actions of alkylating agents, myelosuppression (bone marrow suppression) is the primary dose-limiting toxicity of these drugs. Within days after administration, the numbers of erythrocytes, leukocytes, and platelets begin to decline, reaching a nadir at 9 to 14 days. These drugs are withheld if red blood cell (RBC), white blood cell (WBC), and platelet counts fall below a predetermined limit during therapy. Epithelial cells lining the gastrointestinal (GI) tract are also damaged by alkylating agents, causing nausea, vomiting, and diarrhea. Alopecia may be expected from most of the alkylating agents. The nitrosoureas and mechlorethamine are also strong vesicants, and great care must be taken to avoid skin contact or extravasation. Like many other antineoplastics, secondary malignancies may occur with the alkylating agents. A small percentage of the patients treated with alkylating agents develop acute myelogenous leukemia 4 years or more after chemotherapy has been completed.

When alkylating agents are taken for prolonged periods, cancer cells can develop resistance to them. The mechanism of resistance is incompletely understood. However, possible mechanisms include decreased drug uptake by cancer cells, increased cellular inactivation of the drug, and increased production of DNA repair enzymes.



CONNECTION Checkpoint 57.1

From what you learned in Chapter 43, explain why vaccinations are usually contraindicated in patients who are receiving antineoplastic drugs. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Cyclophosphamide (Cytoxan)

Classification **Therapeutic:** Antineoplastic
Pharmacologic: Alkylating agent, nitrogen mustard, disease-modifying antirheumatic drug, immunosuppressant

Therapeutic Effects and Uses: Approved in 1959 by the U.S. Food and Drug Administration (FDA), cyclophosphamide is available as an oral (PO) or injectable preparation. It has a very broad spectrum of action and is approved in combination with other antineoplastics in the chemotherapy of Hodgkin's and non-Hodgkin's lymphoma, acute lymphocytic and myelogenous leukemia, ovarian cancer, breast cancer, multiple myeloma, chronic lymphocytic and myelogenous leukemia, mycosis fungoides, neuroblastoma, sarcomas, and retinoblastoma. It may be used off-label to treat lung cancer, endometrial cancer, Ewing's

(a) Alkylation occurring during G_0 (resting) phase of cell cycle

(b) Strand breaks occurring when DNA replicates during S phase of cell cycle

Figure 57.1 Mechanism of action of the alkylating agents.

sarcoma, osteogenic sarcoma, prostate cancer, rhabdomyosarcoma, and other neoplastic conditions. It is used in both children and adults. In children, it is also approved to treat nephritic syndrome when standard therapies have failed.

Cyclophosphamide is an effective immunosuppressant. Although immunosuppression is considered an adverse effect during cancer chemotherapy, this drug is used to intentionally cause it, often in combination therapy with corticosteroids. Off-label immunosuppressive indications include prophylaxis of organ transplant rejection, severe rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and scleroderma.

Mechanism of Action: Cyclophosphamide is a prodrug that is converted to its active form (phosphoramide mustard) in the liver. Cyclophosphamide binds to DNA and forms cross-links, which prevent the synthesis of DNA, ribonucleic acid (RNA), and protein. It is a cell cycle nonspecific drug.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Well absorbed from the GI tract
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; also found in brain tissue
Primary metabolism	Extensive hepatic metabolism by CYP2B6 and other CYP isozymes
Primary excretion	Renal
Onset of action	7 days
Duration of action	Half-life: 3–12 h; metabolites can still be identified in serum after 21 days

Adverse Effects: Adverse effects include those common to other antineoplastic drugs, such as anorexia, nausea, vomiting, weight loss, diarrhea, and mouth sores. Alopecia occurs more frequently with cyclophosphamide than with other antineoplastics; 50% of patients will develop total baldness. Other common adverse effects are jaundice, acne, blistered skin, and darkened or thickened skin. Bone marrow suppression is a potentially life-threatening adverse reaction that occurs between days 9 and 14 of therapy; the patient is at dangerous risk for

severe infection and sepsis during this period. Bone marrow recovery occurs by days 18 through 25. Other life-threatening adverse effects include secondary cancers, cardiotoxicity, and pulmonary fibrosis. Hematuria may signal hemorrhagic cystitis, which can be severe and even fatal. Interference with the ability to reproduce may occur in both males and females, and this may be irreversible. Cyclophosphamide can cause sterility in both males and females and can cause fetal harm. This drug is associated with an increased risk of secondary malignancies, including bladder cancer, lymphoma, and leukemia, that may take several years after completion of chemotherapy to become apparent.

Contraindications/Precautions: The only contraindications to the use of cyclophosphamide are pregnancy, lactation, and severe myelosuppression. The drug must be used cautiously in patients with leukopenia, thrombocytopenia, previous radiation therapy, bone marrow infiltration of tumor cells, chronic kidney disease (CKD), impaired hepatic function, recent history of steroid use, or previous therapy that caused cytotoxicity.

Drug Interactions: Many drug interactions are possible with cyclophosphamide due to its extensive hepatic metabolism. This medication has additive immunosuppressive effects if administered with other drugs that cause bone marrow toxicity. There may be an increased anticoagulant effect if it is given with anticoagulants. Increased cardiotoxicity may result if it is given with doxorubicin. Insulin may increase hypoglycemia. Lower serum digoxin levels can be expected in the patient who takes digoxin. Phenobarbital use may lead to an increased rate of metabolism of cyclophosphamide, whereas phenytoin use may lead to an increased risk of toxicity. **Herbal/Food:** St. John's wort may increase the toxic effects of cyclophosphamide.

Pregnancy: Category D.

Treatment of Overdose: Overdose can result in severe myelosuppression with the possibility of infection. General supportive measures are administered.

Nursing Responsibilities: Key nursing implications for patients receiving cyclophosphamide are included in the Nursing Practice Application for Patients Receiving Cancer Chemotherapy.

Drugs Similar to Cyclophosphamide (Cytoxan)

Alkylating agents include other nitrogen mustards, including bendamustine, chlorambucil, estramustine, ifosfamide, mechlorethamine, and melphalan; the nitrosoureas, including carmustine, lomustine, and streptozocin; the platinum compounds, including carboplatin, cisplatin, and oxaliplatin; and miscellaneous alkylating agents, including busulfan, dacarbazine, procarbazine, temozolomide, and thiotepa.

Bendamustine (Treanda): Approved in 2008, bendamustine is similar to mechlorethamine. Available by the IV route, bendamustine has two indications: chronic lymphocytic leukemia and non-Hodgkin's lymphoma that has not responded to rituximab therapy. Like many alkylating agents, the dose-limiting toxicity is myelosuppression. The most common nonhematologic adverse effects are pyrexia, nausea, and vomiting. Rare, though serious, toxicity includes anaphylaxis, Stevens–Johnson syndrome (SJS), and tumor lysis syndrome. It is a pregnancy category D drug.

Busulfan (Busulfex, Myleran): Approved in 1954, busulfan (Myleran) is a potent alkylating agent given PO for palliative treatment of chronic myelogenous leukemia for those patients who are no longer responsive to radiation therapy or other chemotherapeutic drugs. In combination with cyclophosphamide, busulfan (Busulfex) is given IV for bone marrow ablation prior to stem cell transplantation. Busulfan has a black box warning that myelosuppression is a serious adverse effect, and blood counts must be closely monitored. Pancytopenia occurs in 100% of patients who are taking high doses of this drug, and this condition may last as long as 2 years. Nausea, vomiting, stomatitis, and anorexia are common adverse effects. Because of the potential for infertility, men and women within childbearing years should be counseled regarding the drug's adverse reproductive effects. It is a pregnancy category D drug.

Carmustine (BiCNU, Gliadel): Carmustine, a nitrosourea alkylating agent, is one of the few drugs in its class that can penetrate the blood–brain barrier. Thus it is used to treat brain tumors such as malignant glioma, astrocytoma, ependymoma, and brain metastases. In addition to brain tumors, carmustine is also given for Hodgkin's and non-Hodgkin's lymphomas and multiple myeloma. Carmustine is usually administered by the IV route. A wafer form of the drug (Gliadel) is available for implantation into the cavity created by removal of a brain tumor. The wafer dissolves over 2 to 3 weeks, delivering 1000 times the amount of carmustine to the tumor site than could be obtained through IV administration. Carmustine carries a black box warning that it can cause serious bone marrow suppression and pulmonary toxicity. Neurologic adverse effects include seizures and encephalopathy. Other adverse effects are those typical of other alkylating agents. This is a pregnancy category D drug.

Chlorambucil (Leukeran): Chlorambucil, a nitrogen mustard alkylating agent, is used to treat chronic lymphocytic leukemia, lymphomas, and Hodgkin's disease. Because it is an immunosuppressant, chlorambucil is occasionally

used off-label to treat nephrotic syndrome, RA, SLE, and other inflammatory disorders. Chlorambucil has a black box warning for severe myelosuppression, which is the major dose-limiting toxicity. Blood values usually return to baseline 3 to 4 weeks after administration. In general, chlorambucil produces less toxicity than most other alkylating agents and has a slower onset of action. Approved in 1957, it is available via the PO route. This is a pregnancy category D drug.

Cisplatin (Platinol) and other platinum agents: Cisplatin is a heavy metal complex containing platinum, chloride, and ammonia. It is cell cycle nonspecific and usually used as combination therapy to treat metastatic testicular or ovarian tumors, bladder cancer, osteosarcoma, and soft tissue sarcomas and as adjuvant therapy in head, neck, esophageal, prostate, lung, and cervical cancers. It is available only as an injectable preparation. Cisplatin carries black box warnings for myelosuppression, ototoxicity, anaphylaxis, nausea and vomiting, and nephrotoxicity, the major dose-limiting toxicity. Acute renal failure may occur within 24 hours after administration, and permanent damage to renal tubular cells may eventually cause CKD. Renal function must be closely monitored during therapy. Peripheral neuropathy is another potentially serious adverse effect with symptoms that include numbness that begins in the fingers and toes and proceeds up the limbs toward the trunk. Ototoxicity is common and can result in permanent impairment. The nurse should be prepared for anaphylactic-like reactions that may occur within minutes of cisplatin administration. Cisplatin is a pregnancy category D drug.

Carboplatin (Paraplatin): Approved for the first-line palliative treatment of advanced ovarian cancer, carboplatin may be used off-label to treat acute lymphocytic leukemia, acute myelogenous leukemia, bladder cancer, breast cancer, and other tumors. Approved in 1989, carboplatin is administered by the IV route, is structurally similar to cisplatin, and works by the same mechanism but is less toxic. The drug carries a black box warning for anaphylaxis and severe myelosuppression, the dose-limiting toxicity. Neurotoxicity and nephrotoxicity occur less often than with cisplatin. The nurse should be prepared for anaphylactic-like reactions that may occur within minutes of carboplatin administration. This is a pregnancy category D drug.

Oxaliplatin (Eloxatin): Approved in 2002, oxaliplatin is a platinum drug that is approved only to treat advanced colorectal cancer in combination with fluorouracil, although it may be used off-label for other solid tumors. It acts by a different mechanism than cisplatin and exhibits little ototoxicity or nephrotoxicity. It does, however, cause significant levels of peripheral neuropathy, which can be dose limiting. An acute form of peripheral neuropathy begins within days of chemotherapy and resolves in 1 to 2 weeks. A more persistent form has a delayed onset and can cause functional impairment and discontinuation of therapy. The drug carries a black box warning for anaphylactic-like reactions that may occur within minutes of oxaliplatin administration. This is a pregnancy category D drug.

Dacarbazine (DTIC-Dome): Approved in 1998, dacarbazine is available by IV administration. It is approved to treat metastatic malignant melanoma and refractory Hodgkin's disease and is used off-label for sarcomas and neuroblastomas. Adverse GI effects occur in most patients, but tolerance to these adverse effects may develop over subsequent administrations. Myelosuppression occurs during therapy, although to a lesser extent than many other drugs in this class. Dacarbazine carries a black box warning that hepatic necrosis has occurred with the use of this drug. Unlike other alkylating agents, dacarbazine is a pregnancy category C drug, although use during the first trimester of pregnancy is contraindicated.

Temozolomide (Temodar): Temozolomide is a prodrug that is metabolized to the same active compound as dacarbazine. Unlike dacarbazine, however, temozolomide can be administered by either the IV or PO route. Approved in 1999, it is indicated to treat malignant glioma (glioblastoma multiforme) concomitantly with radiotherapy, and for refractory astrocytoma. It may also be used off-label to treat advanced metastatic melanoma. Adverse effects are similar to those of dacarbazine and include hepatotoxicity, myelosuppression, nausea, and vomiting. This is a pregnancy category D drug.

Estramustine (Emcyt): Estramustine is unusual because it is a dual molecule. One portion is a nitrogen mustard alkylating agent and the other is a molecule of estradiol. Thus, the drug may be classified as both an alkylating agent and a hormone. It is administered by the PO route for the palliative therapy of metastatic or advanced prostate cancer and may be used off-label to treat metastatic renal cell carcinoma. Unlike other alkylating agents, however, myelosuppression is infrequent. Nausea and vomiting are the dose-limiting toxicities. The estrogen component of the drug can cause gynecomastia, mastalgia, thromboembolic disease, and fluid retention. This is a pregnancy category D drug.

Ifosfamide (Ifex): Ifosfamide is a nitrogen mustard alkylating agent approved in 1988 for the treatment of testicular cancer. Off-label indications include breast, lung, pancreatic, bladder, and cervical cancers, sarcomas, and non-Hodgkin's lymphoma. The drug has black box warnings for urotoxicity, central nervous system (CNS) toxicity, and myelosuppression. Myelosuppression is the primary dose-limiting toxicity, with blood count nadirs occurring after 5 days and

recovering by 4 weeks. Nephrotoxicity also limits its use, and hematuria, hemorrhagic cystitis, and renal insufficiency occur in many patients. Signs of CNS toxicity such as confusion, drowsiness, hallucinations, and depression occur in about 12% of patients who are taking the drug. Cardiac toxicity may include dysrhythmias, heart failure, and myocarditis. This is a pregnancy category D drug.

To prevent hemorrhagic cystitis in patients who are taking ifosfamide, the drug mesna (Mesnex) is administered at the time of chemotherapy by the IV route and 2 to 6 hours later by the IV or PO route. Mesna binds the toxic metabolites in the urinary bladder, reducing the incidence of hematuria by 70% to 100%, depending on the dose of ifosfamide. Mesna may be used off-label for patients taking cyclophosphamide.

Lomustine (CCNU, CeeNU): Approved in 1976, lomustine is an oral nitrosourea alkylating agent that has actions similar to those of carmustine. It is used as palliative therapy in combination with other chemotherapeutic drugs or other treatment modalities in primary and metastatic brain tumors and as secondary therapy in Hodgkin's disease. The drug carries a black box warning for myelosuppression, which is its most serious dose-limiting toxicity. Delayed myelosuppression may occur up to 6 weeks following administration of the drug. Severe nausea and vomiting occur in most patients and require antiemetic therapy. This is a pregnancy category D drug.

Mechlorethamine (Mustargen): Mechlorethamine is one of the oldest antineoplastics, approved in 1949. It is available by the IV, intrathecal, or topical routes. It is usually used to provide palliation in patients with Hodgkin's disease (Stages III and IV), lymphosarcoma, polycythemia vera, bronchogenic carcinoma, and chronic myelocytic or chronic lymphocytic leukemia. It may also be used for palliative treatment of metastatic cancer in intrapleural, intrapericardial, and intraperitoneal spaces when effusion has occurred as a result of the tumor. Nausea and vomiting are acute and require antiemetic therapy. Myelosuppression occurs in 8 to 14 days after drug administration and can be severe. Like cyclophosphamide, infertility is a potential adverse effect. This drug carries a black box warning to use extreme care when handling it because exposure to mucous membranes or inhaling the dust can cause toxicity. This drug is a vesicant; extravasation requires the administration of sodium thiosulfate to the injection site. This is a pregnancy category D drug.

Melphalan (Alkeran): Melphalan is a nitrogen mustard approved for the palliative treatment of ovarian cancer and multiple myeloma. It may also be used off-label to treat breast or testicular cancer, osteogenic sarcoma, and non-Hodgkin's lymphoma. Because it has strong immunosuppressive and myelosuppressive effects, it has been used off-label for bone marrow ablation prior to stem cell transplantation in combination with other drugs. It is available as both a PO and an IV preparation. Melphalan carries black box warnings regarding myelosuppression, hypersensitivity reactions, and the possibility of secondary leukemia. Hematologic toxicity is the primary dose-limiting toxicity. Blood count nadirs usually occur 2 to 3 weeks after therapy starts, and recovery is seen 4 to 5 weeks after treatment. Unlike some of the other alkylating agents, melphalan is not highly emetogenic. The nurse should use extra caution to prevent skin exposure (to both nurse and patient) to the drug because it can cause skin necrosis. Because of the potential for infertility, men and women in childbearing years should be counseled regarding the drug's adverse reproductive effects. This is a pregnancy category D drug.

Procarbazine (Matulane): Procarbazine is an oral alkylating agent that was approved in 1969 for the treatment of Hodgkin's disease. It may be used off-label for treating non-Hodgkin's lymphomas and CNS tumors such as medulloblastoma, malignant glioma, and astrocytoma. It is also used as an adjunct in the palliative treatment of Hodgkin's disease. Because it has strong immunosuppressive effects, it may be used off-label for bone marrow ablation prior to stem cell transplantation in combination with other drugs. Myelosuppression is the primary dose-limiting toxicity. Blood count nadirs usually occur in week 4 after therapy starts, and recovery is seen 6 weeks after treatment. Nausea and vomiting are also common adverse effects that may be severe. CNS adverse effects are common and may include paresthesias, peripheral neuropathy, seizures, depression, and psychosis. When given by the IV route, neurotoxicity can be dose limiting. This is a pregnancy category D drug.

Streptozocin (Zanosar): Approved in 1982, streptozocin is a nitrosourea alkylating agent that is more toxic than many other alkylating agents. A clinically effective response most likely will be accompanied by some evidence of serious toxicity. It is available IV to treat metastatic islet cell cancers of the pancreas either as monotherapy or in combination with fluorouracil. It may be used off-label to treat colorectal cancer and other solid tumors. Streptozocin carries black box warnings regarding nephrotoxicity, nausea, vomiting, diarrhea, hepatotoxicity, and hematologic toxicity. The most serious dose-limiting toxicity is nephrotoxicity, which occurs in more than half of the patients taking the drug and can cause permanent impairment and death. Nausea and vomiting are also severe adverse effects of streptozocin. This is a pregnancy category D drug.

Thiotepa: Thiotepa is an alkylating agent approved in 1994 to treat bladder, ovarian, and breast cancers and both Hodgkin's and non-Hodgkin's lymphomas. It is administered IV or by the intravesical route for bladder tumors.

Myelosuppression is the primary dose-limiting toxicity, although neurotoxicity may also cause delay or discontinuation of therapy. Nausea and vomiting are uncommon. Injections and instillations of thiotepa can cause intense local pain. Intravesical administration causes bladder irritation, dysuria, and increased urgency. Note that the drug may be absorbed during intravesical administration and cause serious myelosuppression. This is a pregnancy category D drug.

Antimetabolites

57.3 Antimetabolites disrupt the critical cellular pathways of cancer cells.

Rapidly growing cancer cells require large quantities of nutrients to construct proteins and nucleic acids. Antimetabolite drugs are structurally similar to these nutrients, but they do not perform the same functions as their natural counterparts. When cancer cells attempt to synthesize proteins, RNA, or DNA using the antimetabolites, metabolic pathways are disrupted, and the cancer cells die or their growth is slowed. Some of these structural similarities are illustrated in Figure 57.2.

Some antimetabolites become incorporated into the DNA of cancer cells and interfere with DNA replication and function. Others inhibit the enzymes that synthesize the vital components of the cell. All antimetabolites are cell cycle specific, with most of them affecting the S phase, although some can act during any of the active phases of the cell cycle. The three classes of antimetabolites are the folic acid analogs, the purine analogs, and the pyrimidine analogs. These drugs are listed in Table 57.2.

Folic acid analogs: Folic acid, or folate, is vitamin B_9, which is essential for the growth and maintenance of cells. It is especially important during periods of rapid cell growth because this vitamin is needed to replicate DNA. Lack of vitamin B_9 during pregnancy can cause neural tube defects in the fetus. Additional details on folic acid are presented in Chapter 61.

Three folic acid analogs are used as antineoplastic drugs. Methotrexate is the oldest and is prescribed for several autoimmune disorders in addition to cancer. Pemetrexed (Alimta) and pralatrexate (Folotyn) have very limited therapeutic applications. Some folic acid analogs are used as anti-infectives. These include trimethoprim (Primsol), pyrimethamine (Daraprim), and trimetrexate (Neutrexin).

As antineoplastics, folic acid analogs are given at high doses, which can be toxic to normal cells as well as cancer cells. To "rescue" normal cells, the drug leucovorin is administered following chemotherapy with methotrexate. Leucovorin, or folinic acid, is a reduced form of folic acid that is able to enter normal cells but not cancer cells. The normal cells can thus continue metabolism and replication using leucovorin. Available by both the IV and PO routes, **leucovorin rescue therapy** must be initiated at very specific times following the methotrexate dose. Leucovorin is also used to treat overdose or prevent toxicity with other folic acid analogs such as pyrimethamine and trimethoprim. When used with fluorouracil (5-FU) in the treatment of colorectal cancer, leucovorin has been found to enhance cell killing. A new form of leucovorin, levoleucovorin (Fusilev), was approved in 2008. Given by IV infusion, levoleucovorin is an isomer of leucovorin that is reported to have fewer adverse effects.

Purine and pyrimidine analogs: Purines and pyrimidines are bases used in the biosynthesis of DNA and RNA. The purine and pyrimidine analogs are drugs structurally

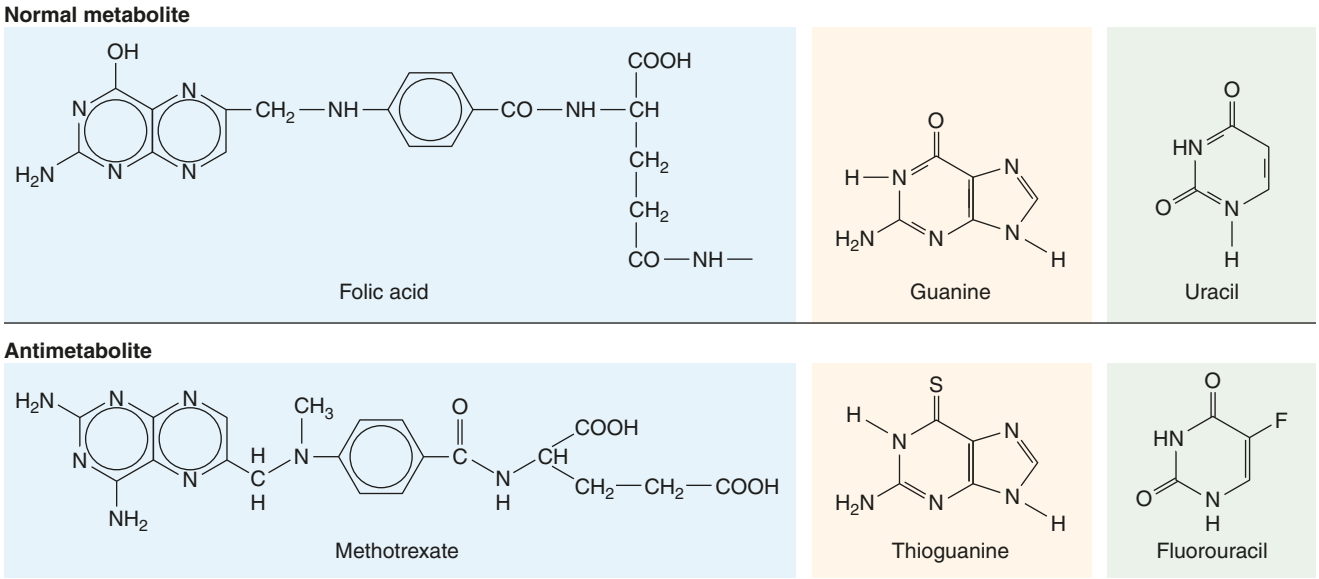


Figure 57.2 Structural similarities between antimetabolites and their natural counterparts.

Table 57.2 Antimetabolites

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Folic Acid Analogs		*Nausea, vomiting, stomatitis, anorexia, rash, fatigue, alopecia, headache* Myelosuppression, severe nausea, vomiting, diarrhea, mucositis, hepatotoxicity, pulmonary toxicity, cytarabine syndrome, neurotoxicity (nelarabine), anaphylaxis and other hypersensitivity reactions
methotrexate (MTX, Rheumatrex, Trexall)	PO: 10–30 mg/day for 5 days	
pemetrexed (Alimta)	IV: 500 mg/m^2 on day 1 of each 21-day cycle	
pralatrexate (Folotyn)	IV: 30 mg/m^2 once weekly for 6 wk in 7-wk cycles	
Purine Analogs		
cladribine (Leustatin)	IV: 0.09 mg/kg/day as a continuous infusion for 7 days	
clofarabine (Clolar)	IV: 52 mg/m^2/day over 2 h for 5 days	
fludarabine (Fludara)	IV: 25 mg/m^2/day for 5 consecutive days	
mercaptopurine (6-MP, Purinethol)	PO: 1.5–2.5 mg/kg/day	
nelarabine (Arranon)	IV: 1500 mg/m^2 on days 1, 3, and 5; repeat every 21 days	
pentostatin (Nipent)	IV: 4 mg/m^2 every other wk	
thioguanine (Tabloid)	PO: 2 mg/kg/day	
Pyrimidine Analogs		
capecitabine (Xeloda)	PO: 1250 mg/m^2/day bid for 2 wk	
cytarabine (Cytosar-U, Depot-Cyt)	IV: 100 mg/m^2 as a continuous infusion over 24 h	
floxuridine (FUDR)	Intra-arterial: 0.1–0.6 mg/kg/day as an intra-arterial infusion	
fluorouracil (5-FU, Adrucil, Carac, Efudex)	IV: 12 mg/kg/day for 4 consecutive days	
gemcitabine (Gemzar)	IV: 1000–1250 mg/m^2 once weekly for 7 wk	
trifluridine/tipiracil (Lonsurf)	PO: 35 mg/m^2 bid on days 1 through 5 and days 8 through 12 of each 28-day cycle	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

similar to their naturally occurring counterparts that can act in several ways. They can inhibit the synthesis of purine or pyrimidine bases, thus limiting the precursors needed for DNA and RNA biosynthesis. The analogs can also become incorporated into the structures of DNA and RNA, resulting in a disruption of nucleic acid function.

Most of the purine and pyrimidine analogs used as antineoplastics are prodrugs that are converted to their active forms on entering the body. A few purine analogs are used for immunosuppression, gout, and antiviral therapy.

CONNECTION Checkpoint 57.2

Trimethoprim is a folic acid analog that is nearly always combined with another antibiotic medication. From what you learned in Chapter 50, name the antibiotic combination that contains trimethoprim and give its primary indications. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Methotrexate (MTX, Rheumatrex, Trexall)

Classification **Therapeutic:** Antineoplastic
Pharmacologic: Antimetabolite, folic acid analog, immunosuppressant, disease-modifying antirheumatic drug (DMARD)

Therapeutic Effects and Uses: Approved in 1953, methotrexate is a widely prescribed antimetabolite available by the PO, parenteral, and intrathecal routes. The PO route is preferred for low-dose therapy. It is approved for a large number of neoplasms, including osteosarcoma, acute lymphocytic and lymphoblastic leukemias, and lymphosarcomas in children; certain inoperable head, neck, and pelvic cancers; breast cancers; lung cancers; and advanced stage non-Hodgkin's lymphoma. Its primary use as an antineoplastic is in combination therapy to maintain induced remissions in those individuals who have had surgical resection or amputation for a primary tumor.

Because of its powerful immunosuppressant properties, methotrexate is used with success in patients with severe RA who have had inadequate response to nonsteroidal anti-inflammatory drugs (NSAIDs) and at least one or more antirheumatic drugs. It also is used to treat severe psoriasis that is unresponsive to other forms of therapy. Off-label uses include other autoimmune disorders such as active Crohn's disease, ulcerative colitis, and SLE. Methotrexate may be used to terminate pregnancy, usually in combination with misoprostol.

Mechanism of Action: Methotrexate is specific for the S phase of the cell cycle. It blocks an enzyme that is responsible for converting folic acid to reduced folate, which interferes with DNA synthesis, repair, and cellular

replication mainly in actively proliferating tissues. This action is what enables it to be effective in treating psoriasis and arthritis in addition to treating cancer.

Pharmacokinetics:

Route(s)	PO, intramuscular (IM), IV, subcutaneous, intrathecal
Absorption	Variable absorption from the GI tract; well absorbed by the subcutaneous or IM routes
Distribution	Widely distributed; crosses the placenta and blood–brain barrier; secreted in breast milk; 60% bound to plasma protein
Primary metabolism	Hepatic, extensive first-pass metabolism
Primary excretion	Renal
Onset of action	Peak: 1–4 h PO; 0.5–2 h IM, IV
Duration of action	Half-life: 2–4 h

Adverse Effects: Methotrexate has many adverse effects, some of which can be serious. Nausea and vomiting are severe at high doses. **Black Box Warnings:** Methotrexate combined with NSAIDs may cause severe and sometimes fatal myelosuppression, which is the primary dose-limiting toxicity of this drug. The drug is hepatotoxic and may cause liver cirrhosis with prolonged use. Ulcerative stomatitis and diarrhea require suspension of therapy because they may lead to hemorrhagic enteritis and death from intestinal perforation. Potentially fatal opportunistic infections, including *Pneumocystis* pneumonia, may occur during therapy. Pulmonary toxicity may result in acute or chronic interstitial pneumonitis at any dose level. Severe, sometimes fatal, dermatologic reactions such as toxic epidermal necrolysis and SJS have been reported.

Contraindications/Precautions: The use of methotrexate as an antineoplastic is contraindicated in thrombocytopenia, anemia, leukopenia, concurrent administration of hepatotoxic drugs and hematopoietic suppressants, alcoholism, or lactation. Precautions must be taken in patients with CKD, impaired hepatic function, active infections, ulcerative colitis, and peptic ulcers; in patients with cancer who have preexisting bone marrow impairment; in the very young or old or debilitated; and in those with poor nutritional status. This drug is a confirmed teratogen and precautions must be taken to avoid pregnancy during therapy. Caution should be used in handling this drug because it can cause severe skin reactions.

Drug Interactions: Methotrexate interacts with many drugs. Increased serum methotrexate levels can occur with the penicillins, vancomycin, cyclosporine, and para-aminobenzoic acid (PABA). Chloramphenicol may decrease the intestinal absorption of methotrexate. An increased methotrexate effect can occur with probenecid, ibuprofen, aspirin, and tetracyclines. Folic acid may alter the body's response to methotrexate. Sulfonamides can lead to an increased risk of methotrexate-induced immunosuppression. Methotrexate can cause decreased phenytoin effects, leading to increased seizure activity. Immunization during methotrexate therapy is not effective and any live vaccine use may lead to a severe reaction that is secondary to the immunosuppressant activity of methotrexate. **Herbal/Food:** Food delays the oral absorption of methotrexate. Echinacea may increase the risk of hepatotoxicity. More than 180 mg/day of caffeine (3 to 4 cups of coffee) may decrease the effectiveness of methotrexate when taken for arthritis.

Pregnancy: Category X.

Treatment of Overdose: Leucovorin or levoleucovorin (Fusilev) is given as soon as possible after overdose to decrease the toxic effects of methotrexate. In some cases, leucovorin is given 24 to 36 hours after methotrexate chemotherapy to "rescue" normal cells from the adverse effects of the antineoplastic.

Nursing Responsibilities: Key nursing implications for patients receiving methotrexate are included in the Nursing Practice Application for Patients Receiving Cancer Chemotherapy.

Drugs Similar to Methotrexate (MTX, Rheumatrex, Trexall)

Pemetrexed and pralatrexate are other folic acid analogs used in cancer chemotherapy. The purine analogs used for cancer chemotherapy include cladribine, clofarabine, fludarabine, mercaptopurine, nelarabine, pentostatin, and thioguanine. The pyrimidine analogs include capecitabine, cytarabine, floxuridine, fluorouracil, gemcitabine, and the combination drug trifluridine/tipiracil.

Capecitabine (Xeloda): Capecitabine is a pyrimidine analog that is converted into fluorouracil, another antimetabolite, by a series of three enzymatic steps. One of these enzymes, thymidine phosphorylase, is found in especially high amounts in cancer cells; thus the drug is converted to a toxic form inside the cancer cell. Capecitabine blocks the synthesis of pyrimidines and can also be incorporated into nucleic acid molecules. It is available PO to treat metastatic breast cancer refractory to other treatments, colorectal cancer, or as adjuvant therapy for colon cancer following resection. Capecitabine causes less immunosuppression than many antineoplastics. Diarrhea is the dose-limiting toxicity; antidiarrheal therapy with loperamide is often indicated during chemotherapy. Nausea, vomiting, stomatitis, and abdominal pain are common adverse effects. An unusual adverse effect with this drug is palmar-plantar

erythrodysesthesia (hand and foot syndrome), which can occur in over half the patients receiving the drug. Hand and foot syndrome is characterized by numbness, tingling, swelling, erythema, blistering, and severe pain. Capecitabine carries a black box warning that patients receiving warfarin (Coumadin) must be closely monitored to prevent serious or fatal bleeding. It is a pregnancy category D drug.

Cladribine (Leustatin): Cladribine is an IV purine analog that is a preferred drug for active hairy cell leukemia. It may be used off-label to treat chronic lymphocytic leukemia, non-Hodgkin's lymphoma, acute and chronic myelogenous leukemia, and mycosis fungoides. Approved in 1993, cladribine differs from other purine analogs in that it is effective against both dividing (S phase) and nondividing cancer cells. Cladribine carries black box warnings regarding myelosuppression, neurotoxicity, and nephrotoxicity. Myelosuppression is the primary dose-limiting toxicity, with a nadir occurring in 14 days and recovery at 5 weeks. Lymphocyte counts may take up to a year to return to normal values, resulting in a high number of opportunistic infections. Fever and chills, which are often associated with infections, are common. Rash occurs in most patients but is not usually serious. Nausea and vomiting are mild compared to other antineoplastics. This is a pregnancy category D drug.

Clofarabine (Clolar): Clofarabine is an IV purine analog that was approved in 2004. It only has one indication: the treatment of relapsed or refractory acute lymphocytic leukemia after at least two prior regimens have proven unsuccessful. It is approved for patients ages 1 to 21 years. Common adverse events include myelosuppression, opportunistic infections, nausea, vomiting, diarrhea, anorexia, fever, fatigue, abdominal pain, and edema. This is a pregnancy category D drug.

Cytarabine (Cytosar-U, Depot-Cyt): Approved in 1969, cytarabine is a pyrimidine antimetabolite available for IV, subcutaneous, or intrathecal administration. It is approved for remission induction in acute myelogenous leukemia. It may be used off-label for other hematologic malignancies, including acute lymphatic leukemia, chronic myelogenous leukemia, and Hodgkin's and non-Hodgkin's lymphoma. Cytarabine is specific for the S phase of the cell cycle. It is converted to its active form, Ara-CTP, and then becomes incorporated into DNA, where it suppresses further DNA synthesis. Cytarabine carries a black box warning regarding myelosuppression. The myelosuppression has a nadir occurring at week 1 and resolution by week 3 or 4. High-dose therapy can cause severe nausea, vomiting, and other GI toxicities. A cluster of symptoms, called the cytarabine syndrome, can occur within 6 to 12 hours of treatment. Symptoms include bone pain, fever, myalgia, rash, and fatigue. Other serious adverse effects include peripheral neuropathy, respiratory distress, encephalopathy, palmar-plantar erythrodysesthesia, and hepatotoxicity. Cytarabine is a pregnancy category D drug.

DepoCyt is a liposomal delivery system that requires less frequent dosing than conventional cytarabine. It is administered only by the intrathecal route for carcinomatous meningitis due to solid tumors. Liposomal cytarabine has been associated with potentially fatal chemical arachnoiditis that occurs within 48 hours of administration. Nervous system symptoms such as confusion, ataxia, dizziness, and impaired cognition are common. In 2017 a fixed-dose liposome encapsulated combination of cytarabine and daunorubicin (Vyxeos) was approved to treat adult myelocytic leukemia.

Floxuridine (FUDR): Floxuridine is a pyrimidine analog antimetabolite that was approved in 1970. Because it is nearly entirely removed by hepatic first-pass metabolism, it has very limited applications. Its only approved indication is as a continuous intra-arterial infusion via a hepatic artery catheter for the palliative treatment of metastatic liver cancer. Due to its high concentration in the liver, floxuridine can cause elevated liver function enzymes and serious hepatotoxicity. This drug carries a black box warning regarding myelosuppression. Other adverse effects, such as nausea, vomiting, anorexia, diarrhea, rash, and alopecia, are common to other antineoplastics. This is a pregnancy category D drug.

Fludarabine (Fludara): Approved in 1991, fludarabine is an IV purine analog with a similar action to cladribine. It is approved only to treat chronic lymphocytic leukemia that has not responded to treatment with alkylating agents, but it may be used off-label to treat other leukemias and non-Hodgkin's lymphoma. It is believed to be cell cycle specific for the S phase, where it inhibits DNA replication. Fludarabine carries black box warnings regarding myelosuppression, neurotoxicity, autoimmune complications, and pulmonary toxicity. Severe myelosuppression is the most common dose-limiting toxicity. Like cladribine, lymphocyte levels may take up to a year to return to normal levels. Rare instances of life-threatening autoimmune hemolytic anemia have been reported. High doses of fludarabine are neurotoxic and can result in blindness, coma, and death. Fever and infections are common, including serious interstitial pneumonitis. Nausea and vomiting are mild compared to other antineoplastics but may be severe at high doses. This is a pregnancy category D drug.

Fluorouracil (5-FU, Adrucil, Carac, Efudex): Approved in 1962, fluorouracil is an antimetabolite that inhibits DNA and RNA synthesis in the S phase of the cell cycle. It is available as an injection, a topical solution, and a topical cream. The IV form is used to treat solid tumors, including

inoperable breast, ovarian, cervical, urinary bladder, liver, colon, rectal, stomach, and pancreatic cancers. As a topical preparation it is used to treat superficial basal cell carcinomas and multiple actinic keratoses. A formulation of fluorouracil cream using a microsponge delivery system (Carac) allows for once-daily dosing and a sustained release of the drug. Fluorouracil carries a black box warning regarding myelosuppression, which may be dose limiting with a nadir at 9 to 14 days and recovery by 30 days. Palmar-plantar erythrodysesthesia occurs in up to 40% of patients receiving a prolonged IV infusion of this drug. Serious GI toxicity, including ulceration, stomatitis, diarrhea, anorexia, and vomiting, is common. Topical applications may cause local photosensitivity, burning, erythema, swelling, and desquamation. Fluorouracil is a pregnancy category D drug.

Gemcitabine (Gemzar): Gemcitabine is an IV pyrimidine analog approved in 1996 that kills cancer cells during the S phase of the cell cycle. Indications include locally advanced or metastatic solid tumors of the pancreas, breast, ovary, or lung. Gemcitabine is the most effective drug for treating advanced pancreatic cancer, a disease that has a very low 5-year survival rate. The dose-limiting toxicity for gemcitabine is myelosuppression, which occurs in nearly all patients taking the drug. Serious pulmonary, renal, and hepatic toxicity has been reported. Fever, nausea, vomiting, and infection are common adverse effects. This is a pregnancy category D drug.

Mercaptopurine (6-MP, Purinethol): Mercaptopurine is an older purine analog, approved in 1953, that is cell cycle specific to the S phase. It is a prodrug that has very similar actions, indications, and adverse effects to thioguanine. Mercaptopurine is indicated for acute lymphocytic and myelogenous leukemia in both adults and children. It is less effective in treating adults than children but remains a preferred drug. It can produce a temporary remission in patients with chronic granulocytic leukemia. Due to its powerful immunosuppressant activity, it may be used off-label to produce temporary remissions in patients with ulcerative colitis and Crohn's disease. The most frequent dose-limiting toxicity of mercaptopurine is myelosuppression, which results in leukopenia, thrombocytopenia, and anemia in nearly every patient. Nausea and vomiting are not severe, but diarrhea may require fluid replacement therapy. This is a pregnancy category D drug.

Nelarabine (Arranon): Approved in 2005, nelarabine is an IV purine analog approved to treat T-cell acute lymphoblastic leukemia and T-cell lymphoblastic lymphoma in both adults and children. Its use is limited to patients who have not responded to or have relapsed during treatment with at least two chemotherapy regimens. The drug carries a black box warning for neurotoxicity, which is the major dose-limiting adverse effect with nelarabine. Neurologic signs and symptoms may include impaired cognition, severe somnolence, seizures, peripheral neuropathies, ataxia, tremor, dizziness, and cerebral hemorrhage. Myelosuppression occurs in most patients; fatigue, fever, and infection occur frequently. Nausea, vomiting, and other GI complaints are usually not a major cause of discontinuation. This is a pregnancy category D drug.

Pemetrexed (Alimta) and pralatrexate (Folotyn): Pemetrexed and pralatrexate are folic acid inhibitors given by IV injection that have very specific therapeutic applications. Approved in 2004, pemetrexed is approved to treat malignant pleural mesothelioma that is unresectable or for patients who are not candidates for surgery. It is administered along with cisplatin in these patients. It is also used to treat locally advanced or metastatic non–small-cell lung cancer after prior chemotherapy. Pralatrexate was approved in 2009 for the treatment of refractory T-cell lymphoma.

Myelosuppression is the primary dose-limiting toxicity for these drugs. GI adverse effects may be serious and include nausea, vomiting, anorexia, and mucositis. Patients may experience serious and even fatal skin reactions. With pemetrexed, caution must be used to ensure adequate kidney function because impairment may cause pemetrexed to accumulate to fatal levels in the blood. To reduce toxicity from pemetrexed and pralatrexate, patients usually receive folic acid and vitamin B_{12} supplements preceding therapy. These are pregnancy category D drugs.

Pentostatin (Nipent): Pentostatin is an IV purine analog approved in 1991 to treat active hairy cell leukemia that has not responded to interferon (IFN) alfa. It may be used off-label to treat other leukemias and lymphomas. It is cell cycle specific in the S phase. Pentostatin has black box warnings regarding renal, liver, and pulmonary toxicities. Hematologic toxicity is dose limiting and patients experience a high rate of fever, chills, and infections. Rash and other skin reactions occur in most patients and may be severe. Neurologic toxicity is a serious problem with high doses. This is a pregnancy category D drug.

Thioguanine (Tabloid): Approved in 1966, thioguanine is very similar to mercaptopurine in its actions and adverse effects. Like other antimetabolites, it is active in the S phase of the cell cycle. It is available PO to treat acute nonlymphocytic leukemia. Off-label indications include chronic myelogenous leukemia, psoriasis, refractory ulcerative colitis, and Crohn's disease. Myelosuppression is the most common dose-limiting toxicity. Long-term, continuous use of thioguanine is not recommended due to the risk for serious hepatotoxicity. Adverse GI effects are generally not severe at normal doses. This is a pregnancy category D drug.

Trifluridine/tipiracil (Lonsurf): One of the newer drugs in this class, Lonsurf is a combination drug approved in 2015 to treat metastatic colorectal cancer when at least two other therapies have failed to achieve successful results. The active ingredient is trifluridine, which is a pyrimidine that is incorporated into the DNA of the cancer cell. Tipiracil is added as a pharmacokinetic booster to increase the levels of trifluridine in the blood. The most serious adverse effect is myelosuppression. This drug causes fetal harm and death in laboratory animals but has no pregnancy rating. As eyedrops, trifluridine is available to treat ocular herpes (see Chapter 54).

PharmFACT

Although breast cancer is the second leading cause of cancer death in women, death rates have been declining since 1989. This is likely due to earlier detection, increased awareness, and better treatments for the disease (American Cancer Society, 2017).

Antitumor Antibiotics

57.4 The antibiotic antineoplastics contain substances obtained from bacteria that have the ability to kill cancer cells.

Antitumor properties have been identified in a number of chemicals isolated from microorganisms. These substances are more cytotoxic than traditional antibiotics, and their use is restricted to treating a few specific types of cancer. The antitumor antibiotics are listed in Table 57.3.

The antitumor antibiotics bind to DNA and affect its function by a mechanism similar to that of the alkylating agents; therefore, their general actions and adverse effects are like those of the alkylating agents. Unlike the alkylating agents, however, all the antitumor antibiotics must be administered IV or through direct instillation via a catheter into a body cavity or organ. As with many other antineoplastics, the primary dose-limiting toxicity of drugs in this class is myelosuppression. These drugs can cause major damage to the skin, subcutaneous tissue, and nerves should extravasation occur.

The antitumor antibiotics are divided into two groups, the anthracyclines and nonanthracyclines. The anthracyclines include daunorubicin, doxorubicin, epirubicin, idarubicin, and mitoxantrone. The anthracyclines are closely related in structure, and all exhibit cardiotoxicity, a major limiting adverse effect. Cardiotoxicity may occur within minutes of administration, or it may be delayed for months or years after chemotherapy has been completed. The nonanthracyclines, which include bleomycin, dactinomycin, and mitomycin, tend to cause less cardiotoxicity than the anthracyclines.

In 1995, the cardioprotective drug dexrazoxane (Zinecard) was approved to specifically treat doxorubicin cardiotoxicity. Started by slow IV infusion 30 minutes before doxorubicin, dexrazoxane reduces the incidence and severity of cardiomyopathy from the antitumor antibiotic. In 2007, a second form of dexrazoxane (Totect) was approved to treat the pain, inflammation, and tissue necrosis associated with extravasation of anthracyclines. For this indication, IV dexrazoxane is administered as soon as possible after confirmation of anthracycline extravasation, with subsequent doses at 24 and 48 hours. Dexrazoxane may add to the myelosuppression caused by anthracyclines.

PROTOTYPE DRUG **Doxorubicin (Adriamycin)**

Classification **Therapeutic:** Antineoplastic
Pharmacologic: Antitumor antibiotic, anthracycline

Therapeutic Effects and Uses: Approved in 1975, doxorubicin is a cytotoxic antibiotic obtained from *Streptomyces* that has a wide spectrum of antitumor activity and is considered one of the most effective single drugs against solid tumors. Doxorubicin is highly toxic to rapidly proliferating cells as well as slowly developing

Table 57.3 Antitumor Antibiotics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
bleomycin (Blenoxane)	IV: 0.25–0.5 units/kg q4–7days	*Nausea, vomiting, stomatitis, anorexia, headache, rash, alopecia*
dactinomycin (Actinomycin-D, Cosmegen)	IV: 400–600 mcg/m^2/day for 5 days	
daunorubicin (Cerubidine)	IV: 30–45 mg/m^2/day for 3–5 days	Myelosuppression, severe nausea, vomiting, diarrhea, mucositis, pulmonary or cardiac toxicity, anaphylaxis and other hypersensitivity reactions, tissue necrosis (due to extravasation), hemolytic uremic syndrome (mitomycin), hepatotoxicity (dactinomycin)
doxorubicin (Adriamycin)	IV: 40–60 mg/m^2 as a single injection q21–28days	
doxorubicin liposomal (Doxil, Evacet)	IV: 20 mg/m^2 q3wk	
epirubicin (Ellence)	IV: 100–120 mg/m^2 as a single dose	
idarubicin (Idamycin)	IV: 8–12 mg/m^2/day for 3 days	
mitomycin (Mutamycin)	IV: 20 mg/m^2 as a single dose	
mitoxantrone (Novantrone)	IV: 12 mg/m^2 q3days	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

tumors. It is approved to treat neuroblastoma and solid tumors of the bone, bladder, breast, ovary, GI tract, lung, and thyroid. It is also part of many chemotherapy regimens for other tumors, such as acute lymphoblastic and myeloblastic leukemias, Wilms' tumor, soft tissue sarcomas, and multiple myeloma. Given by the IV route, it may also be instilled into the bladder for bladder cancer. It is also effective as a preradiation therapy to sensitize superficial tumors.

Doxorubicin liposomal (Doxil, Evacet) is a form of the drug incorporated into liposomes, closed, spherical molecules that encase the drug. Administered IV the liposomes have a long half-life and produce a prolonged duration of action. In addition, the liposomes tend to stay in the circulation until they reach tumors, which often have leakier capillaries than normal tissues. Once inside the tumor, the drug is released from its carrier. Doxorubicin liposomal is approved for use in patients with acquired immunodeficiency syndrome (AIDS)–related Kaposi's sarcoma, refractory ovarian tumors, and relapsed multiple myeloma.

Mechanism of Action: Doxorubicin binds to DNA, causing strand splitting and inhibition of DNA synthesis. It is cell cycle nonspecific.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Widely distributed; crosses the placenta but does not cross the blood–brain barrier; secreted in breast milk; 75% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Bile
Onset of action	Peak: 1/2–2 h
Duration of action	Triphasic half-life: 12 min, 3.3 h, and 30–40 h

Adverse Effects: Doxorubicin has many adverse effects, some of which are serious. These include severe nausea, vomiting, mucositis, rash, excessive lacrimation, hepatotoxicity, anaphylaxis, complete alopecia, and radiation recall phenomenon (a skin reaction due to prior radiation therapy). Doxorubicin turns urine and tears a red color, which is harmless but anxiety provoking. Temporary decreased fertility is likely in both men and women. **Black Box Warnings:** Severe myelosuppression may occur, which is the major dose-limiting toxicity. It may manifest as thrombocytopenia, leukopenia (especially granulocytes), and anemia. The neutropenia nadir occurs at 7 days and recovers by 14 days. Doxorubicin exhibits significant cardiotoxicity, which may be either acute or chronic. Cardiac adverse effects can be life threatening and may include sinus tachycardia, bradycardia, delayed heart failure, acute left ventricular failure, and myocarditis. Heart failure may occur months or years after the termination of chemotherapy. Acute, infusion-related reactions may occur, including anaphylaxis. Severe local necrosis may result if extravasation occurs. Secondary malignancies, especially acute myelogenous leukemia, may occur 1 to 3 years following therapy.

Contraindications/Precautions: Contraindications to the use of doxorubicin include pregnancy, lactation, myelosuppression, thrombocytopenia, preexisting cardiac disease, obstructive jaundice, lactation, or previous treatment with complete cumulative doses of doxorubicin or daunorubicin. Precautions include CKD, impaired hepatic function, history of atopic dermatitis, and patients who have received cyclophosphamide or pelvic radiation therapy to areas surrounding the heart. Doxorubicin is a severe vesicant and precautions must be taken to avoid contact with the skin or soft tissue. Skin contact or extravasation should be treated immediately with local ice packs to reduce absorption of the drug.

Drug Interactions: Increased toxicity may occur with other antineoplastics, radiation therapy, or mercaptopurine. Cyclophosphamide may increase the risk of hemorrhagic cystitis or cardiac toxicity. Paclitaxel may decrease the clearance of doxorubicin, leading to more profound neutropenia and stomatitis. Phenobarbital and other barbiturates increase the elimination of doxorubicin. Possible decreased phenytoin levels may occur. Concurrent use with verapamil can raise the serum levels of doxorubicin, thus increasing the risk for cardiotoxicity. Use with paclitaxel will result in an increased incidence of stomatitis, neutropenia, and heart failure. Because doxorubicin causes thrombocytopenia, concurrent use with NSAIDs, anticoagulants, or platelet inhibitors may cause excessive bleeding. **Herbal/Food:** Unknown.

Pregnancy: Category D.

Treatment of Overdose: If myelosuppression occurs, administration of antibiotics, platelets, and granulocytes may be necessary. Symptoms of mucositis and heart failure must be treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving doxorubicin are included in the Nursing Practice Application for Patients Receiving Cancer Chemotherapy.

Drugs Similar to Doxorubicin (Adriamycin)

The anthracyclines include doxorubicin, doxorubicin liposomal, daunorubicin, epirubicin, idarubicin, and mitoxantrone. The nonanthracyclines are bleomycin, dactinomycin, and mitomycin.

Anthracyclines:

Daunorubicin (Cerubidine): Approved in 1979, daunorubicin is an IV antitumor antibiotic obtained from *Streptomyces*. Cell cycle specific for the S phase, daunorubicin binds to DNA, causing strand splitting and inhibition of DNA synthesis. Closely related structurally to doxorubicin, daunorubicin is approved to induce remission in acute myelogenous leukemia in adults and acute lymphocytic leukemia in children and adults. It is less effective than doxorubicin in treating solid tumors. Daunorubicin carries black box warnings regarding tissue necrosis following extravasation, cardiotoxicity, and myelosuppression. Myelosuppression is the major dose-limiting toxicity, and the drug exhibits the same types of cardiotoxicity as doxorubicin although to a lesser extent. Other adverse effects, such as nausea, vomiting, alopecia, urine discoloration, and vesicant properties, are the same as those of doxorubicin. This drug is pregnancy category D.

Epirubicin (Ellence): Approved in 1999, epirubicin is an IV antitumor antibiotic closely related to doxorubicin in both structure and function. Epirubicin is approved only for adjuvant therapy for axillary node–positive breast cancer but may be used off-label for bladder, gastric, lung, head, neck, and liver cancers. Carrying black box warnings for extravasation, cardiotoxicity, myelosuppression, and secondary malignancies, epirubicin exhibits the same types of adverse effects as doxorubicin. Myelosuppression is the major dose-limiting toxicity, with a nadir occurring at 10 to 14 days and recovery at 21 days. Cardiotoxicity, including fatal heart failure, has been reported. Moderate to severe nausea, vomiting, and alopecia occur in many patients. Severe local tissue necrosis can occur with extravasation. Secondary acute myelogenous leukemia has been reported in patients treated with epirubicin. This is a pregnancy category D drug.

Idarubicin (Idamycin): Approved in 1990, idarubicin is an IV antitumor antibiotic structurally similar to daunorubicin. Its only approved indication is for acute myelogenous leukemia, although it may be used off-label for other leukemias, advanced metastatic breast cancer, and refractory non-Hodgkin's lymphoma. Idarubicin carries black box warnings regarding tissue necrosis following extravasation, cardiotoxicity, and myelosuppression. Like other drugs in this class, myelosuppression is the primary dose limitation, with a nadir by day 15 and recovery by day 25. Idarubicin is a vesicant, and care must be taken to not allow extravasation or exposure to skin. Other common adverse effects include alopecia, cardiotoxicity, and moderate nausea and vomiting. This is a pregnancy category D drug.

Mitoxantrone (Novantrone): Although not an anthracycline, mitoxantrone is structurally similar to the anthracyclines and shares some common properties. Approved in 1987, it is approved to treat acute myelogenous leukemia and for the palliation of severe pain associated with advanced prostate cancer. Off-label antineoplastic indications include other leukemias, breast cancer, metastatic ovarian cancer, liver cancer, and non-Hodgkin's lymphoma. It is also approved for reducing neurologic disability associated with chronic multiple sclerosis. It is administered by IV infusion. Mitoxantrone carries black box warnings regarding extravasation, cardiotoxicity, myelosuppression, and secondary malignancies. The dose-limiting toxicity is myelosuppression, with a nadir at 10 to 14 days and recovery by 2 to 3 weeks. It is less cardiotoxic than the anthracyclines, but this is still a significant adverse effect of mitoxantrone. Other adverse effects include stomatitis, moderate nausea, vomiting, alopecia, injection-site reactions, and secondary malignancy (leukemia). This is a pregnancy category D drug.

Nonanthracyclines:

Bleomycin (Blenoxane): Approved in 1973, bleomycin is an antitumor antibiotic obtained from *Streptomyces* that is cell cycle specific to the G2 phase. Bleomycin is used for palliative therapy for many different cancers, including Hodgkin's and non-Hodgkin's lymphomas, testicular cancer, vulvar cancer, cervical cancer, and squamous cell carcinoma. It can be administered by the IM, IV, subcutaneous, and intrapleural routes. Bleomycin causes less myelosuppression than other drugs in this class. A black box warning states that the drug can cause severe and potentially fatal lung injury, with signs such as pulmonary fibrosis, or pleural effusions. Patients who have received radiation treatment to the chest or cumulative doses of bleomycin are at increased risk for lung injury. The warning also states that bleomycin can cause a severe idiosyncratic reaction, similar to anaphylaxis, consisting of hypotension, mental confusion, fever, chills, and wheezing. Serious dermatologic reactions may require lower doses or discontinuation of the drug. Nausea and vomiting are generally mild; however, anorexia and weight loss are common. This is a pregnancy category D drug.

Dactinomycin (Actinomycin-D, Cosmegen): Approved in 1973, dactinomycin is an IV antitumor antibiotic obtained from *Streptomyces* that binds to DNA to inhibit RNA synthesis and is cell cycle nonspecific. Its primary indication is to treat Wilms' tumor and rhabdomyosarcoma, but it is also approved for choriocarcinoma, Ewing's sarcoma, and testicular carcinoma. Off-label indications include Kaposi's sarcoma, malignant melanoma, and osteogenic sarcoma. Dactinomycin has several dose-limiting toxicities. Myelosuppression can be severe and lead to serious infections with a nadir at 7 to 21 days. Nausea and

vomiting are severe and require antiemetic therapy. Other GI effects include oral or esophageal ulceration, anorexia, and diarrhea. Hepatotoxicity, including hepatomegaly, ascites, hepatitis, and hyperbilirubinemia, can be serious, especially at high doses. Alopecia and dermatologic skin reactions are common. This drug carries a black box warning that special handling is required because the powder, dust, and solution are extremely irritating to soft tissue and mucous membranes. This is a pregnancy category D drug.

Mitomycin (Mutamycin): Mitomycin is an IV antitumor antibiotic extracted from *Streptomyces* that was approved in 1974. It is effective against both slowly developing and rapidly proliferating cells in solid tumors, including some tumors unresponsive to radiation and other chemotherapeutic drugs. Mitomycin is approved only for gastric and pancreatic cancers but may be used off-label for bladder cancer, colorectal cancer, breast cancer, and squamous cell carcinoma of the head, neck, lung, or cervix. Mitomycin carries black box warnings regarding myelosuppression and hemolytic uremic syndrome. The primary dose-limiting toxicity is bone marrow suppression with a nadir at 3 weeks. Recovery may take 4 to 8 weeks. Hemolytic uremic syndrome is a serious complication involving hemolytic anemia, thrombocytopenia, and irreversible renal failure. Severe skin reactions such as ulceration and cellulitis can occur, especially following extravasation. Lung toxicity is rare, but occurrences of interstitial pneumonitis can be fatal. Nausea, vomiting, anorexia, and fatigue may be persistent during therapy. This is a pregnancy category X drug.

Hormones and Hormone Antagonists

57.5 Hormones and hormone antagonists block the substances necessary for continued growth of tumors.

A number of hormones are used in cancer chemotherapy, including corticosteroids, progestins, estrogens, and androgens. In addition, several hormone antagonists have been found to exhibit antitumor activity. Endocrine, or hormonal therapy, is limited to treating hormone-sensitive tumors of the breast or prostate.

The mechanism of hormone antineoplastic activity is largely unknown. It is likely, however, that these antitumor properties are independent of their normal hormone mechanisms because the doses utilized in cancer chemotherapy are magnitudes larger than the amount normally present in the body. The student should refer to other chapters in this text for a complete discussion of hormone therapy. The antitumor hormones and hormone antagonists are listed in Table 57.4.

In general, the hormones and hormone antagonists act by blocking the substances essential for tumor growth. Because these drugs are not cytotoxic, they produce few of the life-threatening toxic effects of antineoplastics from other classes. They can, however, produce significant adverse effects when given at high doses for prolonged periods. Because they rarely produce cancer cures when used singly, these drugs are normally given for palliation. The four general classes of hormone antagonists are:

- Selective estrogen receptor modifiers
- Aromatase inhibitors
- Gonadotropin-releasing hormone analogs
- Androgen receptor blockers

Selective estrogen receptor modifiers: Estrogen is a hormone produced by the ovary and the adrenal gland that has profound metabolic actions on many organs. Estrogen produces its actions throughout the body by activating estrogen receptors (ERs). Estrogen receptors are overexpressed in many breast cancers, which are known as ER-positive tumors. Estrogen promotes the growth of ER-positive breast tumors.

Selective estrogen receptor modifiers (SERMs) are drugs that act to either activate or inhibit ERs. SERMs have the ability to activate ERs in some tissues (such as bone), while blocking ERs in other tissues (such as breast). SERMs that block ERs have an antiestrogen effect that slows tumor growth of ER-positive breast cancer. Tamoxifen is the most widely prescribed SERM and serves as the prototype for antineoplastic hormones.

Aromatase inhibitors: Aromatase is the enzyme that catalyzes the last step in the synthesis of estrogen. During this step, aromatase converts androgens (testosterone and androstenedione) to estrogens (estradiol) in peripheral tissues such as fat and muscle. Blocking this step reduces the level of estrogen in the blood, starving ER-dependent tumors of a major growth stimulus.

The aromatase inhibitors cannot prevent estradiol formation in the ovary, which is the primary site of estrogen synthesis in premenopausal women. Because of this, the drug is effective only in postmenopausal women, who secrete almost no estrogen from their ovaries.

Aromatase inhibitor therapy has become a first-line treatment for postmenopausal women with ER-positive breast cancer. Studies suggest that the aromatase inhibitors are more effective at preventing reoccurrences of advanced breast cancer in postmenopausal women than tamoxifen. Aromatase inhibitors can be started as primary therapy, or instituted after the completion of 2 to 3 years of tamoxifen therapy. Extending treatment for up to 10 years has been shown to significantly reduce the risk of breast cancer recurrence (Goss et al., 2016).

Table 57.4 Hormone and Hormone Antagonists Used for Neoplasia

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Selective Estrogen Receptor Modifiers (SERMS)		
fulvestrant (Faslodex)	IM: 500 mg once monthly	*Hot flashes, leg cramps, atrophic vaginitis, menstrual changes* Venous thromboembolism (including stroke, deep vein thrombosis, and pulmonary embolism), retinal changes, cataracts, fetal toxicity
raloxifene (Evista)	PO: 60 mg once daily	
tamoxifen	PO: 20–40 mg/day (treatment) or 20 mg/day (prophylaxis)	
toremifene (Fareston)	PO: 60 mg/day	
Androgen Blockers		
abiraterone (Zytiga)	PO: 1 g once daily in combination with prednisone	*Joint swelling, hypokalemia, muscle weakness, back pain, diarrhea, hot flashes, gynecomastia, urinary tract infection, asthenia* Hepatotoxicity, fetal toxicity
bicalutamide (Casodex)	PO: 50 mg/day	
enzalutamide (Xtandi)	PO: 160 mg once daily	
flutamide (Eulexin)	PO: 250 mg tid	
nilutamide (Nilandron)	PO: 150–300 mg once daily	
Aromatase Inhibitors		
anastrozole (Arimidex)	PO: 1 mg/day	*Hot flashes, vasodilation, fatigue, mood disturbances, nausea, vomiting* Fetal toxicity, fracture, ischemic heart disease, serious hypertension
exemestane (Aromasin)	PO: 25 mg/day after a meal	
letrozole (Femara)	PO: 2.5 mg/day	
GnRH Analogs and Related Drugs		
degarelix (Firmagon)	Subcutaneous: 240-mg loading dose followed by 80 mg q28days	*Hot flashes, hyperglycemia (increased risk for diabetes mellitus), mood disturbances, bone pain, injection-site pain, fatigue* Seizures, spinal cord compression, QT interval prolongation
goserelin (Zoladex)	Subcutaneous: 1 implant q12wk (10.8 mg)	
histrelin (Supprelin LA, Vantas)	Subcutaneous: 1 implant every 12 months (50 mg)	
leuprolide (Eligard, Lupron, Viadur)	Subcutaneous: 1 implant every 12 months (65 mg) IM depot: 22.5–45 mg every 3–6 months	
triptorelin (Trelstar)	IM: 3.75 mg once monthly or 22.5 mg q24wk	
Hormones		
dexamethasone (Decadron, others)	PO: 2 mg bid–qid	*Weight gain, insomnia, abdominal distention, sweating, flushing, diarrhea, nervousness, gynecomastia, hirsutism (testosterone)* Thrombophlebitis, muscle wasting (dexamethasone, prednisone), osteoporosis, hepatotoxicity
diethylstilbestrol (DES, Stilbestrol)	PO: 1–15 mg/day	
ethinyl estradiol (Estinyl, others)	PO: 1 mg tid for 2–3 months (breast cancer); 0.15–3 mg/day (prostate cancer)	
fluoxymesterone	PO: 10 mg tid	
medroxyprogesterone (Depo-Provera, Provera)	IM: 400–1000 mg every wk	
megestrol (Megace)	PO: 40–160 mg bid–qid	
prednisone (Deltasone, others)	PO: 20–100 mg/day	
testosterone (AndroGel, Delatestryl, Testred, others)	IM: 200–400 mg q2–4wk	

Gonadotropin-releasing hormone analogs: Gonadotropin-releasing hormone (GnRH) analogs mimic the actions of endogenous GnRH and provide feedback to the pituitary gland. Initially, the effect is to increase the production of interstitial cell–stimulating hormone (ICSH), which increases the secretion of testosterone by the testes. ICSH is also known as follicle-stimulating hormone (FSH). With continued therapy, the pituitary becomes insensitive to the effects of GnRH, and the production of testosterone falls. In fact, testosterone secretion declines to near zero levels such that treatment with a GnRH analog is considered a type of chemical castration. All are approved for the management of prostate cancer. The loss of testosterone "starves" prostate cancer cells of the hormone essential for their growth. Some drugs in this class are also approved to treat endometriosis and uterine leiomyomata and for the palliative treatment of advanced breast cancer. The GnRH analogs are administered by the IM route or subcutaneous implants. All GnRH analogs are pregnancy category X drugs and contraindicated during pregnancy.

Androgen receptor blockers: Growth of prostatic carcinoma is usually androgen dependent. The androgen receptor blockers prevent testosterone and other androgens

from reaching their receptors on cancer cells, thus depriving the cells of an important growth promoter. Drugs in this group are all administered PO and are used only to treat prostate cancer. They have an additive or synergistic effect when used in combination with GnRH analogs.

PROTOTYPE DRUG **Tamoxifen**

Classification **Therapeutic:** Antineoplastic
Pharmacologic: Hormonal agent, estrogen receptor blocker

Therapeutic Effects and Uses: Approved in 1985, tamoxifen is an oral SERM that has an antiestrogen effect on ER-positive tumors. It has no effect on ER-negative cancers. Tamoxifen is approved for the palliative treatment of advanced, metastatic, ER-positive breast cancer in men and postmenopausal women. Off-label indications include astrocytoma, malignant glioma, malignant melanoma, and ovarian cancer.

Tamoxifen and raloxifene are the only antineoplastics approved for the *prophylaxis* of breast cancer in women who have a high risk of developing the disease. In addition, it is approved as adjunctive therapy in women following a mastectomy to decrease the potential for cancer in the contralateral breast. It is not to be used for prophylaxis in women at low risk of acquiring breast cancer because the risks may outweigh the benefits in this population. Risk factors that may qualify a woman for tamoxifen prophylactic therapy depend on age and also include the following:

- One first-degree relative with a history of breast cancer
- Two or more benign biopsies and a history of a breast biopsy showing atypical hyperplasia
- At least two first-degree relatives with a history of breast cancer and a personal history of at least one breast biopsy
- Lobular carcinoma *in situ*
- Age at first live birth less than or equal to 25 years of age and age at menarche less than or equal to 11 years
- At least two first-degree relatives with a history of breast cancer and age at first live birth of less than or equal to 19 years
- One first-degree relative with a history of breast cancer and a personal history of a breast biopsy showing atypical hyperplasia.

Tamoxifen has several nonneoplastic indications, all of which are off-label. For the treatment of infertility, it may be used to induce ovulation in women who do not ovulate but desire to become pregnant. It may be used to reduce the pain associated with gynecomastia in both women and men.

CONNECTIONS: Lifespan Considerations

Neurotoxicity and Mobility Effects of Chemotherapy on the Older Adult

Many chemotherapy drugs used in the treatment of cancer have neurotoxic effects, some of which persist for years after treatment or cause permanent dysfunction. Peripheral neuropathy caused by chemotherapy may be severe and unpredictable and often causes sensory effects such as decreased touch, temperature, and other sensations, including muscle cramping. Neuropathic pain is also common and may be severe enough to result in the need to slow or stop treatment. Reduced deep tendon reflexes (DTRs) may be an early sign of peripheral neuropathy, and autonomic dysfunction may also occur, resulting in symptoms such as orthostatic hypotension and constipation.

Although adults over the age of 65 account for a significant number of cancer patients and survivors, they are not well represented in research. There are few studies of the effects of chemotherapy on the older adult's mobility and balance. It is known that indicators of frailty such as grip strength and functional dependence, that is, requiring assistance for activities of daily living (ADLs), are associated with a poorer prognosis and tolerance to cancer therapy (Klepin et al., 2016; Versteeg, Konings, Lagaay, van de Loosdrecht, & Verheul, 2014). Whereas positive therapeutic responses to chemotherapy may be similar to those of younger colleagues, older adults often experience adverse effects of chemotherapy at more severe levels and for longer periods. With the increased risk of chemotherapy-related peripheral neuropathy and other neurotoxic effects associated with many drugs, the older adult is at extreme risk for falls and injury, especially when an individual has preexisting visual or hearing conditions (Ward, Wong, Moore, & Naeim, 2014).

Nurses can be proactive in helping the older adult to plan for and manage potential adverse effects from chemotherapy. Prior to beginning the drug regimen, a physical therapy consultation may be beneficial to establish baseline function. Periodic consultations thereafter can assist in the detection of developing neuropathies and other adverse effects so that they can be managed appropriately or the drug regimen reevaluated if needed. Low to moderate intensity aerobic exercise may also be of benefit, not only in maintaining muscle mass, but also in positive effects on the chemotherapy-induced anemia (Mohamady, Elsisi, & Aneis, 2017). The nurse is a valuable member of the collaborative oncology team and is often the member who will have the most frequent contact with the patient. Weakness or mobility problems related to chemotherapy may have a profound impact on the older adult, and early intervention may help reduce these effects.

Mechanism of Action: Tamoxifen binds to ERs, producing agonist effects in some tissues (bone) and antagonist effects in other tissues (breast). The binding in breast tissue inhibits DNA replication and affects other growth factors in cancer cells.

Pharmacokinetics:

Route(s)	PO
Absorption	Slowly from the GI tract
Distribution	Widely distributed; crosses the placenta; unknown if secreted in breast milk
Primary metabolism	Hepatic by CYP3A, CYP2C9, and CYP2D6
Primary excretion	Feces
Onset of action	Peak serum concentration: 5 h
Duration of action	Half-life: 5–7 days

Adverse Effects: Tamoxifen has few serious adverse effects other than nausea and vomiting, which occurs in 12% to 25% of patients who are taking the drug. This can be controlled with antiemetics as necessary. Other common adverse effects include hot flashes, vaginal discharge, irregular menses, vaginal bleeding, fluid retention, headaches, lightheadedness, and rash. **Black Box Warnings:** The most serious problem associated with tamoxifen use is the increased risk of endometrial cancer. The benefits of tamoxifen outweigh the risks in women taking tamoxifen to *treat* breast cancer. The benefit versus risk is not as clear in women who are taking tamoxifen to *prevent* breast cancer. There is also a slightly increased risk of thromboembolic disease, including stroke, pulmonary embolism, and deep vein thrombosis (DVT) with the use of tamoxifen. The risk of a thromboembolic event is believed to be about the same as for oral contraceptives.

Contraindications/Precautions: Contraindications to the use of tamoxifen include anticoagulant therapy, preexisting endometrial hyperplasia, history of thromboembolic disease, pregnancy, and lactation. Precautions should be observed in patients with leukopenia, thrombocytopenia, visual disturbances, cataracts, bone marrow suppression, hypercalcemia, and hypercholesterolemia.

Drug Interactions: Tamoxifen is extensively metabolized by hepatic CYP enzymes and may interact with inducers or inhibitors of these enzymes. Use with warfarin increases the risks of bleeding. Cytotoxic antineoplastics may increase the risk of thromboembolism. Bromocriptine may increase tamoxifen levels, whereas aminoglutethimide, medroxyprogesterone, or rifamycin may decrease tamoxifen levels. Selective serotonin reuptake inhibitors (SSRIs) may decrease the effectiveness of tamoxifen. This drug should not be used concurrently with oral contraceptives. **Herbal/Food:** Black cohosh should not be taken unless approveçd by the healthcare provider.

Pregnancy: Category D.

Treatment of Overdose: Seizures, neurotoxicity, and QT-interval changes may occur with overdose. The patient is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving tamoxifen are included in the Nursing Practice Application for Patients Receiving Cancer Chemotherapy.

Drugs Similar to Tamoxifen

The drugs in this broad category of antineoplastics are divided into SERMs, aromatase inhibitors, gonadotropin-releasing hormone analogs, and androgen receptor blockers. Dexamethasone, diethylstilbestrol, medroxyprogesterone, prednisone, and testosterone are hormones used for nonneoplastic indications. Information on these drugs may be found in other chapters of this text. Abarelix (Plenaxis) is a hormone antagonist that has been discontinued in the United States.

Selective estrogen receptor modifiers:

Fulvestrant (Faslodex): Approved in 2002, fulvestrant selectively binds to the ERs of breast cancer cells and inhibits cell division. It is used to treat advanced breast cancer in ER-positive, postmenopausal women with disease progression following antiestrogen therapy. Fulvestrant is a pure estrogen antagonist and, unlike tamoxifen, it has no estrogen agonist activity. Administered by IM injection once a month, it appears to be as effective as the aromatase inhibitors. It is well tolerated, with the most common adverse effects being nausea, vomiting, constipation, diarrhea, headache, abdominal pain, hot flashes, back pain, and pharyngitis. Temporary injection-site pain and inflammation are possible. Fulvestrant is a pregnancy category D drug.

Raloxifene (Evista): Raloxifene is an oral SERM that has antagonist effects on the ERs in the breast. It activates ERs in bone, which decreases bone resorption and increases bone mineral density. Unlike tamoxifen, it does not have agonist actions on the ERs in the uterus. Originally approved in 1997 for osteoporosis, its indications were expanded to include prophylaxis of breast cancer in postmenopausal women who are at high risk for developing the disease. It is used off-label to treat uterine leiomyomata in postmenopausal women. Raloxifene is associated with an increased risk of thromboembolic disorders such as DVT, pulmonary embolism, and retinal thrombosis. Hot flashes and leg cramps are common adverse effects. It is classified as pregnancy category X. A prototype feature for raloxifene is presented in Chapter 72.

Toremifene (Fareston): Approved in 1997, toremifene is a PO medication closely related to tamoxifen that exerts antiestrogenic effects at ERs in the breast. Toremifene is indicated for the treatment of metastatic breast cancer in postmenopausal women with ER-positive or unknown tumors. Common adverse effects include hot flashes, vaginal discharge, diaphoresis, and fluid retention. Serious adverse effects are

uncommon but may include stroke, angina, and increased intraocular pressure. Toremifene carries a black box warning that the drug prolongs the QT interval, resulting in dysrhythmias. It should not be given to patients with preexisting QT prolongation or uncorrected hypokalemia or hypomagnesemia. This is a pregnancy category D drug.

Aromatase inhibitors:

Anastrozole (Arimidex): Anastrozole is an oral hormone antagonist highly specific for the aromatase enzyme. Anastrozole restricts tumor growth by inhibiting the biosynthesis of estrogens, thus depriving the tumor of necessary estrogen. First approved in 1995 for the treatment of advanced breast cancer, indications were expanded to include the adjuvant treatment of early breast cancer in postmenopausal women with ER-positive disease. An off-label indication of anastrozole is for the treatment of uterine leiomyomata. It is contraindicated in premenopausal women. Serious adverse effects are uncommon during anastrozole therapy. The most common adverse effects are hot flashes, asthenia, arthritis, pharyngitis, bone pain, nausea, vomiting, and depression. Osteoporosis during therapy may lead to an increased incidence of spinal fractures. Women with preexisting ischemic heart disease have an increased incidence of ischemic cardiovascular events. As an antiestrogen, anastrozole will block the effects of estrogen-containing products. Anastrozole is a pregnancy category D drug.

Exemestane (Aromasin): Exemestane is an oral aromatase inhibitor that reduces serum estradiol concentrations by binding irreversibly to the aromatase enzyme. Exemestane has greater antiestrogen actions than tamoxifen or anastrozole and is effective when tumors develop resistance to other drugs in this class. First approved in 1999 for the treatment of advanced breast cancer, indications now include the adjuvant treatment of early breast cancer in postmenopausal women with ER-positive disease. It is contraindicated in premenopausal women. Adverse effects are the same as those of other aromatase inhibitors and include hot flashes, nausea, vomiting, arthralgia, and fatigue. Bone mineral density often decreases during exemestane use. An increase in ischemic heart disease has been reported during therapy. Exemestane is a pregnancy category D drug.

Letrozole (Femara): Letrozole is an oral aromatase inhibitor that reduces serum estrogen levels. First approved in 1997, its indications include the adjuvant treatment of early breast cancer in patients who have received 5 years of adjuvant tamoxifen therapy; first-line treatment of patients with ER-positive or unknown, locally advanced, or metastatic cancer; advanced breast cancer with disease progression following antiestrogen therapy; and the adjuvant treatment of patients with hormone receptor–positive early breast cancer. Off-label indications include the treatment of infertility in anovulatory women who wish to become pregnant and to increase the height of boys with idiopathic short stature or delayed puberty. It is contraindicated in premenopausal women. This drug is generally well tolerated, with the most common adverse effects being nausea, vomiting, asthenia, fatigue, headache, and bone and other musculoskeletal pain. Like other drugs in this class, bone mineral density decreases during therapy. Letrozole is a pregnancy category D drug.

Gonadotropin-releasing hormone analogs and related drugs:

Degarelix (Firmagon): Approved in 2008, degarelix acts by a different mechanism than other drugs in this class. Rather than being an analog of GnRH, it is an antagonist, blocking the receptors for GnRH in the pituitary. Although its mechanism differs, the pharmacologic indications, actions, and adverse effects are similar to those of the GnRH agonists. It is given by the IM route for the treatment of patients with advanced prostate cancer. The most common adverse effects are pain and swelling at the injection site, hot flashes, increased weight, and increases in serum levels of transaminases and gamma-glutamyltransferase. Long-term use can prolong the QT interval. This drug is pregnancy category X.

Goserelin (Zoladex): Approved in 1989, goserelin is a GnRH analog that is administered as a depot implant into the abdominal wall every 28 days. By inhibiting pituitary GnRH secretion, goserelin reduces testosterone levels in men to castration levels and lowers estrogen levels in women to postmenopausal levels. In men, the drug is approved for the treatment of early prostate cancer in combination with flutamide and radiotherapy and for the palliative management of advanced prostate cancer. In women, indications for goserelin include endometriosis and the palliative treatment of advanced breast cancer. It may be used off-label to treat uterine leiomyomata or benign prostatic hyperplasia. Hot flashes occur in most patients. Men experience sexual dysfunction and gynecomastia, whereas women experience amenorrhea, decreased libido, and breast atrophy. Bone pain and irritation at the injection site are common. Tumor flare phenomenon may occur, which includes a transient worsening of tumor symptoms during the first few weeks of treatment. Men have an increased risk of sudden cardiac death when using GnRH analogs. Goserelin is classified as a pregnancy category X drug.

Histrelin (Supprelin LA, Vantas): Approved in 2004, histrelin is a GnRH analog that is given subcutaneously as an implant, usually in the inner aspect of the upper arm. This drug is slowly released over a period of 12 months, at which time the implant is removed. Histrelin (Vantas) is approved for the palliation of advanced prostate cancer. Hot flashes occur in the majority of patients and inflammation may occur at the site of implantation. Men may

experience impotence, gynecomastia, and testicular atrophy. Tumor flare phenomenon may occur during the first few weeks of treatment. Men have an increased risk of sudden cardiac death when using GnRH analogs. Histrelin is classified as a pregnancy category X drug.

Histrelin (Supprelin LA) uses the same implant technology to treat central precocious puberty in children. This condition is defined by the premature development of pubertal body characteristics earlier than age 8 in boys or age 9 in girls. Children with this disorder may have reduced adult height and psychosocial problems. Supprelin LA reduces estradiol levels (in girls) and testosterone levels (in boys) and stabilizes the condition. The most common adverse effect in these children is implant-site soreness and pain.

Leuprolide (Eligard, Lupron, Viadur): The GnRH analog leuprolide is an effective androgen antagonist for treating hormone-dependent tumors. It reduces testosterone levels in men to castration levels and lowers estrogen levels in women to postmenopausal levels. It is used as a palliative treatment for advanced prostate cancer as an alternative to orchiectomy or estrogen therapy. It may be used off-label to induce ovarian ablation in premenopausal women with ER-positive breast cancer. Nonneoplastic indications include the treatment of endometriosis, uterine leiomyomata (fibroids), and central precocious puberty. It is occasionally used to treat female infertility by hyperstimulating the ovary (see Chapter 70). Viadur and Eligard are subcutaneous implants for prostate cancer that release the drug over a period of 1 to 12 months, depending on the formulation. Lupron Depot is an IM formulation that releases the drug over 1 to 6 months, depending on the dose. Leuprolide causes nausea, vomiting, hot flashes, and diaphoresis in both men and women. Women develop amenorrhea and men experience testicular atrophy due to reduced testosterone levels. CNS effects such as migraines, depression, insomnia, asthenia, and dizziness may occur. Injection-site reactions are frequent. This is a pregnancy category X drug.

Triptorelin (Trelstar): Triptorelin is a GnRH analog that was approved in 2000 for the palliative management of advanced prostate cancer. This drug is administered once monthly by the IM route, and most patients achieve the castration levels of androgens in less than a month. Off-label uses include advanced breast cancer, uterine leiomyomata, and precocious puberty. Adverse effects are similar to those of other GnRH analogs. This is a pregnancy category X drug.

Androgen blockers:

Abiraterone (Zytiga) and enzalutamide (Xtandi): Abiraterone (approved in 2011) and enzalutamide (approved in 2012) are given PO for the treatment of castration-resistant prostate cancer in patients. Prednisone is given concurrently with abiraterone. Abiraterone and enzalutamide lower testosterone levels by inhibiting enzymes required for the biosynthesis of androgens. Abiraterone must be taken on an empty stomach because the presence of food results in increased risk of toxicity. Common adverse effects for abiraterone include joint swelling, peripheral edema, hypokalemia, hypertension, and urinary tract infection. The most common adverse effects with enzalutamide are fatigue, back pain, diarrhea, arthralgia, hot flashes, peripheral edema, headache, respiratory infection, dizziness, insomnia, spinal cord compression, hematuria, paresthesia, anxiety, and hypertension. Both drugs are contraindicated in pregnant women due to the potential for fetal harm.

Bicalutamide (Casodex), flutamide (Eulexin), and nilutamide (Nilandron): These three antiandrogen agents are all closely related in structure and function. All are given PO and have only one indication: the chemotherapy of metastatic prostate cancer. Because androgens promote the growth of prostate cancer, blocking androgen receptors can slow tumor growth. Bicalutamide and flutamide are used in combination with a GnRH analog such as goserelin or leuprolide. Bicalutamide and flutamide block androgen receptors, whereas the added GnRH analog decreases the secretion of testosterone. Nilutamide is given following an orchiectomy. Adverse effects are mild to moderate and are those expected of blocking androgen secretion such as hot flashes, mastalgia, impotence, decreased libido, and gynecomastia. They are indicated only for prostate cancer and thus should not be administered to women. Flutamide carries a black box warning regarding the potential for serious hepatotoxicity. A black box warning for nilutamide states that 2% of patients receiving the drug develop pulmonary fibrosis. Bicalutamide and flutamide are pregnancy category X drugs; nilutamide is a pregnancy category C drug.

Natural Products

57.6 Natural products that are derived from plants include the vinca alkaloids, taxanes, and topoisomerase inhibitors.

Agents with antineoplastic activity have been isolated from a number of plants, including the common periwinkle (*Vinca rosea*), Pacific yew (*Taxus baccata*), mandrake (May apple), and the shrub *Camptotheca acuminata*. Although structurally very different, medications in this class have the common ability to arrest cell division; thus, some of them are called mitotic inhibitors. The plant extracts, or natural products, are listed in Table 57.5. The three subdivisions of this group of antineoplastics are:

- Vinca alkaloids
- Taxanes
- Topoisomerase inhibitors.

Table 57.5 Natural Products Used as Antineoplastic Therapy

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Vinca Alkaloids		*Nausea, vomiting, stomatitis, anorexia, rash, alopecia, fatigue* Myelosuppression, severe nausea, vomiting, diarrhea, mucositis, pulmonary or cardiac toxicity, nephrotoxicity (vincristine), neurotoxicity (docetaxel, vincristine), anaphylaxis and other hypersensitivity reactions, severe fluid retention (docetaxel), severe diarrhea with electrolyte imbalances (topoisomerase inhibitors), hemorrhage (omacetaxine), interstitial pneumonia (cabazitaxel)
vinblastine (Velban)	IV: 3.7–18.5 mg/m^2 every 7–10 days	
vincristine (Marqibo, Oncovin)	IV: 1.4 mg/m^2 every wk (max: 2 mg/m^2) IV (Marqibo): 2.25 mg/m^2 once every wk	
vinorelbine (Navelbine)	IV: 30 mg/m^2 every wk	
Taxanes		
cabazitaxel (Jevtana)	IV: 25 mg/m^2 q3wk	
docetaxel (Taxotere)	IV: 60–100 mg/m^2 q3wk	
paclitaxel (Abraxane, Taxol)	IV: 100–260 mg/m^2 q3wk	
Topoisomerase Inhibitors		
etoposide (VePesid)	IV: 35–100 mg/m^2 daily for 5 days	
irinotecan (Camptosar)	IV: 125 mg/m^2 once every wk for 4 wk	
teniposide (Vumon)	IV: 165 mg/m^2 q3–4days for 4 wk	
topotecan (Hycamtin)	IV: 1.5 mg/m^2 daily for 5 days	
Miscellaneous Natural Products		
eribulin (Halaven)	IV: 1.4 mg/m^2 on days 1 and 8 of a 21-day cycle	
omacetaxine (Synribo)	Subcutaneous: 1.25 mg/m^2 for 14 consecutive days	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Vinca alkaloids: The vinca alkaloids vincristine (Marqibo, Oncovin) and vinblastine (Velban) are older drugs derived from the periwinkle plant. The medicinal properties of this plant were described in folklore in several regions of the world long before their antineoplastic properties were discovered. Despite being derived from the same plant, vincristine, vinblastine, and the semisynthetic vinorelbine (Navelbine) exhibit different effects and toxicity profiles.

Taxanes: The taxanes, which include cabazitaxel (Jevtana), paclitaxel (Abraxane, Taxol), and docetaxel (Taxotere), were originally isolated from the bark of the Pacific yew, an evergreen found in forests throughout the western United States. Although the taxanes are mitotic inhibitors like the vinca alkaloids, they act by a different mechanism. Myelosuppression is usually the dose-limiting factor for the taxanes.

Topoisomerase inhibitors: DNA exists in a double-stranded supercoiled state. The two strands must be separated if the macromolecule is to replicate or serve as a template for RNA synthesis (see Chapter 56). Topoisomerase is an enzyme that cuts the DNA strand, thus changing it to a more relaxed structure that can be used for DNA and RNA synthesis. The topoisomerase enzyme exists in two closely related forms: Topoisomerase I causes breaks in one strand of the DNA molecule, and topoisomerase II causes breaks in both DNA strands.

Topoisomerase inhibitors bind to the enzyme, preventing it from causing the strand breaks necessary for DNA to perform its functions. The cancer cell is unable to properly uncoil its DNA, and DNA replication prematurely terminates. Topoisomerase inhibitors are natural products, and they are available for IV administration only.

Native Americans described uses of the May apple or wild mandrake (*Podophyllum peltatum*) long before pharmacologists isolated podophyllotoxin, which is the primary active ingredient in the plant. As a botanical, podophyllum has been used as an antidote for snakebites, as a cathartic, and as a topical treatment for warts. Teniposide (Vumon) and etoposide (VePesid) are semisynthetic products of podophyllotoxin that inhibit topoisomerase II.

The topoisomerase I inhibitors include topotecan (Hycamtin) and irinotecan (Camptosar). These drugs are sometimes called camptothecins because they were first isolated from *Camptotheca acuminata*, a tree native to China. The camptothecins are administered IV, and their indications are limited. As with many other cytotoxic natural products, myelosuppression is the dose-limiting toxicity for the camptothecins.

PROTOTYPE DRUG Vincristine (Marqibo, Oncovin)

Classification **Therapeutic:** Antineoplastic
Pharmacologic: Vinca alkaloid, mitotic inhibitor, natural product

Therapeutic Effects and Uses: Vincristine is an antineoplastic obtained from the periwinkle plant that is specific for the M phase of the cell cycle where it inhibits cell division. It is approved to treat acute lymphocytic leukemia, Hodgkin's and non-Hodgkin's lymphomas, lymphosarcoma, malignant glioma, neuroblastoma,

rhabdomyosarcoma, soft tissue sarcoma, and Wilms' tumor. It may be used off-label for breast, colorectal, and lung cancers. It is administered only by the IV route. A newer form of vincristine (Marqibo), encased in a liposomal carrier, is approved for acute lymphoblastic leukemia that has failed to respond to at least two other therapies for the disease.

Mechanism of Action: Vincristine binds to tubulin, which is a protein that makes up the microtubules of the cell that are necessary for cell division. This disrupts the process whereby chromosomes are distributed to the daughter cells during mitosis, resulting in cell death. Paclitaxel and colchicine also produce pharmacologic actions by binding to tubulin, but they bind at a different location than vincristine.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Widely distributed; does not cross the blood–brain barrier; crosses the placenta; unknown if secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Bile and feces (80%); renal (20%)
Onset of action	15–20 min
Duration of action	Triphasic half-life: 0.85 min, 7.4 min, and 164 min

Adverse Effects: Vincristine is a toxic medication, and even therapeutic doses may result in serious adverse effects. The major dose-limiting toxicity of vincristine is neurotoxicity. This manifests as motor difficulties, peripheral neuropathy, paresthesias (especially of the hands and feet), weakness, cranial nerve palsies (diplopia, hoarseness, deafness, trigeminal neuralgia, vocal cord paralysis), and decreased reflexes. Neurotoxicity may take several months to resolve. CNS effects may include seizures, depression, hallucinations, and coma. GI-related adverse effects include nausea, vomiting, anorexia, stomatitis, severe constipation, and abdominal pain. Other adverse reactions include hepatotoxicity, rash, paralytic ileus (especially in children), and alopecia. **Black Box Warnings:** Myelosuppression may be severe and predispose to opportunistic infections. Extravasation can cause intense pain, inflammation, and tissue necrosis. If extravasation occurs, treatment with warm compresses and hyaluronidase is implemented; cold compresses will significantly increase the toxicity of vinca alkaloids.

Contraindications/Precautions: Contraindications to the use of vincristine include obstructive jaundice, men and women of childbearing age, active infection, adynamic ileus, radiation of the liver, infants, pregnancy, and lactation. Cautions must be taken when administering vincristine to patients with leukopenia, preexisting neuromuscular or neurologic disease, hypertension, CKD, or hepatic impairment; those who are taking drugs with neurotoxic properties; and older adults. Doses should be reduced in patients with hepatic or biliary disease. Vincristine is a vesicant and caution must be used to avoid exposure of the skin to this drug.

Drug Interactions: Vincristine is a substrate for CYP3A4, and drugs that induce CYP3A4 (such as carbamazepine or phenytoin) may increase the metabolism of vincristine and decrease the effects of the medication. Vincristine will increase the action of methotrexate, bleomycin, and anticoagulants. Decreased digoxin and phenytoin levels will occur. Administration of L-asparaginase just prior to vincristine will cause additive neurotoxicity. Concurrent administration with mitomycin may cause acute dyspnea and severe bronchospasm. Neurotoxicity may occur with peripheral nervous system drugs. **Herbal/Food:** Unknown.

Pregnancy: Category D.

Treatment of Overdose: Overdose may cause life-threatening symptoms or death. Symptoms are extensions of the adverse effects of vincristine. There is no antidote and patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving vincristine are included in the Nursing Practice Application for Patients Receiving Cancer Chemotherapy.

Drugs Similar to Vincristine (Oncovin)

The two additional vinca alkaloids are vinblastine and vinorelbine. Other classes of natural products include the taxanes (cabazitaxel, docetaxel, and paclitaxel) and the topoisomerase inhibitors (etoposide, irinotecan, teniposide, and topotecan).

Vinblastine (Velban): Vinblastine is obtained from the periwinkle plant and has a chemical structure and mechanism of action very similar to those of vincristine. However, the toxicities and spectrum of actions of the two drugs differ. The use of vinblastine has declined because of the development of more effective drugs, but it has traditionally been used to treat Hodgkin's disease and testicular tumors. Off-label uses include treatment of prostate, bladder, and lung cancers and metastatic malignant melanoma. It is administered only by the IV route. Unlike vincristine, neurotoxicity with vinblastine is infrequent. Instead, myelosuppression is the dose-limiting toxicity (especially neutropenia) with a nadir at 4 to 10 days and recovery between days 7 and 21. Extravasation can cause intense pain, inflammation, and tissue necrosis. This drug

carries the same black box warnings as vincristine. Nausea and vomiting are generally mild. Other potential adverse effects include hypertension, stroke, dyspnea, and Raynaud's phenomenon. This is a pregnancy category D drug.

Vinorelbine (Navelbine): Vinorelbine is a semisynthetic drug derived from vinblastine to which it shares structural and functional similarities. In addition to having the same mechanism of action as the vinca alkaloids, vinorelbine also inhibits RNA synthesis and blocks the cellular use of glutamic acid that is needed for purine synthesis. Its only approved use is to treat non–small-cell lung cancer but it may be used off-label to treat metastatic breast cancer, head and neck cancers, ovarian cancer, and Hodgkin's disease. The primary dose-limiting toxicity is myelosuppression (especially neutropenia) with a nadir at 7 to 14 days and recovery between days 14 and 24. Like vinblastine, neurotoxicity is infrequent. Extravasation can cause intense pain, inflammation, and tissue necrosis. This drug carries the same black box warnings as vincristine and vinblastine. Other adverse effects include mild nausea, vomiting, thromboembolic events, asthenia, fatigue, and pulmonary hypersensitivity. Vinorelbine is a pregnancy category D drug.

Taxanes:

Cabazitaxel (Jevtana): Approved in 2010, cabazitaxel is a mitotic inhibitor indicated for hormone-refractory metastatic prostate cancer that has not responded to a docetaxel-containing regimen. Cabazitaxel carries black box warnings regarding severe hypersensitivity reactions and low neutrophil counts. Deaths due to severe neutropenia have been reported and the drug is contraindicated in patients with neutrophil counts of less than 1500 cells/mm^3. To reduce the incidence of severe hypersensitivity reactions, patients are premedicated with dexamethasone, diphenhydramine, and ranitidine at least 30 minutes prior to cabazitaxel administration. Diarrhea may be extreme and requires premedication with antidiarrheals. Nonhematologic adverse effects include fatigue, nausea, vomiting, constipation, asthenia, abdominal pain, hematuria, and peripheral neuropathy. This is a pregnancy category D drug.

Docetaxel (Taxotere): Approved in 1996, docetaxel is a semisynthetic taxane that is administered only by the IV route. It disrupts normal microtubule function and is a mitotic inhibitor. Docetaxel is approved to treat solid tumors, including advanced gastric cancer, head and neck cancers, metastatic breast or refractory prostate cancer, and non–small-cell lung cancer that has failed to respond to therapy with platinum antineoplastics. Off-label indications include metastatic malignant melanoma and advanced ovarian cancer. Docetaxel is a toxic drug that carries multiple black box warnings regarding increased mortality in patients with hepatic impairment, myelosuppression, skin toxicity, severe hypersensitivity reactions, and fluid retention. To reduce the incidence and severity of fluid retention and hypersensitivity reactions, patients receiving docetaxel are administered dexamethasone for 3 days prior to chemotherapy. Without premedication, a hypersensitivity reaction occurs in about 20% of patients within minutes of the injection. Severe fluid retention occurs in some patients and may include peripheral or generalized edema, dyspnea, pleural effusion, cardiac tamponade, and ascites. The major dose-limiting toxicity is myelosuppression, especially neutropenia, which occurs in nearly all patients. The nadir occurs at 7 days with recovery at 14 days. This drug is contraindicated in patients with neutrophil counts of less than 1500 cells/mm^3. Skin reactions, primarily erythema, rash, and pruritus on the feet and hands, occur in the majority of patients. Severe skin toxicity occurs in about 5% of patients. Neurologic toxicity such as paresthesias and peripheral neuropathy occur in half the patients taking this drug. Mild to moderate nausea, vomiting, diarrhea, stomatitis, and esophagitis are common. Docetaxel is a pregnancy category D drug.

Paclitaxel (Abraxane, Taxol): Approved in 1992, paclitaxel is a semisynthetic taxane that is administered by the IV route and approved to treat solid tumors, including metastatic breast cancer, ovarian cancer, Kaposi's sarcoma, and non–small-cell lung cancer in combination with cisplatin. Off-label indications include the chemotherapy of bladder, head, and neck cancers. Paclitaxel carries black box warnings regarding severe hypersensitivity reactions and low neutrophil counts. The major dose-limiting toxicity is myelosuppression, which occurs in nearly all patients. The nadir occurs at 11 days. This drug is contraindicated in patients with neutrophil counts of less than 1500 cells/mm^3. Anaphylaxis and severe hypersensitivity reaction may occur, usually within an hour after the start of the infusion. To reduce the incidence of severe hypersensitivity reactions, patients should be premedicated with dexamethasone and diphenhydramine prior to paclitaxel administration. A protein-bound form of this drug (Abraxane) approved in 2013 does not require premedication. Abraxane is approved to treat late-stage pancreatic cancer (in combination with gemcitabine), non–small-cell lung cancer (in combination with carboplatin), and metastatic breast cancer. Extravasation of paclitaxel can result in an acute and delayed injection-site reaction. A local hyaluronidase injection may be beneficial in treating severe extravasation symptoms. Other common adverse events include musculoskeletal pain, asthenia, hypotension, rash, peripheral neuropathy, mild to moderate nausea, vomiting, diarrhea, and stomatitis. Alopecia occurs in nearly every patient. Paclitaxel is a pregnancy category D drug.

Topoisomerase inhibitors:

Etoposide (VePesid): Approved in 1983, etoposide is a derivative of podophyllotoxin that inhibits topoisomerase II. It is one of the few antineoplastic natural products that are

administered by both PO and IV routes. It is approved for patients with small-cell lung cancer and for testicular tumors in patients who have already received surgery, chemotherapy, and radiation without success. Off-label indications may include acute leukemia, Hodgkin's and non-Hodgkin's lymphoma, refractory ovarian cancer, gastric cancer, neuroblastoma, and malignant glioma. Etoposide carries a black box warning for severe, dose-limiting myelosuppression that has a nadir at day 16 and recovery by days 20 through 22. Alopecia occurs in a majority of patients. Anaphylaxis has been reported in up to 2% of patients who are receiving this drug. Secondary malignancies, especially acute nonlymphocytic leukemia, may occur in children who are treated with this drug. Etoposide is a pregnancy category D drug.

Irinotecan (Camptosar): Approved in 1996, irinotecan is a cytotoxic alkaloid obtained from *Camptotheca acuminata.* Like topotecan, it acts by inhibiting topoisomerase I, which interferes with DNA replication during the S phase of the cell cycle. Irinotecan is indicated for the treatment of metastatic colorectal cancer that has progressed despite treatment with fluorouracil. Off-label uses include advanced breast, cervical, ovarian, gastric, and lung cancers. Hematologic toxicity is dose limiting, with anemia, leukopenia, and neutropenia occurring in most patients. Irinotecan carries a black box warning about diarrhea, which can be severe and dose limiting. Early diarrhea occurs during or immediately after the infusion and may be accompanied by cholinergic symptoms such as rhinitis, increased salivation, miosis, lacrimation, diaphoresis, and abdominal cramping. Late diarrhea occurs more than 24 hours after the infusion and may be life threatening due to prolonged dehydration and electrolyte imbalances. Nausea and vomiting are common and severe enough to require pretreatment with antiemetics. Other adverse events that occur at a high rate include asthenia, fever, dyspnea, abdominal pain, anorexia, and dizziness. This drug is pregnancy category D.

Teniposide (Vumon): Approved in 1992, teniposide is an IV derivative of podophyllotoxin that inhibits topoisomerase II. It is approved only to treat refractory childhood acute lymphoblastic leukemia but may be used off-label for neuroblastoma, bladder cancer, lung cancer, and non-Hodgkin's lymphoma. Teniposide carries black box warnings regarding myelosuppression and hypersensitivity reactions. Bone marrow toxicity (especially neutropenia) is its most common dose-limiting toxicity. Hypersensitivity reactions occur in about 5% of patients. GI adverse reactions occur in most patients and include severe stomatitis, diarrhea, mild nausea, and vomiting. Alopecia occurs in about 9% of patients. Secondary malignancies, especially acute nonlymphocytic leukemia, may occur in children who receive this drug for prolonged periods. This drug is pregnancy category D.

Topotecan (Hycamtin): Approved in 1996, this drug is an IV camptothecin, topoisomerase I inhibitor very similar to irinotecan, although its indications are different. Topotecan is approved to treat small-cell lung cancer after failure of traditional chemotherapy and inoperable cervical cancer. It may be used off-label to treat rhabdomyosarcoma in children. Topotecan carries a black box warning regarding myelosuppression, which is a dose-limiting toxicity. The drug is contraindicated in patients with neutrophil counts of less than 1500 cells/mm^3. Nausea and vomiting are usually mild. Topotecan can cause infertility in both males and females. Other common adverse events include alopecia, fatigue, asthenia, fever, musculoskeletal pain, dyspnea, interstitial lung disease, and headache. This drug is pregnancy category D.

PharmFACT

Lung cancer is the most common type of cancer, but it has one of the lowest survival rates because it is rarely discovered in its early stages. The 5-year survival rate for Stage I non–small-cell lung cancer is 49%, but at Stage IV it is only 1% (American Cancer Society, 2016).

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Cancer Chemotherapy

Assessment

Baseline assessment prior to administration:

- Understand the reason the drug has been prescribed in order to assess for therapeutic effects.
- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic or renal disease, and the possibility of pregnancy. Obtain a drug history including allergies (e.g., specific reactions to drugs), current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of current infections and for history of herpes zoster or chickenpox.
- Obtain an immunization history, especially recent vaccinations with live vaccines, particularly varicella.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], platelet count, urinalysis, hepatic and renal function studies, uric acid, electrolytes, glucose).
- Assess findings from other diagnostic tests specific to type of antineoplastic therapy regimen planned (e.g., audiology or cardiac testing, electrocardiogram [ECG], electromyography [EMG]).
- Obtain baseline height, weight, and vital signs. Assess level of fatigue and presence of pain. Assess DTRs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Assessment

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., indicators of treatment success or palliation specific to the type of cancer: slowed growth in solid tumors, able to attend to normal ADLs, absence of signs and symptoms of concurrent infections).
- Continue frequent monitoring of laboratory work (e.g., CBC, absolute neutrophil count [ANC], platelet count, urinalysis, hepatic and renal function studies, uric acid, electrolytes, glucose). ANC = WBC count multiplied by the total percentage of neutrophils (segmented plus banded); e.g., WBC 5000 × (0.45 segs 1 0.5 bands) = 5000 × 0.5 = ANC of 2500. An ANC of less than 500 indicates that the patient is at great risk for infection.
- Continue to monitor findings from other diagnostic tests specific to the type of antineoplastic therapy regimen planned (e.g., audiology or cardiac testing, ECG, EMG).
- Assess for the presence of nausea or pain.
- Assess DTRs and ECG as specific to the type of antineoplastic drugs given.
- Continue to record daily weights and report any weight gain or loss of more than 1 kg (2 lb) in 24 hours.
- Assess for adverse effects: nausea, vomiting, anorexia, abdominal cramping, diarrhea, constipation, chills, fever, fatigue, dizziness, dysrhythmia, angina, dyspnea, muscle or joint pain, paresthesia, diminished or absent DTRs, hypotension, hyperglycemia, bruising, or bleeding. Fever exceeding parameters established by the oncology provider, severe diarrhea, jaundice, decreased urine output or hematuria, excessive bruising or bleeding, respiratory distress, or angina should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects: radiographic evidence of diminished tumor mass, decreased production of abnormal cell growth, absence of signs and symptoms of infection, maintenance of appetite, food and fluid intake, nausea and vomiting are decreased or absent, able to perform acceptable levels of ADLs. (Antineoplastic drugs do not have immediately observable results. Results will be measured over time. These drugs have many potential adverse effects affecting many body systems.)	• Provide explanations for all testing and treatments used. Provide general information on the expected course of chemotherapy: requirements for invasive lines (e.g., peripheral and central access ports), initial infusion or dosing, frequency of expected treatments, nausea control, hydration and nutrition needs, frequent laboratory testing, onset of alopecia, techniques for managing fatigue, nutrition and fluid needs, follow-up appointments, in-hospital versus outpatient clinic locations, and how to reach the oncology team, especially during off-hours. Involve the family and caregivers in information sessions and provide written materials whenever possible.
Minimizing adverse effects: General Care • Continue to monitor vital signs, especially temperature. Report increasing temperature that exceeds parameters (e.g., three temperatures taken every 4 h over 38.1°C [100.5°F] or any single temperature over 38.3°C [101°F]) to the oncology provider. Avoid taking rectal temperatures. (Increasing fever, even low-grade temperatures less than 38.3°C [101°F], may be a sign of infection. Significant myelosuppression may allow infections to occur and disseminate rapidly. GI endothelial cells are affected by chemotherapy, and rectal mucosa may be damaged if rectal temperatures are used.)	• Teach the patient to take his or her temperature every 4 h if behavior or symptoms indicate the need (e.g., increased body warmth, general malaise, lethargy) or as ordered by the oncology provider. Include instructions on when to call the oncology team if parameters are exceeded. • Instruct the patient that antipyretics are not to be used unless explicitly approved by the oncology provider. Antipyretics may mask the symptoms of an infection, allowing rapid dissemination.
• Continue to monitor frequent laboratory work: CBC, ANC, platelet count, hepatic and renal function tests, electrolytes, glucose, and urinalysis. (Myelosuppression and resulting blood dyscrasias are expected adverse effects and will be monitored by ANC, CBC, and platelet counts.)	• Teach the patient the need for frequent laboratory work. Provide instructions for outpatient laboratory tests, and have the patient alert laboratory personnel of chemotherapy use. • If peripheral veins are used for phlebotomy, scrupulous cleansing of the site prior to the needlestick and prolonged pressure may be required during periods around the nadir. If central line access is used, scrupulous cleansing of the port is required and appropriate flush solution(s) used afterward to maintain catheter patency.
• Continue to monitor nutritional and fluid intake. (Nausea and vomiting are common adverse effects and usually require antiemetic therapy to manage. Dietary consultation may be required to maintain optimal nutrition.)	• Provide antiemetic therapy routinely during administration of drugs with high and moderate emetic potential. If the patient has had previous treatment with the chemotherapy regimen, assess the extent of nausea and vomiting and which antiemetics or routines had the most success in preventing nausea. • Encourage increased fluid intake, up to 2 L/day, taken in frequent small amounts as allowed. • Encourage small, high-calorie, nutrient-dense meals rather than large infrequent meals. Nutritional supplements, such as Boost or Ensure, may help boost caloric intake. • Avoid spicy, highly scented foods and excessively hot or cold foods during periods of nausea. Small sips of carbonated beverages, especially ginger ale, may provide nonmedicinal relief. If GI effects predominate (e.g., diarrhea), avoid high-roughage foods. • Encourage frequent oral hygiene: rinsing the mouth, especially after eating, applying lip balm, and avoiding alcohol-based mouthwash, which can be drying to the mucosa. • Provide referral to a dietary consultation as needed.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to assess for presence of pain and provide for adequate pain medication. (Pain may result from advanced disease or adverse drug effects. In advanced disease, pain medication is not withheld. Assess possible drug-related causes for pain, and treat the cause when possible.)	• Encourage the patient to seek pain relief when needed. Teach the patient, family, and caregiver that the absence of pain is a goal in the treatment of advanced disease, and pain medication should not be withheld.
• Provide for adequate rest. Schedule daily routines, diagnostic studies, and meals throughout the day if fatigue is profound. (Fatigue related to anemia and adverse drug effects is common, especially around the nadir and immediately after. Fatigue may continue after cell counts return to normal and may persist for several years after chemotherapy.)	• Teach the patient the importance of spacing daily routines throughout the day. Encourage rest whenever fatigue occurs. • Assess transportation needs if fatigue affects the ability to drive. Provide referral to social services as needed.

• Protect the patient from infection: e.g., frequent hand hygiene before patient care, maintaining scrupulous infection control measures for all IV lines or venous punctures, and encouraging the patient to maintain daily hygiene measures to limit skin flora. Assess for symptoms of opportunistic infections such as yeast, and acquire early treatment or prophylaxis. (Myelosuppression places patients at high risk for infection. Prophylactic therapy with antifungal and antibacterial mouth rinses or protective isolation may be required depending on the level of neutropenia.)	• Teach the patient, family, and caregiver infection control measures:
	  • Avoid crowded indoor places.
	  • Avoid people with known infections or young children, who have a higher risk of having an infection.
	  • Cook food thoroughly, allowing the family or caregiver to prepare raw foods and perform cleanup; avoid consuming raw fruits or vegetables, which may carry bacteria on the surface.
	  • Report any fever per the parameters set by the healthcare provider, and report symptoms of infection such as wounds with redness or drainage, increasing cough, increasing fatigue, white patches on oral mucous membranes, white and itchy vaginal discharge, or itchy blister-like vesicles on the skin.

• Provide for emotional support for the patient, family, and caregiver. (Cancer results in profound emotional reactions from all involved. Encourage discussion of concerns, appropriate referrals for social support or spiritual assistance, and assess the patient or family for distress that may require a mental health referral. Cost issues may be a concern, and financial assistance may be required.)	• Encourage the patient, family, and caregiver to discuss concerns or questions and to seek appropriate spiritual or social support as desired. • Assess financial concerns and provide appropriate social service referral as needed.
Minimizing adverse effects: Care Specific to Drug Therapy • Monitor DTRs, neurologic status, and level of consciousness. (*Alkylating agents* such as cyclophosphamide and *natural product* antineoplastics such as vincristine have neurologic adverse effects. Changes may occur in DTRs that are not noticeable to the patient in early stages but may affect dexterity or steadiness when walking. **Lifespan:** Be particularly cautious with older adults who are at increased risk for falls. Monitor infants and children for growth or developmental delays.)	• Teach the patient to be cautious when walking or performing manual tasks requiring extra dexterity or when carrying hot or heavy objects. Promptly report any significant difficulty with dexterity or clumsiness when carrying out ADLs or when walking. • Encourage increased intake of fluids and moderate fiber in the diet if constipation is experienced related to decreased peristalsis. Drug therapy such as MiraLAX may be required if constipation is severe or to prevent straining during defecation.
• Monitor cardiovascular status including ECG, heart and breath sounds, presence of edema, angina, or chest wall pain. (*Alkylating agents* such as cyclophosphamide, *antitumor antibodies* such as doxorubicin, *natural product* antineoplastics such as vincristine, and *hormone and hormone antagonists* such as tamoxifen have cardiovascular adverse effects such as pericarditis and effects on the cardiac conduction system.)	• Teach the patient about the need for frequent monitoring of cardiac status. Report any chest wall pain, angina, palpitations, dyspnea, lung congestion, or dizziness immediately.
• Monitor respiratory status including breath sounds and pulmonary function tests. (*Alkylating agents* such as cyclophosphamide, *antimetabolites* such as methotrexate, *antitumor antibodies* such as doxorubicin, *natural product* antineoplastics such as vincristine, and *biologic response modifiers* such as IFN alpha-2 have respiratory adverse effects such as interstitial pneumonitis.)	• Teach the patient about the need for frequent monitoring of respiratory status. Report any chest wall pain, dyspnea, lung congestion, or dizziness immediately. • Teach the patient pulmonary hygiene measures such as increasing fluid intake to moisten the respiratory tract, avoiding crowded indoor places and people with known respiratory disease, and avoiding the use of room or body sprays that may irritate the respiratory tract.
• Monitor hepatic and renal status and for urinary tract dysfunction, including hepatic and renal function tests, urinalysis, and signs and symptoms such as jaundice, decreased urine output, or hematuria. (Antineoplastic drugs may cause significant hepatotoxicity and nephrotoxicity. *Alkylating agents* such as cyclophosphamide may cause hemorrhagic cystitis. **Diverse Patients:** Because some antineoplastics [e.g., tamoxifen, vincristine] are metabolized through the CYP450 system, monitor ethnically diverse patients frequently to ensure optimal therapeutic effects and minimize adverse effects. **Lifespan:** Age-related physiologic differences place older adults at greater risk for hepatotoxicity or nephrotoxicity.)	• Teach the patient to immediately report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light- or clay-colored stools, diminished urine output, darkening of urine, suprapubic pain, or blood in the urine. • Advise the patient to increase fluid intake to 2 to 3 L/day as allowed.
• Monitor for ototoxicity. Periodic audiology testing may be ordered. (*Alkylating agents* such as cyclophosphamide and *antimetabolites* such as methotrexate may cause ototoxicity, affecting hearing or balance, or both.)	• Teach the patient about the need for periodic monitoring of hearing. Immediately report any dizziness, vertigo, or nausea related to motion, buzzing, ringing, or humming in ears.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for ocular toxicity. Periodic ophthalmology examinations may be ordered. (*Hormone and hormone antagonists* such as tamoxifen may cause ocular toxicity. Frequent monitoring is necessary to prevent or limit toxicity.)	• Teach the patient about the need for periodic eye examinations. Immediately report any blurred vision, eye pain, halos, or other visual disturbances. • Encourage the patient to wear eye protection (sunglasses) when in sunlight.
• Monitor for dermatologic toxicity. (*Alkylating agents* such as cyclophosphamide may cause significant skin reactions including SJS.)	• Teach the patient to promptly report any unusual changes to skin, rashes, or sunburn-like appearance. Immediately report any purplish-red, blistering rash, or peeling skin.
• Monitor for mucositis. (Antineoplastic drugs may cause significant mucositis related to the effects of rapidly dividing GI endothelial cells.)	• Teach the patient to inspect the oral cavity at least once daily and maintain regular dental examinations. Maintain good oral hygiene and rinse the mouth with plain water or solution as prescribed by the healthcare provider after eating. Use antibacterial and antifungal mouth rinses as ordered, and do not rinse the mouth with water after using; swallow mouth rinse if directed to do so by the healthcare provider. Avoid excessively hot or cold foods. • Teach the patient to avoid high-roughage foods, spicy foods, carbonated and acidic beverages, alcohol, and caffeine. If diarrhea is severe, drug therapy may be required. Immediately report any excessive diarrhea, especially if it contains mucus or blood.
• Monitor for hypersensitivity and allergic reactions. (Antineoplastic drugs may cause significant hypersensitivity and allergic responses, including anaphylaxis. Because reactions may not always be predictable, caution and frequent monitoring are essential to ensure prompt treatment.)	• Teach the patient to immediately report any itching, rashes, swelling, particularly of the face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing.
• Follow agency-specific policies and procedures related to antineoplastic administration and spill management before working with or giving chemotherapy. All IV infusions with antineoplastics will be given via monitored pump. IV push drugs may utilize a push–pull technique, i.e., aspirate for blood return, administer dose, aspirate, administer. All spills will be managed via OSHA and agency protocols. Larger spills may require HAZMAT intervention. (Intensive education programs are required prior to administering vesicants and other chemotherapy. Protection of the nurse, pharmacy personnel, and others involved in the preparation and administration of chemotherapy is essential.)	• Provide the patient, family, and caregiver education and support when giving chemotherapy. • Instruct the patient, family, or caregiver on the specific procedures of handling and administering the drugs if any drug solutions are to be used in the home. Gloves will be required when working with oral solutions. Specific instructions should be obtained from the oncology provider or pharmacist if a spill occurs at home.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, and caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, and caregiver in proper self-administration techniques followed by teach-back as needed. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Provide explicit instructions for the patient, family, and caregiver on the routine to follow for any antineoplastic drugs used at home. Encourage the use of calendars for recording drugs and doses used; provide information on handling a liquid spill and on proper disposal of any unused drug. (Consult local pharmacies; many will accept unused drugs for proper disposal. Chemotherapy drugs should *never* be flushed down the toilet, poured in a drain, or thrown away in the trash.)

Biologic Response Modifiers and Targeted Therapies

57.7 Biologic response modifiers and targeted therapies enhance the body's ability to kill tumor cells.

A biologic response modifier is a substance that enhances the ability of body defenses to remove cancer cells. Biologic response modifiers may produce their effects directly, by binding to cancer cells and destroying them, or indirectly, by activating general aspects of the immune response. Biologic response modifiers may be grouped into two general classes: cytokines and monoclonal antibodies. These drugs are listed in Table 57.6.

Cytokines that act as biologic response modifiers include the following:

- Interferons are natural proteins produced by T cells in response to viral infection and other antigens. They bind to specific receptors on cancer cell membranes and suppress cell division, enhance the phagocytic activity of macrophages, and promote the cytotoxic activity of T lymphocytes. PegIFN alfa-2a (Pegasys,

Table 57.6 Selected Monoclonal Antibodies and Targeted Therapies

Drug	Indication	Drug	Indication
ado-trastuzumab (Kadcyla)	Metastatic breast cancer	necitumumab (Portrazza)	Metastatic lung cancer
alectinib (Alecensa)	Metastatic lung cancer	nilotinib (Tasigna)	Chronic myeloid leukemia
atezolizumab (Tecentriq)	Urothelial cancer, metastatic lung cancer	niraparib (Zejula)	Ovarian cancer
axitinib (Inlyta)	Advanced renal cell carcinoma	nivolumab (Opdivo)	Metastatic melanoma, lung cancer, renal cell carcinoma, Hodgkin's lymphoma, head and neck cancer
bevacizumab (Avastin, Mvasi)	Metastatic colorectal cancer	obinutuzumab (Gazyva)	Chronic lymphocytic leukemia
blinatumomab (Blincyto)	Acute lymphoblastic leukemia	ofatumumab (Arzerra)	Chronic lymphocytic leukemia
bortezomib (Velcade)	Multiple myeloma, mantle cell lymphoma	olaparib (Lynparza)	Ovarian cancer
bosutinib (Bosulif)	Chronic myelogenous leukemia	olaratumab (Lartruvo)	Soft tissue sarcoma
brentuximab (Adcetris)	Hodgkin's lymphoma, large cell lymphoma	osimertinib (Tagrisso)	Metastatic lung cancer
cabozantinib (Cabometyx, Cometriq)	Renal cell carcinoma, metastatic thyroid cancer	palbociclib (Ibrance)	Advanced breast cancer
carfilzomib (Kyprolis)	Multiple myeloma	panitumumab (Vectibix)	Metastatic colorectal cancer
ceritinib (Zykadia)	Lung cancer	panobinostat (Farydak)	Multiple myeloma
cetuximab (Erbitux)	Head and neck cancer, metastatic colorectal cancer	pazopanib (Votrient)	Advanced renal cell carcinoma, advanced soft tissue sarcoma
cobimetinib (Cotellic)	Metastatic melanoma	pembrolizumab (Keytruda)	advanced melanoma, head and neck cancer, advanced non-small cell cancer, Hodgkin's lymphoma, advanced urothelial carcinoma, advanced gastric cancer
crizotinib (Xalkori)	Metastatic lung cancer	pertuzumab (Perjeta)	Metastatic breast cancer
daratumumab (Darzalex)	Multiple myeloma	ramucirumab (Cyramza)	Advanced gastric cancer, metastatic lung cancer
dasatinib (Sprycel)	Chronic myeloid or acute lymphoblastic leukemia	regorafenib (Stivarga)	Metastatic colorectal cancer, metastatic GI stromal tumor
dinutuximab (Unituxin)	Neuroblastoma	ribociclib (Kisqali)	Breast cancer
elotuzumab (Empliciti)	Multiple myeloma	rituximab (Rituxan)	Non-Hodgkin's lymphoma, chronic lymphocytic leukemia
erlotinib (Tarceva)	Metastatic lung cancer, metastatic pancreatic cancer	rucaparib (Rubraca)	Ovarian cancer
gefitinib (Iressa)	Advanced or metastatic lung cancer	sonidegib (Odomzo)	Recurrent basal cell cancer
ibritumomab (Zevalin)	Non-Hodgkin's lymphoma	sorafenib (Nexavar)	Hepatic cancer, advanced renal cell carcinoma, metastatic thyroid cancer
ibrutinib (Imbruvica)	Mantle cell lymphoma, chronic lymphocytic leukemia	sunitinib (Sutent)	GI stromal tumor, advanced renal cell carcinoma, pancreatic cancer
idelalisib (Zydelig)	Non-Hodgkin's lymphoma, chronic lymphocytic leukemia	talimogene (Imlygic)	Recurrent melanoma
imatinib (Gleevec)	Chronic myeloid leukemia, acute lymphoblastic leukemia, others	trastuzumab (Herceptin)	Metastatic breast cancer, metastatic gastric cancer
ipilimumab (Yervoy)	Metastatic melanoma	vandetanib (Caprelsa)	Thyroid cancer
ixazomib (Ninlaro)	Multiple myeloma	vemurafenib (Zelboraf)	Metastatic melanoma
lapatinib (Tykerb)	Advanced or metastatic breast cancer	venetoclax (Venclexta)	Chronic lymphocytic leukemia
lenvatinib (Lenvima)	Metastatic thyroid cancer, renal cell carcinoma	vismodegib (Erivedge)	Advanced or metastatic basal cell carcinoma
		ziv-aflibercept (Zaltrap)	Metastatic colorectal cancer

Sylatron) and IFN alfa-2b (Intron A) are approved to treat hairy cell leukemia, chronic myelogenous leukemia, Kaposi's sarcoma, and chronic hepatitis B and C. In 2011, the indications for pegIFN alfa-2a were extended to include melanoma with nodal involvement. Doses of the interferons and a prototype feature for IFN alfa-2b are provided in Chapter 42.

- Interleukin-2 activates cytotoxic T lymphocytes and promotes other actions of the immune response. Marketed as aldesleukin (Proleukin), this drug is indicated only for metastatic renal cell carcinoma. A prototype feature for aldesleukin is provided in Chapter 42.
- **Hematopoietic growth factors** promote the formation of specific blood cells. These drugs enhance the ability

of the immune system to respond and reduce some of the myelosuppression caused by antineoplastic medications. Hematopoietic growth factors include epoetin alfa (Epogen, Procrit), filgrastim (Granix, Neupogen, Zarxio), and sargramostim (Leukine). The doses and prototype features for epoetin alfa and filgrastim are given in Chapter 39.

Although cancer cells originate from normal cells, researchers have identified a large number of differences between the two. This has allowed scientists to develop drugs that specifically target these differences. **Targeted therapies** are drugs that block the growth, progression, and spread of cancer by interfering with a molecular process that is specific to the cancer cell. Targeted therapies differ from standard chemotherapy in that they attack one specific aspect of the cancer cell. Indeed, these drugs have been deliberately engineered to interact with their target. In general, they are effective against one specific type of cancer cell and they are less toxic to normal cells than standard chemotherapy drugs. Examples of targeted therapies include the following:

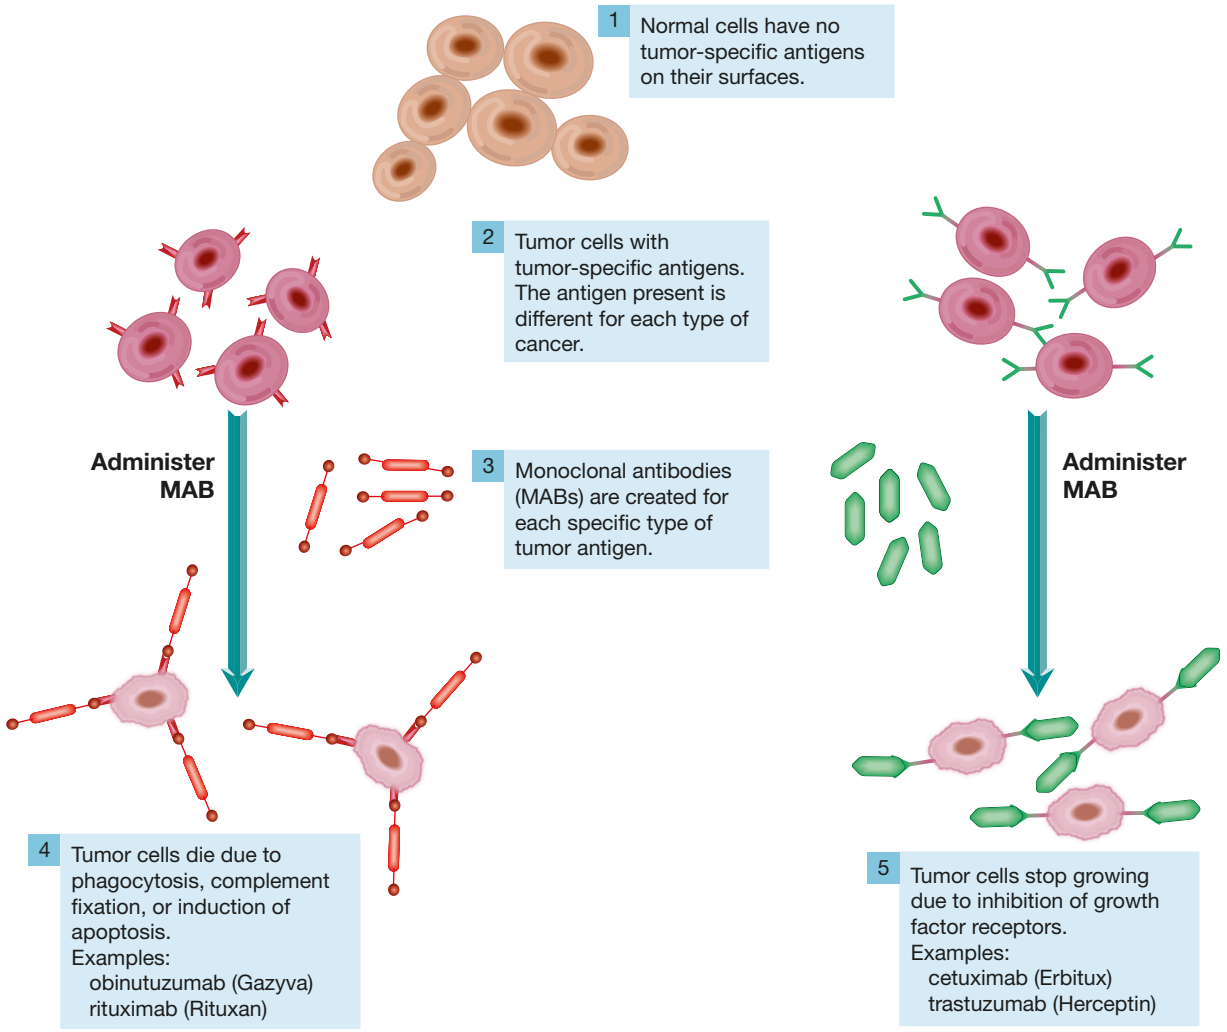
- Tyrosine kinase (TK) is an enzyme that activates certain proteins in internal signaling pathways that regulate cell growth. In normal cells, the TK enzyme is turned on and off, depending on the cell's need for growth. Certain types of cancer cells turn on the TK enzyme permanently, leading to uncontrolled cell growth. Imatinib (Gleevec), dasatinib (Sprycel), alectinib (Alecensa), and crizotinib (Xalkori) are examples of drugs that are able to inhibit TKs, thus stopping this unchecked cell growth. Everolimus (Afinitor, Zortress) inhibits a different type of kinase and is approved as an antineoplastic drug as well as for the prophylaxis of transplant rejection (see Chapter 42). Vemurafenib (Zelboraf), midostaurin (Rydapt) and cobimetinib (Cotellic) are designed to specifically inhibit multiple types of kinases and are indicated for malignant melanoma.
- The epidermal growth factor receptor (EGFR) is a cell-surface receptor that, when activated, results in cell growth. Mutations of the EGFR can result in uncontrolled cell growth and cancer. Antineoplastic drugs known as EGFR inhibitors are targeted to shut down this activation and slow the growth of certain neoplasms. Cetuximab (Erbitux), erlotinib (Tarceva), necitumumab (Portrazza), osimertinib (Tagrisso), and trastuzumab (Herceptin) are examples of drugs that target the EGFR.
- Vascular endothelial growth factor (VEGF) is a protein that signals the formation of new blood vessels during embryonic development or following injury or blockage to tissues. VEGF, also called *angiogenesis inhibitors*, prevents the formation of new blood vessels that are vital to the formation of new tumors. These drugs do not kill cancer cells, but they are able to slow tumor growth. Bevacizumab (Avastin, Mvasi) was the first drug to specifically target angiogenesis. An additional VEGF inhibitor, ramucirumab (Cyramza) was approved in 2014 to treat advanced gastric cancer. Thalidomide (Thalomid) and lenalidomide (Revlimid) are miscellaneous drugs, shown in Table 57.7, that possess antiangiogenic properties.
- CD20 is a protein located on the surface of B lymphocytes. While the normal function of CD20 is not completely understood, it has been found in high concentrations in certain lymphomas and leukemias. Monoclonal antibody drugs have been developed that target CD20 and kill the cancer cells expressing this protein. Examples of CD20 antibody medications include rituximab (Rituxan), ofatumumab (Arzerra), and ibritumomab (Zevalin).

Monoclonal antibodies (MABs) are biologic response modifiers that are a type of targeted therapy. Once the MAB binds to its specific antigen, the cancer cell is either killed directly by the drug or is marked for destruction by other cells of the immune response. For example, rituximab (Rituxan) is a MAB that binds to CD20, a surface protein present on premature B lymphocytes involved in certain leukemias and lymphomas. Once bound, rituximab lyses the tumor cells. As is typical of MABs, the action of rituximab is very specific: It was designed to affect only cells with the CD20 protein, in this case tumor B cells. The key point about MABs is that the tumor cells must possess the specific protein receptor; otherwise, the MAB will be ineffective. The general mechanism of action of MABs is shown in Pharmacotherapy Illustrated 57.1.

A few MABs carry a toxin that directly kills the tumor cell once it is bound. For example, gemtuzumab ozogamicin (Mylotarg) carries a cytotoxic antitumor antibiotic. The MAB reaches its target antigen and enters the cancer cell, where the toxic antibiotic is released to cause cell death. Tositumomab (Bexxar) carries radioactive iodine (^{131}I) to its specific antigen, whereby the tumor cell receives a dose of ionizing radiation.

CONNECTION Checkpoint 57.3

PegIFN alfa-2a and 2b are used as antineoplastics. From what you learned in Chapter 42, what are the indications for IFN alfacon-1 (Infergen), IFN alfa-n3 (Alferon N), and IFN beta-1a (Avonex, Rebif)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*



Miscellaneous Antineoplastics

57.8 Several miscellaneous antineoplastics act by unique mechanisms.

Some antineoplastics are classified as miscellaneous because they are structurally dissimilar to any of the

Pharmacotherapy Illustrated 57.1

Monoclonal Antibodies and Cancer Cells

previously discussed groups. Because these medications are unique, their adverse reactions vary. Doses for the miscellaneous antineoplastics are listed in Table 57.7.

Altretamine (Hexalen): Altretamine is an oral antineoplastic that has effects similar to those of alkylating agents. When metabolized it forms toxic metabolites that bind to cellular macromolecules, resulting in a cytotoxic effect. Its only indication is for refractory ovarian cancer that has not responded well to other therapies. Severe myelosuppression is observed in 15% of patients with a nadir at 3 to 4 weeks and recovery at 6 weeks. The most frequent adverse effects are mild to moderate nausea and vomiting. Altretamine causes mild to moderate neurotoxicity, including peripheral neuropathy, mood disorders, disorders of consciousness, ataxia, dizziness, and vertigo. This is a pregnancy category D drug.

Arsenic trioxide (Trisenox): Approved in 2000, arsenic trioxide is a toxic metal that has only one indication: acute promyelocytic leukemia. Its mechanism of action is incompletely understood but it appears to cause DNA fragmentation that is characteristic of apoptosis, or programmed cell death. It is administered by IV infusion. Leukocytosis, thrombocytopenia, anemia, nausea, vomiting, abdominal pain, diarrhea, constipation, and anorexia are common adverse effects. Skin reactions include injection-site inflammation, dermatitis, and pruritus. Neurotoxicity is relatively common and manifests as headache, insomnia, paresthesias, anxiety, dizziness, and tremors. Because arsenic trioxide can cause

Table 57.7 Miscellaneous Antineoplastics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
altretamine (Hexalen)	PO: 260 mg/m^2/day for 14–21 days	*Hyporeflexia, paresthesias, nausea, vomiting, muscle weakness, peripheral numbness* Leukopenia, thrombocytopenia, Parkinson-like tremors
arsenic trioxide (Trisenox)	IV: 0.15 mg/kg/day (max: 60 doses)	*Fever, leukocytosis, nausea, vomiting, diarrhea, abdominal pain, anorexia, rash, pruritus, fatigue, edema, headache, insomnia* Thrombocytopenia, anemia, ecchymosis, epistaxis, bleeding, dysrhythmias
asparaginase *E. chrysanthemum* (Erwinaze), pegaspargase (Oncaspar)	IV/IM (Oncaspar): 2500 international units/m^2 IV/IM (Erwinaze): 10,000 international units/m^2	*Hyperglycemia, elevated transaminases* Anaphylaxis, thrombosis, pancreatitis
belinostat (Beleodaq)	IV: 1000 mg/m^2 on days 1–5 of 21-day cycle	*Nausea, fatigue, pyrexia, anemia, vomiting* Blood dyscrasias, hepatotoxicity, tumor lysis syndrome, embryotoxicity
bexarotene (Targretin)	PO: 100–400 mg/m^2/day Topical: 1% gel applied to lesion 1–4 times/day	*Hyperlipidemia, leukopenia, rash, pruritus, headache, asthenia, nausea, vomiting* Acute pancreatitis, elevated hepatic enzymes, hypothyroidism
hydroxyurea (Droxia, Hydrea, Mylocel)	PO: 80 mg/kg q3days or 30 mg/kg/day	*Nausea, vomiting, diarrhea, stomatitis, rash* Myelosuppression
ixabepilone (Ixempra)	IV: 40 mg/m^2 infused over 3 h q3wk	*Alopecia, diarrhea, fatigue, asthenia, musculoskeletal pain, peripheral sensory neuropathy, stomatitis, mucositis, nausea, and vomiting* Anemia, neutropenia, thrombocytopenia
lenalidomide (Revlimid)	PO: 25 mg/day	Same as thalidomide
mitotane (Lysodren)	PO: 9–10 g/day in divided doses tid or qid	*Anorexia, nausea, vomiting, diarrhea, rash, lethargy, drowsiness* Hemorrhagic cystitis
pomalidomide (Pomalyst)	PO: 4 mg/day on days 1–21 of repeated 28-day cycles	Same as thalidomide
romidepsin (Istodax)	IV: 14 mg/m^2 on days 1, 8, and 15 of a 28-day cycle	*Nausea, fatigue, infections, vomiting, anorexia* Blood dyscrasias, anemia, ECG T-wave changes
sipuleucel-T (Provenge)	IV: 3 doses at 2-wk intervals; each dose contains 50 million autologous CD54 cells	*Chills, fatigue, fever, back pain, nausea, joint ache, headache* Acute infusion-related reactions
thalidomide (Thalomid)	PO: 200–400 mg/day	*Fatigue, constipation, nausea, diarrhea, dyspnea, respiratory infections, back pain, pyrexia* Neutropenia, venous thromboembolism
vorinostat (Zolinza)	PO: 400 mg once daily	*Diarrhea, nausea, vomiting, anorexia, fatigue, chills, taste disorders* Blood dyscrasias, pulmonary embolism
zoledronic acid (Zometa)	IV: 4 mg over at least 15 min	*Flulike symptoms, bone, muscle pain* Dysrhythmias, electrolyte imbalances, osteonecrosis of jaw

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

QT-interval prolongation and complete atrioventricular block, other drugs that prolong the QT interval should be discontinued during therapy. This is a pregnancy category D drug.

Asparaginase (Erwinaze, Oncaspar): Asparaginase is an enzyme that deprives cancer cells of asparagine, an essential amino acid, causing a marked reduction in protein, RNA, and DNA synthesis. It is approved only to

treat acute lymphocytic leukemia in combination with other antineoplastics. It is administered by the IM or IV routes. Hypersensitivity reactions occur in many patients with symptoms ranging from urticaria to anaphylactic shock. Pretreatment with corticosteroids reduces the incidence of hypersensitivity reactions. This drug is hepatotoxic and may cause hypoalbuminemia and decreased synthesis of coagulation factors. Asparaginase may cause fatal pancreatitis. This is a pregnancy category C drug.

Pegaspargase (Oncaspar) is asparaginase with a molecule of PEG bonded to it. Pegylation increases the half-life of the drug and allows for less frequent dosing. Erwinaze is a form of the drug made from chrysanthemums for patients who are allergic to *E. coli* proteins that may be found in vials of Oncaspar. The two drugs share the same adverse effects and indications.

Belinostat (Beleodaq), romidepsin (Istodax), and vorinostat (Zolinza): These three drugs induce apoptosis in cancer cells by inhibiting the activity of the enzyme histone deacetylase. They are approved for the treatment of cutaneous or peripheral T-cell lymphoma in patients who have progressive, persistent, or recurrent disease. Fatigue, diarrhea, nausea, anorexia, and blood dyscrasias are common adverse effects. Pulmonary embolism is a rare, though serious, adverse effect of vorinostat. These drugs are pregnancy category D.

Bexarotene (Targretin): Approved in 1999, bexarotene is a retinoid, a group of drugs related to vitamin A that are usually used for skin conditions such as psoriasis and acne (see Chapter 73). This drug is approved by the PO and topical routes to treat cutaneous T-cell lymphoma that has not responded to other therapies. Off-label indications include lung cancer, Kaposi's sarcoma, metastatic breast cancer, and severe psoriasis. Adverse effects of the oral formulation include hyperlipidemia, hypothyroidism, acute pancreatitis, leukopenia, headache, asthenia, anemia, anorexia, and photosensitivity. Topical bexarotene can cause rash, erythema, and pruritus. This is a pregnancy category X drug.

Hydroxyurea (Droxia, Hydrea, Mylocel): Hydroxyurea is an oral antineoplastic approved in 1967 for chemotherapy of chronic myelogenous leukemia, head and neck cancers, malignant melanoma, and ovarian cancer. It may be used off-label for acute myelogenous leukemia, astrocytoma, lung cancer, and malignant glioma. Sickle cell disease is a nonneoplastic indication for the drug. Hydroxyurea causes myelosuppression, especially neutropenia. This drug carries a black box warning that long-term use may cause secondary leukemias. Nausea, vomiting, stomatitis, and diarrhea are common. Skin ulcers and gangrene have been reported. This is a pregnancy category C drug.

Ixabepilone (Ixempra): Approved in 2007, ixabepilone acts by the same mechanism as the taxanes but it has different pharmacokinetic properties. It is used in combination with capecitabine to treat metastatic or advanced breast cancer resistant to treatment with first-line medications such as the taxanes. At least 20% of patients experience alopecia, diarrhea, fatigue, asthenia, musculoskeletal pain, peripheral sensory neuropathy, stomatitis, mucositis, nausea, and vomiting. More than 40% of patients experience anemia, neutropenia, and thrombocytopenia. Ixabepilone carries a black box warning that it must not be given to patients with elevated serum aspartate aminotransferase (AST), alanine transaminase (ALT), or bilirubin levels due to increased risk of toxicity and neutropenia-related death. This is a pregnancy category D drug.

Mitotane (Lysodren): Mitotane, which is similar to the insecticide DDT, poisons cancer cells by forming links to proteins. Given by the PO route, its only indication is for the chemotherapy of advanced, inoperable adrenocortical cancer. Because the drug is cytotoxic to the adrenal gland, symptoms of acute adrenal insufficiency may emerge. Mitotane carries a black box warning that the drug should be temporarily stopped after shock or severe trauma due to its adrenal suppression effects. Most patients experience adverse GI effects such as nausea, vomiting, and diarrhea. CNS effects such as lethargy, drowsiness, and vertigo are observed in up to 40% of patients who are taking the drug. Mitotane is a pregnancy category C drug.

Sipuleucel-T (Provenge): Approved in 2010, sipuleucel-T is very different from other antineoplastic medications. Three days prior to sipuleucel-T administration, the patient undergoes leukapheresis during which antigen-presenting cells (APCs) are collected. The APCs are then incubated with granulocyte-macrophage colony-stimulating factor (GM-CSF) and a prostate cancer antigen, which activates the collected cells. The product, consisting of GM-CSF mature and activated APCs, is reinfused into the patient to cause an immune response against prostate cancer cells. The product can be used only for the patient from whom the APCs were collected. Because acute infusion-related effects such as chills and fever have been reported, the patient is usually premedicated with acetaminophen and an antihistamine. The drug is not indicated for women so it carries no pregnancy rating.

Zoledronic acid (Zometa): Approved in 2001, zoledronic acid is a bisphosphonate, a drug class commonly used to

treat osteoporosis. The primary action of the drug is to inhibit bone resorption by osteoclasts. In addition to its use in managing osteoporosis, this drug is approved to treat multiple myeloma in patients with osteolytic metastases, severe hypercalcemia caused by malignancy, and Paget's disease. It is given by IV infusion. Adverse effects include flulike symptoms, fever, fatigue, headache, anemia, anorexia, bone pain, arthralgia, and osteonecrosis of the jaw. This is a pregnancy category D drug.

Drugs for Reducing Adverse Effects

57.9 Medications are used to relieve the adverse effects experienced by patients undergoing chemotherapy.

Most patients who are undergoing chemotherapy will require drugs to treat the severe adverse effects of antineoplastic medications. In many cases, medications are given to prevent adverse effects from occurring. Some of these are well-established drugs with usefulness that has been proven over the years. Others are drugs that were developed specially to deal with the adverse effects of chemotherapy.

Antiemetics are given to nearly all patients who are undergoing chemotherapy to decrease or prevent nausea and vomiting. Examples include ondansetron (Zofran), lorazepam (Ativan), dronabinol (Marinol), and prochlorperazine (Compazine). The type and dose of the antiemetic is based on the known emetogenic potential of the specific antineoplastic drugs employed. Chapter 60 provides complete information on the antiemetics.

Drugs for bowel disorders may be ordered to decrease either constipation or diarrhea. Laxatives or stool softeners may be indicated, such as polyethylene glycol 3350 (MiraLAX), Milk of Magnesia, psyllium (Metamucil), or docusate (Surfak, Colace). Patients may require a medication such as diphenoxylate with atropine (Lomotil), loperamide (Imodium), or bismuth salts (Pepto Bismol) to stop or decrease diarrhea. The student should refer to Chapter 60 for information on drugs for bowel disorders.

Myelosuppression is a disabling adverse effect of many chemotherapy drugs. Three types of drugs are commonly used to prevent serious complications of myelosuppression:

- Epoetin alfa (Epogen, Procrit) is a hematopoietic growth factor that stimulates the production of RBCs, which may prevent the development of anemia. A prototype feature for epoetin alfa is included in Chapter 39.
- Colony-stimulating factors such as filgrastim (Granix, Neupogen, Zarxio) increase neutrophil production in the bone marrow and enhance the phagocytic and cytotoxic functions of existing neutrophils. Administration of filgrastim shortens the duration of neutropenia in patients with cancer. A prototype feature for filgrastim is included in Chapter 39.
- Oprelvekin (Neumega) is used to stimulate the production of platelets in patients who are at risk for severe thrombocytopenia caused by chemotherapy. A prototype feature for oprelvekin is included in Chapter 39.

Denosumab (Xgeva), approved in 2010, is given to patients with bone metastases. This drug inhibits osteoclasts, which cause excessive bone resorption, pain, and possible fractures in these patients. Given by the subcutaneous route once every 4 weeks, denosumab is being investigated as a treatment for osteoporosis.

Other medications are ordered as the patient's condition warrants, including analgesics, antibiotics, appetite stimulants, and antidepressants. The pharmacotherapy of neoplasia may include a dozen or more drugs, which makes patient care extremely challenging.

Preparing and Administering Antineoplastics

57.10 Nurses who are preparing and delivering antineoplastics must exercise extreme caution to protect themselves from medication exposure.

Many healthcare agencies allow only an **oncology nurse** who has received special training to care for patients with cancer and to administer chemotherapy. A large number of antineoplastic medications are absorbed through the skin and mucous membranes, so the individual preparing and administering them is at risk for absorbing them. Nurses and other healthcare professionals engaged in the preparation or administration of antineoplastics must be extremely diligent about always wearing protective clothing, including gloves, whenever handling them. Both the Oncology Nursing Society and the Occupational Safety and Health Administration (OSHA) have established and publicized guidelines for safe handling of antineoplastic medications. The guidelines include information on safe storage and disposal as well as safe handling.

Understanding Chapter 57

Key Concepts Summary

57.1 Antineoplastic drugs kill or stop the growth of cancer cells and may be classified in multiple ways.

57.2 Alkylating agents change the shape of the DNA double helix and prevent cancer cells from dividing normally.

57.3 Antimetabolites disrupt the critical cellular pathways of cancer cells.

57.4 The antibiotic antineoplastics contain substances obtained from bacteria that have the ability to kill cancer cells.

57.5 Hormones and hormone antagonists block the substances necessary for continued growth of tumors.

57.6 Natural products that are derived from plants include the vinca alkaloids, taxanes, and topoisomerase inhibitors.

57.7 Biologic response modifiers and targeted therapies enhance the body's ability to kill tumor cells.

57.8 Several miscellaneous antineoplastics act by unique mechanisms.

57.9 Medications are used to relieve the adverse effects experienced by patients undergoing chemotherapy.

57.10 Nurses who are preparing and delivering antineoplastics must exercise extreme caution to protect themselves from medication exposure.

CASE STUDY: Making the Patient Connection

Remember the patient "Zack Amos" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Zack is a 12-year-old boy who had been in good health with no significant medical history until 6 months ago. At that time he began to experience episodic migraine-like headaches, and with a paternal family history of migraines, Zack was evaluated for possible antimigraine therapy if the headaches continued. After 3 months of increasing severity of the headaches, he was diagnosed by CT scan with a brain tumor. Zack underwent craniotomy for evacuation of a malignant tumor and began chemotherapy 1 month after surgery, prior to planned radiation therapy treatments. He has completed one cycle of chemotherapy over 2 months and will have a second cycle prior to radiation. He visits the oncology clinic today for evaluation prior to his second round of chemotherapy.

Physical examination on this clinic visit reveals a pleasant young boy in no obvious distress. Zack weighs 43.6 kg (96 lb) and is 157.5 cm (62 in.) in height. BP is 92/40 mmHg, pulse rate is 92 beats/min, respirations of 24 breaths/min, and temperature of 37.1°C (98.8°F). Zack denies having any pain and his neurologic examination is unremarkable except for diminished patellar DTRs, graded at 1 (decreased but present; normal of 2). His WBC count is 3420/mm^3; ANC, 1800; hemoglobin (Hgb), 13 g/dL; hematocrit (Hct), 36.5%; and his platelet count is 225,000. CBC is within the range expected postchemotherapy. Zack will be hospitalized for approximately 2 days for administration of cyclophosphamide (Cytoxan), carboplatin (Paraplatin), and vincristine (Oncovin) and will continue to receive doses of vincristine as an outpatient and start etoposide (VePesid) in several weeks. Because he experienced significant nausea and vomiting with the last round of chemotherapy, he will also be given ondansetron (Zofran) regularly with supplemental corticosteroids IV as needed.

Critical Thinking Questions

1. Why are four antineoplastic drugs used for Zack? What is the pharmacologic classification of each of the drugs used?
2. What overlapping toxicities might Zack experience with these drugs? Considering his physical assessment findings from today, what system toxicities would be of most concern?
3. Fifteen days after the start of the second cycle of chemotherapy, Zack experiences his nadir. At this time his WBC count is 340/mm^3; ANC, 98; Hgb, 9.3 g/dL; Hct, 25.7%; and the platelet count is 55,000. Zack has

been receiving filgrastim (Neupogen) subcutaneously since discharge and will continue until the WBC count begins to rise. Considering these laboratory values, what would be of most concern to the oncology team? What teaching should Zack and his family receive?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Ansen Rosenthal is a 25-year-old man who has recently begun chemotherapy at the local oncology center for treatment of Hodgkin's lymphoma. He has tolerated the chemotherapy fairly well but has experienced mild, daily nausea with occasional vomiting, usually controlled by granisetron (Kytril). His main concern is the fatigue he experiences and the impact it has on his work as a computer science engineer. He also admits that he has been experiencing anorexia and "just doesn't feel like eating much," something which may be contributing to his fatigue. He has lost 2 kg (more than 4 lb) since his last clinic visit 2 weeks ago.

1. If you were Ansen's nurse, how might you manage his chemotherapy-related nausea and anorexia?
2. What suggestions might assist Ansen in managing his fatigue?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is preparing to administer cyclophosphamide (Cytoxan) and knows that the patient will experience a nadir in approximately 9 to 14 days. Which laboratory value(s) will indicate to the nurse that the patient has reached the nadir?
    1. Blood urea nitrogen and creatinine
    2. White blood cell count and absolute neutrophil count
    3. Ionized calcium
    4. Serum albumin

2. A patient has been receiving vincristine (Oncovin) as one of the drugs in a chemotherapy regimen. What important findings will the nurse monitor to prevent or limit the main dose-related toxicity for this patient? (Select all that apply.)
    1. Numbness of the hands or feet
    2. Angina and dysrhythmias
    3. Constipation
    4. Diminished reflexes
    5. Dyspnea and pleuritis

3. A nurse is caring for a patient who is receiving tamoxifen for treatment of breast cancer. The nurse will teach the patient that postchemotherapy monitoring will be necessary to detect or treat which drug-associated adverse effect?
    1. Paralytic ileus
    2. Alopecia
    3. Pulmonary fibrosis
    4. Endometrial cancer

4. A patient with acute lymphoblastic leukemia has started therapy with doxorubicin (Adriamycin). The nurse will assist the patient with what important intervention during the course of this treatment?
    1. Perform active or assisted range-of-motion (ROM) exercises to maintain strength.
    2. Participate in relaxation therapy to control pain.
    3. Use daily mouth rinses as prescribed.
    4. Maintain bed rest during treatment.

5. The patient will continue to take methotrexate (MTX, Rheumatrex, Trexall) for treatment of osteosarcoma. When teaching the patient prior to discharge, what over-the-counter drugs must not be taken concurrently with methotrexate?
    1. Nonsteroidal anti-inflammatory drug pain relievers
    2. Antihistamines
    3. Laxatives
    4. Cough suppressants

6. A patient receiving carboplatin (Paraplatin) is also receiving filgrastim (Neupogen). The nurse will explain to the patient that the filgrastim is used for what effect?
    1. It boosts the effects of the carboplatin so a decreased dosage is needed.
    2. It prevents the development of secondary cancers related to the carboplatin.
    3. It shortens the duration of neutropenia and associated infection risk related to the carboplatin.
    4. It prevents bone loss and osteoporosis.

CHAPTER 62 Enteral and Parenteral Nutrition / 1147

CHAPTER 63 Weight Reduction Strategies and the Pharmacotherapy of Obesity / 1162

Chapter 58
Review of the Gastrointestinal System

Chapter Outline

- Overview of the Digestive System
- Physiology of the Upper Gastrointestinal Tract
- Physiology of the Lower Gastrointestinal Tract
- Physiology of the Accessory Organs of Digestion
- Regulation of Digestive Processes
- Nutrient Categories and Metabolism

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the major anatomic structures of the digestive system.
2. Outline the steps in the process of digestion.
3. Describe the primary functions of the stomach.
4. Analyze how the anatomic structures of the small intestine promote the absorption of nutrients and drugs.
5. Describe the primary structures and functions of the large intestine.
6. Describe the functions of the liver and their relevance to drug therapy.
7. Explain the hepatic portal system and its importance to drug therapy.
8. Explain the nervous control of digestion.
9. Explain the enzymatic breakdown of nutrients by the digestive system.

Key Terms

accessory organs of digestion, 1075
alimentary canal, 1075
chief cells, 1076
chyme, 1076
defecation, 1075
digestion, 1075
digestive system, 1075
enteric nervous system (ENS), 1080
enteroendocrine cells, 1076
hepatic portal system, 1079
ingestion, 1075
parietal cells, 1076
peristalsis, 1075

Very little of the food we eat is directly available to body cells. Food must be broken down, absorbed, and chemically modified before it is in a form that is useful to cells. The digestive system performs these functions and many more. This chapter focuses on the aspects of digestion and physiology that are applicable to pharmacotherapy. For a complete review of the digestive system, the student should refer to an anatomy and physiology textbook.

Overview of the Digestive System

58.1 The function of the digestive system is to extract nutrients from food to fuel metabolic processes in the body.

The **digestive system** consists of two basic anatomic divisions: the alimentary canal and the accessory organs. The **alimentary canal**, or gastrointestinal (GI) tract, is a long, continuous, hollow tube that extends from the mouth to the anus. The **accessory organs of digestion** include the salivary glands, liver, gallbladder, and pancreas. The major structures of the digestive system are illustrated in Figure 58.1.

The overall function of the digestive system is to extract nutrients from food so that they may be used to fuel the metabolic processes in the body. Because food is a complex substance, multiple steps are necessary before cells can use its components. These steps are ingestion, propulsion, digestion, absorption, and defecation.

Ingestion is taking food into the body by mouth. In some patients, ingestion bypasses the mouth and delivers nutrients directly into the stomach or small intestine via a feeding tube.

Substances are propelled along the GI tract by **peristalsis**, which is the rhythmic contractions of layers of smooth muscle. The speed at which substances move through the GI tract is critical to the absorption of drugs, nutrients, and water and for the removal of wastes. If peristalsis is too fast, substances will not have sufficient contact with the GI mucosa to be absorbed. In addition, the large intestine will not have enough time to absorb water, and diarrhea may result. Abnormally slow transit may result in constipation or even obstructions in the small or large intestine.

Digestion is the mechanical and chemical breakdown of food into a form that may be absorbed into the systemic circulation. To chemically break down ingested food, a large number of enzymes and other substances are required. Digestive enzymes are secreted by the salivary glands, stomach, small intestine, and pancreas. The liver makes bile, which is stored in the gallbladder until it is needed for lipid digestion.

Absorption is the movement of nutrients and other substances from the alimentary canal to the circulation. The inner lining of the alimentary canal, called the mucosa layer, provides a surface area on which the various acids, bases, and enzymes can break down food. In many parts of the alimentary canal, the mucosa is folded and contains deep grooves and pits. The small intestine is lined with tiny projections called villi and microvilli that provide a huge surface area for the absorption of nutrients and medications.

Not all components of ingested food are useful to the human body or can be digested. The elimination of indigestible substances from the body is called **defecation**.

PharmFACT

Most people believe that people with obesity have larger stomachs. However, people who are naturally thin have the same size as or even larger stomachs than people who have problems with weight control. Weight has nothing to do with the size of the stomach (Bouchez, n.d.).

Physiology of the Upper Gastrointestinal Tract

58.2 The upper gastrointestinal tract is responsible for mechanical and chemical digestion.

The upper GI tract consists of the mouth, pharynx, esophagus, and stomach. From a pharmacologic perspective, the most important regions of the upper GI tract are the buccal and sublingual areas of the mouth and the stomach.

The epithelial mucosa of the buccal and sublingual regions is very thin, being only 40 to 50 cells in thickness.

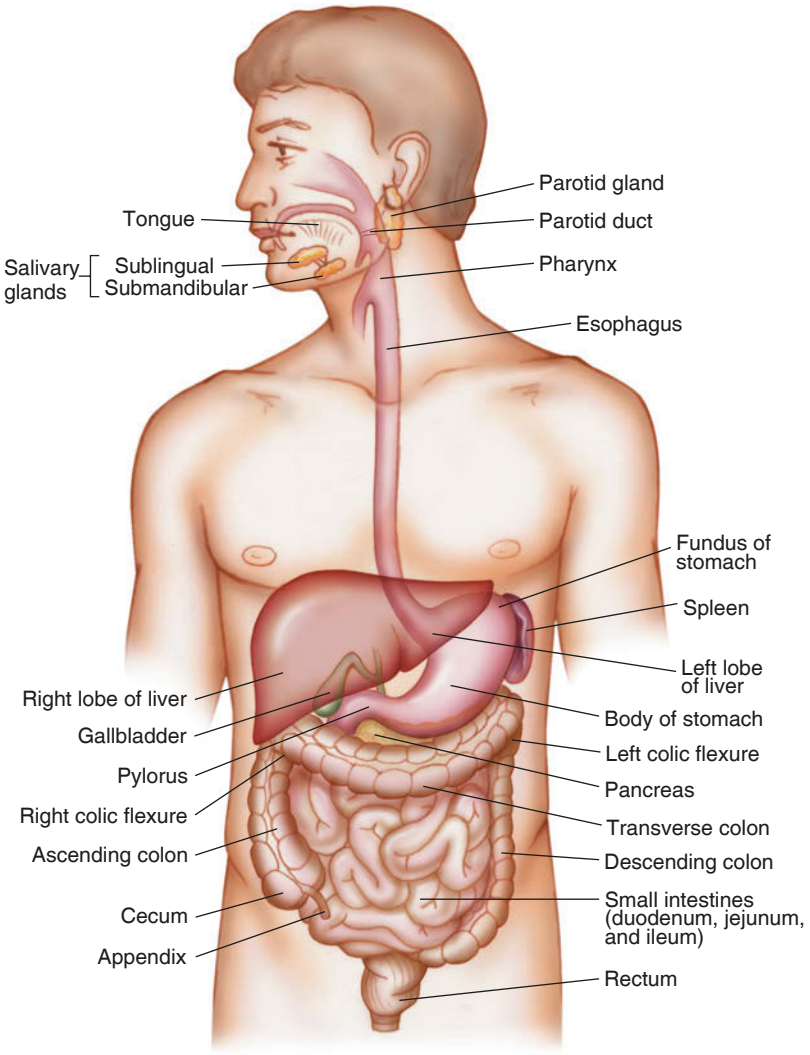

Figure 58.1 The digestive system.

The mucosal layer, along with the salivary glands, secretes mucus, which lubricates and moistens the oral cavity. The mucus also serves as a liquid medium for drug administration inside the mouth. The oral mucosa in the sublingual region is relatively permeable, and drugs are rapidly absorbed. The buccal region is less permeable, and drug absorption is slower. The buccal region, however, has less salivary flow and drugs can be retained longer, making it better suited for sustained release delivery systems. For example, Striant is a buccal form of testosterone that is designed to release the drug over an 8- to 12-hour period.

The pharynx and esophagus serve as passageways for ingested food and liquids. Obstruction of these areas, or a loss of the swallowing reflex, precludes the administration of oral drugs. Little absorption occurs across the pharyngeal or esophageal mucosa because drugs travel quickly through these regions of the alimentary canal.

Food passes from the esophagus to the stomach by traveling through the lower esophageal (cardiac) sphincter. This ring of smooth muscle usually prevents the stomach contents from moving backward, a condition known as gastroesophageal reflux. The stomach has both mechanical and chemical functions. The muscular squeezing of the stomach churns and mixes the food, breaking it down mechanically to a semisolid known as **chyme**. Strong peristaltic contractions push the chyme toward the pylorus, where it encounters a second ring of smooth muscle called the pyloric sphincter. Located at the entrance to the small intestine, this sphincter regulates the flow of substances leaving the stomach. Chyme moves in "spurts" through the sphincter into the small intestine. Large pieces of food are refluxed back into the body of the stomach, where they are subjected to more churning to reduce them in size to about 2 mm so that they may pass through the sphincter.

The stomach also secretes substances that promote the processes of chemical digestion. Gastric glands extending deep into the mucosa of the stomach contain several cell types that are critical to digestion and that are important to the pharmacotherapy of digestive disorders:

- **Chief cells** secrete pepsinogen, an inactive form of the enzyme pepsin that chemically breaks down proteins.
- **Parietal cells** secrete 1 to 3 liters of hydrochloric acid each day. This strong acid helps to break down food, activates pepsinogen, and kills microbes that may have been ingested. Parietal cells also secrete intrinsic factor, which is essential for the absorption of vitamin B_{12}.
- **Enteroendocrine cells** secrete hormones that modify the digestive processes. In the stomach, the most important secretion is gastrin, which stimulates acid production by the parietal cells.

The combined secretion of the chief and parietal cells, known as gastric juice, is the most acidic fluid in the body, having a pH of 1.5 to 3.5. A number of natural defenses protect the stomach mucosa against this extremely acidic fluid. Certain cells that line the surface of the stomach secrete a thick, mucous layer and bicarbonate ion to neutralize the acid. These form such an effective protective layer that the pH at the mucosal surface is nearly neutral. On reaching the duodenum, the stomach contents are further neutralized by bicarbonate from pancreatic and biliary secretions.

The pharmacologic importance of the stomach lies in its capacity to absorb drugs. For most oral drugs, the stomach is not the primary site of absorption because the drug

does not stay long in the organ. Stomach acidity (pH 1 to 2) can either assist in the absorption process or destroy the drug entirely. Drugs that are weak acids tend to be absorbed in the stomach. Protein drugs are destroyed by pepsin in the stomach before they are absorbed or have a chance to reach the small intestine.

CONNECTION Checkpoint 58.1

Nitroglycerin is the most frequently prescribed sublingual medication. From what you learned in Chapter 35, what is the primary indication for nitroglycerin and what is the time for onset of action of the drug when it is given by the sublingual route? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Physiology of the Lower Gastrointestinal Tract

58.3 The small intestine is the longest portion of the alimentary canal and is the primary organ for absorption.

The lower GI tract consists of the small and large intestines. With its many folds and finger-like projections of villi and microvilli, the small intestine is highly specialized for absorption. The lining of each villus is composed of a single layer of epithelial cells and contains blood capillaries, as illustrated in Figure 58.2. Essentially, only a single cell separates a nutrient or drug molecule from the intestinal lumen of the body's circulatory system.

The duodenum, the first 10 inches of the small intestine, is the site where chyme mixes with bile from the gallbladder and digestive enzymes from the pancreas. Bile and pancreatic juice enter through an opening in the duodenum known as the duodenal papilla. The duodenum is sometimes considered part of the upper GI tract because of its proximity to the stomach. Peptic ulcer, the most common disorder of the duodenum, is discussed in Chapter 59.

The remainder of the small intestine consists of the jejunum and ileum. Because of its length and enormous absorptive surface, the first 1 to 2 meters (3 to 6.5 feet) of the jejunum is the site of the majority of nutrient and drug absorption. As the jejunum becomes the ileum, the diameter of the intestinal lumen diminishes and the villi become fewer in number. The terminal ileum is a primary site for the absorption of vitamin B_{12}, long-chain fatty acids, and fat-soluble vitamins. The ileum empties its contents into the large intestine through the ileocecal valve. Travel time for chyme through the entire small intestine varies from 3 to 6 hours.

The mucosa of the small intestine secretes intestinal juice, which is a mixture of mucus and digestive enzymes. The mucus has an alkaline pH, which neutralizes the acidity from the stomach. The small intestine also secretes cholecystokinin, a hormone that promotes pancreatic enzyme secretion, and secretin, which stimulates bicarbonate production to make the small intestine more alkaline.

CONNECTION Checkpoint 58.2

Many oral drugs have enteric coatings. From what you learned in Chapter 3, what is the purpose of the enteric coating and why are these drugs not to be split or crushed? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

58.4 The large intestine contains host flora and is a major site of water reabsorption.

The large intestine, or colon, receives chyme from the ileum in a fluid state. The large intestine does not secrete digestive enzymes nor does it have enteroendocrine cells to secrete hormones. With few exceptions, little reabsorption of nutrients occurs during the 12- to 24-hour journey through the colon. The large intestine does secrete a large amount of mucus, which helps lubricate the fecal matter. The major functions of the colon are to reabsorb water and electrolytes from the waste material and excrete the remaining fecal material from the body.

The colon harbors a substantial amount of bacteria and fungi, called the host flora, which serve a useful purpose by synthesizing B-complex vitamins and vitamin K. Disruption of the normal host flora can lead to diarrhea.

From a pharmacologic perspective, the large intestine may be the site of therapeutic or adverse drug effects. A large number of drugs cause either diarrhea or constipation. These effects are usually self-limiting and can be prevented or managed through nursing interventions. When bowel patterns are significantly disrupted, drugs may be given to slow the activity (antidiarrheals) or increase the activity (laxatives) of the large intestine.

Of additional pharmacologic importance are the drugs given by the rectal route. The mucosa of the rectum provides an excellent and rapid absorptive surface for drugs. It is a route of particular importance in children and in patients who are unable to take oral medications due to nausea, vomiting, or other pathology that prevents oral administration. The onset of action is usually slower than the oral route, and drug action is limited by the length of time the patient can retain the drug without defecation.

Physiology of the Accessory Organs of Digestion

58.5 The liver is the most important accessory digestive organ.

The accessory organs of digestion include the teeth, tongue, salivary glands, pancreas, gallbladder, and liver. Of these, the pancreas and liver have the most pharmacologic importance.

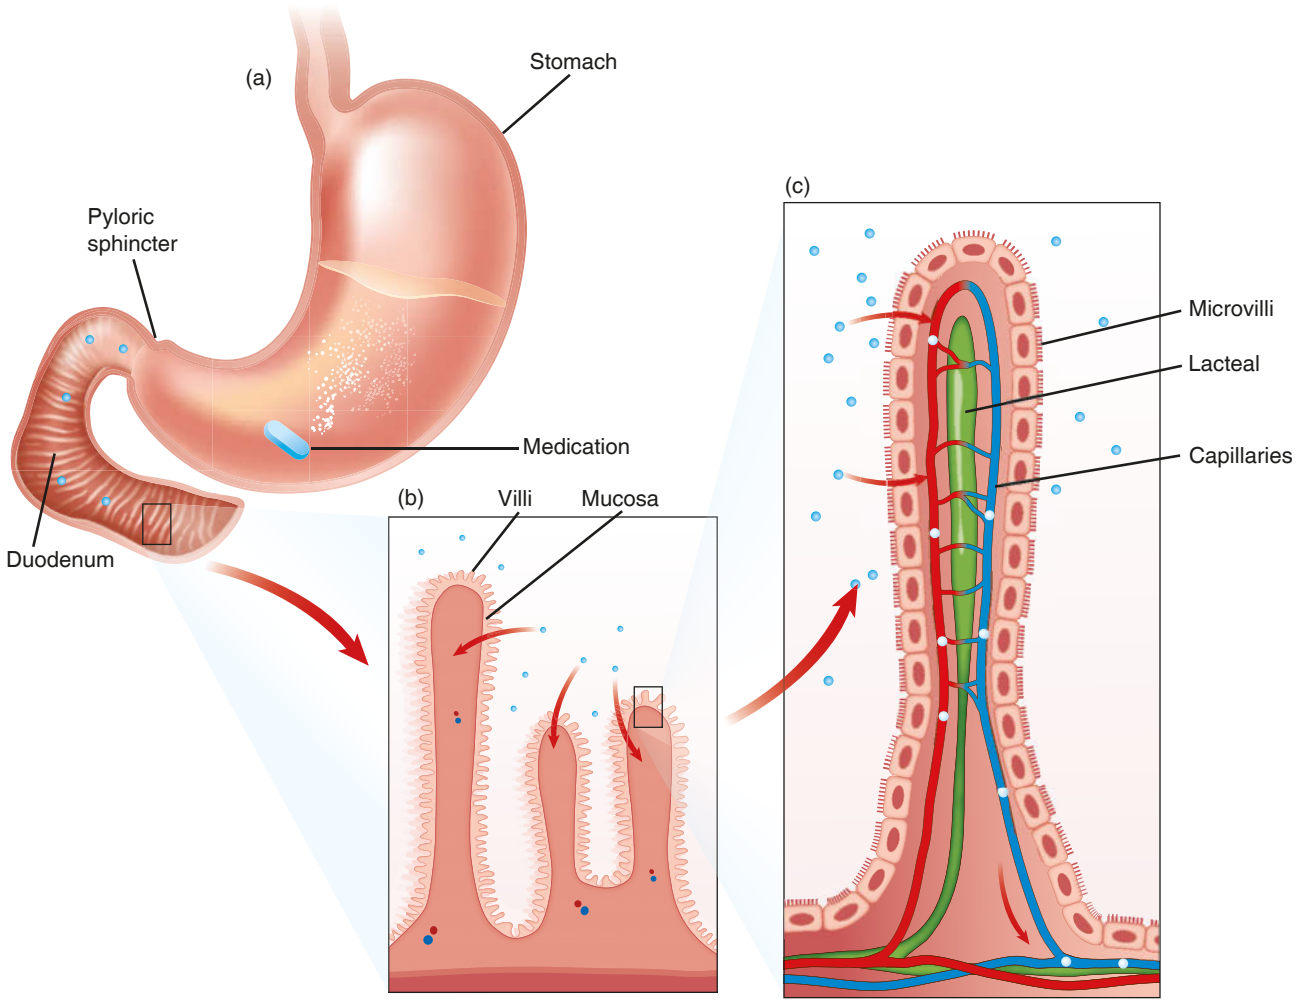

Figure 58.2 Villi and microvilli of the small intestine: (a) Tablet dissolves in the stomach. (b) Medication reaches the villi of the duodenum. (c) Drug molecules are absorbed into the microvilli capillaries.

The endocrine functions of the pancreas, which include the secretion of insulin and glucagon, are presented in Chapter 66.

The liver is one of the most important organs in pharmacology. Along with the kidneys, any drug that reaches the circulation, regardless of its route of administration, will pass through the liver. The overall function of the liver is to filter and process the nutrients and drugs delivered to it. Substances may be stored, chemically altered, or removed from the blood before they reach the general circulation. The following are some of the primary functions of the liver:

- **Regulation.** It stabilizes the serum levels of glucose, triglycerides, and cholesterol.
- **Protection.** It removes toxic substances and waste products such as ammonia.
- **Synthesis.** It synthesizes bile, plasma proteins, and certain clotting factors.
- **Storage.** It stores iron and fat-soluble vitamins.

When most drugs reach the liver, they are metabolized to less toxic substances that are more easily excreted by the kidney. The cytochrome P450 (CYP450) enzyme system in liver cells is especially active at metabolizing drugs; the various isozymes of CYP450 are discussed in Chapter 3. In a few cases, the liver changes the drug to a more active form. It is important to note that the handling of drugs and toxic substances by the liver can damage hepatocytes and impair their functions. This is especially true if the hepatocytes are chronically exposed to harmful substances such as alcohol. Hepatic impairment is a relatively common adverse effect of certain drugs. Whereas drug-induced hepatic impairment is often transient and asymptomatic, some drugs can cause severe, permanent, and even fatal liver damage.

PharmFACT

Acetaminophen (Tylenol) overdose is the leading cause of acute liver failure in the United States. Normal doses of the drug can cause acetaminophen poisoning in malnourished patients or those with chronic alcohol abuse (Farrell, 2016).

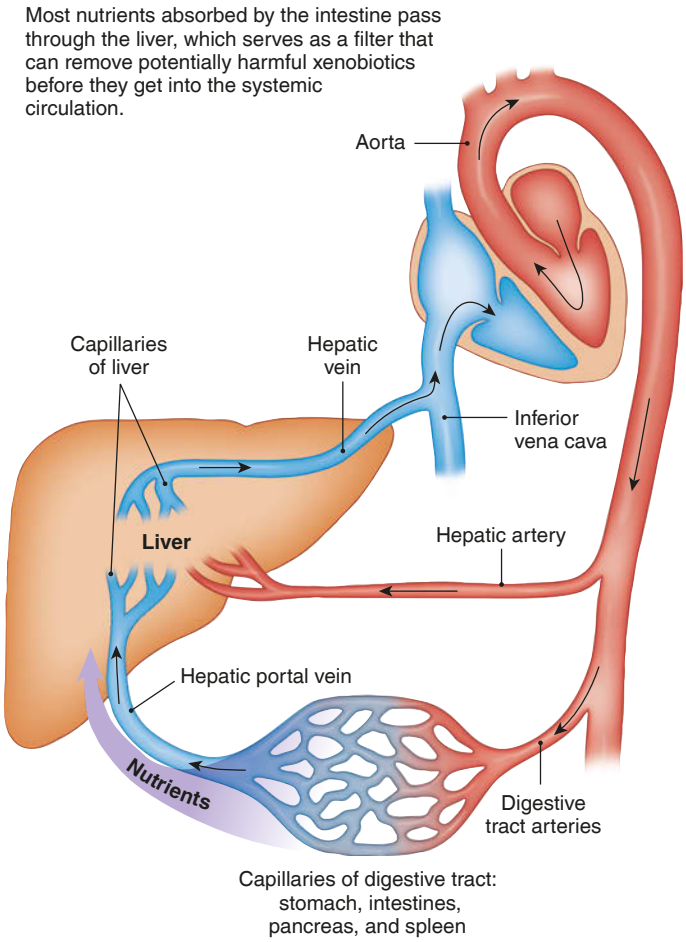

Figure 58.3 The hepatic portal system.
From *Human Physiology: An Integrated Approach* (7th ed.) by D. U. Silverthorn, 2016. Reprinted and Electronically reproduced by permission of Pearson Education, Inc., New York, NY.

The unique structure of the vascular system serving the liver is important to digestion as well as pharmacology. The liver receives both oxygenated and deoxygenated blood. The **hepatic portal system**, shown in Figure 58.3, is a network of venous vessels that collects blood draining from the stomach, small intestine, and most of the large intestine. This blood is extremely rich in nutrients because it contains substances absorbed during digestion. It is important to know that this blood is delivered to the liver via the hepatic portal vein before it reaches the arterial circulation. The liver then can remove, store, excrete, or perform metabolic functions on these substances before they are sent into the inferior vena cava to reach other organs.

The hepatic portal system serves as an important homeostatic mechanism, allowing a relatively stable composition of blood to circulate through the body. In terms of drug therapy, nearly all oral medications enter the hepatic portal vein for processing by the liver before they reach their target tissue. In some cases, the liver inactivates a substantial percentage of the drug before it reaches the inferior vena cava, a phenomenon called the *first-pass effect*. Drugs that have a significant first-pass effect may be given by other routes, such as intramuscular, intravenous, subcutaneous, or topical. Although a drug will still eventually reach the liver by these routes, it will have an opportunity to also reach its target tissue. Note that the venous systems serving the head and the lower rectum are not parts of the hepatic portal system. Thus, drugs that are given by the buccal, sublingual, or rectal routes bypass the first-pass effect of the liver.

As the liver makes bile, the bile is sent to the gallbladder where it is stored. When lipids enter the small intestine, the gallbladder contracts and sends its contents into the duodenum. The bile salts emulsify the lipids, making them easier to digest enzymatically. When bile salts reach the terminal portion of the ileum, 95% are reabsorbed back into the hepatic portal circulation by a process called *enterohepatic recirculation*. This process has direct implications to pharmacotherapy. Certain drugs, including digoxin (Lanoxin), morphine, and estrogens, are eliminated in the bile and are reabsorbed by enterohepatic recirculation. Enterohepatic recirculation recycles the drug multiple times and can significantly extend a drug's half-life. Interactions can occur if one drug interferes with the enterohepatic recycling of another drug. Preventing this recycling can speed the elimination of a drug and reduce its therapeutic effectiveness. An example of such an interaction is when cholestyramine (Questran) interferes with the recycling of lorazepam (Ativan) and increases the clearance of lorazepam from the body.

The pancreas is an essential accessory digestive organ, secreting about a quart of pancreatic fluid into the duodenum each day. This fluid is alkaline (pH 7.5 to 8.8) and contains digestive enzymes to chemically break down carbohydrates, lipids, proteins, and nucleic acids. From a pharmacologic perspective, the pancreas is relatively protected from drugs and there are only a few therapies for pancreatic digestive disorders.

CONNECTION Checkpoint 58.3

The tricyclic antidepressant imipramine is a substrate for the CYP2D6 enzyme, and the selective serotonin reuptake inhibitor (SSRI) fluoxetine is a potent inhibitor of this enzyme. From what you learned in Chapter 5, predict the type of drug interaction that will occur in a patient stabilized on imipramine therapy when fluoxetine is added to the regimen. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Regulation of Digestive Processes

58.6 Digestion is regulated by numerous hormonal and nervous factors.

Digestion is controlled through a large number of hormonal and nervous factors that influence the speed of peristalsis and the amount of saliva, mucus, acid, and enzyme secretions. Various negative feedback loops help to regulate these activities so that digestion is a smooth, continuous process. Disruption of normal homeostatic mechanisms can

cause cramping, due to excessive peristalsis, or peptic ulcers, due to the overproduction of gastric acid.

The nervous control of digestion is provided at several levels. Chapter 12 discusses the role of the autonomic nervous system (ANS) in controlling the contraction of smooth muscle and glandular secretion. Activation of the parasympathetic nervous system stimulates the digestive processes by increasing peristalsis, salivation, and digestive gland secretion. The sympathetic nervous system has opposite effects, with beta$_2$-adrenergic receptors in the intestinal wall and alpha$_1$-adrenergic receptors in the salivary glands. Drugs that affect the ANS often affect the digestive processes.

The GI tract is also regulated by local reflexes called the **enteric nervous system (ENS)**. This system consists of a vast network of neurons in the submucosa of the alimentary canal that has sensory and motor functions. Chemoreceptors and stretch receptors sense the presence and amount of food in the GI tract and respond accordingly by changing motility without sending signals to the ANS.

The GI tract functions at an automatic level; no conscious thought is required as the system goes about its daily tasks of secretion and digestion. The central nervous system (CNS), however, can greatly influence the activity of digestive functions. For example, merely thinking of food can evoke powerful images. These may be positive, such as perhaps thinking of a steak sizzling on the grill or bread baking in the oven, and increase salivation and peristalsis. Images may also be negative and evoke feelings of nausea and vomiting at the sight or smell of food. Mental health conditions such as depression, anxiety, excessive stress, or bipolar disorder can affect the appetite and digestive processes.

Nutrient Categories and Metabolism

58.7 The chemical breakdown of food is accomplished by digestive enzymes.

The three basic nutrients are carbohydrates, lipids, and proteins. In food these nutrients are large molecules that cannot be absorbed across the mucosa of the alimentary canal. Chemical digestion must break down these complex food molecules into simpler substances so that they can be absorbed and used by the body for metabolic processes.

Table 58.1 Major Digestive Enzymes

Nutrient	Enzyme	Source
Carbohydrates and starches	Salivary amylase	Saliva
	Pancreatic amylase	Pancreatic juice
	Maltase, sucrase, lactase	Small intestine
Lipids	Pancreatic lipase	Pancreatic juice
Proteins and polypeptides	Pepsin	Gastric glands
	Trypsin, chymotrypsin, carboxypeptidase	Pancreatic juice
	Aminopeptidase	Small intestine

The breakdown of complex carbohydrates, lipids, and proteins requires digestive enzymes to be delivered when food is present at various parts of the alimentary canal, primarily the stomach and small intestine. These enzymes and their locations are listed in Table 58.1. Secretion of digestive enzymes is regulated by hormones and the nervous system, as described in Section 58.6. Patients who secrete insufficient quantities of digestive enzymes may be administered these substances as drugs.

In addition to the three basic nutrients, the body requires a host of other vitamins and minerals for proper metabolism. Deficiency symptoms will be observed if a patient has insufficient intake of these substances. The pharmacotherapy of vitamins and minerals is presented in Chapter 61.

The intake of various nutrients in sufficient amounts is necessary to maintain good health and to allow the body to heal during periods of illness or injury. The intake of sufficient amounts of proteins, carbohydrates, fats, vitamins, and minerals can often be achieved by eating a well-balanced diet of foods and fluids. When this does not occur, enteral or parenteral therapy may be indicated, as presented in Chapter 62.

Understanding Chapter 58

Key Concepts Summary

58.1 The function of the digestive system is to extract nutrients from food to fuel metabolic processes in the body.

58.2 The upper gastrointestinal tract is responsible for mechanical and chemical digestion.

58.3 The small intestine is the longest portion of the alimentary canal and is the primary organ for absorption.

58.4 The large intestine contains host flora and is a major site of water reabsorption.

58.5 The liver is the most important accessory digestive organ.

58.6 Digestion is regulated by numerous hormonal and nervous factors.

58.7 The chemical breakdown of food is accomplished by digestive enzymes.

Chapter 59
Pharmacotherapy of Peptic Ulcer Disease

Chapter Outline

- Physiology of the Upper Gastrointestinal Tract
- Etiology and Pathogenesis of Peptic Ulcer Disease
- Etiology and Pathogenesis of Gastroesophageal Reflux Disease
- Pharmacotherapy of Peptic Ulcer Disease and Gastroesophageal Reflux Disease

  Pharmacotherapy with Proton Pump Inhibitors

  PROTOTYPE *Omeprazole (Prilosec), p. 1090*

  Pharmacotherapy with H_2-Receptor Antagonists

  PROTOTYPE *Ranitidine (Zantac), p. 1093*

  Pharmacotherapy with Antacids

  PROTOTYPE *Aluminum Hydroxide (AlternaGEL, Others), p. 1095*

  Pharmacotherapy of ***Helicobacter pylori*** Infection

  Miscellaneous Drugs Used for Peptic Ulcer Disease and Gastroesophageal Reflux Disease

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the physiologic regulation of gastric acid secretion.
2. Describe factors that suppress and those that promote the formation of peptic ulcers.
3. Compare and contrast duodenal ulcers and gastric ulcers.
4. Identify the etiology, signs, and symptoms of peptic ulcer disease and gastroesophageal reflux disease.
5. Outline the treatment goals for the pharmacotherapy of peptic ulcer disease and gastroesophageal reflux disease.
6. Identify the classification of drugs used to treat peptic ulcer disease and gastroesophageal reflux disease.
7. Explain the pharmacologic strategies for eradicating *Helicobacter pylori*.
8. Describe the nurse's role in the pharmacologic management of patients with peptic ulcer disease and gastroesophageal reflux disease.
9. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
10. Apply the nursing process to care for patients receiving pharmacotherapy for peptic ulcer disease and gastroesophageal reflux disease.

Acid-related diseases of the upper gastrointestinal (GI) tract are some of the most common medical conditions. Because drugs for these disorders are available over the counter (OTC), many patients attempt self-treatment before seeking assistance from their healthcare provider. Signs and symptoms of acid-related conditions of the upper GI tract, however, may indicate more serious disease. This chapter examines the pharmacotherapy of two common disorders of the upper digestive system: peptic ulcer disease (PUD) and gastroesophageal reflux disease (GERD).

Physiology of the Upper Gastrointestinal Tract

59.1 The stomach secretes acid, enzymes, and hormones that are essential to digestive physiology.

The upper GI tract consists of the mouth, pharynx, esophagus, and stomach. The duodenum, the first 10 inches of the small intestine, is sometimes considered part of the upper GI tract because of its proximity to the stomach. The structures and functions of the upper GI tract are reviewed in Chapter 58.

Gastric glands in the stomach contain several cell types that are critical to digestion and important to the pharmacotherapy of digestive disorders. Chief cells secrete the enzyme pepsinogen, which is then activated to become **pepsin**, which is the digestive enzyme that breaks down proteins from food. Parietal cells secrete gastric (hydrochloric) acid in the stomach, which provides a strongly acidic environment that promotes the conversion of pepsinogen to pepsin, helps to break down food, and kills microbes that may have been ingested. Parietal cells also secrete intrinsic factor, which is essential for the absorption of vitamin B_{12} (see Chapter 58). Parietal cells are targets for the classes of drugs that reduce acid secretion. The cell types present in gastric glands are shown in Figure 59.1.

Parietal cells receive messages from several sources, which signal them to increase or decrease acid production. These cells contain receptors for the hormone gastrin, histamine (H_2), and the neurotransmitter acetylcholine, which are the three principal physiologic stimuli that regulate acid secretion from the proton pump, or H^+, K^+-ATPase, located on the surface of parietal cells.

Ingestion of food and distention of the stomach stimulate the secretion of the hormone gastrin into the bloodstream. The target cells for gastrin are enteroendocrine cells in the gastric glands. When gastrin binds to their cell surface, the enteroendocrine cells produce and secrete histamine. Histamine then binds to the H_2 receptor on the parietal cell to stimulate acid secretion. In addition to promoting acid secretion, gastrin signals the chief cells to secrete pepsin, promotes the production of pancreatic enzymes, and increases gastric blood flow.

Like most hormones, gastrin is regulated by a negative feedback loop. As the stomach contents reach pH 3 or lower, the hormone **somatostatin** is released by cells in the stomach, small intestine, and pancreas. This hormone suppresses the secretion of gastrin, thus lowering acid secretion. Interestingly, somatostatin is also released by the anterior pituitary gland and is known as growth hormone-inhibiting hormone. However, the nervous system secretion and actions are independent of its digestive actions.

Cells lining the surface of the stomach mucosa secrete a thick mucous layer that provides a continuous, protective physical barrier against acid and pepsin. Bicarbonate ion is also secreted by the epithelial cells in the stomach and serves to neutralize gastric acid on the mucosal surface. The mucus and bicarbonate ion form such an effective protective layer that the pH at the mucosal surface is nearly neutral. Once the stomach contents reach the duodenum, they are further neutralized by the bicarbonate ion from pancreatic and biliary secretions.

Another protective substance is the hormone **prostaglandin E_2**. This hormone stimulates the secretion of mucus and bicarbonate, promotes repair of damaged gastric mucosal cells, and increases blood flow to the mucosa to help maintain optimal mucosal conditions. Several frequently prescribed drugs, including corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs), cause peptic ulcers because they are prostaglandin antagonists. The natural defenses of the stomach are shown in Figure 59.2.

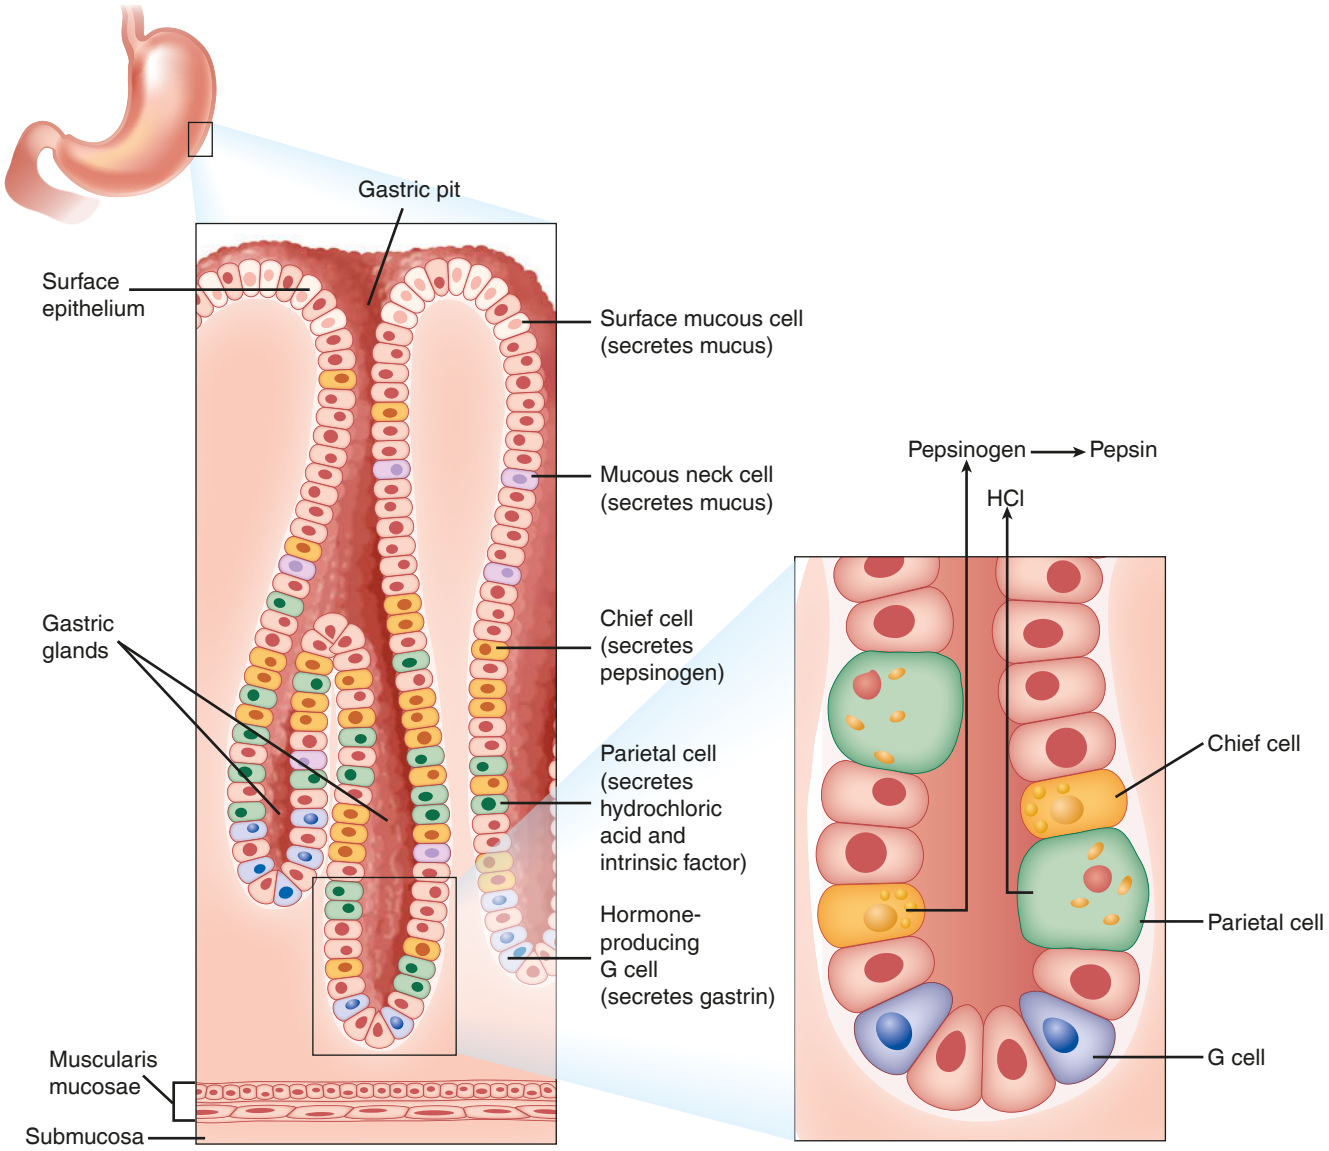

Figure 59.1 The stomach lining: gastric glands and the secretion of hydrochloric acid.

Etiology and Pathogenesis of Peptic Ulcer Disease

59.2 Peptic ulcer disease is associated with a number of etiologic risk factors.

A **peptic ulcer** is a lesion or erosion located in either the stomach (gastric) or small intestine (duodenal) mucosa that is usually associated with acute inflammation. PUD was an uncommon condition until the 19th century. Thus it is considered to be a "disease of civilization." Although PUD occurs most often in middle age, it may occur at any time, including infancy and childhood. A significant family history is present in at least half of children with PUD.

PUD occurs when there is an imbalance of protective factors versus aggravating factors: The levels of protective mucus and bicarbonate ion secretions are unable to protect against the aggravating factors of pepsin and gastric acid. Complications of PUD include bleeding, perforation, penetration, and GI obstruction due to scarring. The incidence of PUD is associated with the following risk factors:

- Infection with the bacterium *Helicobacter pylori*
- Close family history of PUD
- Use of drugs, particularly corticosteroids, NSAIDs, and platelet inhibitors such as aspirin and clopidogrel
- Blood group O (the intestinal epithelial cells bind to *H. pylori* more strongly in these individuals)
- Smoking tobacco (increases gastric acid secretion and reduces bicarbonate production)
- Consumption of beverages and foods that contain excessive caffeine
- Excessive psychologic stress.

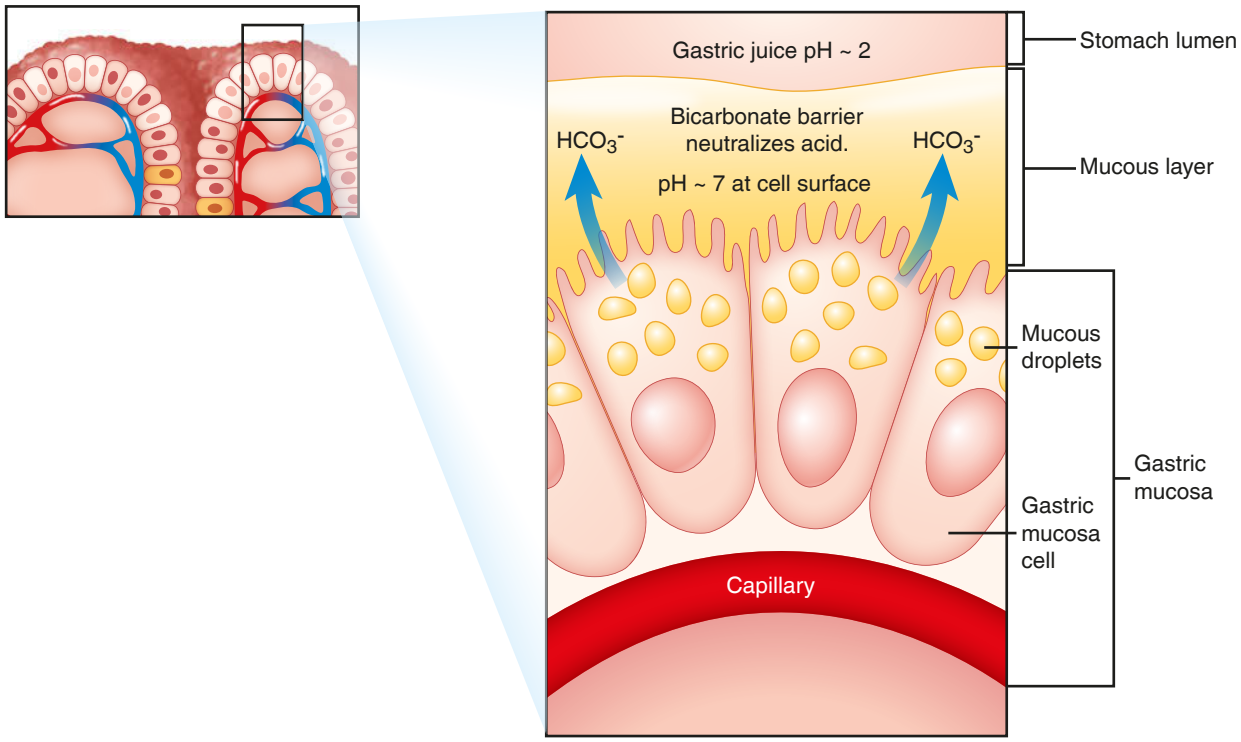

Figure 59.2 Natural defenses against stomach acid.

PharmFACT

Approximately 4.5 million Americans are affected by PUD, and about 10% of Americans will experience an ulcer in their lifetime (Anand, 2017).

For many decades, it was thought that mental and physiologic stress, smoking, and spicy foods were the primary causes of PUD. It was theorized that bacteria could not survive the acidic environment of the stomach; thus the hypothesis that an infectious agent could be the cause of PUD was not accepted. In the 1980s, however, researchers discovered an association between the gram-negative bacterium *H. pylori* and PUD. Over time, the hypothesis was accepted, and treatment of PUD as an infectious disease was aggressively promoted by the Centers for Disease Control and Prevention (CDC). The pharmacotherapy of *H. pylori* is described in Section 59.8.

Many causes of PUD are not related to *H. pylori* infection. For example, drug therapy with NSAIDs is likely responsible for almost half of peptic ulcer cases. Gastric and duodenal ulcers occur in about 20% of patients using NSAIDs on a regular basis, with 4% experiencing serious bleeding.

NSAIDs promote ulcer formation and inflammation both topically and systemically. Topically, NSAIDs cause direct cellular damage to GI mucosal cells. Systemically NSAIDs interfere with prostaglandin synthesis via the enzyme cyclooxygenase (COX) in the stomach, which normally aids in the production of mucus and bicarbonate. NSAIDs decrease gastric blood flow and slow cellular repair. NSAIDs are also weak acids that are nonionized in gastric acid and able to diffuse across the mucous barrier into the gastric epithelial cells, which leads to further cellular damage.

Risk factors for NSAID-induced PUD include long-term use of NSAIDs, advanced age, history of ulcers, concomitant use of corticosteroids or anticoagulants, or alcohol and cigarette smoking. In addition, *H. pylori* infection and NSAIDs act synergistically to promote ulcers. The combination poses a 3.5-fold greater risk of ulcers than either factor alone.

The characteristic symptom of duodenal ulcer is a gnawing or burning, upper abdominal pain that occurs 1 to 3 hours after a meal. The pain is usually worse when the stomach is empty and often disappears with ingestion of food. This is because the presence of food closes the pyloric sphincter and allows the acid to remain in the stomach, rather than to come into contact with the duodenal ulcer. Nighttime pain may awaken the patient. If the erosion progresses deeper into the mucosa, bleeding occurs and may be evident as either bright red blood in vomit or black, tarry stools. Many duodenal ulcers heal spontaneously, although scar tissue remains, predisposing the mucosa to future ulceration, and they frequently recur after months of remission. Perforation and hemorrhage are sometimes the

first signs of a duodenal ulcer in infants. Many patients with PUD are asymptomatic.

Gastric ulcers are less common than the duodenal type and have different symptoms. Pain is often relieved with food; however, in some patients the pain is exacerbated with eating. Anorexia, weight loss, and vomiting are more common with gastric ulcers. Remissions may be infrequent or absent. Medical follow-up of gastric ulcers should continue for several years because a small percentage of the erosions become cancerous. The most severe ulcers may penetrate the wall of the stomach and cause death. Whereas duodenal ulcers most frequently occur in men in the 30- to 50-year age group, gastric ulcers are more common in women over age 60. NSAID-related ulcers are more likely to produce gastric ulcers, whereas *H. pylori*–associated ulcers are more likely to be duodenal.

Patients who are experiencing physiologic stress resulting from severe trauma, surgery, burns, illness, or shock may experience stress ulcers. Stress ulcers are typically asymptomatic initially, and about 25% of patients present with painless upper GI bleeding. Vasoconstriction secondary to sympathetic nervous system involvement causes decreased blood flow to the small intestine, which may play a role in the development of stress ulcers. Patients who are placed on mechanical ventilation and other seriously ill patients are sometimes administered prophylactic antiulcer drugs to prevent complications due to PUD.

Zollinger-Ellison syndrome (ZES) is a less common cause of PUD. It is caused by a gastrinoma, a tumor of the pancreas or duodenum that secretes large amounts of the hormone gastrin. Because the presence of gastrin is the hormonal signal for increasing hydrochloric acid secretion, the huge amounts of acid easily overcome the protective defenses, leading to multiple gastric and duodenal ulcers. Peptic ulcers are persistent, difficult to treat, and slow to heal. Symptoms of ZES are the same as those of PUD. The acid also irritates the GI tract, resulting in diarrhea. Treatment involves aggressive acid suppression with drugs.

Ulceration in the distal small intestine is known as Crohn's disease, and erosions in the large intestine are called ulcerative colitis. These diseases, together categorized as inflammatory bowel disease (IBD), are discussed in Chapter 60.

CONNECTION Checkpoint 59.1

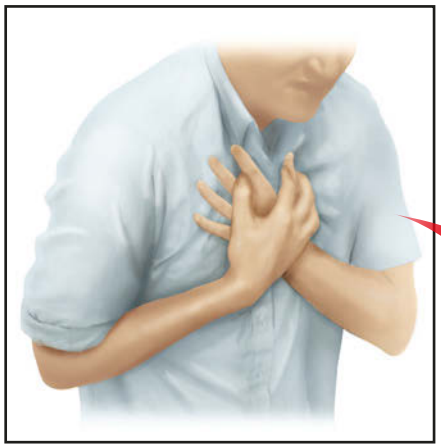
Although surgery is often indicated for ZES, chemotherapy with doxorubicin (Adriamycin) plus streptozocin (Zanosar) is a common combination. From what you learned in Chapter 57, what are the drug classes for these two antineoplastics? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Etiology and Pathogenesis of Gastroesophageal Reflux Disease

59.3 Gastroesophageal reflux disease is a chronic condition characterized by persistent heartburn.

Gastroesophageal reflux disease (GERD) results when acidic stomach contents enter the esophagus. Although most often considered a disease of people older than age 40, GERD can also occur in infants. The prevalence of the disease is increasing among both children and adults.

In adults, the cause of GERD is usually transient weakening or relaxation of the lower esophageal sphincter (LES), a specialized muscle segment at the end of the esophagus. The sphincter may no longer close tightly, allowing movement of gastric contents upward into the esophagus when the stomach contracts. The acidic gastric contents cause an intense burning (heartburn) and, in some cases, injury to the esophagus. In addition, the pathogenesis of GERD involves decreased salivary secretions and diminished esophageal motility. The pathophysiology of GERD is shown in Pharmacotherapy Illustrated 59.1.



Symptoms of GERD include heartburn, dysphagia, dyspepsia, chest pain, nausea, and belching. Symptoms worsen following large meals, exercise, or when in a reclining or recumbent position. There is growing evidence that patients with GERD may also present with symptoms such as chronic cough, wheezing, bronchitis, sore throat, or hoarseness. GERD is a chronic condition with alternating periods of exacerbation and remission.

A large number of substances and conditions can worsen GERD symptoms. These include caffeine, alcohol, citrus fruits, tomato-based products, onions, carbonated beverages, spicy food, chocolate, smoking, pregnancy, and obesity. Certain medications may also contribute to or worsen GERD. They include nitrates, benzodiazepines, anticholinergics, beta blockers, alpha blockers, estrogen, progesterone, iron, calcium channel blockers, NSAIDs, tricyclic antidepressants, opioids, levodopa, bisphosphonates, and some chemotherapy drugs.

Left untreated, GERD can lead to complications such as esophagitis, esophageal ulcers, or strictures. Approximately 10% of patients diagnosed with GERD will develop **Barrett's esophagus**, a condition that is associated with an increased risk of esophageal cancer. Warning signs and symptoms of GERD that suggest a more complicated disease may include unexplained weight loss, early satiety, anemia, vomiting, initial onset of GERD symptoms after age 50, and prolonged anorexia or dysphagia. Patients who are experiencing these symptoms should notify their healthcare provider.

Treatment

- Remove acid-causing food and drugs
- Administer proton pump inhibitors
- Administer H_2-receptor antagonists

PharmFACT

Twenty-five to forty percent of adults in the United States have GERD. Men are two to three times more likely to have the condition than women (Patti, 2016).

If a patient's GERD is associated with obesity, losing weight may eliminate the symptoms. Other lifestyle changes that can improve GERD symptoms include elevating the head of the bed, avoiding fatty or acidic foods, eating smaller meals at least 3 hours before sleep, and eliminating tobacco and alcohol use. Because patients often self-treat this disorder with OTC drugs, a good medication history may give clues to the presence of GERD. Also, patients should be informed that some medications can provoke GERD, and reviewing their medication history

may prove helpful. Because drugs provide only symptomatic relief, surgery may become necessary to eliminate the cause of persistent GERD.

An emerging theory suggests that GERD may be a premalignant condition and that chronic acid suppression leads to an increase in esophageal malignancy. This theory is not universally accepted, however, and acid suppression currently remains the mainstay in the treatment of GERD. The presence of GERD does not warrant testing for *H. pylori* infection. Large studies have shown that neither the presence nor absence of *H. pylori* has any influence on the development of GERD.

Pharmacotherapy of Peptic Ulcer Disease and Gastroesophageal Reflux Disease

59.4 Peptic ulcer disease and gastroesophageal reflux disease are best treated with a combination of pharmacotherapy and lifestyle changes.

Before initiating pharmacotherapy, patients are usually advised to change lifestyle factors that may be contributing to the severity of PUD or GERD. For example, eliminating tobacco and alcohol use and reducing stress often allow healing of the ulcer and cause it to go into remission. Avoiding certain foods and beverages can lessen the severity of symptoms. For patients with GERD, losing weight may alleviate symptoms of the disorder.

The goals of PUD pharmacotherapy are to provide immediate relief from symptoms, promote healing of the ulcer, prevent complications, and prevent future recurrence of the disease. Eradication of *H. pylori* and discontinuing NSAIDs or other ulcer-promoting medications when possible are key factors.

For patients who are taking NSAIDs, the initial approach to PUD is to switch to an alternative medication, such as acetaminophen or another analgesic. This is not always possible, however, because NSAIDs are first-line drugs for treating chronic arthritis and other disorders associated with pain and inflammation. Those with a history of PUD should be advised to avoid NSAIDs in the future to prevent ulcer recurrences. If discontinuation of the NSAID is not possible, concurrent antiulcer drugs are indicated. Platelet inhibitors such as aspirin or clopidogrel should be used cautiously in patients at risk for ulcer complications.

For patients with PUD with *H. pylori* infection, elimination of the bacteria using anti-infective therapy is the primary goal of pharmacotherapy. If the treatment includes only antiulcer drugs without eradicating *H. pylori*, a very high recurrence rate of PUD is observed. It has also been found that eradicating *H. pylori* infection prophylactically decreases the incidence of peptic ulcers in patients who subsequently take NSAIDs.

Once NSAIDs and *H. pylori* have been addressed, suppressing or neutralizing gastric acid is the aim of the pharmacologic treatment of both PUD and GERD. A wide variety of both prescription and OTC drugs are available to suppress acid secretion. The mechanisms of action of the major drug classes for PUD are shown in Pharmacotherapy Illustrated 59.2. These drugs fall into three primary classes and one miscellaneous group:

- Proton pump inhibitors (PPIs)
- H_2-receptor antagonists
- Antacids
- Miscellaneous drugs.

Because medications used to treat GERD and PUD suppress acid, keep in mind that certain nutrients and drugs need an acidic environment for complete absorption. For example, long-term acid suppression could lead to deficiencies in folic acid, iron, and vitamin B_{12}. Also, the effects of certain drugs such as fluconazole, tetracyclines, and indomethacin may be decreased because these drugs require an acidic environment for complete absorption.

Pharmacotherapy with Proton Pump Inhibitors

59.5 Proton pump inhibitors block gastric acid secretion and are preferred drugs for the therapy of peptic ulcer disease and gastroesophageal reflux disease.

The **proton pump inhibitors (PPIs)** act by blocking **H^+, K^+-ATPase**, the enzyme that is responsible for secreting hydrochloric acid in the stomach. PPIs are indicated for treatment of gastric and duodenal ulcers for 4 to 8 weeks, treatment of GERD, maintenance therapy to prevent recurrence, and treatment of ZES. Omeprazole, esomeprazole, and lansoprazole are available OTC. These and other PPIs are listed in Table 59.1.

PPIs reduce acid secretion in the stomach by binding irreversibly to the H^+, K^+-ATPase enzyme at the surface of the parietal cell, thereby blocking the final step in acid production. This enzyme acts as a pump to release acid (also called H^+, or protons) onto the surface of the GI mucosa. The PPIs reduce acid secretion to a greater extent than the H_2-receptor antagonists and have a longer duration of action. About 95% of the acid production is blocked, making the PPIs the most effective drugs for the maintenance therapy of acid-related disease.

Because the proton pump is activated by food intake, the PPI should be taken 20 to 30 minutes before the first major meal of the day. This allows the peak serum drug

Pharmacotherapy Illustrated 59.2

Mechanisms of Action of Antiulcer Drugs

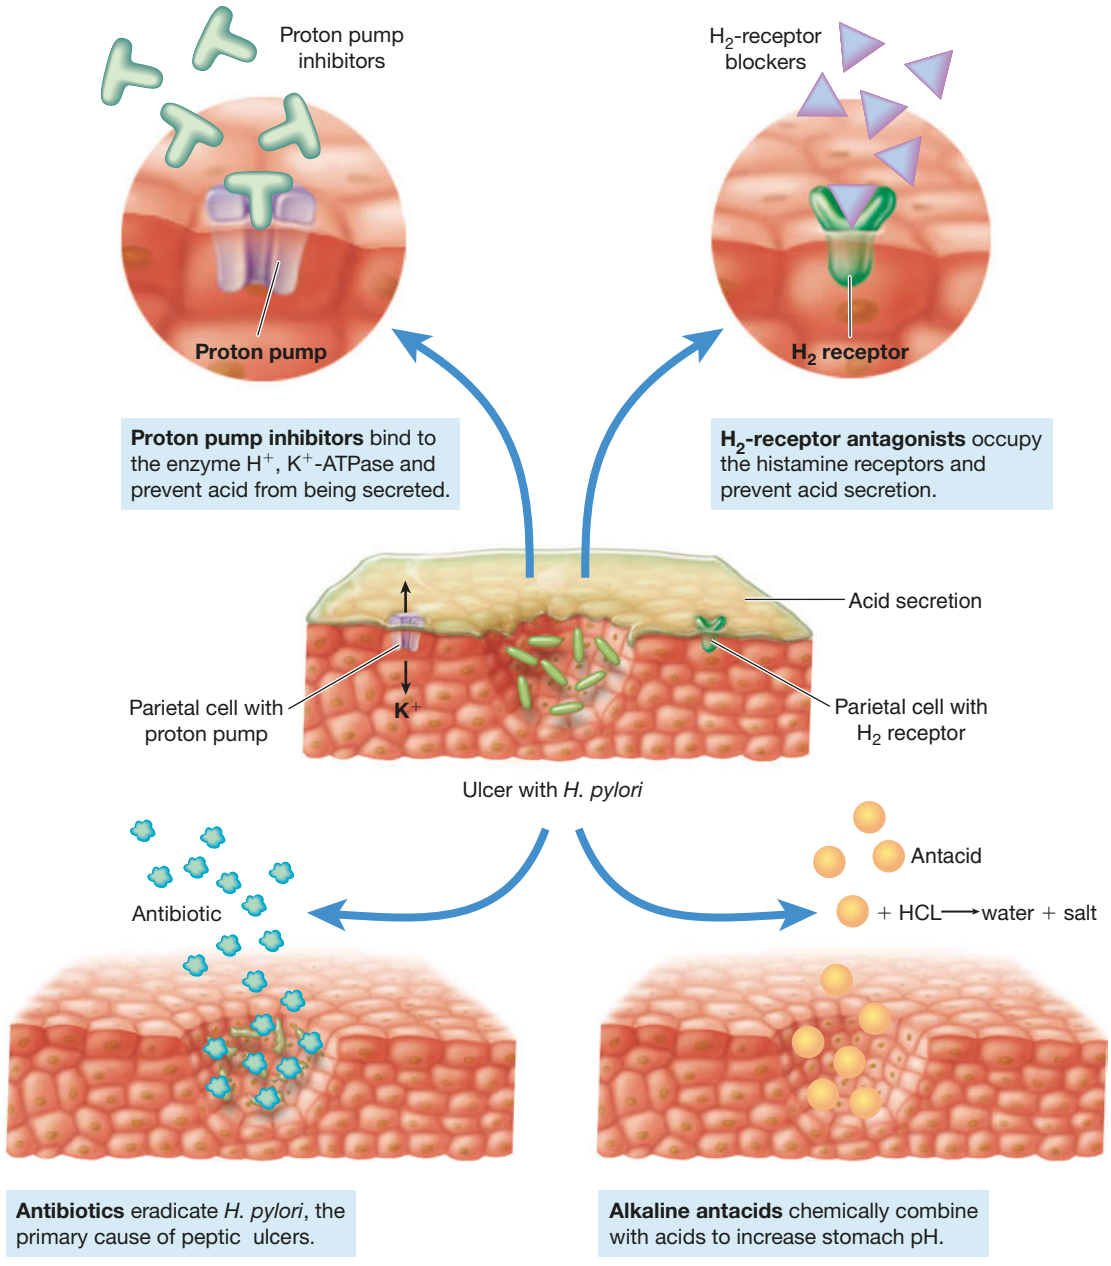

Table 59.1 Proton Pump Inhibitors

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
esomeprazole (Nexium)	PO/IV: 20–40 mg once daily	*Diarrhea, headache, nausea, rash, abdominal pain* Increased risk for osteoporosis-related fractures of the hip, wrist, or spine; acute interstitial nephritis
lansoprazole (Prevacid)	PO: 15–30 mg daily	
omeprazole (Prilosec)	PO: 20–60 mg daily or bid	
pantoprazole (Protonix)	PO: 20–40 mg daily IV: 40 mg daily for up to 7–10 days	
rabeprazole (AcipHex)	PO: 20–60 mg once daily	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

levels to coincide with the time at which the proton pumps are activated. PPIs are formulated in a delayed release formation because the drug would be destroyed in the acidic environment of the stomach.

Although the PPIs have a short serum half-life, they continue to suppress acid for about 24 hours because the inactivation of the proton pump is irreversible. Because not all of the proton pumps are inactivated with the first dose, several days of PPI therapy are needed to achieve maximal acid inhibition. Beneficial effects continue for 3 to 5 days after the drugs have been discontinued. The PPIs are highly protein bound, metabolized in the liver, and excreted in the urine (80%) and feces (20%). Doses do not need to be adjusted for patients with renal insufficiency because there is negligible renal clearance.

All drugs in this class have similar effectiveness and adverse effects. The incidence of adverse effects with PPIs is very low, with headache, abdominal pain, diarrhea (including that associated with *Clostridium difficile*), nausea, and vomiting being the most commonly reported ones. Rashes and blood dyscrasias are rare. Rebound hypersecretion of acid does not appear to occur after the drugs are discontinued. PPIs can mask an *H. pylori* infection because of the marked reduction in the bacterial load that they initiate. Long-term therapy with PPIs increases the risk for osteoporosis-related fractures, perhaps due to their interference with calcium absorption. Some healthcare providers recommend calcium supplements during therapy to prevent these types of fractures.

PPIs heal more than 90% of duodenal ulcers within 4 weeks and about 90% of gastric ulcers in 6 to 8 weeks. GERD may require 8 to 12 weeks of therapy for symptoms to diminish, and long-term maintenance therapy may be needed. PPIs are best suited for the long-term prevention of heartburn rather than the treatment of acute symptoms. In patients with PUD who must take NSAIDs for a chronic pain or inflammatory condition, PPIs taken once daily are effective in reducing the incidence of ulcers.

PROTOTYPE DRUG **Omeprazole (Prilosec)**

Classification **Therapeutic:** Antiulcer drug
Pharmacologic: Proton pump inhibitor

Therapeutic Effects and Uses: Omeprazole was the first PPI to be approved by the U.S. Food and Drug Administration in 1989 for PUD and is available by prescription and OTC. By prescription it is approved for the short-term,

CONNECTIONS: Preparing for Advanced Practice

Treating GERD

Case

Ginny McCarthy is a self-employed child care provider without health insurance. She is a 42-year-old mother of two who has been in good health, has never smoked, and rarely (less than once a month) drinks a glass of wine. She has no change in diet, and no change in bowel habits. She exercises 3 times a week and is active with her own children and the children she watches in her home. Three months ago she began experiencing episodes of chest pain that occur mostly after meals and during the night, when she lies down. During the past month she has experienced worsening symptoms and noticed a bad taste in her mouth. Ginny presented to the community clinic for care.

Her medical history and physical examination were consistent with GERD. However, because of the complaints of chest pain, she should undergo a cardiac stress test to look for signs of coronary artery disease. Because she is under the age of 50 and does not have a history of weight loss, endoscopy to rule out cancer of the stomach or esophagus is not the standard of care and would not be indicated for Ginny. When Ginny asked about the cost of the cardiac stress test, you told her it would be $500 or more. She looked worried and stated that she could not afford to pay that. A discussion ensued, and although the standard approach for managing such a presentation involved ruling out cardiac disease, Ginny's symptoms were highly suggestive of being GI and not cardiac in nature.

The decision was to treat Ginny for GERD by starting a PPI, omeprazole 20 mg/day, at a cost of $15 per month, and educating her about foods that would worsen her symptoms. You also taught her that she should elevate the head of her bed at night and should sit upright for 30 minutes after eating or drinking. You tell Ginny that she requires a follow-up in 2 weeks to make sure symptoms are improving. Additionally, you educated Ginny about cardiac symptoms that would require an immediate visit to the emergency department.

Discussion

With nearly 28 million uninsured people and even more people who are underinsured in the United States, many providers are confronted with patients who cannot afford the high cost of healthcare. When patients lack sufficient healthcare insurance, financial matters become intertwined in the process of clinical decision making. Providers should explicitly ask patients about financial concerns and be knowledgeable about the community resources available for the medically indigent.

Treating Ginny with a PPI, diet education, and environmental considerations such as elevation of the head of the bed and sitting upright for 30 minutes after eating or drinking, combined with medical follow-up and instructions on when to seek additional emergency care, is appropriate in this particular case. Clinical judgment using medical history and physical examination considerations is needed on a case-by-case basis.

4- to 8-week therapy of active duodenal and gastric ulcers, GERD, and maintenance of erosive esophagitis. OTC, it is indicated for the relief of heartburn. Most patients are symptom free after 2 weeks of therapy. It is used for longer periods and in higher doses in patients who have ZES. It is combined with antibiotics in regimens for eliminating *H. pylori*. Omeprazole may be prescribed off-label to prevent PUD in patients taking NSAIDs.

Although omeprazole can take 2 hours to reach therapeutic levels, its effects last up to 72 hours. Omeprazole is available by the oral (PO) route and is approved for pediatric use in children ages 2 years and older. Zegerid is a combination drug that contains omeprazole and the antacid sodium bicarbonate.

Mechanism of Action: Omeprazole reduces acid secretion in the stomach by binding irreversibly to the enzyme H^+, K^+-ATPase. It inhibits the final pathway involved in acid secretion and effectively inhibits the active proton pumps.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed; food does not influence bioavailability
Distribution	Bioavailability after oral dosing: 50–60%; crosses the placenta; secreted in breast milk; 95% bound to plasma protein
Primary metabolism	Hepatic; significant first-pass effect due to metabolism by CYP2C19
Primary excretion	Renal with small amounts in bile
Onset of action	0.5–3.5 h
Duration of action	3–4 days; half-life: 0.5–1.5 h

Adverse Effects: PPIs are generally well-tolerated drugs. The most common adverse effects are minor and include headache, nausea, diarrhea, rash, and abdominal pain. Although rare, blood disorders may occur, causing unusual fatigue and weakness. Long-term studies have been conducted on the possible effects of omeprazole on cardiovascular events and gastric tumors. None of the studies has shown any significant increase in cardiovascular adverse effects or gastric cancer. Delayed release omeprazole has been associated with an increased risk of *C. difficile*–associated diarrhea (CDAD) in hospitalized patients.

Contraindications/Precautions: The only contraindication is hypersensitivity to the drug. It is not recommended for children under 2 years of age. Patients with hepatic impairment should be treated with caution. The drug should be avoided or used with caution in pregnant or lactating patients.

Drug Interactions: Clinically significant interactions with PPIs are uncommon. Omeprazole has been shown to both inhibit and induce certain hepatic CYP450 enzyme systems. Therefore, concurrent use with other drugs using the CYP450 system, including warfarin, carbamazepine, diazepam, and phenytoin, may inhibit or delay metabolism and cause increased blood levels of these drugs. Concurrent use of omeprazole and clopidogrel (Plavix) reduces the conversion of clopidogrel to its active metabolite, thus reducing its effectiveness. Thus, concurrent use with warfarin may increase the likelihood of bleeding. Coadministration of omeprazole and clarithromycin has been shown to increase plasma levels of both omeprazole and clarithromycin.

PPIs increase gastric pH and have the potential to affect the bioavailability of medications that depend on a lower pH for absorption (e.g., iron salts, digoxin, ampicillin, ketoconazole, atazanavir, rilpivirine). Because an acidic environment promotes mineral absorption, mineral deficiencies could occur with long-term PPI use. Decreased vitamin B_{12} absorption may occur because an acid is optimal for vitamin B_{12} absorption. **Herbal/Food:** Ginkgo and St. John's wort may decrease the plasma concentration of omeprazole.

Pregnancy: Category C.

Treatment for Overdose: Overdose is uncommon and is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving omeprazole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Peptic Ulcer Disease.

Drugs Similar to Omeprazole (Prilosec)

The other PPIs include esomeprazole, lansoprazole, pantoprazole, and rabeprazole.

Esomeprazole (Nexium): Approved in 2001, this drug is an isomer of omeprazole, making the two medications very similar in structure, effectiveness, and safety. It is available by the PO and intravenous (IV) routes. Adverse effects include headache, diarrhea, and nausea. Similar to other PPIs, esomeprazole is available as once-daily dosing for uncomplicated PUD and GERD and twice-daily dosing for complicated conditions such as ZES. It is approved for the prophylaxis of ulcers in patients who are taking NSAIDs. Esomeprazole capsules can be opened and the pellets mixed with soft foods and swallowed without chewing. With all PPIs there is a risk of pneumonia due to the elevation in gastric pH. Esomeprazole is pregnancy category B.

Lansoprazole (Prevacid) and dexlansoprazole (Dexilant): Approved in 1995, lansoprazole has a similar effectiveness

and safety profile to omeprazole and is available by the PO route. Its antisecretory effects can last up to 24 hours. Similar to other PPIs, its adverse effects include headache, diarrhea, and nausea. As with other PPIs, lansoprazole offers once-daily dosing for uncomplicated PUD and GERD and twice-daily dosing for ZES. With lansoprazole, as with other PPIs, there is a risk of pneumonia due to the elevation in gastric pH. This drug is eliminated from the body by the biliary system. It is available by prescription as well as OTC.

For patients who have difficulty swallowing capsules, lansoprazole is available in an oral liquid suspension or as a PO disintegrating tablet (Prevacid SoluTab) that is placed under the tongue and disintegrates within 1 minute. Capsules of lansoprazole should be swallowed whole and not crushed or split. Dexlansoprazole (Dexilant) is a stereoisomer of lansoprazole that has identical effects to its parent drug. Lansoprazole is pregnancy category B.

Pantoprazole (Protonix): Approved in 2000, pantoprazole has a similar efficacy and safety profile to omeprazole and is available by PO and IV routes. Adverse effects include headache, diarrhea, and nausea. Because pantoprazole does not inhibit CYP450 enzymes, it is not likely to affect the metabolism of other drugs.

As with the other PPIs, pantoprazole offers once-daily dosing for uncomplicated PUD and GERD and twice-daily dosing for ZES. With all PPIs, there is a risk of pneumonia due to the elevation in gastric pH. Pantoprazole may be prescribed off-label to prevent ulcers in patients taking NSAIDs. Pantoprazole is pregnancy category B.

Rabeprazole (AcipHex): Although rabeprazole is similar to omeprazole, it causes reversible inhibition of the proton pump; thus its effects are of shorter duration. Approved in 1999, rabeprazole is available by the PO route. The tablets should be swallowed whole and not crushed or chewed. Like other PPIs, rabeprazole accentuates the eradication of *H. pylori* when used with appropriate antibiotics. Although rabeprazole is metabolized by the hepatic CYP450 drug-metabolizing system, it exhibits few significant drug interactions. Adverse effects are mild and transient and include headache, diarrhea, nausea, malaise, dizziness, and rash. Rabeprazole is pregnancy category B.

CONNECTIONS: Lifespan Considerations

Use of Proton Pump Inhibitors in the Older Adult

New studies have further strengthened existing evidence linking the use of PPIs to an increased risk for osteoporosis (Andersen, Johansen, & Abrahamsen, 2016). Long-term use has also been considered as a possible cause of iron and vitamin B_{12} deficiencies. Because age-related changes in the gastric acid levels of older adults may also explain these conditions, the links are inconclusive. Risk reduction strategies to avoid long-term complications such as osteoporosis or iron and vitamin B_{12} deficiencies in the older adult include increasing the intake of calcium and magnesium, reducing the intake of carbonated soft drinks, increasing weight-bearing exercise to a minimum of 3 times weekly, and increasing intake of iron and vitamin B_{12}-rich foods such as meats, fish, fortified cereals, and green leafy vegetables.

Pharmacotherapy with H_2-Receptor Antagonists

59.6 The H_2-receptor antagonists suppress gastric acid secretion and are widely prescribed for treating peptic ulcer disease and gastroesophageal reflux disease.

The discovery of the **H_2-receptor antagonists**, or H_2 blockers, in the 1970s marked a major breakthrough in the treatment of PUD. Since then they have become available OTC and are used extensively in the treatment of mild to moderate hyperacidity disorders of the GI tract. H_2-receptor antagonists are indicated for treatment of PUD and GERD to promote healing and prevent recurrence. Duodenal ulcers usually heal in 6 to 8 weeks, but gastric ulcers may require up to 12 weeks of therapy. All of the H_2-receptor antagonists are available OTC for the short-term (2 weeks) treatment of heartburn. These drugs are listed in Table 59.2.

Histamine has two types of receptors: H_1 and H_2. Activation of the H_1 receptors produces the classic symptoms of inflammation and allergy, whereas the H_2 receptors, which are located on the parietal cells in the stomach, promote gastric acid secretion when activated. The H_2-receptor antagonists effectively reduce both fasting and food-stimulated secretion and are also helpful in decreasing nocturnal acid secretion, which is largely dependent on histamine.

Pharmacokinetic properties of drugs in this class include rapid absorption from the small intestine, which is not affected by food, and a 30-minute onset of action. These drugs undergo hepatic metabolism and renal excretion and their half-lives range from 1 to 4 hours. Although there are no known harmful effects on the fetus, these drugs cross the placenta and are secreted in breast milk. All drugs in this class have similar safety profiles: Their adverse effects are minor and rarely cause discontinuation of therapy. Patients who are receiving higher doses, those with chronic kidney disease (CKD) or hepatic disease, or older adults may experience confusion, restlessness, hallucinations, or depression. With moderate to severe kidney disease, doses of H_2-receptor antagonists should be cut in half to avoid toxicity. Antacids should not be

Table 59.2 H_2-Receptor Antagonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
cimetidine (Tagamet)	Active ulcers: PO: 300 mg q6h or 800 mg at bedtime IV: 300 mg q6h or 37.5 mg/h by continuous infusion GERD: 400 mg q6h or 800 mg bid	*Diarrhea, constipation, headache, fatigue, nausea, gynecomastia* Rare: hepatitis, blood dyscrasias, anaphylaxis, dysrhythmias, skin reactions, galactorrhea, confusion, or psychoses
famotidine (Pepcid)	Active ulcers: PO: 20–40 mg/day GERD: PO: 20 mg bid for 6 wk IV: 20 mg q12h	*Headache, nausea, dry mouth* Rare: musculoskeletal pain, tachycardia, blood dyscrasias, blurred vision
nizatidine	Active ulcers: PO: 150–300 mg once daily GERD: PO: 150 mg bid	
ranitidine (Zantac)	PO: 150–300 mg/day IV/IM: 50 mg q6–8h by intermittent bolus or infusion	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

taken at the same time as H_2-receptor antagonists because absorption is diminished.

PROTOTYPE DRUG Ranitidine (Zantac)

Classification **Therapeutic:** Antiulcer drug
Pharmacologic: H_2-receptor antagonist

Therapeutic Effects and Uses: Approved in 1983, ranitidine has a higher potency than cimetidine, which allows it to be administered PO, once daily, usually at bedtime. Adequate healing of the ulcer takes 4 to 8 weeks, although those at high risk for PUD may continue on drug maintenance for prolonged periods to prevent recurrence. Gastric ulcers heal more slowly than duodenal ulcers and thus require longer therapy. IV and intramuscular (IM) forms are available for the treatment of acute stress-induced bleeding ulcers or hypersecretory conditions in hospitalized patients. Tritec is a combination drug with ranitidine and bismuth citrate. An OTC preparation of ranitidine is also available.

Ranitidine is indicated for duodenal ulcers, gastric ulcers, hypersecretory conditions, heartburn, and GERD. In some cases, it is used off-label to prevent PUD in those who are taking medications known to cause peptic ulcers. It is not effective as monotherapy for the elimination of *H. pylori*. Ranitidine is available in a dissolving tablet form (EFFERdose) for treating GERD in children and infants older than 1 month of age.

Mechanism of Action: Ranitidine acts by blocking H_2 receptors on the parietal cells in the stomach to decrease acid production. Both daytime and nocturnal basal gastric acids are suppressed.

Pharmacokinetics:

Route(s)	PO, IV, IM (rare)
Absorption	Rapid absorption following PO administration; all three routes achieve comparable blood levels
Distribution	PO bioavailability is approximately 50%; very little enters the central nervous system (CNS); crosses the placenta; secreted in breast milk; 15% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal (mostly unchanged)
Onset of action	30–60 min; peak effect: 1–3 h
Duration of action	6–12 h; half-life: 2–3 h

Adverse Effects: Adverse effects are uncommon and transient. Although rare, blood dyscrasias, especially neutropenia and thrombocytopenia, have been reported; thus, periodic blood counts should be performed. Confusion may occur rarely and is usually in the older patient or with IV dosing. High doses may result in gynecomastia, impotence, or loss of libido in men, although these effects are more common with cimetidine.

Contraindications/Precautions: Contraindications include hypersensitivity to H_2-receptor antagonists, acute porphyria, and OTC administration in children younger than 12 years of age. The drug should be used with caution in patients with CKD; dosages should be reduced.

Drug Interactions: Because ranitidine has much less affinity for CYP450 enzymes, it is less likely to participate in drug–drug interactions than cimetidine. Ranitidine may reduce the absorption of cefpodoxime, ketoconazole, and itraconazole because of the increase in gastric pH induced by H_2-receptor antagonists. Concurrent use can increase the effects of alcohol, sulfonylureas, salicylates, and warfarin. Antacids should not be given within 1 hour of H_2-receptor antagonists because their effectiveness may be decreased due to reduced absorption. Smoking decreases the effectiveness of ranitidine. **Herbal/Food:** Absorption of vitamin B_{12} depends on an acidic environment, so deficiency may occur. Iron is also better absorbed in an acidic environment.

Pregnancy: Category B.

Treatment of Overdose: Overdose is uncommon and is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving ranitidine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Peptic Ulcer Disease.

Drugs Similar to Ranitidine (Zantac)

Other H_2-receptor antagonists include cimetidine, famotidine, and nizatidine.

Cimetidine (Tagamet): Approved in 1977, cimetidine was the first of the H_2 blockers. It is used less frequently than other drugs in this class because (1) it inhibits hepatic drug-metabolizing enzymes and exhibits numerous drug–drug interactions; (2) it has a high incidence of adverse effects; and (3) it must be taken up to four times a day. Because cimetidine interacts with CYP450 enzymes, it may delay the metabolism of other drugs metabolized in the liver, including warfarin, phenytoin, diazepam, and theophylline. Cimetidine also may cause gynecomastia or impotence, because it binds to androgen receptors, causing antiandrogenic effects. Cimetidine crosses the blood–brain barrier and therefore is more likely to cause CNS depression and confusion than the other H_2-receptor antagonists. A low-dose OTC preparation is available. Routes of administration include PO, IM, and IV. This drug is pregnancy category B.

Famotidine (Pepcid): Approved in 1986, famotidine has indications, actions, and adverse effects that are almost identical to those of ranitidine. Famotidine does not inhibit CYP450 enzymes; therefore, it exhibits fewer drug–drug interactions than cimetidine. Famotidine is the most potent of the H_2-receptor antagonists. It is available OTC and may be given by the PO or IV route. This drug is pregnancy category B.

Nizatidine: Although thought to have a safety and adverse effect profile similar to those of ranitidine and famotidine, nizatidine is not metabolized by the liver CYP450 enzyme system and therefore causes fewer drug–drug interactions. Adverse effects are infrequent and transient. Nizatidine is available PO and indicated for up to 8 weeks of PUD therapy or 12 weeks for GERD. Prescription nizatidine was approved in 1988 and an OTC preparation is also available. This drug is pregnancy category B.

CONNECTION Checkpoint 59.2

From what you learned in Chapter 3, how is the excretion of drugs affected when they are metabolized through the hepatic CYP450 system? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy with Antacids

59.7 Antacids are alkaline substances that neutralize stomach acid to treat symptoms of heartburn.

Prior to the development of H_2-receptor antagonists and PPIs, antacids were the mainstay of peptic ulcer and GERD pharmacotherapy. Indeed, many patients still use these inexpensive and readily available OTC drugs. Antacids may provide temporary relief from heartburn or indigestion, but they are no longer recommended as the primary drug class for acid-related disorders. Although antacids relieve symptoms of heartburn, they do not promote ulcer healing or help to eliminate *H. pylori*. These drugs are listed in Table 59.3.

Antacids are inorganic compounds containing aluminum, magnesium, sodium, or calcium that neutralize gastric acid and inactivate pepsin. They are also thought to stimulate prostaglandin production in the mucosa and increase LES tone, which reduces gastroesophageal reflux. These drugs do not protect the stomach by coating the stomach wall. To be considered therapeutic, the dose of antacids should increase the gastric pH to a minimum of 3.5.

Self-medication with antacids is safe when taken in doses as directed on the labels. Although antacids act within 10 to 15 minutes, their duration of action is only 2 hours; thus, they must be taken often during the day. Combinations of aluminum hydroxide and magnesium hydroxide, the most common types, are capable of rapidly neutralizing stomach acid.

All the antacids are equally effective at neutralizing acid and reducing symptoms of heartburn when given in therapeutic doses. Each type has certain disadvantages that may preclude their use:

- **Sodium.** Antacids that contain sodium should not be taken by patients on sodium-restricted diets or by those with hypertension (HTN), heart failure, or CKD because they may promote fluid retention.
- **Magnesium.** Absorption of magnesium from high doses of magnesium-containing antacids can cause symptoms of hypermagnesemia (fatigue, hypotension, and dysrhythmias). Magnesium also acts as a laxative when it reaches the large intestine.
- **Calcium.** Antacids that contain calcium can cause constipation and may cause or aggravate kidney stones. When absorbed, hypercalcemia is possible, and kidney failure may occur at very high doses. Administering calcium carbonate antacids with milk or any items with vitamin D can cause **milk-alkali syndrome** to occur. Early symptoms are the same as those of hypercalcemia and include headache, urinary frequency, anorexia, nausea, and fatigue. Milk-alkali syndrome may result in permanent kidney damage if the drug is continued at high doses.

Table 59.3 Antacids

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aluminum hydroxide (AlternaGEL, others)	PO: 600 mg tid–qid	*Constipation, nausea* Fecal impaction, hypophosphatemia with chronic use
calcium carbonate (Titralac, Tums)	PO: 1–2 g bid–tid	*Constipation, flatulence*
calcium carbonate with magnesium hydroxide (Mylanta Supreme, Rolaids)	PO: 2–4 capsules or tablets prn (max: 12 tablets/day)	Fecal impaction, metabolic alkalosis, hypercalcemia, renal calculi
magaldrate (Riopan)	PO: 540–1080 mg/day (5–10 mL suspension or 1–2 tablets) (max: 20 tablets or 100 mL/day)	*Diarrhea, nausea, vomiting, abdominal cramping*
magnesium hydroxide (Milk of Magnesia) magnesium trisilicate and aluminum hydroxide (Gaviscon)	PO: 5–15 mL or 2–4 tablets up to 4 times daily PO: 2–4 tablets (max: 16 tablets/day)	Hypermagnesemia (in patients with CKD), dysrhythmias (when given parenterally)
magnesium hydroxide and aluminum hydroxide with simethicone (Mylanta, Maalox Plus, others)	PO: 10–20 mL (max: 120 mL/day) or 2–4 tablets (max: 24 tablets/day)	
sodium bicarbonate (Alka-Seltzer, baking soda)	PO: 325 mg–2 g 1–4 times/day	*Abdominal distention, belching* Metabolic alkalosis, fluid retention, edema, hypernatremia

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

- **Aluminum.** Aluminum antacids are not absorbed to any great extent but they can cause constipation. The constipation effect is balanced when aluminum is combined with magnesium salts. Aluminum carbonate and aluminum hydroxide may interfere with dietary phosphate absorption to cause hypophosphatemia.
- **Bicarbonate.** Being a base, antacids that contain bicarbonate may provoke metabolic alkalosis (e.g., fatigue, mental status changes, muscle twitching, depressed respiratory rate) in patients at risk. Bicarbonate combines with gastric acid to form carbon dioxide, which causes bloating and belching.

Drug interactions with antacids occur by several mechanisms. Because antacids increase stomach pH, they affect the solubility and absorption of many oral drugs. Drugs that are weak acids are nonionized in the acidic environment of the stomach and are thus readily absorbed. If an antacid is given concurrently with a weak acid, the pH of the stomach will rise and result in a more ionized drug that is less readily absorbed. On the other hand, a drug that is a weak base is absorbed in a more alkaline medium. In other words, when taken with antacids, acidic drugs may have less therapeutic effect, and basic drugs may exhibit a greater effect. Examples of acidic drugs include NSAIDs, sulfonylureas, salicylates, warfarin, barbiturates, isoniazid, and digoxin. Basic drugs include morphine sulfate, antihistamines, tricyclic antidepressants, amphetamines, and quinidine.

Enteric-coated or delayed release drugs are designed to dissolve when they reach the alkaline environment in the small intestine. By raising the pH of the stomach, antacids may "fool" enteric-coated tablets into dissolving early and releasing their contents into the stomach. The drug may either irritate the stomach lining, causing nausea or vomiting, or be inactivated.

Drug interactions may also occur if the antacid physically binds to other drugs. For example, certain antacids form chemical complexes with tetracyclines, preventing the antibiotic from being absorbed. Digoxin is another drug whose absorption is affected by binding to antacids.

A third mechanism of drug interaction is due to the effects of antacids on urine pH. Making the urine pH more alkaline increases the excretion of acidic drugs such as aspirin and inhibits the excretion of basic drugs such as amphetamines.

Because antacids are widely used OTC by patients for self-treatment, nurses must emphasize that these drugs should be used only as directed on the label due to the potential for adverse effects. To decrease the potential for antacid–drug interactions, nurses should advise that other medications be taken at least 1 hour before or 2 hours after giving an antacid.

PROTOTYPE DRUG Aluminum Hydroxide (AlternaGEL, Others)

Classification **Therapeutic:** Antiheartburn drug
Pharmacologic: Antacid

Therapeutic Effects and Uses: Aluminum hydroxide is an inorganic drug used alone or in combination with other antacids such as magnesium hydroxide. Combining aluminum compounds with magnesium (Gaviscon, Maalox, Mylanta) increases their effectiveness and reduces the potential for constipation. Unlike calcium-based antacids that can be absorbed and cause systemic effects, aluminum compounds are minimally absorbed. Their primary

action is to neutralize stomach acid by raising the pH of the stomach contents. Unlike H_2-receptor antagonists and PPIs, aluminum antacids do not reduce the volume of acid secretion. They are most effectively used in combination with other antiulcer drugs for the symptomatic relief of heartburn due to PUD or GERD. A second aluminum salt, aluminum carbonate (Basaljel), is also available to treat heartburn.

Mechanism of Action: Aluminum hydroxide combines with gastric (hydrochloric) acid to produce aluminum chloride and water. This raises the pH of the stomach contents and inactivates pepsin.

Pharmacokinetics:

Route(s)	PO
Absorption	17–30% absorbed
Distribution	Widely distributed
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	20–40 min
Duration of action	2 h when taken with food; 3 h when taken 1 h after meals

Adverse Effects: Aluminum antacids frequently cause constipation. At high doses aluminum products bind with phosphate in the GI tract and long-term use can result in phosphate depletion. Those at risk include people who are malnourished, those who have alcoholism, and those with CKD. The antacids are often combined with magnesium compounds, which counteract the constipation commonly experienced with aluminum antacids.

Contraindications/Precautions: Prolonged use in patients with low serum phosphate levels should be avoided. This drug should not be used in patients with suspected bowel obstruction.

Drug Interactions: Aluminum compounds should not be taken with other medications because they may interfere with their absorption. Concurrent use decreases the absorption of cimetidine, ciprofloxacin and other fluoroquinolones, digoxin, isoniazid, chloroquine, NSAIDs, iron salts, phenytoin, tetracycline, and thyroxine. Use with sodium polystyrene sulfonate may cause systemic alkalosis. Use of anticholinergic drugs can increase the effects of antacids. **Herbal/Food:** Aluminum antacids may inhibit the absorption of dietary iron.

Pregnancy: Category C.

Treatment of Overdose: There is no specific treatment for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving aluminum hydroxide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Peptic Ulcer Disease.

Drugs Similar to Aluminum Hydroxide (AlternaGEL, Others)

All aluminum salts have similar effects to those of aluminum hydroxide.

Pharmacotherapy of *Helicobacter pylori* Infection

59.8 The gram-negative bacterium *H. pylori* is associated with approximately 70% of patients with peptic ulcer disease.

It is estimated that 60% to 80% of patients with duodenal ulcers are infected with *H. pylori* and that the majority of patients with gastric ulcers have the bacterium. Research has shown that the eradication of *H. pylori* decreases the recurrence of PUD. Risk factors for *H. pylori* include residing in a developing country, domestic crowding, unclean water, and exposure to the gastric contents of an infected individual.

H. pylori is the only known microorganism that has been found to survive the hostile conditions in the stomach. In fact, it has adapted well to the stomach's acidic environment. It has devised ways to neutralize the high acidity surrounding it and make chemicals called **adhesins** that allow the organism to penetrate the GI mucosa and alter the epithelial cell structure, which initiates inflammation. The inflammatory and immune responses lead to the chronic production of inflammatory cells, including lymphocytes, plasma cells, and macrophages. This response then leads to the formation of immunoglobulin G antibodies and increased production of cytokines, including interleukins and tumor necrosis factor, all of which contribute to the inflammation of the gastric mucosa. Increased gastrin secretion and decreased bicarbonate production also play a role in ulcer formation caused by *H. pylori*.

Another mechanism involves ammonia. *H. pylori* produces large amounts of urease, an enzyme that breaks down urea to ammonia and carbon monoxide. Ammonia neutralizes the acid around the bacterium and allows *H. pylori* to survive in the acidic environment of the stomach. Unfortunately, the ammonia is toxic to mucosal cells and erodes the mucous barrier. *H. pylori* then finds its home in the submucosal layer of the stomach, producing damage to the gastric and duodenal mucosae, which allows pepsin and gastric acid to further damage the mucosae. There may also be a genetic predisposition that determines one's susceptibility to *H. pylori* infection.

Perforated, bleeding, or refractory ulcers are usually tested for the presence of *H. pylori*. The most reliable means of diagnosis is by obtaining a culture during endoscopy. Less

invasive means include checking for antibodies to *H. pylori* in a stool sample or by using a breath test to check for urease.

Prior to the identification of the link between *H. pylori* and ulcers, PUD was treated with acid-reducing drugs. Although this therapy was successful at treating symptoms, the majority of patients experienced relapses. This is because the acid-reducing drugs have little effect on *H. pylori*, which can remain active for life if not treated appropriately. Thus for infected patients, elimination of this bacterium is the prime pharmacologic objective. Eradication of the organism allows ulcers to heal more rapidly and remain in remission longer, often permanently.

A combination of antibiotics is used concurrently to eradicate *H. pylori* and help decrease antibiotic resistance. A PPI or bismuth compound is usually included in the regimen. Once eliminated from the stomach, reinfection with *H. pylori* is uncommon. Those with peptic ulcer who are not infected with *H. pylori* should not receive antibiotics because it has been shown that these patients have a worse outcome if they receive *H. pylori* treatment. Thus, patients should be tested for *H. pylori* before initiating treatment for infection. Example regimens used to eradicate *H. pylori* include the following:

- **Initial regimen.** Omeprazole, clarithromycin (Biaxin), and amoxicillin (Amoxil, others)
- **Alternative regimens.**
  - Omeprazole (or other PPI), clarithromycin (Biaxin), and metronidazole (Flagyl), or
  - Omeprazole (or other PPI), bismuth subsalicylate (Pepto-Bismol), metronidazole (Flagyl), and tetracycline.

Although technically not antibiotics, bismuth compounds inhibit bacterial growth by disrupting their cell wall and preventing *H. pylori* from adhering to the gastric mucosa. The PPI further suppresses *H. pylori,* and the increased pH that results from PPI administration creates a hostile environment for *H. pylori*, thus enhancing the effectiveness of the antibiotics.

H. pylori therapy generally continues for 7 to 14 days. Should resistance occur, rifabutin (Mycobutin) and fluoroquinolones have been and can be used as part of the regimen. Drug regimens continue to evolve as antibiotic resistance patterns change.

Indiscriminate use of antibiotics can lead to antibiotic resistance; thus treatment should be reserved for patients who would benefit from the regimen. Patient adherence is vital to the successful eradication of *H. pylori*. Patients should be instructed on the importance of completing the drug regimen, because discontinuing the anti-infectives too soon may result in reinfection. Interestingly, following treatment for eradication of *H. pylori* infection, certain other conditions such as idiopathic thrombocytopenic purpura (ITP), a blood disorder, have been alleviated.

CONNECTION Checkpoint 59.3

From what you learned in Chapter 46, explain why antibiotic resistance has become a major public health problem throughout the world. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Miscellaneous Drugs Used for Peptic Ulcer Disease and Gastroesophageal Reflux Disease

59.9 Several miscellaneous drugs, including sucralfate, bismuth subsalicylate, and misoprostol, are beneficial in treating peptic ulcer disease.

A few additional drugs are used in the pharmacotherapy of PUD and GERD. These drugs act by mechanisms other than the ones described for PPIs, H_2-receptor blockers, or antacids.

Sucralfate: Sucralfate (Carafate) is a PO medication that consists of sucrose (a sugar) plus aluminum hydroxide (an antacid). This drug stimulates mucus, bicarbonate, and prostaglandin secretion, all of which enhance mucosal defenses. Sucralfate also acts locally to produce a thick protective barrier that coats and binds to the ulcer, protecting it against further erosion from acid and pepsin to promote healing. It does not affect the secretion of gastric acid. It is intended for short-term therapy (up to 8 weeks). It is sometimes used in critically ill patients to prevent bleeding from stress-related gastritis. Sucralfate is not effective in preventing NSAID-related ulcers.

Other than constipation, the adverse effects of sucralfate are minimal because little of the drug is absorbed from the GI tract. Because sucralfate requires an acid medium to work effectively, concurrent use of antacids, H_2-receptor antagonists, and PPIs will reduce its effectiveness. Sucralfate may bind to other drugs and decrease their absorption, especially digoxin, warfarin, the quinolones and tetracyclines, and phenytoin. Antacids and other medications should be taken 2 hours before or after a dose of sucralfate. A major disadvantage of sucralfate is that it must be taken 4 times daily.

Bismuth compounds: In the United States the only bismuth compound available is bismuth subsalicylate (Kaopectate, Pepto-Bismol), a nonprescription formula containing both bismuth and salicylate. Bismuth subsalicylate stimulates mucosal bicarbonate and prostaglandin production and inhibits *H. pylori* from adhering to the ulcerated tissue. It has been shown to have local antimicrobial actions to *H. pylori* by causing cell wall death to the bacterium. Bismuth is often included as a component of a multidrug regimen containing tetracycline and metronidazole (Pylera, Helidac) to eradicate *H. pylori* infection. As

monotherapy, it is approved to treat dyspepsia, heartburn, and diarrhea.

Therapeutic doses of bismuth produce no significant adverse effects. This drug can cause stools to turn black, which is a normal side effect. In stomach acid bismuth subsalicylate is converted to salicylic acid, which is absorbed. Patients who are taking other salicylates, such as aspirin, may experience adverse effects such as tinnitus, headache, nausea, vomiting, or dizziness. In addition, it is not recommended for use in pediatric patients under the age of 19 because of the increased risk of Reye's syndrome associated with salicylate use. A "Children's Pepto" is available that contains the antacid calcium carbonate but no salicylates.

Misoprostol: Misoprostol (Cytotec) is a synthetic form of prostaglandin E_2 that stimulates the production of protective mucus and inhibits gastric acid secretion. Normally, the stomach synthesizes a number of prostaglandins, which suppress acid, promote bicarbonate secretion, and maintain blood flow to the gastric mucosa. The primary use of misoprostol is for the prevention of gastric ulcers in patients who are taking high doses of NSAIDs or corticosteroids. It has a serum half-life of less than 30 minutes and is administered 3 to 4 times per day.

Diarrhea and abdominal cramping are relatively common with misoprostol. The drug carries a black box warning that it is contraindicated during pregnancy (pregnancy category X) and it should be prescribed for women with gastric ulcers only if the possibility of pregnancy has been ruled out. This drug is combined with mifepristone for pregnancy termination (see Chapter 70). The use of misoprostol as an antiulcer drug is rare because of the availability of safer, more effective drugs.

Metoclopramide: Approved in 1985, metoclopramide (Reglan) is occasionally used for the short-term (4–12 weeks) therapy of symptomatic GERD or PUD in patients who fail to respond to first-line drugs. It is more commonly prescribed to treat nausea and vomiting associated with surgery or cancer chemotherapy. Metoclopramide is available by the PO, IM, or IV routes. It causes muscles in the upper intestine to contract, resulting in faster emptying of the stomach. It also decreases esophageal relaxation and blocks food from entering the esophagus, which is of benefit in patients with GERD.

CNS adverse effects such as drowsiness, fatigue, confusion, and insomnia may occur in a significant number of patients. Metoclopramide carries a black box warning that it can cause tardive dyskinesia. Because the risk of this serious condition increases with duration of treatment, therapy should be limited to a maximum of 12 weeks. Due to the availability of safer, more effective drugs, metoclopramide is rarely prescribed to treat peptic ulcer. This drug is pregnancy category B.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Peptic Ulcer Disease

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including GI, hepatic, renal, respiratory, or cardiovascular disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain a history of past and current symptoms, noting any correlations between onset and presence of any pain related to meals, sleep, positioning, or other medications. Also note what measures have been successful to relieve the pain (e.g., eating).
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, hepatic or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminishing gastric area pain, lessened bloating or belching).
- Continue periodic monitoring of CBC, electrolytes, hepatic and renal function laboratory values. Testing for *H. pylori* may be needed if symptoms fail to resolve.
- Assess for adverse effects: nausea, vomiting, diarrhea, headache, drowsiness, or dizziness. Immediately report severe abdominal pain, vomiting, coffee-ground emesis, hematemesis, blood in stool, or tarry stools.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Follow appropriate administration guidelines. (For best results, follow administration guidelines regarding timing of the drug around meals. See "Patient Self-Administration" below.)	• Teach the patient to take the drug, following appropriate guidelines, and not to crush, open, or chew tablets unless directed to do so by the healthcare provider or label directions.
• Encourage appropriate lifestyle changes: lowered fat intake, eliminating alcohol intake, smoking cessation, increasing intake of yogurt and acidophilus-containing foods. (Smoking and alcohol use are known to increase gastric acid and irritation and should be eliminated. Correlating symptoms with dietary intake or activities may help to eliminate a triggering factor. Overall healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient to adopt a healthy lifestyle of low-fat food choices, increased exercise, and elimination of alcohol consumption and smoking. Provide for dietitian consultation or information on smoking cessation programs as needed. • Teach the patient to keep a food diary, noting correlations between discomfort or pain and meals or activities.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Continue to monitor for the presence of gastric area pain. Continued discomfort or pain should be reported. (Continued symptoms may indicate ineffectiveness of the current drug therapy or the need to test for *H. pylori*.)	• Teach the patient that while some easing of discomfort may be noticed after beginning drug therapy, full effects may take several days to weeks or longer. Consistent drug therapy will provide the best results. If gastric discomfort or pain continue or worsen after several weeks of therapy, the healthcare provider should be notified.
• Monitor for any severe abdominal pain, vomiting, coffee-ground emesis or hematemesis, blood in stool, or tarry stools, and report immediately. (The drugs decrease gastric acidity, making the gastric environment less favorable for ulcer development, but they do not heal existing ulcers. Severe abdominal pain or blood in emesis or stools may indicate a worsening of the disease or a more serious condition and should be reported immediately.)	• Teach the patient that severe abdominal pain or any blood in emesis or stools should be reported immediately to the healthcare provider.
• Continue to monitor periodic electrolyte levels. (PPIs have been associated with a possible increase in osteopenia and osteoporosis. Calcium and magnesium supplements or other preventive drug therapy may be needed.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor respiratory status and for fever, congestion, adventitious breath sounds such as crackles or wheezing, and dyspnea. Immediately report adventitious sounds or dyspnea accompanied by fever to the provider. (The drugs raise the gastric pH and impact the body's normal defense mechanisms against respiratory pathogens. Antibacterial therapy may be needed if respiratory infections develop.)	• Teach the patient to report symptoms of respiratory infection and report lung congestion or dyspnea accompanied by fever to the healthcare provider.
• Monitor for severe diarrhea, especially if mucus, blood, or pus is present. (Severe diarrhea may indicate the presence of CDAD, or pseudomembranous colitis [PMC]. Drugs that raise gastric pH have been associated with an increased risk for CDAD.)	• Instruct the patient to immediately report any diarrhea that increases in frequency or amount or that contains mucus, blood, or pus. • Instruct the patient to consult the healthcare provider before taking any antidiarrheal drugs, which cause the retention of harmful bacteria. • Teach the patient to increase intake of dairy products containing live active cultures, such as yogurt, kefir, or buttermilk, to help restore normal intestinal flora.
• Continue to monitor periodic hepatic and renal function tests and CBC, platelets, and electrolyte levels. (Abnormal liver function tests may indicate drug-induced adverse hepatic effects. **Diverse Patients:** Because some drugs used in PUD therapy [e.g., omeprazole, cimetidine] are metabolized through the CYP450 system, monitor ethnically diverse patients frequently to ensure optimal therapeutic effects and minimize adverse effects. **Lifespan:** Age-related physiologic differences may place older adults at greater risk for hepatotoxicity or nephrotoxicity. Decreased RBC, WBC, or platelets have been noted with long-term H_2-receptor antagonist therapy, and decreases should be reported to the healthcare provider. Excessive use of antacids may affect electrolyte levels.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor the effectiveness of other drugs taken along with PUD therapy. (PPIs, H_2 blockers, and antacids may significantly impair the effects of other drugs [e.g., clopidogrel].)	• Instruct the patient to immediately report any unusual symptoms related to other drugs used (e.g., increased risk of GI bleeding or bruising, or increased angina if clopidogrel is taken concurrently).
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., during the evening meal. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • **PPIs:** Take 30 min before meals. If once-daily dosing is ordered, take the drug in the morning before breakfast. Antacids may be used concurrently. Do not continue taking beyond 3–4 months unless directed by the healthcare provider.
	  • **H_2-receptor blockers:** Take the drug with or immediately after meals unless otherwise instructed. Do not take concurrently with antacids unless using a combination product (e.g., famotidine with calcium and magnesium-based antacids such as Pepcid-Complete). Exceeding the recommended dose increases the risk of adverse effects such as dizziness or drowsiness.
	  • **Antacids:** Take 2 h before or after meals with a full glass of water. Do not take other medications concurrently unless available as a combination product or directed to do so by the healthcare provider. If relief is not achieved after several weeks of therapy, consult the healthcare provider for additional treatment recommendations.

Understanding Chapter 59

Key Concepts Summary

59.1 The stomach secretes acid, enzymes, and hormones that are essential to digestive physiology.

59.2 Peptic ulcer disease is associated with a number of etiologic risk factors.

59.3 Gastroesophageal reflux disease is a chronic condition characterized by persistent heartburn.

59.4 Peptic ulcer disease and gastroesophageal reflux disease are best treated with a combination of pharmacotherapy and lifestyle changes.

59.5 Proton pump inhibitors block gastric acid secretion and are preferred drugs for the therapy of peptic ulcer disease and gastroesophageal reflux disease.

59.6 The H_2-receptor antagonists suppress gastric acid secretion and are widely prescribed for treating peptic ulcer disease and gastroesophageal reflux disease.

59.7 Antacids are alkaline substances that neutralize stomach acid to treat symptoms of heartburn.

59.8 The gram-negative bacterium *H. pylori* is associated with approximately 70% of patients with peptic ulcer disease.

59.9 Several miscellaneous drugs, including sucralfate, bismuth subsalicylate, and misoprostol, are beneficial in treating peptic ulcer disease.

CASE STUDY: Making the Patient Connection

Remember the patient "Hugh Marshall" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Hugh Marshall is a 71-year-old man who has been taking ibuprofen (Motrin) for a shoulder injury and assumed that this was the cause of his stomach pain. He is a one-pack-per-day smoker and drinks one glass of wine every night with dinner. His medical history includes HTN for which he takes a combination diuretic and angiotensin-converting enzyme (ACE) inhibitor. He stopped taking his ibuprofen, but the stomach pain did not subside. Because of worsening symptoms, an endoscopy was performed, which confirmed the presence of *H. pylori*. He is worried about taking antibiotics because he has been allergic to penicillin in the past.

Critical Thinking Questions

1. Based on the scenario above, what risk factors for PUD does Hugh have?
2. How would you as the nurse describe the recommended treatment for *H. pylori*–induced PUD to him?
3. Why would you be concerned about this patient with a history of HTN using NSAIDs?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Sara Gaggi is a 51-year-old White woman who is overweight and has HTN. She presents for an evaluation of heartburn that has been increasing in both intensity and frequency during the past 18 months. She reports epigastric burning after eating. It is worse after eating spicy foods or drinking red wine. She is occasionally awakened at night with symptoms. OTC antacids and H_2-receptor antagonists relieved her symptoms initially, but lately they have provided only minimal relief. Her only routine medication is amlodipine, a calcium channel blocker for her HTN. Because the symptoms are increasing and her current therapy is not relieving her symptoms, an endoscopy was performed, which revealed the presence of GERD.

1. How would you describe to Sara the dangers of self-medicating GERD symptoms with OTC medications?
2. What three risk factors in this case predispose Sara for the development of GERD?
3. What medications will her healthcare provider likely prescribe?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient has developed severe diarrhea following 4 days of self-administered antacid preparation. The nurse suspects that the diarrhea may be caused by which type of antacid?
    1. Aluminum compounds
    2. Magnesium compounds
    3. Calcium compounds
    4. Sodium compounds

2. Omeprazole (Prilosec) is prescribed for a patient with gastroesophageal reflux disease. The nurse would monitor a reduction in which symptom to determine if the drug therapy is effective? (Select all that apply.)
    1. Dysphagia
    2. Dyspepsia
    3. Appetite
    4. Nausea
    5. Belching

3. The nurse is scheduling the patient's daily medication. When would be the most appropriate time for the patient to receive proton pump inhibitors?
    1. At night
    2. After fasting at least 2 hours
    3. About 1/2 hour before a meal
    4. About 2 to 3 hours after eating

4. A patient who has duodenal ulcers is receiving long-term therapy with ranitidine (Zantac). The nurse includes in the care plan that the patient should be monitored for which adverse effects?
    1. Photophobia and skin irritations
    2. Neutropenia and thrombocytopenia
    3. Dyspnea and productive coughing
    4. Urinary hesitation and fluid retention

5. A patient has been diagnosed with *H. pylori* as the causative factor for a gastric ulcer. Which of the following drug orders would be considered first-line therapy? (Select all that apply.)
    1. Omeprazole
    2. Metronidazole
    3. Sucralfate
    4. Bismuth subsalicylate
    5. Fluconazole

6. The nurse who is caring for a patient with gastroesophageal reflux disease should question the order for which drug?
    1. H_2-receptor antagonists
    2. Proton pump inhibitors
    3. Antibiotics
    4. Antacids

See Answers to Chapter Review in Appendix A.

"This is ruining my life! I can't go to class; I can't go out with friends! I wish I'd never heard the term 'irritable bowel syndrome'!"
Patient "Kerry O'Grady"

Chapter 60
Pharmacotherapy of Bowel Disorders and Other Gastrointestinal Conditions

Chapter Outline

- Pathophysiology of Constipation
- Pharmacotherapy with Laxatives
  PROTOTYPE *Psyllium Mucilloid (Metamucil, Naturacil, Others), p. 1107*
- Pathophysiology of Diarrhea
- Pharmacotherapy of Diarrhea
  PROTOTYPE *Diphenoxylate with Atropine (Lomotil), p. 1110*
- Pharmacotherapy of Inflammatory Bowel Disease
  PROTOTYPE *Sulfasalazine (Azulfidine), p. 1115*
- Pharmacotherapy of Irritable Bowel Syndrome
- Pathophysiology of Nausea and Vomiting
- Pharmacotherapy of Nausea and Vomiting
  PROTOTYPE *Ondansetron (Zofran, Zuplenz), p. 1123*
- Pharmacotherapy of Pancreatitis
  PROTOTYPE *Pancrelipase (Creon, Pancreaze, Zenpep), p. 1126*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the definition of constipation used by patients to that used for diagnosis by healthcare providers.
2. Compare and contrast the different mechanisms of action of laxatives.
3. Explain the pathogenesis of constipation and diarrhea.
4. Compare and contrast the types of drugs used to treat inflammatory bowel disease and irritable bowel syndrome.
5. Explain conditions for which the pharmacotherapy of nausea and vomiting is indicated.
6. Identify drugs that are used to treat acute and chronic pancreatitis.
7. Describe the nurse's role in the pharmacologic management of bowel disorders, nausea and vomiting, and other gastrointestinal conditions.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients who are receiving pharmacotherapy for bowel disorders, nausea and vomiting, and other gastrointestinal conditions.

vomiting, 1118
vomiting center, 1118

Bowel disorders, nausea, and vomiting are among the most common complaints for which patients seek medical consultation. Nonspecific symptoms of gastrointestinal (GI) distress may be caused by a large number of infectious, metabolic, inflammatory, neoplastic, or neuropsychologic disorders. In addition, nausea, vomiting, constipation, and diarrhea are the most common adverse effects of oral (PO) medications. Although symptoms often resolve without the need for pharmacotherapy, when severe or prolonged, these conditions may lead to serious consequences unless drug therapy is initiated. This chapter examines the pharmacotherapy of these and other conditions associated with the GI tract. The anatomy and physiology of the lower GI tract are reviewed in Chapter 58.

Pathophysiology of Constipation

60.1 Constipation is characterized by infrequent or difficult bowel movements.

A large percentage of the water we drink is reabsorbed as it travels through the large intestine. Reabsorption of the proper amount of water results in stools of a normal, soft-formed consistency. If feces remain in the colon for an extended period, too much water will be reabsorbed, leading to small, hard stools that are difficult to evacuate from the rectum without straining. Abdominal distention, discomfort, and flatulence may result.

Patients often define **constipation** as the infrequent passage of abnormally hard and dry stools. This definition, however, is not entirely satisfactory for diagnosis because the normal frequency of bowel movements varies widely among individuals, from two to three per day to as few as one per week. Constipation occurs more frequently in older adults because fecal transit time through the colon slows with aging. This population also exercises less, has diminished food intake, and is more likely to take certain drugs that cause constipation at a higher rate than in younger adults. Variations in frequency are normal and a daily bowel movement is not a requirement for good health.

Constipation is not a disease but a symptom of an underlying disorder or condition, some of which are shown in Table 60.1. A diagnosis of chronic constipation includes at least two of the following symptoms without the use of laxatives over the course of a year:

- Fewer than three bowel movements per week
- Lumpy or hard stools at least 25% of the time
- Straining to pass stools at least 25% of the time
- A feeling of incomplete evacuation at least 25% of the time.

Occasional constipation is self-limiting and does not require drug therapy. Lifestyle modifications that incorporate increased dietary fiber, fluid intake, and physical activity should be considered before drugs are utilized for

Table 60.1 Etiology of Constipation

Condition	Causes
Dietary	Inadequate fiber intake Inadequate fluid intake Inadequate food intake Specific foods: alcoholic beverages, products with a high content of refined white flour, dairy products, and chocolate
GI disorders	Bowel obstruction Diverticulitis Irritable bowel syndrome Tumors
Lifestyle	Lack of exercise
Medications	Antacids containing bismuth, calcium, or aluminum Barium sulfate Calcium channel blockers Drugs with anticholinergic action: antihistamines, phenothiazines, tricyclic antidepressants, some antiparkinsonism drugs Iron supplements Nonsteroidal anti-inflammatory drugs (NSAIDs) Opioids
Metabolic disorders	Diabetes Hypercalcemia or hypocalcemia Hypothyroidism
Neurogenic/central nervous system (CNS) disorders	Clinical depression Diminished peristalsis Head or spinal trauma Parkinson's disease Strokes
Pregnancy	Diminished exercise, change in diet, pressure of fetus on the colon

constipation. Chronic, infrequent, and painful bowel movements that are accompanied by severe straining may justify initiation of treatment. Excessive straining may lead to anorectal pathology such as anal fissures, hemorrhoids, or rectal prolapse. In its most severe form, constipation can lead to a fecal impaction and complete obstruction of the bowel.

Constipation that is accompanied by acute pain and abdominal distention is a sign of a potential bowel obstruction or paralytic ileus. These conditions are medical emergencies, and laxatives, enemas, and other therapies are absolutely contraindicated until the patient receives a full medical evaluation.

Pharmacotherapy with Laxatives

60.2 Laxatives are drugs that increase the frequency and quality of bowel movements.

Laxatives, drugs that promote defecation (evacuation of the bowel), are commonly used to prevent and treat constipation. **Cathartic** is a related term that implies an accelerated, stronger, and more complete bowel emptying. A variety of prescription and over-the-counter (OTC) laxatives, including tablet and liquid formulations, are available. Suppositories are used for infants or patients who are unable to take PO drugs. Laxatives and their doses are listed in Table 60.2.

Laxatives have several important indications. These may be divided into prophylaxis of constipation and treatment of constipation:

Prophylaxis

- Patients who have had a myocardial infarction (MI) or those with rectal pathology who should not be straining
- Patients receiving drug therapies that have constipation as a known adverse effect
- Patients who are bedridden or otherwise unable to exercise
- Patients who are pregnant
- Older patients with weak abdominal or perineal muscles

Table 60.2 Laxatives and Cathartics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Bulk Forming		
calcium polycarbophil (Equalactin, FiberCon, others)	PO: 1 g daily	*Abdominal fullness or cramping, fainting* Esophageal or GI obstruction if taken with insufficient fluid
methylcellulose (Citrucel)	PO: 5–20 mL tid in 8–10 oz liquid	
psyllium mucilloid (Metamucil, Naturacil, others)	PO: 2.5 g in 8 oz liquid daily prn	
Saline/(Osmotic)		
magnesium hydroxide (Milk of Magnesia)	PO: 20–60 mL or 6–8 tablets daily prn	*Diarrhea, abdominal cramping* Hypermagnesemia with magnesium hydroxide (dysrhythmias, respiratory failure)
polyethylene glycol (MiraLAX)	PO: 17 g/day in 8 oz liquid daily for 2–4 days	
sodium biphosphate (Fleet Phospho-Soda)	PO: 15–30 mL mixed in liquid daily prn	
Stimulants		
bisacodyl (Correctol, Dulcolax, others)	PO: 10–15 mg daily prn	*Abdominal cramping, nausea, fainting, diarrhea* Fluid and electrolyte loss
castor oil (Emulsoil, Neoloid)	PO: 15–60 mL daily prn	
Surfactants (Stool Softeners)		
docusate (Colace, DulcoEase)	PO: 50–500 mg daily	*Abdominal cramping, diarrhea* No serious adverse effects
Herbal Products		
castor oil	PO: 15–60 mL daily	*Abdominal cramping, diarrhea* No serious adverse effects
senna (Ex-Lax, Senokot, others)	PO: 8.6–17.2 mg daily	
Opioid Antagonists		
alvimopan (Entereg)	PO: 12 mg prior to surgery followed by 12 mg bid beginning the day after surgery for up to 7 days (maximum: 15 doses)	*Dyspepsia, nausea, abdominal pain, hyperhidrosis (methylnaltrexone)* GI perforation, opioid withdrawal, MI (alvimopan)
methylnaltrexone (Relistor)	Subcutaneous: 8 or 12 mg every other day	
naloxegol (Movantik)	PO: 25 mg in the morning	
Miscellaneous Laxatives		
mineral oil	PO: 15–30 mL bid	*Diarrhea, nausea* Nutritional deficiencies, pneumonia (with aspiration)
plecanatide (Trulance)	PO: 3 mg once daily	*Diarrhea* Serious dehydration in pediatric patients

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Treatment

- Relieve simple, chronic constipation.
- Accelerate the removal of ingested toxic substances following overdose or poisoning.
- Accelerate the removal of dead parasites following antihelminthic drug therapy.
- Cleanse the bowel prior to diagnostic or surgical procedures of the colon or genitourinary tract, including colonoscopy or barium enema.
- Relieve opioid-induced constipation.

The most common adverse effects of laxatives include abdominal distention and cramping. Diarrhea may result from excessive use. When cleansing the bowel prior to a colonoscopy or purging the bowel of toxic substances or parasites, forceful, frequent bowel movements are expected outcomes. Care must be taken to rule out acute abdominal pathology such as bowel obstruction prior to administration, because the drugs will increase colon pressure and possibly cause bowel perforation.

Laxatives may be classified into six primary groups and a miscellaneous category. The choice of a particular drug depends on the reason for use (treatment or prophylaxis), the onset of action desired (rapid or slow), and the completeness of evacuation needed (cathartic or laxative).

Bulk-forming laxatives: Bulk-forming drugs absorb water, thus adding size to the fecal mass. Because fiber absorbs water and expands to provide bulk, these drugs must be taken with plenty of water. Bulk-forming laxatives are first-line drugs for the treatment and prevention of chronic constipation and may be taken on a regular basis without ill effects. Because of their slow onset of action, they are not used when a rapid and complete bowel evacuation is necessary. Bulk-forming laxatives are pregnancy category C and their onset of action is 24 to 48 hours.

Saline (osmotic) cathartics: Saline cathartics, also called osmotic laxatives, are poorly absorbed in the intestine. They pull water into the fecal mass to create a more watery stool. These drugs can produce a bowel movement very quickly but should not be used on a regular basis due to the possibility of dehydration and fluid and electrolyte depletion. Saline laxatives are highly effective and are an important component of colonoscopy prep and for purging toxins from the body. Most saline cathartics are pregnancy category B. Their onset of action is 1 to 6 hours in high doses.

Stimulant laxatives: Stimulant laxatives promote peristalsis by irritating the bowel. They are rapid acting and are more likely to cause diarrhea and cramping than the bulk-forming type of laxatives. They should not be used routinely, because they may cause laxative dependence, abdominal cramping, and depletion of fluid and electrolytes. These products are often used to prepare the bowel prior to colon examination or surgery, sometimes in combination with other laxatives and enemas. Stimulant laxatives are pregnancy category C and their onset of action is 6 to 12 hours (PO) or 1 to 6 hours (rectal).

Surfactant (stool softener) laxatives: Surfactants, commonly called stool softeners, cause more water and fat to be absorbed into the stools. They are ineffective at treating constipation but are most often used to prevent the condition. Stool softeners are generally prescribed for patients who have a condition that puts them at risk for constipation, such as a surgery, an injury, or an MI where straining during defecation should be avoided. Stimulant laxatives are pregnancy category C and their onset of action is 24 to 48 hours.

Herbal laxatives: Herbal laxatives are natural products that are available OTC and are widely used for self-treatment of constipation. The most commonly used herbal laxative is senna, a potent herb that stimulates the bowel and increases peristalsis. Other natural laxatives include rhubarb, cascara sagrada, aloe, flaxseed, and dandelion. Patients should be advised to exercise caution when using herbal products because many have not been evaluated through controlled studies for safety or effectiveness. The pregnancy category for natural products has not been determined and their onset of action varies.

Opioid antagonists: Opioids relieve pain by occupying mu receptors in the brain. Opioids, however, also occupy mu receptors at peripheral sites such as the large intestine, producing constipation. This constipation may be severe, resulting in a potential ileus following surgery. The drugs in this class block the opioid mu receptors in the large intestine, but they do not pass through the blood–brain barrier in any significant amount. This allows the patient to experience central pain relief from the opioids without peripheral side effects on the large intestine.

Approved by the U.S. Food and Drug Administration (FDA) in 2008, methylnaltrexone (Relistor) is specifically used to treat chronic constipation in patients with advanced illness who are receiving opioids for palliative care. A newer laxative approved in 2014 is naloxegol (Movantik), which is indicated specifically for constipation induced by opioid medications. Alvimopan (Entereg) is available only for short-term, hospital use due to an increased risk for MI.

Miscellaneous drugs: Mineral oil is a miscellaneous drug that acts by lubricating the stool and the colon mucosa. The use of mineral oil should be discouraged because it interferes with the absorption of fat-soluble vitamins and can cause other potentially serious adverse effects. Its onset of action is 24 to 48 hours. Approved in 2017, plecanatide (Trulance) is an oral drug approved to

treat chronic idiopathic constipation. Its mechanism of action is unique: It activates the enzyme guanylate cyclase in the intestine. This causes increased secretion of chloride and bicarbonate ion into the intestinal lumen, resulting in increased amounts of intestinal fluid and accelerated fecal transport. Plecanatide carries a black box warning that it is contraindicated in patients younger than age 6 and should be avoided in children ages 6 through 17 due to the potential for serious dehydration.

PROTOTYPE DRUG **Psyllium Mucilloid (Metamucil, Naturacil, Others)**

Classification **Therapeutic:** Drug for constipation
Pharmacologic: Bulk-type laxative

Therapeutic Effects and Uses: Psyllium is derived from a natural product—the seeds of the plantain plant. Like other bulk-forming laxatives, psyllium is an insoluble fiber that is indigestible and not absorbed from the GI tract. When taken with a sufficient quantity of water, psyllium swells and increases the size of the fecal mass. The larger the size of the fecal mass, the greater will be the neural stimulus for defecation.

Several doses of psyllium may be needed over 1 to 3 days to produce an optimal therapeutic effect. Several 2.5-g doses may be taken each day. Frequent use of psyllium (7 g/day) may effect a small reduction in blood cholesterol level. This drug is available as granules, powder, and wafers.

Mechanism of Action: Psyllium expands the size of the stool and promotes colon peristalsis that closely resembles a natural bowel movement.

Pharmacokinetics:

Route(s)	PO
Absorption	Not absorbed; remains in the GI tract
Distribution	Not distributed
Primary metabolism	Not metabolized
Primary excretion	Feces
Onset of action	12–24 h
Duration of action	Unknown

Adverse Effects: Psyllium is the safest laxative and rarely produces adverse effects. It generally causes less cramping than the stimulant-type laxatives and results in a more natural bowel movement. If taken with insufficient water, psyllium may swell in the esophagus and cause obstruction.

Contraindications/Precautions: Psyllium should not be administered to patients with undiagnosed abdominal pain, suspected intestinal obstruction, or fecal impaction.

Drug Interactions: Psyllium may decrease the absorption and effects of warfarin, digoxin, nitrofurantoin, antibiotics, and salicylates. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose from psyllium is unlikely.

Nursing Responsibilities: Key nursing implications for patients receiving psyllium are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Laxatives or Antidiarrheals.

Drugs Similar to Psyllium Mucilloid (Metamucil, Naturacil, Others)

Other popular laxatives include bisacodyl, castor oil, docusate, and magnesium salts.

Bisacodyl (Correctol, Dulcolax, others): Bisacodyl is the most frequently used stimulant-type laxative. It acts by irritating the mucosa in the colon and by altering intestinal and electrolyte absorption. Only 15% of the drug is absorbed after oral administration. Onset of action is 8 to 12 hours (PO) if taken at bedtime or 15 to 60 minutes per rectal suppository. Bisacodyl should not be taken with milk or other dairy products because these can dissolve the enteric coating and cause dyspepsia. The enteric-coated tablets should not be crushed or chewed. Minor adverse effects include abdominal pain and cramping. Prolonged use may lead to laxative dependence and fluid and electrolyte loss. Bisacodyl is pregnancy category C.

Castor oil (Emulsoil, Neoloid): Castor oil is one of the oldest and worst-tasting laxatives. It was approved in 1939. A stimulant-type laxative, castor oil acts on the small intestine and produces a bowel movement in 2 to 6 hours. It causes more adverse effects than other laxatives, including diarrhea, cramping, nausea, vomiting, and dizziness. This drug is pregnancy category X and must not be used during pregnancy.

Docusate (Colace, DulcoEase): Docusate is the most frequently prescribed surfactant-type laxative or stool softener. This drug permits additional water and lipids to penetrate the stool, making it softer. Docusate takes several days to act and therefore is not effective when a rapid and complete bowel evacuation is necessary. Only small amounts are absorbed systemically. Adverse effects are rare. Docusate sodium (Colace) should not be given to patients on sodium restriction. Docusate potassium (Dialose) should not be given to patients with chronic kidney disease (CKD). Docusate increases the systemic absorption of mineral oil, so these two medications should not be given concurrently. Docusate should not be taken with certain herbal products such as senna, cascara, rhubarb, or aloe, because it will increase their absorption and the risk of liver toxicity. Docusate is pregnancy category C.

Magnesium hydroxide (Milk of Magnesia): Magnesium hydroxide has two effects on the GI tract. Taken PO it exerts an antacid effect because it neutralizes gastric hydrochloric acid to form magnesium chloride. About 30% of the magnesium chloride is absorbed systemically. The remainder continues along the GI tract and reaches the colon, where it exerts a laxative effect by drawing water and electrolytes to form a larger and softer fecal mass. This drug has a chalky taste and has a small incidence of nausea, vomiting, and abdominal cramping. Patients with impaired renal function should be monitored for hypermagnesemia. Magnesium hydroxide can bind to other drugs, delaying their absorption; thus it should be taken at least 2 hours apart from other medications. Drugs that may result in decreased absorption include H_2-receptor antagonists, iron salts, phenytoin, digoxin, and tetracyclines. Magnesium citrate and magnesium sulfate are other saline-type laxatives with rapid onsets of action (30 minutes to 4 hours).

CONNECTIONS: Using Research in Practice

Fecal Microbiota Transplant

The role that normal intestinal flora, or *intestinal microbiota*, plays in maintaining body health and immunity is becoming more apparent—and appreciated. Multiple organisms populate the intestinal tract. Their functions include boosting immune protection against toxins produced by some pathogenic bacteria and guarding against septic shock. In addition, they may play a role in preventing obesity.

When normal intestinal flora is disrupted, such as by antibiotic therapy, the pathogenic bacteria may overgrow and cause serious infection. *Clostridium difficile*–associated diarrhea (CDAD) is a serious bowel infection that most often results from antibiotic therapy. It results in watery diarrhea that contains blood and pus, and rapid dehydration may occur because of fluid loss. The standard treatment for CDAD includes fluid replacement; for severe and recurrent cases, PO vancomycin may be prescribed. Recent research, however, has explored a process called fecal microbiota transplant (FMT), which involves transplanting small amounts of healthy intestinal flora from a donor into a recipient who has CDAD. The outcomes have been positive.

In FMT, donors are prescreened for serious viral diseases (e.g., HIV, hepatitis), syphilis, ova and parasites, and colon cancer. The donor stool is suspended in liquid and then instilled into the patient by enema, colonoscopy, or nasogastric tube. More recent studies suggest that frozen fecal microbiota may be administered orally through capsules with positive results (Youngster et al., 2016). FMT has led to significant improvements, with resolution of CDAD in 83% to 100% of patients (Chapman et al., 2016). Current research is investigating the use of FMT for inflammatory bowel conditions such as Crohn's disease (Vaughn et al., 2016).

CONNECTION Checkpoint 60.1

From what you learned in Chapter 22, describe the indications for using magnesium to treat seizure disorders. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pathophysiology of Diarrhea

60.3 Diarrhea is an abnormal increase in the frequency and fluidity of bowel movements.

The small intestine receives about 9 L of fluid, or chyme, daily. Most is reabsorbed, such that only about 1 L reaches the colon. Travel through the colon results in even more reabsorption, and only about 100 mL remains to form stools. Should the small or large intestines fail to reabsorb sufficient fluids, diarrhea may occur. **Diarrhea** is an increase in the frequency and fluidity of bowel movements.

Like constipation, occasional diarrhea is a self-limiting disorder that does not warrant drug therapy. In some cases, diarrhea is a type of body defense, rapidly and completely eliminating toxins and pathogens. When prolonged or severe, especially in children, diarrhea can result in a significant loss of body fluids, and pharmacotherapy is indicated. In underdeveloped countries, diarrhea is a major cause of illness and death in young children. Prolonged diarrhea may lead to fluid, acid–base, or electrolyte imbalances.

Because diarrhea is a nonspecific symptom of an underlying condition or disease, a primary treatment goal is to identify and treat the cause. Assessing the patient's recent travels, dietary habits, immune system competence, and drug history may provide important clues about the etiology. Because such a large number of conditions can cause diarrhea, pinpointing an exact cause may be difficult. Therefore, symptomatic therapy is provided for the diarrhea while identifying its cause. Common etiologies include the following:

- **Infection.** Viral and bacterial infections are the most common cause of diarrhea. Intestinal protozoans and helminths are less common causes. The most frequently encountered diarrhea-producing organisms are *Campylobacter*, *Salmonella*, *Cryptosporidium*, *Giardia*, *Shigella*, *Escherichia coli* (traveler's diarrhea), and *Staphylococcus*.
- **Drugs.** Antibiotics often cause diarrhea by killing normal intestinal flora, thereby allowing an overgrowth of opportunistic pathogenic organisms. Laxatives, magnesium antacids, digoxin, orlistat, and NSAIDs are also common causes.
- **Inflammation.** Ulcerative colitis, Crohn's disease, and irritable bowel syndrome (IBS) cause inflammation of the bowel mucosa, leading to periods of intense diarrhea.

- **Foods.** Various foods can cause diarrhea, such as dairy products in lactose-intolerant patients, foods with capsaicin (hot pepper), and chronic alcohol ingestion.
- **Malabsorption.** Diseases of the small intestine and pancreas can cause insufficient absorption of foods and fluid.

Pharmacotherapy of Diarrhea

60.4 Opioids are the most effective drugs for controlling severe diarrhea.

Pharmacotherapy related to diarrhea depends on the severity of the condition and any identifiable etiologic factors. If the cause is an infectious disease, then an antibiotic or antiparasitic drug is indicated. Should the etiology be inflammatory, then anti-inflammatory drugs are warranted. When the cause appears to be due to an adverse effect of pharmacotherapy, the healthcare provider should discontinue the offending medication, lower the dose, or substitute an alternative drug.

The most effective drugs for the symptomatic treatment of diarrhea are the opioids, which dramatically slow peristalsis in the colon. The most common opioid antidiarrheals are codeine and diphenoxylate with atropine (Lomotil). Diphenoxylate is a Schedule V drug that acts directly on the intestine to slow peristalsis, thereby allowing for more fluid and electrolyte absorption in the large intestine. The opioids cause central nervous system (CNS) depression at high doses and are generally reserved for the short-term therapy of acute diarrhea because of their potential adverse effects and the potential for dependence. Details on the indications and adverse effects of opioids are found in Chapter 25.

OTC drugs for diarrhea act by a number of different mechanisms. Loperamide (Imodium) is an analog of meperidine (Demerol), although it has no narcotic effects and is not classified as a controlled substance. Low-dose loperamide is available OTC; higher doses are available by prescription. Other OTC treatments include bismuth subsalicylate (Pepto-Bismol), which acts by binding and absorbing toxins. Psyllium preparations may also slow diarrhea because they absorb large amounts of fluid, which helps to form bulkier stools. Probiotic supplements containing *Lactobacillus*, a normal inhabitant of the human gut and vagina, are sometimes taken to correct the altered GI flora following a serious diarrhea episode. A good source of healthy *Lactobacillus* is yogurt with active cultures, although a freeze-dried form of the bacteria is available in tablets. The antidiarrheals are listed in Table 60.3.

In general, antidiarrheal medications should not be used to treat diarrhea caused by poisoning or infection by toxin-producing organisms. For these patients, it is important for the toxic substances and organisms to be expelled from the body. Use of antidiarrheals will retain these harmful substances. Antidiarrheal use is contraindicated in cases of diarrhea caused by pseudomembranous colitis that is caused by *C. difficile*. This infection can cause toxic megacolon. In this rare condition, the colon is unable to expel gas and stool, which causes it to become greatly distended and at risk of rupturing. An enlarged or ruptured colon requires emergency surgery and may be fatal.

Table 60.3 Antidiarrheals

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Opioids		
difenoxin with atropine (Motofen)	PO: 1–2 mg after each diarrhea episode (max: 8 mg/day)	*Drowsiness, lightheadedness, nausea, dizziness, dry mouth (from atropine), constipation* Paralytic ileus with toxic megacolon, respiratory depression, CNS depression
diphenoxylate with atropine (Lomotil)	PO: 5 mg 4 times daily (max: 20 mg/day)	
loperamide (Imodium)	PO: 4 mg as a single dose, then 2 mg after each diarrhea episode (max: 16 mg/day)	
opium tincture (Paregoric)	PO: 5–10 mL 1–4 times daily	
Miscellaneous Antidiarrheals		
bismuth subsalicylate (Kaopectate, Pepto-Bismol)	PO: 2 tablets or 30 mL prn	*Constipation, nausea, tinnitus* Impaction, Reye's syndrome
octreotide (Sandostatin)	Subcutaneous/Intravenous (IV): 100–600 mcg/day in 2–4 divided doses	*Nausea, diarrhea, abdominal pain* Hypo- or hyperglycemia, gallstones, cholestatic hepatitis
telotristat (Xermelo)	PO: 250 mg tid with food	*Nausea, headache, depression, flatulence, decreased appetite* Severe constipation, persistent abdominal pain

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PROTOTYPE DRUG **Diphenoxylate with Atropine (Lomotil)**

Classification **Therapeutic:** Antidiarrheal
Pharmacologic: Opioid

Therapeutic Effects and Uses: Approved in 1960, diphenoxylate is an oral opioid available by liquid or tablet that is a Schedule V controlled substance. Like other opioids, diphenoxylate slows peristalsis, allowing time for additional water reabsorption from the intestine and the formation of solid stools. It acts within 45 to 60 minutes. It is effective for moderate to severe diarrhea, but it is not recommended for infants. The atropine in Lomotil is not added for its anticholinergic effect but to discourage patients from taking too much diphenoxylate. At recommended doses the effects of atropine are negligible.

Diphenoxylate is discontinued as soon as the diarrhea symptoms resolve. A low-maintenance dose may be continued for up to 10 days if additional diarrhea is anticipated. Lomotil is approved for use in children 2 years and older.

Mechanism of Action: Diphenoxylate acts on the smooth muscle of the intestine to slow peristalsis.

Pharmacokinetics:

Route(s)	PO
Absorption	90% absorbed
Distribution	Small amounts are secreted in breast milk
Primary metabolism	Hepatic; metabolized to active metabolite
Primary excretion	Bile and feces
Onset of action	45–60 min
Duration of action	3–4 h

Adverse Effects: Unlike most opioids, diphenoxylate has no analgesic properties and has an extremely low potential for abuse. The drug is well tolerated at normal doses. Some patients experience dizziness, lethargy, or drowsiness, and care should be taken not to drive or operate machinery until the effects of the drug are known. At higher doses the anticholinergic effects of atropine, which include drowsiness, flushing, dry mouth, and tachycardia, may be observed.

Contraindications/Precautions: Contraindications to diphenoxylate include hypersensitivity to the drug, severe hepatic impairment, obstructive jaundice, and diarrhea associated with pseudomembranous colitis. Dehydration or electrolyte imbalances should be corrected before diphenoxylate therapy is initiated.

Drug Interactions: Other CNS depressants, including alcohol, will cause additive sedative effects. Opiate antagonists such as naloxone will reduce the effectiveness of diphenoxylate. When taken with monoamine oxidase inhibitors (MAOIs), diphenoxylate may cause hypertensive crisis. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with Lomotil may be serious. Narcotic antagonists such as naloxone may be administered parenterally to reverse respiratory depression within minutes.

Nursing Responsibilities: Key nursing implications for patients receiving diphenoxylate with atropine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Laxatives or Antidiarrheals.

Drugs Similar to Diphenoxylate with Atropine (Lomotil)

Other antidiarrheal drugs include bismuth subsalicylate, difenoxin with atropine, loperamide, octreotide, opium tincture, and telotristat.

Bismuth subsalicylate (Kaopectate, Pepto-Bismol): Bismuth subsalicylate is an oral OTC drug approved for indigestion, heartburn, and diarrhea. Its more recent use is in the treatment of *Helicobacter* infections in patients with peptic ulcer disease. Doses may be taken every 30 to 60 minutes (max: 4 doses/day) until the diarrhea resolves. Adverse effects do not occur at recommended doses. Stools may become discolored, but this is not harmful. In stomach acid, bismuth subsalicylate forms salicylic acid, which is absorbed systemically. Thus this drug should be used with caution by patients using aspirin; otherwise salicylate toxicity may result. In addition, this drug should not be used in children with chickenpox or flu symptoms due to the possibility of Reye's syndrome. A "Children's Pepto" is available that contains calcium carbonate without salicylates. This drug is pregnancy category C.

Difenoxin with atropine (Motofen): Difenoxin is an opioid that is an active metabolite of diphenoxylate; thus the two drugs have the same actions, contraindications, and adverse effects. Like Lomotil, atropine is added to Motofen to discourage substance abusers from using the drug. It is a Schedule IV controlled substance and is pregnancy category C.

Loperamide (Imodium): Approved in 1976, loperamide is an oral, first-line drug for the symptomatic treatment of acute diarrhea and the maintenance therapy of chronic diarrhea. Chemically related to the opioids, it shares the antidiarrheal properties of the opioids but has no analgesic action and does not produce dependence. This drug slows peristalsis, increasing the transit time, thus allowing for better formed stools. If diarrhea is not controlled after 48 hours of loperamide therapy, the patient should seek

medical attention. Adverse effects are rare. A dose may last up to 24 hours. Safety has been established in children less than 2 years of age. This drug is pregnancy category C.

Octreotide (Sandostatin): Approved in 1988, octreotide is closely related to somatostatin (growth hormone-inhibiting hormone). It is approved to treat acromegaly and severe diarrhea associated with cancer. Octreotide is used off-label to treat a wide variety of other conditions including acquired immunodeficiency syndrome (AIDS)–related diarrhea, ileostomy-related diarrhea, and childhood diarrhea. It also directly inhibits intestinal secretions and enhances absorption. It is given only by the intramuscular (IM) or IV route. A long-acting depot form (Sandostatin LAR) is available for long-term use. The most frequent adverse effects are GI related, such as nausea, diarrhea, and abdominal pain. During long-term therapy, more than half the patients who are taking octreotide experience gallbladder pathology, including gallstones, or cholestatic hepatitis. This drug is pregnancy category B.

Opium tincture (Paregoric): Paregoric contains opium, which has morphine and codeine as the active ingredients. Although once widely used in the treatment of severe diarrhea, it can cause opioid-related adverse effects and is a Schedule III controlled substance. This drug may also be used to prevent withdrawal symptoms in newborns of opioid-dependent mothers. Safer drugs have replaced Paregoric. For short-term use, Paregoric is pregnancy category C.

Telotristat (Xermelo): Approved in 2017, telotristat is an oral drug for treating adults experiencing diarrhea from carcinoid syndrome. Carcinoid syndrome is caused by carcinoid tumors, which are rare and generally occur in the GI tract. Telotristat is administered concurrently with a somatostatin analog, such as octreotide. The drug is not pregnancy rated.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Laxatives or Antidiarrheals

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including GI, cardiovascular, and hepatic disease or CKD, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain a history of past and current symptoms, noting what measures have been successful to relieve the symptoms (e.g., increased fluids, fiber, dietary changes).
- Obtain baseline weight and vital signs.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, hepatic or renal function studies).
- Obtain an abdominal assessment (e.g., bowel sounds, softness or firmness, distention, presence of tenderness).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., adequate pattern of elimination, normal stool consistency and volume).
- Continue periodic monitoring of abdominal assessment findings, especially bowel sounds.
- Continue periodic monitoring of CBC, electrolytes, and hepatic and renal function laboratory values as appropriate.
- Assess for adverse effects: nausea, vomiting, diarrhea, constipation, headache, drowsiness, and dizziness. Severe abdominal pain, vomiting, coffee-ground emesis, hematemesis, blood in the stool, or tarry stools should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Treat the cause: If a definitive cause for the current symptoms can be identified (e.g., infection, food poisoning, inadequate fluid intake), correct the cause where possible. (Constipation and diarrhea are usually symptoms of other underlying conditions such as infections, inadequate fluid or fiber intake, stress, or sedentary lifestyle. The patient health history can assist in determining the cause of the symptoms.)	• For recurrent constipation or diarrhea, encourage the patient to maintain a diary of correlations between symptoms, foods, beverages, stress, or medications to help identify causative factors. • Review medications or possibility of illness with the patient or family to help identify factors that may require treatment or alterations in medication.
• Encourage appropriate lifestyle changes. (Ensuring adequate daily amounts of fluids and dietary fiber and increasing activity levels assist in encouraging normal peristaltic activity. Smoking and alcohol use are known to alter normal peristalsis and should be limited or eliminated. Correlating symptoms with medications or stress may help to identify a triggering factor.)	• Encourage the patient to adopt a healthy lifestyle by increasing dietary fiber and fluid intake, exercise, and consumption of yogurt and *acidophilus*-containing foods; managing stress as needed; and limiting or eliminating alcohol consumption and smoking. Provide for dietitian consultation or information on smoking cessation programs as needed. • Encourage the patient to keep a diary, noting correlations between symptoms and foods, beverages, stress, or medications.
• Follow appropriate administration guidelines for best results. Do not administer laxatives if bowel obstruction is possible. Do not administer antidiarrheal drugs if infection is possible. (Bowel obstruction must be ruled out in the presence of hypoactive or absent bowel sounds. If infection is a possible cause of diarrhea, giving antidiarrheal drugs may decrease peristalsis, giving the infection an opportunity to increase and spread.)	• Teach the patient to take the drug following appropriate guidelines or label directions, particularly for any additional fluid intake required, for best results. • Instruct the patient that diarrhea or constipation associated with increasing nausea or vomiting, especially if accompanied by abdominal pain or fever, should be reported to the healthcare provider before taking the drug.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Continue to monitor abdominal assessment findings. Any significant increase or decrease in bowel sounds, new onset, or increased discomfort or pain should be reported promptly. (Any significant change in bowel sound activity or increased discomfort or pain may signal the development of worsening bowel disease or adverse drug effects.)	• Teach the patient that some easing of discomfort related to constipation or diarrhea may be noticed soon after beginning drug therapy, but full effects may take several days or longer. If gastric discomfort or pain continues or worsens, the healthcare provider should be notified.
• Monitor for any severe abdominal pain, vomiting, coffee-ground emesis or hematemesis, blood in stool, or tarry stools, and report immediately. (Severe abdominal pain or blood in emesis or stools may indicate a worsening of disease or more serious conditions and should be reported immediately.)	• Teach the patient that severe abdominal pain or any blood in emesis or stools should be reported immediately to the healthcare provider.
• Ensure patient safety. Observe for lightheadedness or dizziness. Monitor ambulation until the effects of the drug are known. Obtain electrolyte levels if dizziness continues. (Drowsiness or dizziness from opioid-based or related antidiarrheals may occur. **Lifespan:** The older adult is at increased risk of injury and falls. Diphenoxylate with atropine may cause agitation, confusion, or hallucinations in the older adult, particularly if dementia is a preexisting condition. Continued dizziness may indicate electrolyte imbalance, and electrolyte levels should be assessed.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone if dizziness or drowsiness occurs. Provide for a commode or bedpan nearby. For home use, avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known. Immediately report any agitation, confusion, or hallucinations to the healthcare provider.
• Continue to monitor periodic hepatic and renal function tests and electrolyte levels as needed. (Abnormal liver function tests may indicate adverse hepatic effects from drugs such as diphenoxylate with atropine or octreotide. Excessive use of laxatives or continued diarrhea may affect electrolyte levels.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor vital signs, particularly respiratory rate and depth, in patients taking opioid or opioid-related drugs. (Drugs such as diphenoxylate with atropine may depress CNS activity and decrease respiratory rate and depth. Intervention with narcotic antagonists may be needed if overdose occurs.)	• Teach the patient to take the drug as ordered and not to increase dose or frequency unless instructed to do so by the healthcare provider. Any drowsiness, dizziness, or disorientation should be reported to the provider promptly.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken with additional fluids. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient on laxatives to take the drug following appropriate guidelines:
	  • **All laxative drugs:** Take the drug with additional fluids and increase fluid intake throughout the day. Increase the intake of dietary fiber, especially whole grains, fruits, and vegetables. Exceeding the recommended dose or frequent laxative use increases the risk of adverse effects and decreases normal peristalsis over time, resulting in laxative dependence.
	  • **Bulk-forming laxatives:** Take other medications 1 h before or 2 h after the laxative. Powdered formulations should be mixed with a full glass of liquid and taken immediately, followed by an additional full glass of liquid. Powders should never be swallowed dry or esophageal obstruction may result.
	  • **Mineral oil laxatives:** Should not be taken if nausea is present and should not be taken at bedtime to avoid the possibility of aspiration.

Pharmacotherapy of Inflammatory Bowel Disease

60.5 Inflammatory bowel disease is treated with immunosuppressants and anti-inflammatory drugs.

Inflammatory bowel disease (IBD) is characterized by the presence of ulcers in the intestinal tract. Crohn's disease or Crohn's lesions typically appear in the distal region of the small intestine (terminal ileum), although they can affect any region of the GI tract from the mouth to the anus. Crohn's lesions usually are discontinuous: Affected areas of the intestinal mucosa alternate with normal areas. The mucosal erosions characteristic of ulcerative colitis begin in the rectum and progress in an uninterrupted manner throughout the rest of the large intestine. It is estimated that 1 to 2 million Americans have IBD.

The etiology of IBD remains largely unknown. Several genes involved with immune responses are associated with the disorder. It is hypothesized that these defective genes cause hyperactivity of T-cell responses to normal flora in the terminal ileum and colon. These hyperactive responses result in chronic intestinal inflammation.

In addition to genetic susceptibility, certain environmental triggers exacerbate symptoms of IBD. The best studied trigger for Crohn's disease is smoking. Infections, the use of NSAIDs, and a high level of stress are additional environmental factors that have been identified. Less well known are triggers for ulcerative colitis; in many patients, triggers cannot be identified. It is known that symptoms of ulcerative colitis tend to peak between ages 15 and 30 and again between 50 and 70.

Symptoms of IBD range from mild to acute, and the condition is characterized by alternating periods of remission and exacerbation. The most common clinical presentation of ulcerative colitis is abdominal cramping with frequent bowel movements. Severe disease may lead to weight loss, bloody diarrhea, high fever, and dehydration. The patient with Crohn's disease also presents with abdominal pain, cramping, and diarrhea, which may have been present for years before seeking treatment. Symptoms of Crohn's disease are often similar to those of ulcerative colitis. Patients with IBD have an increased risk of acquiring GI cancer.

The expected outcomes for the pharmacotherapy of IBD are as follows:

- Reduce the acute symptoms of active disease by induction therapy and place the disease in remission.
- Keep the disease in remission with maintenance therapy.
- Change the natural course or progression of the disease.

Multiple medications are utilized to treat IBD, and pharmacotherapy is conducted in a stepwise manner, starting with the safest and best established medications for the disorder, as shown in Pharmacotherapy Illustrated 60.1. The first step of IBD treatment usually involves 5-aminosalicylic acid (5-ASA) drugs that include sulfasalazine (Azulfidine), olsalazine (Dipentum), balsalazide (Colazal), and mesalamine (Asacol, Canasa, Lialda, others). These

Pharmacotherapy Illustrated 60.1

Inflammatory Bowel Disease

Mild Symptoms

Aminosalicylates
- Balsalazide
- Mesalamine
- Olsalazine
- Sulfasalazine

Antibiotics
- Ciprofloxacin
- Metronidazole

Moderate Symptoms

Oral corticosteroids
- Budesonide
- Dexamethasone
- Prednisolone
- Prednisone

IV corticosteroids
- Hydrocortisone
- Methylprednisolone

Severe Symptoms

Immunomodulators
- Azathioprine
- Cyclosporine
- Mercaptopurine
- Methotrexate
- Tacrolimus

Biologic therapies
- Adalimumab
- Certolizumab
- Infliximab
- Natalizumab

Table 60.4 Selected Drugs for Inflammatory Bowel Disease and Irritable Bowel Syndrome

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
First-Line Drugs for Inflammatory Bowel Disease		
balsalazide (Colazal, Giazo)	PO (Colazal): 2.25 g tid for 8–12 wk PO (Giazo): 3.3 g bid for up to 8 wk	*Headache, abdominal pain, diarrhea, nausea, vomiting, rash, flulike illness, allergic reactions* Hepatotoxicity, blood dyscrasias, renal impairment, salicylate hypersensitivity, crystalluria (sulfasalazine)
mesalamine (Asacol, Canasa, Lialda, others)	PO (delayed release tablets): 800 mg tid for 6 wk PO (delayed release capsules): 1 g qid for 8 wk	
olsalazine (Dipentum)	PO: 500 mg bid (max: 3 g/day)	
sulfasalazine (Azulfidine)	PO: 1–2 g/day in 4 divided doses (max: 8 g/day)	
Drugs for Irritable Bowel Syndrome		
alosetron (Lotronex)	PO: Begin with 1 mg daily for 4 wk; may increase to 1 mg bid (max: 2 mg/day)	*Constipation, abdominal discomfort, nausea, and rash* Ischemic colitis, ileus
dicyclomine (Bentyl) and hyoscyamine (Anaspaz, Gastrosed, Levsin)	PO/IM (dicyclomine): 20–40 mg qid (max: 160 mg/day PO; 80 mg/day IM) PO (hyoscyamine): 0.15–0.3 mg 1–4 times/day	*Dry mouth, blurred vision, drowsiness, constipation, urinary hesitancy, and tachycardia* Confusion, paralytic ileus
eluxadoline (Viberzi)	PO: 100 mg taken with food	*Constipation, nausea and abdominal pain* Pancreatitis
linaclotide (Linzess)	PO (idiopathic constipation): 72–145 mcg once daily PO (IBS with constipation): 290 mcg once daily	*Abdominal pain and distention, flatulence* Severe diarrhea
lubiprostone (Amitiza)	PO (idiopathic constipation): 24 mcg bid PO (IBS with constipation): 8 mcg bid	*Diarrhea, nausea, headache, abdominal pain* Allergic reaction, dyspnea
rifaximin (Xifaxan)	PO: 550 mg tid	*Nausea, elevated alanine transaminase* No serious adverse effects

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

medications act rapidly and exhibit a higher safety profile than the second-line drugs. While effective at initially reducing symptoms, the 5-ASA medications are not as effective in maintaining remission. Doses for the 5-ASA drugs are listed in Table 60.4. In some cases, a short course of antibiotics may benefit the patient experiencing mild symptoms.

When IBD symptoms are more intense or when patients have not responded well to the 5-ASA drugs, oral corticosteroids such as prednisone are used. Because of their potentially serious long-term adverse effects, however, they are prescribed for the shortest length of time needed to send the disease into remission. In hospitalized patients, IV corticosteroids may be used to put IBD into remission. For a detailed discussion of corticosteroid therapy, refer to Chapter 68.

Budesonide (Entocort-EC) is a corticosteroid with interesting properties that allow it to be used as a first-line therapy for IBD. Entocort-EC is encapsulated to avoid significant absorption in the stomach or duodenum. This drug is released slowly and reaches a high concentration in the terminal ileum and proximal colon—the two most frequently affected sites for IBD. Thus budesonide is in direct contact with the GI mucosa and produces a topical anti-inflammatory effect. In addition, when budesonide is absorbed, it is almost entirely removed by first-pass metabolism in the liver. Thus this drug shows few of the adverse effects seen with the long-term use of the other corticosteroids. It is approved for mild to moderate Crohn's disease. In 2012, a delayed release form of budesonide (Uceris), administered once daily, was approved to treat ulcerative colitis.

Should therapy with corticosteroids fail, step 3 of IBD therapy includes immunosuppressive drugs, such as azathioprine (Imuran), mercaptopurine (Purinethol), or methotrexate (MTX, Rheumatrex, Trexall). These medications are normally not used for induction therapy because they have a 3-month onset of action. They are, however, effective at extending the time between relapses. For a detailed discussion of immunosuppressant therapy, refer to Chapter 42.

The introduction of biologic therapies in the late 1990s gave clinicians another valuable tool in the pharmacotherapy of IBD. The biologic therapies for IBD comprise two classes:

- Tumor necrosis factor (TNF) inhibitors: The TNF inhibitors, such as infliximab (Remicade), have been shown to effectively reduce the acute symptoms of and provide maintenance therapy for both Crohn's disease and ulcerative colitis. Newer anti-TNF drugs include adalimumab (Humira), certolizumab pegol (Cimzia), and golimumab (Simponi).

- Integrin inhibitors: The two drugs in this class are monoclonal antibodies that bind integrins, which are receptors that mediate cell-to-cell communication. This binding impedes the ability of T lymphocytes to migrate to inflamed lymphoid tissue in the intestinal tract. Natalizumab (Tysabri) was approved in 2008 to treat severe Crohn's disease. This drug was previously approved for multiple sclerosis (see Chapter 21). Natalizumab has adverse effects that limit its use, the most serious of which is an increased risk for progressive multifocal leukoencephalopathy (PML), an often-fatal opportunistic viral infection of the brain. In 2014, a second integrin inhibitor, vedolizumab (Entyvio), was approved to treat IBD. No cases of PML have been recorded with vedolizumab. Both natalizumab and vedolizumab are administered by the IV route for patients who have not responded to immunomodulators or TNF inhibitors.

The biologic therapies are expensive, sometimes costing thousands of dollars per injection, and some patients experience a high rate of serious infections due to their immunosuppressive actions. Biologic therapies are usually recommended only when first-line drugs are unable to control symptoms. Because they cause healing of the GI mucosa, it is possible that early use of these drugs could change the progressive course of IBD. This is an area of active research. For additional information on biologic therapies used for immunomodulation and doses of these drugs, refer to Chapter 42.

PROTOTYPE DRUG Sulfasalazine (Azulfidine)

Classification **Therapeutic:** Drug for inflammatory bowel disease, disease-modifying antirheumatic drug (DMARD)
Pharmacologic: 5-aminosalicylate, anti-inflammatory, sulfonamide

Therapeutic Effects and Uses: Approved in 1950, sulfasalazine is a PO drug with anti-inflammatory properties that is approved to treat mild to moderate symptoms of ulcerative colitis for adults and children ages 6 years and older. It is approved as an alternate drug in the pharmacotherapy of rheumatoid arthritis and is classified as a DMARD (see Chapter 72). Sulfasalazine is used off-label to treat Crohn's disease.

Colon bacteria metabolize sulfasalazine to two active metabolites: sulfapyridine and 5-ASA. These metabolites are responsible for its anti-inflammatory properties.

Mechanism of Action: Sulfasalazine and its metabolites inhibit the mediators of inflammation in the colon such as prostaglandins and leukotrienes.

Pharmacokinetics:

Route(s)	PO
Absorption	Sulfasalazine is only 10–15% absorbed, but its metabolites in the colon produce therapeutic effects
Distribution	Crosses the placenta; secreted in breast milk; 93% bound to plasma protein
Primary metabolism	Hepatic; intestinal metabolism to the active metabolites sulfapyridine and 5-ASA
Primary excretion	Renal; active metabolites excreted in the feces
Onset of action	Peak: 1.5–6 h
Duration of action	Half-life: 5–10 h

Adverse Effects: The most common adverse effects of sulfasalazine are GI related and include nausea, vomiting, diarrhea, dyspepsia, and abdominal pain. Dividing the total daily dose evenly throughout the day and using the enteric-coated tablets may improve adherence. Headache is common. Blood dyscrasias occur infrequently during therapy. Skin rashes are relatively common and may be a sign of a more serious adverse effect such as Stevens–Johnson syndrome. This drug may impair male fertility, which reverses when the drug is discontinued. Sulfasalazine can cause photosensitivity.

Contraindications/Precautions: Sulfasalazine is contraindicated in patients with sulfonamide or salicylate (aspirin or 5-ASA) hypersensitivity. Patients with preexisting anemia, folate, or other hematologic disorders should use this drug with caution because it may worsen blood dyscrasias. Sulfasalazine should be used with caution in patients with hepatic impairment because this drug can cause hepatotoxicity. This drug is contraindicated in patients with urinary obstruction and should be used with caution in dehydrated patients because it may cause crystalluria. Patients with diabetes or hypoglycemia should use sulfasalazine with caution because the drug can increase insulin secretion and worsen hypoglycemia.

Drug Interactions: Sulfasalazine may worsen bone marrow suppression caused by methotrexate and also result in additive hepatotoxicity. Absorption of digoxin may be decreased. Sulfasalazine is a folic acid antagonist and will inhibit absorption of this vitamin. Sulfasalazine can displace warfarin from its protein-binding sites, causing increased anticoagulant effects. **Herbal/Food:** Unknown.

Pregnancy: Categories B and D (near term).

Treatment of Overdose: Overdose will cause abdominal pain, anuria, drowsiness, gastric distress,

nausea, seizures, and vomiting. Treatment is mostly supportive with gastric lavage, emesis, and alkalinization of urine.

Nursing Responsibilities:

- Obtain a complete health history, including allergies, drug history, and possible drug interactions.
- Perform a complete assessment of GI functioning and symptoms of IBD, which include abdominal cramping with frequent bowel movements, weight loss, bloody diarrhea, fever, and dehydration.
- Monitor for GI distress, including nausea, vomiting, diarrhea, dyspepsia, and abdominal pain. If symptoms persist, the prescriber may withhold the drug for 5 to 7 days and restart it at a lower dosage level.
- Be aware that adverse reactions generally occur within a few days to 12 weeks after the start of therapy. They are most likely to occur in patients who are receiving high doses.
- Monitor laboratory tests for red blood cell counts and folate levels in patients on high doses (more than 2 g/day); a daily supplement may be prescribed. Patients with preexisting anemia, folate, or other hematologic disorders should use the drug with caution because it may worsen blood dyscrasias.
- Response to therapy and duration of treatment are determined by endoscopic examinations.

Lifespan and Diversity Considerations:

- Because of normal physiologic changes in bowel tone related to aging, monitor bowel sounds in the older adult and for the development of constipation, particularly from prolonged use of the drug.
- Monitor hepatic and renal function laboratory values more frequently in the older adult because normal changes related to aging may affect the drug's metabolism and excretion.
- Monitor electrolyte levels frequently in the older adult who is at greater risk for the development of electrolyte imbalances secondary to the diarrhea.

Patient and Family Education:

- Examine stools and report to the healthcare provider if enteric-coated tablets have passed intact in feces. If this occurs, a conventional tablet form can be ordered.
- Increase fluid intake to 2 to 3 L/day because this drug may cause crystals in the urine. Be aware that this drug may color urine and skin orange-yellow.
- Attend all follow-up examinations. Relapses occur in about 40% of patients after an initial satisfactory response.
- It is recommended that the interval between doses not exceed 8 hours (even if administered at night).
- Men may experience a decreased production of sperm and infertility, which is reversed with the discontinuation of this drug.
- Avoid prolonged sun exposure because the skin may be more sensitive. Wear sunscreen, protective clothing, and sunglasses if exposed to direct sunlight. Report any sunburn or other skin rashes to the provider.

Drugs Similar to Sulfasalazine (Azulfidine)

Other 5-aminosalicylates include balsalazide, mesalamine, and olsalazine.

Balsalazide (Colazal, Giazo): Approved in 2000, balsalazide is a PO anti-inflammatory drug approved for the symptomatic treatment of ulcerative colitis in patients ages 5 and above. A newer formulation of the drug (Giazo) is approved for male patients ages 18 and above. Like sulfasalazine, balsalazide is metabolized in the intestinal mucosa to 5-ASA, which is responsible for its therapeutic effects. Almost 100% of this drug reaches the colon without being absorbed; thus the primary action of the drug is topical rather than systemic. The drug is well tolerated, with headache, abdominal pain, diarrhea, nausea, and vomiting being the most common adverse effects. Patients with salicylate hypersensitivity should not take this drug. Rare cases of hepatotoxicity have occurred. This drug is pregnancy category B.

Mesalamine (Asacol, Canasa, Lialda, others): Approved in 1987, mesalamine is sometimes referred to by its chemical name, 5-ASA. It is approved for the treatment of active ulcerative colitis and used off-label for Crohn's disease. A delayed release formulation (Asacol) was developed for maintenance therapy, and a rectal suppository (Canasa) is available to treat ulcerative proctitis. Like other drugs in this class, mesalamine tablets and capsules are designed to release the drug in the terminal ileum and colon to produce its effects topically in the intestinal mucosa. Headache, abdominal pain, diarrhea, nausea, and vomiting are the most common adverse effects. Rectal irritation may be caused by the suppository forms of the drug. Patients with salicylate hypersensitivity should not take this drug. This drug is pregnancy category B.

Olsalazine (Dipentum): Like other medications in this class, olsalazine is an oral drug that is metabolized in the intestinal mucosa to 5-ASA, which produces a topical anti-inflammatory effect. Nearly 100% of this drug reaches the colon without being absorbed systemically. Approved in 1990, the only indication for this drug is for the maintenance of remission of ulcerative colitis in patients who are unable to tolerate sulfasalazine. The most commonly reported adverse effects are diarrhea, abdominal pain, and rash. Rare cases of hepatotoxicity have occurred. This drug is pregnancy category C.

PharmFACT

Irritable bowel syndrome affects 10% to 20% of adults. Women are 2 to 3 times more likely than men to have the disorder (Lehrer, 2016).

Pharmacotherapy of Irritable Bowel Syndrome

60.6 Irritable bowel syndrome is treated with dietary management, symptomatic therapy, and drugs that regulate intestinal motility.

Irritable bowel syndrome (IBS), also known as spastic colon or mucous colitis, is a common disorder of the lower GI tract characterized by symptoms that include abdominal pain, visible bloating, excessive gas, and colicky cramping. Bowel habits are altered, with diarrhea alternating with constipation, and there may be mucus in the stool. Pain is usually relieved by defecation, although the patient usually feels as if the evacuation is incomplete. Symptoms of IBS are likely caused by altered GI motility, increased peristalsis, and increased pain sensitivity of the GI tract.

The diagnosis of IBS is sometimes one of exclusion, ruling out other diseases such as colon cancer, ulcerative colitis, intestinal infections, Crohn's disease, and diverticulitis. It is not a precursor of more serious disease, and symptoms such as bleeding, anorexia, weight loss, or fever are not usually experienced by patients with IBS. IBS is considered a functional bowel disorder, meaning that the normal operation of the digestive tract is impaired without the presence of detectable organic disease. A diagnosis of IBS requires that the patient has experienced recurrent abdominal pain or discomfort for at least 3 days per month during the previous 3 months that is associated with two or more of the following:

- Relieved by defecation
- Onset associated with a change in stool frequency
- Onset associated with a change in stool form or appearance.

Treatment of IBS is supportive, with drug therapy targeted at symptomatic treatment depending on whether constipation or diarrhea is the predominant symptom. There is no single treatment that is effective for all, or even most, patients.

Lifestyle changes, diet, and aggravating medications: Stress is not a cause of IBS, but it can influence the condition. Attempts should be made to identify stressors and develop positive coping strategies. Psychotherapy, relaxation techniques, and hypnosis may benefit some patients. Food-specific triggers are not always apparent. However, the patient should keep a food diary in an attempt to recognize and avoid foods that appear to worsen the condition. Dietary restriction of caffeine, wheat, or lactose-based products may be attempted. Foods that cause bloating and flatulence such as beans, cabbage, and peas should be avoided.

Part of a medical history for IBS should include drugs that may be contributing to the symptoms of IBS. Common drugs that may cause constipation include NSAIDs, calcium channel blockers, anticholinergics, and opioids. Diarrhea may result from the use of laxatives, magnesium-containing antacids, or antibiotics. Sometimes a change in medication can help reduce IBS symptoms.

Dietary fiber and laxatives: Constipation, diarrhea, cramping, painful bowel movements, and rectal urgency occur frequently in patients with IBS. Because constipation and diarrhea often alternate, pharmacotherapy can be challenging. Fiber supplementation with nonprescription bulk laxatives such as psyllium has long been recommended as a treatment for IBS and can help regulate bowel movements to bring relief to some patients. Unfortunately, increased fiber intake will worsen the symptoms in some patients. Loperamide (Imodium), an antidiarrheal, is effective at relieving symptoms of diarrhea in patients with IBS.

Antidepressant therapy: For many years the tricyclic antidepressants such as amitriptyline, desipramine (Norpramin), and doxepin (Sinequan) have been used to treat patients with IBS who have pain as a major symptom. Studies on the effectiveness of these drugs in reducing pain and diarrhea in patients with IBS are conflicting, but they may be indicated for those who have depression as a comorbid condition. Selective serotonin reuptake inhibitors (SSRIs) such as paroxetine (Paxil) have also been studied but results suggest that their effectiveness at treating IBS is mild at best. While antidepressants may relieve pain for some patients, they are not first-line drugs for IBS.

Drug-specific therapies: Drugs used to treat IBS do not alter the course of the disease and, in some cases, may actually worsen the symptoms. These drugs may not be significantly more effective than nonpharmacologic treatments such as IBS support groups, relaxation therapy, or dietary changes. There is no prototype drug for this condition. Drugs that provide symptomatic relief for some patients include alosetron, antispasmodic drugs (dicyclomine and hyoscyamine), eluxadoline, linaclotide, lubiprostone, and rifaximin .

Alosetron (Lotronex): By inhibiting serotonin (5-HT_3) receptors, alosetron reduces GI-related sensitivity and slows peristalsis in patients with diarrhea-predominant IBS. Alosetron was approved in 2000 but was withdrawn later that same year due to several deaths from ischemic colitis. This drug was allowed to return to the market in 2002 but with severe restrictions on its use. It is approved only for severe diarrhea-predominant IBS in women who

have not responded to conventional therapy. The starting dose was lowered from 1 mg bid to 1 mg daily. No refills are allowed without a follow-up examination by the prescribing healthcare provider. A risk–benefit statement must be signed by the patient and healthcare provider that they agree to adhere to therapy plans. A black box warning states that alosetron can cause serious adverse GI reactions, including ischemic colitis and serious complications of constipation that can cause death. The warning also states that healthcare providers who wish to prescribe alosetron must receive special training and testing to learn to appropriately diagnose and treat IBS. Furthermore, other therapies must have been attempted (and failed) prior to alosetron use. Other adverse effects include abdominal discomfort, nausea, and rash. This drug is pregnancy category B.

Antispasmodic drugs: Antispasmodic drugs are those that relax smooth muscle and slow peristalsis. Dicyclomine (Bentyl) and hyoscyamine (Anaspaz, Gastrosed, Levsin) are older anticholinergic drugs that are used to reduce bowel spasms in patients with IBS (see Chapter 14). Dicyclomine was approved in 1950 for diarrhea-predominant IBS and other functional disorders of GI motility. Dicyclomine may be administered PO or by IM injection. Frequent adverse effects include typical anticholinergic effects such as dry mouth, blurred vision, drowsiness, urinary hesitancy, and tachycardia. This drug is pregnancy category B.

Available since the FDA was established in 1938, hyoscyamine is an anticholinergic drug that is usually administered PO, but parenteral forms are available. It is approved to treat peptic ulcer disease and diarrhea-predominant IBS because the drug decreases acid secretion of the stomach and slows peristalsis. It has also been used to reverse bradycardia, to relieve symptoms of allergic rhinitis, and to dry respiratory and salivary secretions prior to surgery. Whereas in 1938 hyoscyamine may have been a preferred drug for these conditions, it has been replaced by safer and more effective drugs for nearly every indication. This drug is pregnancy category C.

Eluxadoline (Viberzi): Eluxadoline was approved in 2015 for the treatment of diarrhea-dominant IBS in adults. Given PO, it acts by activating the mu and kappa opioid receptors. It is contraindicated in patients with biliary tract obstruction, alcohol abuse, or those with a history of pancreatitis. Eluxadoline does not have a pregnancy rating.

Linaclotide (Linzess): Linaclotide was approved in 2012 for chronic idiopathic constipation and for constipation-dominant IBS. It is an oral drug that acts by the same mechanism as plecanatide: increasing the secretion of chloride and bicarbonate ion into the intestinal lumen, resulting in increased amounts of intestinal fluid and accelerated fecal transport. The most common adverse effects are diarrhea, abdominal pain, flatulence, and abdominal distention. The drug carries a black box warning that it is contraindicated in children up to age 6 and should be avoided in children ages 6 through 17 due to the potential for serious dehydration. This drug is pregnancy category C.

Lubiprostone (Amitiza): Lubiprostone is approved for the treatment of chronic idiopathic constipation and constipation-predominant IBS in women over age 18. Lubiprostone increases fluid secretion by activating chloride channels in the intestinal luminal cells, thereby altering stool consistency and promoting regular bowel movements. The most common adverse effect is nausea, which can be reduced by taking the drug with food. Lubiprostone should not be administered to patients with diarrhea or suspected GI obstruction. Because lubiprostone is teratogenic in laboratory animals, it should be used during pregnancy only if the potential benefits justify the possible risks to the fetus. This drug is pregnancy category C.

Rifaximin (Xifaxan): Rifaximin is an antibiotic similar in structure to rifampin, a first-line therapy for tuberculosis. Originally indicated for traveler's diarrhea, rifaximin was approved to treat diarrhea-dominant IBS in 2015. Given PO for 14 days, the mechanism by which it improves IBS symptoms is unclear. The most common adverse effects include nausea and elevations in alanine transaminase. Rifaximin does not have a pregnancy rating.

CONNECTION Checkpoint 60.2

Anticholinergic drugs can inhibit muscarinic or nicotinic receptors. From what you learned in Chapter 14, which type do dicyclomine and hyoscyamine inhibit? What drug is the prototype for this class? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pathophysiology of Nausea and Vomiting

60.7 Nausea and vomiting occur when the vomiting center in the medulla is stimulated.

Nausea is an unpleasant feeling of the need to vomit that is accompanied by weakness, diaphoresis, dizziness, and hyperproduction of saliva. Intense nausea often leads to **vomiting**, or emesis, in which the stomach contents are forced upward into the esophagus and out of the mouth. Vomiting is a defense mechanism used by the body to rid itself of toxic substances.

Vomiting is a reflex primarily controlled by a portion of the medulla of the brain known as the **vomiting center**, which receives sensory signals from the digestive tract, the inner ear, and the **chemoreceptor trigger zone (CTZ)** in the cerebral cortex. Interestingly, the CTZ is not protected by the blood–brain barrier, as is the vast majority of the brain;

thus these neurons can directly sense the presence of toxic substances in the blood. Once the vomiting reflex is triggered, wavelike contractions of the stomach quickly propel its contents upward and out of the body.

The treatment outcomes for nausea or vomiting should focus on removal of the cause whenever feasible. Nausea and vomiting are common symptoms associated with a wide variety of conditions. Some conditions originate in the GI tract itself, such as peptic ulcer disease, GI obstruction, gallbladder disease, food poisoning, or ingestion of a toxic substance that irritates the mucosa. The nausea and vomiting may originate from systemic sources such as those caused by cancer, pregnancy, radiation sickness, migraine headache, trauma to the head or abdominal organs, inner ear disorders, extreme pain, diabetes, or systemic drug use. In addition to the CTZ, other parts of the nervous system may promote nausea and vomiting in response to nervousness, emotional imbalances, changes in body position (motion sickness), extreme stress, or when confronted with unpleasant sights, smells, or sounds.

The nausea and vomiting experienced by many women during the first trimester of pregnancy is referred to as morning sickness. The cause of nausea and vomiting during pregnancy is not completely understood but is probably due to hormonal changes, especially in levels of estrogen and human chorionic gonadotropin (hCG). All women of childbearing years who present with nausea or vomiting should receive a pregnancy test because this is a common explanation for these symptoms. Should this condition become acute, such as continual vomiting, it may lead to **hyperemesis gravidarum**, a situation in which the health and safety of the mother and developing baby can become severely compromised. Complications may include dehydration, electrolyte imbalances, and significant weight loss. Pharmacotherapy with fluid and electrolyte solutions and antiemetics is initiated after other antinausea measures have proven ineffective.

PharmFACT

Morning sickness occurs in 70% to 85% of pregnancies. Morning sickness has a peak incidence at 8 to 12 weeks of pregnancy but usually ends by week 20 (Khan, 2016).

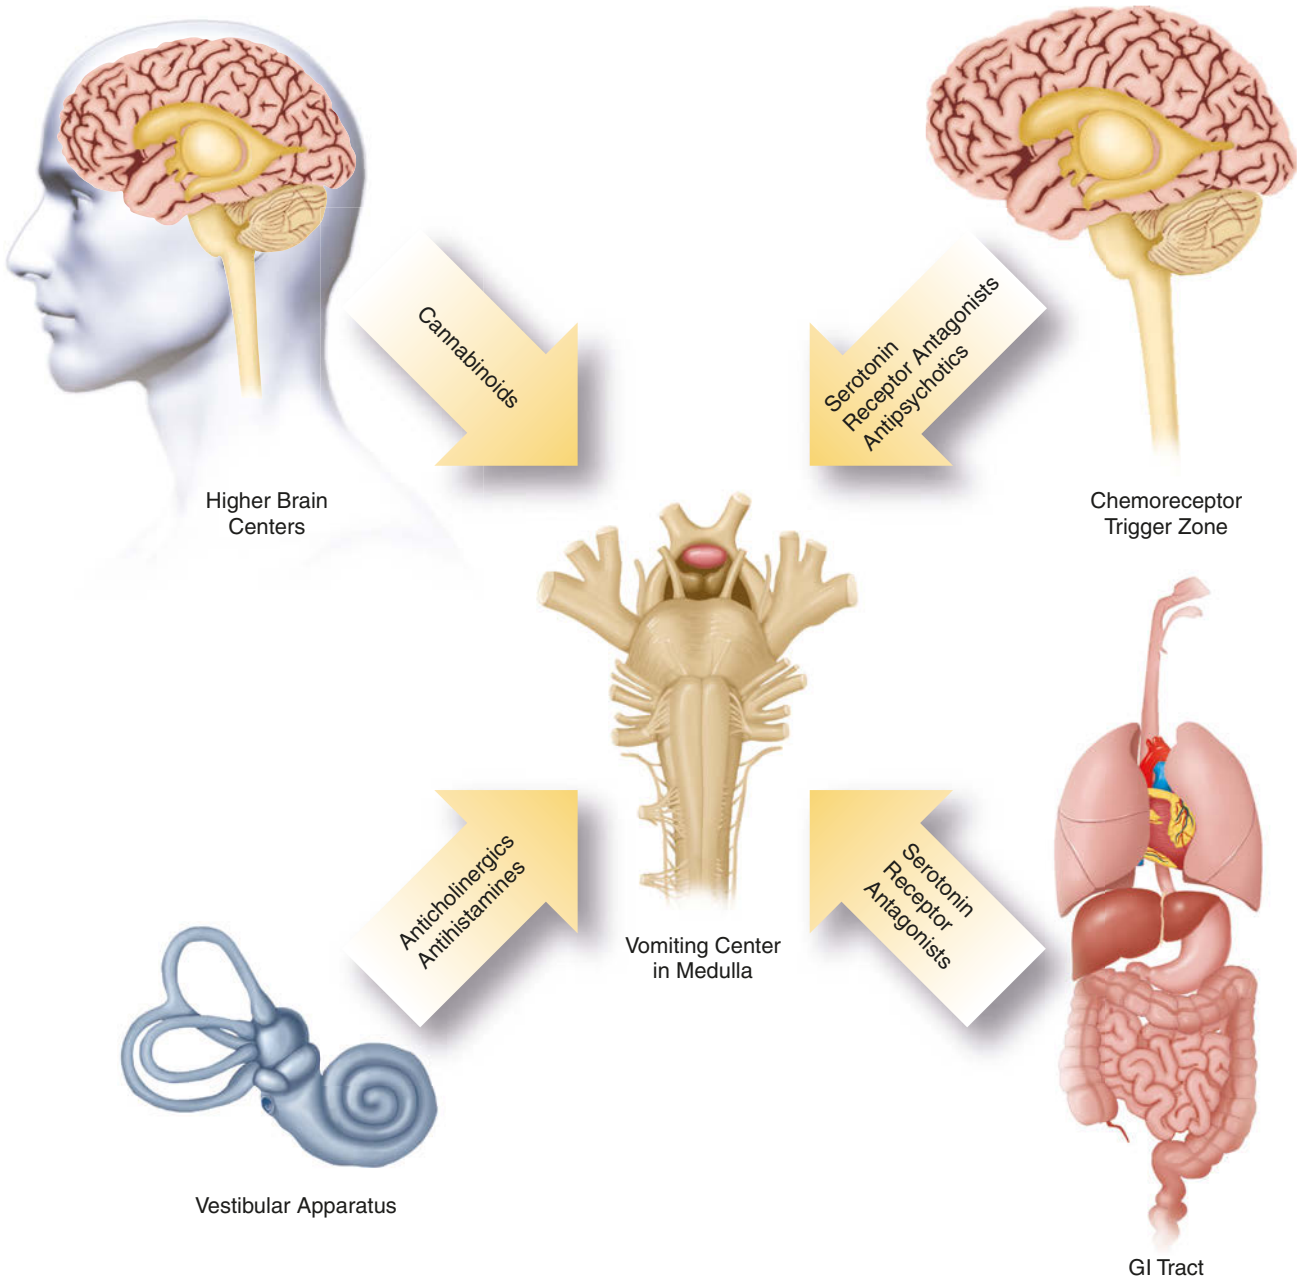
Nausea and vomiting are the most frequently listed adverse effects for oral medications. The nurse should remember that because the vomiting center lies in the brain, nausea and vomiting occur just as frequently with parenteral formulations as with oral drugs. The most extreme example of this occurs with the antineoplastic drugs, most of which cause intense nausea and vomiting regardless of the route by which they are administered. The capacity of a chemotherapeutic drug to cause vomiting is called its **emetogenic potential**. Nausea and vomiting are common reasons for patient lack of adherence to the therapeutic regimen and for discontinuation of drug therapy.

When large amounts of fluids are vomited, dehydration and significant weight loss may occur. Because the contents lost from the stomach are strongly acidic, vomiting may cause a change in the pH of the blood, resulting in metabolic alkalosis. With excessive loss, severe acid–base disturbances can lead to vascular collapse, resulting in death if medical intervention is not initiated. Electrolytes such as sodium, potassium, and chloride are also lost during vomiting and may need to be replaced, especially in the infant, child, and older adult. Dehydration is especially dangerous for infants, small children, and the older adult and is evidenced by dry mouth, sticky saliva, and reduced urine output that is dark yellow-orange to brown in color.

Pharmacotherapy of Nausea and Vomiting

60.8 Antiemetics are prescribed to treat nausea, vomiting, and motion sickness.

Drugs from at least eight different classes are used to prevent or treat nausea and vomiting. Most of these drugs were originally developed for other indications, and their antiemetic characteristics were discovered later. Selection of a specific drug depends on the cause of the nausea and vomiting and its severity.



Patients who are seeking self-treatment have access to several available OTC options. For example, simple nausea and vomiting are sometimes relieved by antacids or diphenhydramine (Benadryl). Peppermint and ginger are the most popular herbal therapies for nausea and vomiting.

Relief of serious nausea or vomiting requires prescription medications. Patients who are receiving antineoplastic drugs may receive three or more antiemetics concurrently to reduce the nausea and vomiting from chemotherapy. In fact, therapy with antineoplastics is one of the most common reasons for prescribing antiemetic drugs. Many antiemetics are available through the IM, IV, or suppository route to prevent loss of the medication due to vomiting. Pharmacotherapy Illustrated 60.2 shows the mechanisms of action of antiemetic medications. Doses for selected antiemetics are listed in Table 60.5.

Anticholinergics and antihistamines: These medications are effective for treating simple nausea, with some being available OTC. For example, nausea due to motion sickness is effectively treated with anticholinergics or antihistamines. Motion sickness is a disorder that affects a portion of the inner ear that is associated with significant nausea. The most common drug used for motion sickness is scopolamine (Hyoscine, Transderm-Scop), an anticholinergic that is

Pharmacotherapy Illustrated 60.2

Mechanisms of Action of Antiemetic Medications

usually administered as a transdermal patch. Antihistamines such as dimenhydrinate (Dramamine), doxylamine, and meclizine (Antivert) are also effective but may cause significant drowsiness in some patients. Drugs that are used to treat motion sickness are most effective when taken 20 to 60 minutes before travel is expected.

When nonpharmacologic measures such as ginger are unable to control hyperemesis gravidarum, therapy with antihistamines may be initiated. Diclegis, a combination drug containing doxylamine (an antihistamine) and pyridoxine (vitamin B_6) has been found to be effective for the mother and safe for the fetus (pregnancy category A). It is the only FDA-approved medication for the condition, although other antihistamines, metoclopramide (Reglan), promethazine (Phenergan), and ondansetron (Zofran) have been used off-label for patients with severe symptoms.

Table 60.5 Selected Antiemetics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Anticholinergics-Antihistamines		
dimenhydrinate (Dramamine, others)	PO: 50–100 mg q4–6h (max: 400 mg/day)	*Drowsiness, dry mouth, blurred vision (scopolamine), hypotension (cyclizine)* Hypersensitivity reaction, sedation, tremors, seizures, hallucinations, paradoxical excitation (more common in children), hypotension
diphenhydramine (Benadryl, others)	PO: 25–50 mg tid–qid (max: 300 mg/day)	
doxylamine and pyridoxine (Diclegis)	PO: 20–40 mg daily	
hydroxyzine (Atarax, Vistaril)	PO: 25–100 mg tid or qid (max: 400 mg/day)	
meclizine (Antivert, Bonine, others)	PO: 25–50 mg daily, take 1 h before travel (max: 50 mg/day)	
scopolamine (Hyoscine, Transderm-Scop)	Transdermal: 0.5 mg (patch) q72h	
Benzodiazepines		
lorazepam (Ativan)	PO: 0.5–2 mg q4–6h (max: 10 mg/day)	*Dizziness, drowsiness, ataxia, fatigue, slurred speech* Paradoxical excitation (more common in children), seizures (if abruptly discontinued), coma
Cannabinoids		
dronabinol (Marinol, Syndros)	PO: 5 mg/m^2 1–3 h before administration of chemotherapy, then q2–4h after chemotherapy for a total of 4–6 doses	*Dizziness, drowsiness, euphoria, confusion, ataxia, asthenia, increased sensory awareness* Paranoia, decreased motor coordination, hypotension
nabilone (Cesamet)	PO: 1–2 mg bid	
Corticosteroids		
dexamethasone (Decadron)	PO: 0.25–4 mg bid–qid	*Mood swings, weight gain, acne, facial flushing, nausea, insomnia, sodium and fluid retention, impaired wound healing, menstrual abnormalities, insomnia* Peptic ulcer, hypocalcemia, osteoporosis with possible bone fractures, loss of muscle mass, decreased growth in children, masking of infections
methylprednisolone (Medrol, Solu-Medrol, others)	PO: 4–48 mg/day in divided doses	
Neurokinin Receptor Antagonist		
aprepitant (Emend Capsules) and fosaprepitant (Emend for Injection)	PO: 125 mg 1 h prior to chemotherapy IV: 115–150 mg 30 min prior to chemotherapy	*Fatigue, constipation, diarrhea, anorexia, hiccups* Dehydration, peripheral neuropathy, blood dyscrasias, pneumonia
Phenothiazine and Phenothiazine-Like Drugs		
metoclopramide (Reglan)	PO: 10–15 mg qid prior to meals	*Dry eyes, blurred vision, dry mouth, constipation, drowsiness, photosensitivity* extrapyramidal symptoms (EPS), neuroleptic malignant syndrome, agranulocytosis, orthostatic hypotension, tardive dyskinesia
perphenazine	PO: 8–16 mg bid–qid	
prochlorperazine (Compazine, others)	PO: 5–10 mg tid or qid Rectal: 25 mg bid IM: 5–10 mg tid or qid IV: 2.5–10 mg tid or qid (max: 10 mg/dose or 40 mg/day)	
promethazine (Phenergan, others)	PO: 12.5–25 mg q4h or qid	
trimethobenzamide (Tigan)	PO: 300 mg once daily IM: 200 mg 3–4 times/day	
Serotonin (5-HT$_3$) Receptor Antagonists		
dolasetron (Anzemet)	PO: 100 mg 1 h prior to chemotherapy	*Headache, drowsiness, fatigue, constipation, diarrhea, flulike symptoms, injection-site reactions* Dysrhythmias, EPS, hepatic failure, serotonin syndrome
granisetron (Sancuso, Sustol)	PO: 2 mg/day 1 h prior to chemotherapy IV: 10 mcg/kg 30 min prior to chemotherapy Transdermal (Sancuso): 1 patch 24–48 h prior to chemotherapy Subcutaneous (Sustol): 10 mg at least 30 min prior to chemotherapy	
ondansetron (Zofran, Zuplenz)	PO: 8 mg bid or tid IV: 32 mg 30 min prior to chemotherapy	
palonosetron (Aloxi)	PO: 0.5 mg single dose 1 h prior to chemotherapy IV: 0.25 mg 30 min prior to chemotherapy	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Serotonin (5-HT$_3$) receptor antagonists: The serotonin antagonists include dolasetron (Anzemet), granisetron (Sancuso, Sustol), ondansetron (Zofran, Zuplenz), and palonosetron (Aloxi). There are no significant differences in effectiveness or toxicity of the serotonin receptor antagonists in treating acute nausea and vomiting. They are available by the PO or parenteral route. Since the 1990s they have become the most widely prescribed drugs for chemotherapy-induced nausea and vomiting. For severe symptoms, the serotonin receptor antagonists are combined with a corticosteroid such as dexamethasone. The serotonin antagonists are most effective in the management of acute nausea and vomiting but are less effective at treating delayed symptoms. The few adverse effects they cause include headache, constipation or diarrhea, and dizziness. In 2014, the combination drug Akynzeo (palonosetron with netupitant) was approved to treat nausea and vomiting caused by highly emetogenic chemotherapy.

Phenothiazines and related drugs (dopamine antagonists): The primary indication for phenothiazines is the treatment of psychoses (see Chapter 20), but they are also very effective antiemetics. Phenothiazines inhibit dopaminergic receptors in the CTZ, and the severe nausea and vomiting associated with antineoplastic therapy are often treated with these drugs. Some of the phenothiazines may cause sedation, and extrapyramidal symptoms (EPS) are a concern with long-term therapy. Promethazine (Phenergan) is an older phenothiazine that is available by the PO, rectal, and parenteral routes that also has significant anticholinergic properties.

Benzodiazepines: The primary indication for benzodiazepines is anxiety. Benzodiazepines are ineffective as antiemetics when used as monotherapy. However, they relax the patient and decrease the anxiety associated with chemotherapy and the anticipation of severe nausea and vomiting. Lorazepam (Ativan) is the drug in this class that is most frequently used as an off-label antiemetic adjunct.

Cannabinoids: Cannabinoids are drugs that contain the same active ingredient as marijuana. Dronabinol (Marinol, Syndros) and nabilone (Cesamet) are given PO to reduce post-chemotherapy nausea and vomiting, with less euphoria compared to marijuana. Dronabinol is also indicated for the treatment of anorexia and weight loss in patients with AIDS. Cannabinoids are not as effective as other antiemetics.

Corticosteroids: Dexamethasone (Decadron) and methylprednisolone (Solu-Medrol) are used to prevent chemotherapy-induced and postsurgical nausea and vomiting. They are reserved for acute cases due to the possibility of serious adverse effects and are most often used in combination with other antiemetics. Dexamethasone is used for the treatment of delayed nausea and vomiting, which are common problems with certain antineoplastic drugs.

Other drugs: Aprepitant (Emend) belongs to a class of antiemetics, called the neurokinin (NK) receptor antagonists,

CONNECTIONS: Complementary and Alternative Therapies

Probiotics for Diarrhea

Description

Probiotics are live microorganisms that are taken in specified amounts to confer a health benefit on the host. Most commercial probiotics are bacteria from the genera *Lactobacillus* and *Bifidobacterium*; however, the yeast *Saccharomyces* is sometimes also used.

History and Claims

Although probiotics have been used for thousands of years, only in the past 20 years has research begun to confirm their health benefits. Probiotics are claimed to improve immune function, decrease cancer risk, lower blood cholesterol, reduce blood pressure, and prevent vaginal infections. Probiotic supplements are available in certain drinks, yogurts, and tablets. Although probiotics are safe, care must be taken not to exceed recommended doses.

Standardization

Supplements include capsules, tablets, and granules, as well as cultured dairy products that contain the probiotic bacteria. Doses are not standardized. Tablet doses range from 50 to 500 mg, and not all dairy products contain active cultures.

Evidence

Most of the evidence supporting the efficacy of probiotics is related to their effects on the intestinal tract. Both *Lactobacillus* and *Bifidobacterium* are normal nonpathogenic inhabitants of a healthy digestive tract. These are considered to be protective flora, inhibiting the growth of potentially pathogenic species such as *E. coli*, *Candida albicans*, *Helicobacter pylori*, and *Gardnerella vaginalis*. Probiotics restore the normal flora of the intestine following diarrhea, particularly diarrhea resulting from antibiotic therapy (National Center for Complementary and Integrative Health, 2016). A 2015 systematic review indicated that probiotics do in fact reduce symptoms of IBS in patients (Didari, Mozaffari, Nikfar, & Abdollahi, 2015). Probiotics have also been shown to be effective at shortening episodes of acute infectious diarrhea and may be considered an option for increasing eradication rates for those with *H. pylori* (Dang, Reinhardt, Zhou, & Zhang, 2014).

Although probiotics have been used for many years, they are not without risk. Infections (including sepsis), lactic acidosis, and other serious adverse effects have been noted (Doron & Snydman, 2015). Because of these, probiotic supplements should be used with caution in critically ill patients.

that reduce the level of substance P, which is involved in the emesis reflex. Aprepitant was FDA approved in 2003 as part of a 3-day antiemetic regimen for antineoplastic chemotherapy in conjunction with a corticosteroid (dexamethasone) and a serotonin receptor antagonist (ondansetron). It is also approved to treat postoperative nausea and vomiting. The IV form of this drug, fosaprepitant, was approved in 2008. Aprepitant is pregnancy category B. In 2015 a new NK receptor antagonist, rolapitant (Varubi), was approved to reduce nausea and vomiting associated with chemotherapy.

On some occasions, it is desirable to stimulate the vomiting reflex with drugs called emetics. Indications for emetics include ingestion of poisons and overdoses of oral drugs. Ipecac syrup, given PO, or apomorphine, given subcutaneously, will induce vomiting in about 15 minutes.

CONNECTION Checkpoint 60.3

From what you learned in Chapter 20, define extrapyramidal adverse effects and provide examples of symptoms that a patient with extrapyramidal symptoms might exhibit. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Ondansetron (Zofran, Zuplenz)**

Classification **Therapeutic:** Antiemetic
Pharmacologic: Serotonin (5-HT_3) receptor antagonist

Therapeutic Effects and Uses: Ondansetron and other drugs in the serotonin receptor antagonist class have replaced older drugs for the treatment of serious nausea and vomiting due to their superior effectiveness and safety. To prevent chemotherapy-induced nausea and vomiting, the medication is started at least 30 minutes prior to chemotherapy and continued for several days after. For radiation-induced nausea and vomiting, the drug is administered 1 to 2 hours before therapy and continued for 1 to 2 days. It is available by the PO, IV, IM, oral disintegrating tablet, and oral soluble film routes. Initially approved in 1991, the drug may be used off-label to treat cholestatic pruritus or opioid-induced pruritus.

Mechanism of Action: Ondansetron acts by blocking serotonin receptors in the chemoreceptor trigger zone, an area of the brain responsible for nausea and vomiting.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Rapidly absorbed
Distribution	Widely distributed; secreted in breast milk; over 70% bound to plasma proteins
Primary metabolism	Extensive hepatic metabolism by multiple CYP450 enzymes
Primary excretion	Renal (44–60%) and feces (25%)
Onset of action	PO: 1–1.5 h
Duration of action	Unknown

Adverse Effects: Ondansetron is well tolerated, with the most common adverse effects being headache, dizziness, drowsiness, and constipation or diarrhea.

Contraindications/Precautions: This drug should not be used in patients with hypersensitivity to other serotonin receptor antagonists. Caution should be used when treating patients with cardiac abnormalities because ondansetron can prolong the QT interval and cause dysrhythmias.

Drug Interactions: Ondansetron exhibits few clinically significant drug interactions. Because the drug is extensively metabolized by hepatic CYP450 enzymes, inhibitors or inducers of these enzymes may affect the availability of ondansetron. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: There is no specific therapy for ondansetron overdose and general supportive measures should be used.

Nursing Responsibilities: Key nursing implications for patients receiving ondansetron are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antiemetics.

Drugs Similar to Ondansetron (Zofran, Zuplenz)

Other serotonin receptor antagonists include dolasetron (Anzemet), granisetron (Sancuso, Sustol), and palonosetron (Aloxi). All drugs in this class have similar effectiveness and safety profiles.

Pharmacotherapy of Pancreatitis

60.9 Pancreatic enzymes are administered as replacement therapy for patients with chronic pancreatitis.

The pancreas secretes insulin as well as essential digestive enzymes. The enzymatic portion of pancreatic juice contains carboxypeptidase, chymotrypsin, and trypsin, which are converted to their active forms once they enter the small intestine. Three other pancreatic enzymes—lipase, amylase, and nuclease—are secreted in their active form but require the presence of bile for optimal activity. When lack of pancreatic enzyme secretion results in malabsorption disorders, replacement therapy is warranted.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antiemetics

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including GI, cardiovascular, hepatic or renal disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight and vital signs, especially blood pressure and pulse.
- Evaluate appropriate laboratory findings (e.g., electrolytes, glucose, CBC, hepatic or renal function studies).
- Obtain an abdominal assessment (e.g., bowel sounds, softness or firmness, distention, presence of tenderness).
- Assess emesis for amount, color, and presence of blood.
- Assess the patient's ability to receive and understand instructions. Include the family and caregiver as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., nausea is decreased, no vomiting present, able to tolerate fluids and increasing solids).
- Continue to monitor and measure any emesis. Assess urine output and maintain intake and output measurements in the hospitalized patient.
- Monitor vital signs, especially blood pressure and pulse, and report any hypotension or tachycardia to the healthcare provider.
- Continue periodic monitoring of abdominal assessment findings, especially bowel sounds.
- Continue periodic monitoring of electrolytes, glucose, CBC, and hepatic or renal function laboratory values as appropriate.
- Assess for adverse effects: headache, drowsiness, dizziness, dry mouth, blurred vision, or fatigue. Immediately report any continued vomiting, severe nausea, emesis with coffee-ground appearance or hematemesis, hypotension, tachycardia, or confusion.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Treat the cause: If a definitive cause for the current symptoms can be identified (e.g., infection, adverse drug effects), correct the cause where possible. (Nausea and vomiting are often symptoms of other underlying conditions such as adverse drug effects or infections.)	• Review medications, foods, or possibility of illness with the patient or family to help identify causative factors. • Decrease noxious stimuli (e.g., strong odors, rapid changes in position) that may increase nausea or vomiting.
• Encourage a small amount of fluids or ice chips and decreased activity level while nauseated, and abstinence from alcohol, smoking cessation, and increased intake of yogurt and *acidophilus*-containing foods after nausea has ceased. (Limiting amounts of fluids and solids during periods of nausea or vomiting and limiting physical activity or movement may help ease symptoms during the acute phase. Ensuring adequate amounts of fluids, including IV if necessary, will help maintain normal fluid balance. Smoking and alcohol use are known to cause gastric irritation.)	• Encourage the patient to limit physical movement or activity during periods of acute nausea or vomiting. Encourage increasing fluid intake gradually, with ice chips or small sips of water. Ginger ale may act as a natural antinausea beverage and may be palatable for some patients.
• Administer antiemetics 30–60 min before anticipated nausea-inducing travel or drug administration (e.g., chemotherapy). Ensure adequate hydration prior to the onset of anticipated nausea. (Antiemetics are most effective when taken before nausea occurs. Ensuring adequate prehydration decreases the risk of dehydration should vomiting occur.)	• Teach the patient to take the antiemetic 30–60 min before travel if nausea is anticipated. If drowsiness or dizziness may occur, encourage the patient to consider a trial run with the medication taken in the evening before bedtime to ascertain the effects prior to taking if driving is required. • Teach patients on at-home chemotherapy to take antiemetics prior to chemotherapy doses or routinely as ordered by the provider.
Minimizing adverse effects: • Monitor vital signs, particularly blood pressure and pulse. Take the blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for hypotension. Report any hypotension, especially associated with tachycardia, immediately. (Excessive vomiting may cause dehydration and decreased blood pressure or hypotension. Antiemetics such as anticholinergics, antihistamines, and phenothiazine or phenothiazine-like drugs may also cause a decrease in blood pressure.)	• Teach the patient to rise slowly from lying or sitting to standing to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Continue to monitor abdominal assessment findings. Any significant increase or decrease in bowel sounds, distention, new onset or increase in discomfort or pain, any severe abdominal pain, coffee-ground emesis, or hematemesis should be reported immediately. (Increasing or severe abdominal pain or hematemesis may indicate a worsening of disease and should be reported immediately.)	• Teach the patient to report any increasing gastric discomfort or pain. • Instruct the patient that severe abdominal pain or any blood in emesis should be reported immediately to the healthcare provider.
• Continue to monitor periodic electrolyte, glucose levels, and hepatic and renal function tests as needed. (Loss of electrolytes may occur with severe vomiting. Abnormal liver function tests may indicate drug-induced adverse hepatic effects.)	• Instruct the patient on the need for laboratory work.
• Monitor intake and output in the hospitalized patient. Initiate IV fluid replacement as ordered when indicated. Hold oral fluids until acute vomiting has ceased and then gradually increase fluid intake, beginning with small sips of water or ice chips. (Continuing oral intake may perpetuate or increase nausea and vomiting. Gradually resuming fluids will allow for hydration without stimulating nausea. IV fluid replacement may be required if fluid loss has been severe and if dehydration is present.)	• Instruct the patient on the need to withhold fluids and food until vomiting has ceased. Initiate incremental increases in intake beginning with small sips of water and clear fluids. • Explain the rationale for any IV hydration required and any equipment used.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• **Lifespan:** If pregnancy is suspected or confirmed, hold the antiemetic until the healthcare provider has been consulted. (Alternative antinausea measures should be used to control or ease nausea when possible. Drug pregnancy class and pregnancy trimester will be considered by the healthcare provider before prescribing the drug to avoid detrimental effects.)	• Teach pregnant patients, or if pregnancy is suspected, to consult with the healthcare provider before taking any antiemetic drug for morning sickness. • Encourage the use of nondrug measures such as dry and unsweetened cereals or crackers taken in small amounts, ginger ale to aid in diminishing nausea, and avoidance of noxious stimuli (e.g., strong odors) during periods of nausea.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, the most commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken with small sips of fluid. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

PharmFACT

The United States has the second-highest incidence of acute pancreatitis in the world. African Americans have a 10 times greater incidence than any other ethnic group (Tang, 2017).

Pancreatitis results when digestive enzymes remain in the pancreas rather than being released into the duodenum. Upon becoming activated and escaping into the surrounding tissue, the enzymes cause inflammation in the pancreas, which can lead to hemorrhage and necrosis. The backed-up enzymes and enteric bacteria may leak into the peritoneum, causing a severe systemic reaction and, possibly, death. Pancreatitis can be either acute or chronic. The two types of pancreatitis have different symptoms, mortality rates, and treatments.

Acute pancreatitis: Acute pancreatitis occurs most frequently in middle-aged adults and is often associated with gallstones in women and alcoholism in men. Symptoms of acute pancreatitis present suddenly, often after eating a fatty meal or consuming excessive amounts of alcohol. The most common symptom is a continuous severe pain in the epigastric area often radiating to the back. Fever, tachycardia, abdominal tenderness, and muscular guarding (involuntary spasm of the abdominal muscles when palpated) are common. Although most patients recover from the illness and regain normal pancreatic functions, a small percentage of patients experience recurring attacks and progress to chronic pancreatitis.

Many patients with acute pancreatitis require only bedrest, fasting, and adequate fluid and electrolyte therapy for a few days for the symptoms to subside. There are no medications specific to acute pancreatitis. For patients with acute pain, an opioid such as hydromorphone (Dilaudid) brings effective relief. To reduce gastric and pancreatic juice secretions, H_2-receptor blockers, such as cimetidine (Tagamet), or proton pump inhibitors, such as omeprazole (Prilosec), may be prescribed. To decrease the amount of pancreatic enzymes secreted, carbonic anhydrase inhibitors, such as acetazolamide (Diamox), or antispasmodics, such as dicyclomine (Bentyl), may be used. In severe cases where enteral nutrition is not tolerated, total parenteral nutrition (TPN) may be necessary.

Cases of pancreatitis accompanied by a high fever and infection have a very high mortality rate. Pharmacotherapy with an antibiotic from the imipenem class is usually begun immediately if there is evidence of pancreatic necrosis.

Chronic pancreatitis: Seventy to eighty percent of chronic pancreatitis cases are associated with alcoholism. Other causes include pancreatic cancer and stones. Alcohol is thought to promote the formation of insoluble proteins that occlude the pancreatic duct. Pancreatic juice is prevented from flowing into the duodenum and remains in the pancreas, damaging cells and causing inflammation. Symptoms include chronic epigastric or left upper quadrant pain, anorexia, nausea, vomiting, and weight loss. **Steatorrhea**, the passing of bulky, foul-smelling fatty stools, occurs late in the course of the disease. Chronic pancreatitis causes permanent structural damage to the organ and may cause scarring of the pancreatic duct system. Chronic pancreatitis is a risk factor for the development of pancreatic cancer. The disease eventually leads to pancreatic insufficiency that may necessitate insulin therapy as well as replacement of pancreatic enzymes.

There is no curative treatment for chronic pancreatitis and the patient is treated symptomatically. Fasting, IV fluids,

and opioid analgesics may be necessary. The chronic, severe pain may lead to high doses of opioids and a possibility of drug dependence. In addition, the patient with chronic pancreatitis may require insulin and antiemetics.

Pancreatic enzyme supplementation is often used in patients with chronic pancreatitis. Supplementation sends a negative feedback message to stop secreting endogenous pancreatic enzymes, which can reduce pain. These supplements are given orally. Pancrelipase (Creon, Pancreaze, Zenpep) is a pancreatic enzyme supplement that helps to digest fats and prevent steatorrhea.

PROTOTYPE DRUG **Pancrelipase (Creon, Pancreaze, Zenpep)**

Classification **Therapeutic:** Pancreatic enzymes
Pharmacologic: None

Therapeutic Effects and Uses: Pancrelipase contains lipase, protease, and amylase of pork origin and is used as replacement therapy for patients with insufficient pancreatic exocrine secretions, including those with pancreatitis and cystic fibrosis. Given PO the capsule dissolves in the alkaline environment of the duodenum and releases its enzymes. The enzymes act locally in the GI tract and are not absorbed. Pancrelipase is available in powder, tablet, and delayed release capsule formulations.

The different trade names of pancrelipase are not interchangeable because the amounts of pancreatic enzymes in each product may vary. Dose is based on the amount of fat in the diet. Doses are taken just prior to meals or with meals.

Mechanism of Action: This drug facilitates the breakdown and conversion of lipids into glycerol and fatty acids, starches into dextrin and sugars, and proteins into peptides.

Pharmacokinetics:

Route(s)	PO
Absorption	Not absorbed
Distribution	Not distributed
Primary metabolism	Metabolized in the small bowel
Primary excretion	Feces
Onset of action	Immediate
Duration of action	Unknown

Adverse Effects: Adverse effects of pancrelipase are uncommon because the enzymes are not absorbed. The most common adverse effects are GI symptoms of nausea, vomiting, and diarrhea. Very high doses are associated with a risk for hyperuricemia. A rare condition known as fibrosing colonopathy may occur when very high doses of pancreatic enzyme replacements are given to patients with cystic fibrosis.

Contraindications/Precautions: Pancrelipase is contraindicated in patients who are allergic to this drug or to pork products. The delayed release products should not be given to patients with acute pancreatitis.

Drug Interactions: Pancrelipase interacts with iron, which may result in decreased absorption of iron. Calcium and magnesium antacids may diminish the effectiveness of pancrelipase. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: High levels of uric acid may occur with overdose. Patients are treated symptomatically.

Nursing Responsibilities:

- Assess for abdominal pain. Determine the type, intensity, and location of pain.
- Assess the patient for pork allergy because the enzymes in pancrelipase come from pork.
- Monitor intake and output ratio and weight. Note the patient's appetite and quality of stools, weight loss, abdominal bloating, polyuria, thirst, hunger, and itching. Pancreatic insufficiency is frequently associated with steatorrhea, bulky stools, and insulin-dependent diabetes. Dose may need to be regulated based on fat intake in the diet.

Lifespan and Diversity Considerations:

- Evaluate the child's or older adult's nutritional status and weigh weekly to ensure that adequate nutritional requirements are being met.

Patient and Family Education:

- Take this drug just before, during, or immediately after meals.
- Capsules may be opened and sprinkled over food, but avoid chewing or crushing the microspheres inside the capsules.
- Do not switch to a different brand of pancrelipase without consulting the prescriber.
- Continue to take pancrelipase even if feeling well. Pancrelipase may control symptoms but will not cure the condition.
- Do not take this drug with iron supplements or with calcium or magnesium antacids unless directed by the provider because they may diminish the effectiveness of this drug.

Drugs Similar to Pancrelipase (Creon, Pancreaze, Zenpep)

There are no drugs similar to pancrelipase. Several unapproved forms of pancreatic enzyme products were removed from the market in 2010, per a directive from the FDA.

Understanding Chapter 60

Key Concepts Summary

60.1 Constipation is characterized by infrequent or difficult bowel movements.

60.2 Laxatives are drugs that increase the frequency and quality of bowel movements.

60.3 Diarrhea is an abnormal increase in the frequency and fluidity of bowel movements.

60.4 Opioids are the most effective drugs for controlling severe diarrhea.

60.5 Inflammatory bowel disease is treated with immunosuppressants and anti-inflammatory drugs.

60.6 Irritable bowel syndrome is treated with dietary management, symptomatic therapy, and drugs that regulate intestinal motility.

60.7 Nausea and vomiting occur when the vomiting center in the medulla is stimulated.

60.8 Antiemetics are prescribed to treat nausea, vomiting, and motion sickness.

60.9 Pancreatic enzymes are administered as replacement therapy for patients with chronic pancreatitis.

CASE STUDY: Making the Patient Connection

Remember the patient "Kerry O'Grady" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Kerry O'Grady is a 20-year-old college sophomore studying to be a middle-school teacher. She was diagnosed with IBS at the end of her freshman year after enduring multiple bouts of abdominal cramping, diarrhea, constipation, gas, and bloating. She thought it was just the stress of her first year of college because her symptoms eased over the summer break. Now it has returned and the diarrhea occurs more often than constipation. Some days she finds that she is unable to sit through an entire class without having to leave for the restroom. She is increasingly worried about her grades and she is sure that the stress is not helping her condition either.

The nurse practitioner in the Student Health Services office has prescribed several weeks of dicyclomine (Bentyl) to be followed by loperamide (Imodium) after the diarrhea has slowed from the dicyclomine.

Critical Thinking Questions

1. How will the dicyclomine (Bentyl) and loperamide (Imodium) help treat Kerry's symptoms?
2. Considering the adverse effects of dicyclomine and loperamide, what should you as the nurse teach Kerry about her college course schedule?
3. What other nondrug measures might Kerry try to ease her symptoms?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Scott Mobley is a 25-year-old man with a diagnosis of ulcerative colitis. He currently reports having three to five loose bowel movements per day, associated with gas, cramps, and urgency of evacuation. He was diagnosed with ulcerative colitis 2 years earlier. Once he is stabilized, he will be placed on sulfasalazine.

1. Scott has asked you, his nurse, how this medication works. What is your response?
2. What adverse effects of this medication should you share with Scott?
3. What contraindications would you teach Scott about the drug sulfasalazine?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is taking diphenoxylate with atropine (Lomotil). What does the nurse assess when monitoring for therapeutic effects?
   1. Reduction of abdominal cramping
   2. Minimal passage of flatus
   3. Decrease in loose, watery stools
   4. Increased bowel sounds

2. The patient who is taking sulfasalazine (Azulfidine) develops a sore throat, bruising, and severe fatigue. The nurse determines that the patient is most likely experiencing drug-induced:
   1. Stevens–Johnson syndrome.
   2. Blood dyscrasias.
   3. Idiosyncratic reaction.
   4. Hypersensitivity response.

3. Ondansetron (Zofran) has been ordered prior to chemotherapy for a patient receiving treatment for lymphoma. Prior to administering this drug, the nurse will review the patient's past medical history for what condition?
   1. Allergy to soy or soy products
   2. History of chronic constipation
   3. Glaucoma
   4. Cardiac dysrhythmias

4. A nurse should question the order for pancrelipase (Pancreaze) for which patient?
   1. The patient with allergy to pork products
   2. The patient with hypertension
   3. The patient with coronary artery disease
   4. The patient with hypersensitivity to iodine products

5. A healthcare provider orders magnesium hydroxide (Milk of Magnesia) for a patient with constipation, secondary to postoperative opioid use. Before administering the drug, the nurse would assess:
   1. Blood pressure.
   2. Dosage of the opioid drug prescribed.
   3. The patient's ability to ambulate to the bathroom.
   4. Bowel sounds.

6. A patient asks the nurse about giving an over-the-counter drug, bismuth subsalicylate (Pepto-Bismol), to treat a daughter's diarrhea. On which of the following will the nurse base the recommendation? (Select all that apply.)
   1. Cause of diarrhea
   2. Normal activity level
   3. Age
   4. Weight
   5. School schedule

See Answers to Chapter Review in Appendix A.

Chapter 61
Vitamins and Minerals

Chapter Outline

- Role of Vitamins in Health and Disease
- Regulation of Vitamins
- Recommended Dietary Allowance
- Fat-Soluble Vitamins
- Water-Soluble Vitamins
- Minerals
  - Macrominerals
  - Microminerals

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the role of vitamins in maintaining wellness.
2. Identify conditions for which vitamin and mineral therapy may be indicated.
3. Explain the governmental regulation of vitamins and minerals.
4. Discuss the role of the recommended dietary allowance in determining the standardized requirement of various vitamins and minerals.
5. Compare and contrast fat-soluble and water-soluble vitamins.
6. For each of the major vitamins, identify the mechanism(s) of action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Identify the major functions of macrominerals and microminerals.
8. Apply the nursing process to care for patients receiving vitamin and mineral supplementation therapy.

Key Terms

fat-soluble vitamins, 1132
hypervitaminosis, 1133
macrominerals, 1141
microminerals, 1142
minerals, 1141
recommended dietary allowances (RDAs), 1133
supplements, 1132
vitamins, 1131
water-soluble vitamins, 1131

More than half of all Americans take vitamin supplements. Recognition of the health benefits of food nutrients dates back 3500 years ago when the Egyptians discovered that eating certain foods such as liver helped night blindness. Today, this nutrient is known as vitamin A. Through subsequent years the relationship of nutrients in food to disease was largely ignored. Many blamed the occurrence of disease on displeased gods, bad air, or witchcraft. Centuries would pass before a connection was made between vitamins and health. This chapter examines the rationales for vitamin and mineral pharmacotherapy.

Role of Vitamins in Health and Disease

61.1 Although the importance of nutrition has been known for centuries, the specific vitamins were discovered in the 1900s.

When ocean voyages became a preferred way of travel in the Renaissance, extended periods onboard a ship often meant limited access to fresh fruits and vegetables. People began to develop scurvy, a disease that causes bleeding of the gums, loss of teeth, ulcers on the lower legs, loss of hair, aching joints, fatigue, depression, hallucinations, blindness, and open wounds with decreased ability to heal. In 1774, James Lind, a Scottish surgeon in the Royal Navy, made a major discovery that saved the lives of many sailors. Lind had surmised that more men died from scurvy than from war injuries. Although he was not the first person to suspect that citrus fruit was important to health, he was the one who performed experiments to address this illness. He divided the affected sailors into groups and added different substances, such as cider, vinegar, barley water, oranges, or lemons, to their diets. Those who ate citrus fruit recovered from scurvy. Lind was ahead of his time because about 40 years passed before authorities accepted the connection between disease and nutrition.

Even in the early 1900s, most people believed that diseases like beriberi and pellagra were infectious processes. Beriberi is now known as a nutritional disease characterized by progressive neuropathy and accompanying dysfunction of the sensory process and an unsteady gait. In the late 1880s, Christiaan Eijkman studied beriberi in the West Indies and determined the cure for beriberi to be rice. He did not understand that it was a specific substance within the rice that caused the cure. In 1905, Dr. William Fletcher observed inmates who had beriberi at a mental asylum and found that ingesting unpolished rice could prevent the disease. This English physician determined that the rice husks contained some substance (thiamine) that treated beriberi. In 1907, Sir Frederick Gowland, an English biochemist, confirmed the positive relationship of food to health. He later joined with Eijkman to win the 1929 Nobel Prize for his work with food nutrients and vitamins. In 1911, a Polish chemist named Casimir Funk coined the term *vitamines*, meaning "nutrients vital for life."

In the 1920s and 1930s, scientists determined that small amounts of specific food substances (vitamins) prevented certain diseases. More than 160 years after Lind's discovery to prevent scurvy, Dr. Albert Szent-Györgyi, a Hungarian researcher, received the Nobel Prize in medicine by isolating and naming vitamin C.

61.2 Vitamins are essential for optimal health.

Today **vitamins** are defined as substances that are required in small amounts for normal growth and nutrition. These naturally occurring organic substances are critical for metabolism as well as regulation of cell function and human growth and development. They contain carbon, are found in living organisms such as plants and animals, and function primarily as catalysts that speed up biochemical processes. Vitamins must be taken into the body from the external environment, usually through the diet, and are not manufactured by the body in adequate amounts to maintain health (with the exception of vitamin D). Lack of sufficient amounts of vitamins results in symptoms of deficiency. People must consume vitamin supplements when their diet is lacking in these necessary nutrients or when they have health conditions that cause vitamin deficiencies. The vitamins and their functions are summarized in Table 61.1.

Vitamins are divided into two basic groups: those that dissolve in water (water soluble) and those that dissolve in lipids (fat soluble). Vitamin C and the B-complex vitamins are the primary **water-soluble vitamins**. This group of vitamins is stored briefly in the body and then excreted in the urine. The body's supply of water-soluble vitamins must be replenished on a daily basis. One exception is B_{12},

Table 61.1 Essential Vitamins

Vitamin	Function(s)	Common Cause(s) of Deficiency
A	Visual pigments, epithelial cells	Prolonged dietary deprivation, particularly when rice is the main food source; pancreatic disease; cirrhosis
B vitamins		
B_1: thiamine	Coenzyme in metabolic reactions, RBC formation	Prolonged dietary deprivation, particularly when rice is the main food source; hyperthyroidism, pregnancy, liver disease, alcoholism
B_2: riboflavin	Coenzyme in oxidation–reduction reactions	Inadequate consumption of milk or animal products, chronic diarrhea, liver disease, alcoholism
B_3: niacin	Coenzyme in oxidation–reduction reactions	Prolonged dietary deprivation, particularly when Indian corn (maize) or millet is the main food source; chronic diarrhea; liver disease; alcoholism
B_6: pyridoxine	Coenzyme in amino acid metabolism and red blood cell (RBC) production	Alcoholism, oral contraceptive use, malabsorption diseases
B_9: folic acid/folate	Coenzyme in amino acid and nucleic acid metabolism	Pregnancy, alcoholism, cancer, oral contraceptive use
B_{12}: cyanocobalamin	Coenzyme in nucleic acid metabolism	Lack of intrinsic factor, inadequate intake of foods with animal origin
C (ascorbic acid)	Coenzyme and antioxidant	Inadequate intake of fruits and vegetables, pregnancy, chronic inflammatory disease, burns, diarrhea, alcoholism
D	Calcium and phosphate metabolism	Low dietary intake, inadequate exposure to sunlight
E	Antioxidant	Prematurity, malabsorption diseases
K	Cofactor in blood clotting	Newborns, liver disease, long-term parenteral nutrition, certain drugs such as cephalosporins and salicylates

which is stored in the liver. In contrast, **fat-soluble vitamins** are stored in the liver and fatty tissue of the human body and need only periodic renewal. Because they are stored and not readily excreted, the possibility of toxicity from overdosing is greater with the fat-soluble group, which includes vitamins A, D, E, and K.

Most people who eat a well-balanced diet receive all the vitamins and minerals they need to maintain proper health. However, many Americans rely on nutrient-poor fast foods and processed edibles as their main diet. Although a healthy diet is the best way to maintain adequate nutrient intake, individual **supplements** are available as an additional way to meet the minimum daily requirements. It is important to remember that vitamin and mineral products should *supplement* a healthy balanced diet; they are not substitutes for good nutrition. Doses for the fat-soluble vitamin supplements are listed in Table 61.2. The water-soluble vitamin doses are listed in Table 61.3.

Regulation of Vitamins

61.3 Government regulations and consumer knowledge about vitamins are limited.

A 2016 survey by the Council for Responsible Nutrition, a Washington-based trade association representing ingredient

Table 61.2 Fat-Soluble Vitamins for Treating Nutritional Disorders

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Vitamin A (Aquasol A)	PO: 100,000 units/day for 3 days, followed by 50,000 units/day for 2 wk; then 10,000–20,000 units/day for 2 months IM: 100,000 units/day for 3 days followed by 50,000 units/day for 2 wk	*Uncommon at recommended doses* High doses: nausea, vomiting, fatigue, irritability, night sweats, alopecia, dry skin
Vitamin D (Calcijex, Rocaltrol)	PO: 0.25 mcg/day (increased for patients with hypoparathyroidism or receiving dialysis); 800–1000 units/day or 50,000 units monthly for severe deficiency	*Uncommon at recommended doses, metallic taste* High doses: nausea, vomiting, fatigue, headache, polyuria, weight loss, hallucinations, dysrhythmias, muscle, and bone pain
Vitamin E (Aquasol E, Vita-Plus E, others)	PO/IM: 60–75 units/day	*Uncommon at recommended doses* High doses: nausea, vomiting, fatigue, headache, blurred vision
Vitamin K (AquaMEPHYTON)	PO/IM/subcutaneous: 2.5–10 mg (max: 25 mcg)	*Facial flushing, pain at the injection site* IV route may result in dyspnea, hypotension, shock, cardiac arrest

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Table 61.3 Water-Soluble Vitamins for Treating Nutritional Disorders

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Vitamin B_1: thiamine	IV/IM: 50–100 mg tid PO: 5–30 mg/day	*Pain at the injection site* IV route may result in angioedema, cyanosis, pulmonary edema, GI bleeding, and cardiovascular collapse
Vitamin B_2: riboflavin	PO: 5–10 mg/day	*Adverse effects have not been reported*
Vitamin B_3: niacin (Niaspan, Nicobid, others)	PO: 100 mg/day for niacin deficiency or 1.5–3g/day for hyperlipidemia	*Uncommon at doses recommended for vitamin therapy* High doses: flushing, rash, diarrhea, hepatotoxicity
Vitamin B_6: pyridoxine (Hexa-Betalin, Nestrex)	PO/IM/IV: 2.5–10 mg/day for 3 wk; then may reduce to 2.5–5 mg/day	*Pain at the injection site* High doses: neuropathy, ataxia, seizures
Vitamin B_9: folic acid/folate (Folvite)	PO/IM/IV/subcutaneous: 0.4–1 mg/day	*Uncommon at recommended doses* Parenteral routes: allergic hypersensitivity
Vitamin B_{12}: cyanocobalamin (Nascobal)	IM/deep subcutaneous: 100–200 mcg/month Intranasal: 500 mcg (1 spray) in one nostril once weekly	*Headache, diarrhea, arthralgia* High doses: thrombosis, hypokalemia, pulmonary edema, heart failure, nasopharyngitis (intranasal route)
Vitamin C: ascorbic acid (Ascorbicap, Cebid, Vita-C, others)	PO/IV/IM/subcutaneous: 150–500 mg/day in 1–2 doses	*Uncommon at recommended doses* High doses: deep vein thrombosis (IV route), crystalluria

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

suppliers and manufacturers in the dietary supplement industry, reported that 170 million U.S. adults (71%) take dietary supplements. The survey confirmed a trend in increased supplement usage among younger adults ages 18 to 34. Eighty-six percent of those surveyed expressed confidence in the safety, effectiveness, and quality of supplements (Council for Responsible Nutrition, 2016).

Most people are unaware that taking too much of a vitamin or mineral can cause serious adverse effects. **Hypervitaminosis**, or toxic levels of vitamins, has been reported for vitamins A, C, D, E, B_6, niacin, and folic acid. In the United States, it is actually more common to observe syndromes of vitamin *excess* than of vitamin *deficiency*.

Consumers may assume that the U.S. Food and Drug Administration (FDA) regulates and approves nutritional supplements, as it does prescription and over-the-counter (OTC) drugs. However, the legislative regulation of supplements is much more limited than that of drugs. The FDA regulates herbal, vitamin, and mineral products as "dietary supplements." In 1994, the Dietary Supplement Health and Education Act required labeling of supplements. In 2007, the FDA passed the "current Good Manufacturing Practice" (cGMP) regulations, which mandated that manufacturers evaluate supplements for purity, strength, and composition (see Chapter 7).

The FDA's Office of Dietary Supplement Programs offers guidelines and tips for consumer safety. The best advice is to be knowledgeable about the purchase and use of supplements. This agency encourages consumers to consult with their healthcare providers before using supplements and to be leery of false claims. Supplements can be expensive, and choosing foods with needed vitamins and minerals is a more natural way to reach nutritional health goals.

PharmFACT

Vitamin toxicity is responsible for over 60,000 calls to poison control centers each year in the United States (Rosenbloom, 2016).

Recommended Dietary Allowance

61.4 The recommended dietary allowance is the dietary intake level that is sufficient to meet the nutrient requirements for most people.

The Food and Nutrition Board of the National Academy of Sciences has established **recommended dietary allowances (RDAs)** for healthy adults. These values represent the minimum amount of vitamins and minerals needed to prevent disease and are based on scientific nutritional research. A newer value, the dietary reference intake (DRI), is based on four parameters: the estimated average requirement, RDA, adequate intake, and tolerable upper intake level.

Although a well-balanced diet provides the necessary vitamins and minerals for most people, the amount of vitamins and minerals needed varies based on certain factors. For example, infants, pregnant women, nursing mothers, older adults, vegans, vegetarians, and those with chronic diseases often require larger amounts of vitamins and minerals to maintain optimal health. Men and women can have different vitamin and mineral needs as do people who participate in vigorous exercise. With normal aging, the absorption of food diminishes and the quantity of ingested food is often reduced, leading to a higher risk of vitamin deficiencies in older adults. Vitamin deficiencies in patients with chronic liver and kidney disease are well documented.

In cases where dietary needs are increased, the RDAs will need adjustment and supplements are indicated to achieve optimal wellness.

Certain drugs have the potential to affect vitamin metabolism. Alcohol is known for its ability to inhibit the absorption of thiamine and folic acid: Alcohol abuse is the most common cause of thiamine deficiency in the United States. Folic acid levels may be reduced in patients who are taking phenothiazines, oral contraceptives, phenytoin (Dilantin), or barbiturates. Vitamin D deficiency can be caused by therapy with certain anticonvulsants. Inhibition of vitamin B_{12} absorption has been reported with a number of drugs, including omeprazole (Prilosec) and metformin (Glucophage), alcohol, and oral contraceptives. Nurses must be aware of these drug interactions and recommend vitamin supplements when appropriate.

Vitamin deficiencies follow certain patterns. The following are general characteristics of vitamin deficiency disorders:

- Patients more commonly present with multiple vitamin deficiencies than with a single vitamin deficiency.
- Symptoms of deficiency are nonspecific and often do not appear until the deficiency has been present for a long period.
- Deficiencies in the United States are most often the result of poverty, fad diets, chronic alcohol or drug abuse, or prolonged parenteral feeding.

Fat-Soluble Vitamins

61.5 Fat-soluble vitamins include vitamins A, D, E, and K.

The fat-soluble vitamins A, D, E, and K are found in fatty foods and oils. Because they are stored in lipid tissue, the body may go several weeks or months with insufficient dietary intake before signs of deficiency are noted. Excessive intake of these vitamins may be harmful.

Vitamin A (Aquasol A)

Therapeutic Effects and Uses: Vitamin A is essential for the normal growth and development of bones and teeth, immune function, integrity of epithelial and mucosal surfaces, and for the synthesis of visual purple necessary for adaptation to the dark. Beta-carotene is a plant pigment that is converted to vitamin A after ingestion of food.

Vitamin A deficiency is rare in the United States; however, certain people have an increased need for the vitamin. Vitamin A replacement therapy is used when metabolic needs are increased such as in pregnancy and during lactation. Vitamin A can be used in replacement therapy for conditions affecting the absorption, mobilization, or storage of vitamin A such as steatorrhea, severe biliary obstruction, liver cirrhosis, or total gastrectomy. Vitamin A has antioxidant properties and can be used as a screening test for fat malabsorption.

CONNECTIONS: Preparing for Advanced Practice

Vitamins during Pregnancy

Case

Ana and her husband, Tyler, were thrilled to find out they were pregnant with their second baby. They had been trying to get pregnant for 3 years. They also have an almost 5-year-old girl, Maddie. While she was trying to conceive, Ana had been eating with pregnancy in mind and had been taking an OTC prenatal supplement daily. When she comes to her first prenatal appointment at 11 weeks, she has mild morning sickness and reports frequent periods of dizziness and shortness of breath with exercise. Her family and medical histories are unremarkable. She reports healthy behaviors, exercising 3 times a week, and refraining from caffeine, tobacco products, and drugs. Her body mass index is 23. She has been a vegan for the past 10 years and is able to verbalize food sources that are rich in iron and high in protein. Her vital signs and physical examination are all normal and the fetal heart tones are strong. Her initial prenatal laboratory tests revealed mild anemia (hematocrit, 33%; hemoglobin, 10.5 g/dL). What additional vitamins does Ana need because she is anemic as well as a vegan?

Discussion

A common practice in prenatal care is for pregnant women to take vitamin supplements containing numerous nutrients. Because birth defects can take place early in pregnancy, taking prenatal vitamins is recommended while the mother is trying to conceive. Vegan diets may be low in vitamin B_{12}, vitamin D, calcium, protein, iron, and iodine. Vegans may need additional folic acid (vitamin B_9), calcium, and iron, which are especially important for pregnant women. Folic acid prevents birth defects such as spina bifida, other neural tube problems, and congenital heart conditions. Consuming adequate amounts of calcium during pregnancy can be challenging for the vegan or vegetarian mother. Supplementation can stop the loss of bone density in the mother as the fetus absorbs calcium for bone growth. Iron is a central component in hemoglobin that carries oxygen for both mother and baby. Anemia can occur with insufficient iron intake and is a common issue for vegans. Iron supplements should be taken separately from calcium-rich food and caffeine because they interfere with iron absorption. Vitamin C enhances the absorption of iron, so the two can be taken concurrently. Because high amounts are extremely toxic, iron supplements should be kept away from children to avoid unintentional poisoning.

Mechanism of Action: As a fat-soluble vitamin, vitamin A acts as a cofactor in the synthesis of mucopolysaccharides, synthesis of cholesterol, and metabolism of steroids. It is easily absorbed through the gastrointestinal (GI) tract with bile salts, pancreatic lipase, and dietary fat, and it is stored in the liver. Small amounts may also be stored in the kidney and body fat. Vitamin A passes to the newborn through breast milk. It is metabolized in the liver and excreted in feces and urine.

Adverse Effects: Adverse effects with vitamin A are uncommon but the healthcare provider should be notified of difficulty breathing; hives; swelling of the lips, face, or tongue; or closing of the throat. Overdose may result in hypervitaminosis syndrome symptoms that include fatigue, nausea, vomiting, decreased appetite, headache, gingivitis, dryness or cracking of the lips or skin, irritability, or loss of hair. Rare adverse effects include increased intracranial pressure, jaundice, leukopenia, anemia, and elevated prothrombin time (PT).

Contraindications/Precautions: Contraindications to vitamin A therapy include a history of sensitivity to vitamin A or to any ingredient in the formulation, or hypervitaminosis. Oral (PO) administration to patients with malabsorption syndrome is also contraindicated. Its safe use in amounts exceeding 6000 international units during pregnancy is not established. Vitamin A may falsely increase serum cholesterol determinations or falsely elevate bilirubin determination.

Drug Interactions: Caution should be used if the patient is taking vitamin A analogs such as isotretinoin because their actions are additive. The patient should consult with the healthcare provider if using mineral oil because this can deplete fat-soluble vitamins. Cholestyramine may decrease the absorption of vitamin A. Oral contraceptives can increase serum levels of vitamin A.

Pregnancy: Category A (at RDA value).

Recommended Intake: **RDA:** 2500 international units for children, 5000 international units for males, and 4000 international units for females. The FDA has mandated that, starting in 2018, vitamin A labels must list units in micrograms (mcg) of retinol activity equivalents (RAEs). The RDA values converted to RAEs are 300–600 mcg/day for children (ages 1–13), 900 mcg/day for males (ages 14 and above), and 700 mcg/day for females (ages 14 and above). Values are 750–770 mcg/day during pregnancy and 1200–1300 mcg/day during lactation.

Nursing Responsibilities: Key nursing implications for patients receiving vitamin A are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Vitamin D (Calcijex, Rocaltrol)

Therapeutic Effects and Uses: Vitamin D maintains normal blood calcium and phosphate electrolyte levels by enhancing their intestinal absorption and by promoting mobilization of calcium from bone and the renal reabsorption of phosphate. This fat-soluble vitamin is necessary to develop and maintain strong bones. Vitamin D is used to treat skeletal diseases that weaken the bones such as familial hypophosphatemia (vitamin D–resistant rickets), osteomalacia (adult rickets), osteoporosis, renal osteodystrophy, and hypocalcemia associated with hypoparathyroidism. Vitamin D is used as prophylaxis for and treatment of nutritional rickets, and hypophosphatemia in Fanconi's syndrome. Sometimes vitamin D is helpful in treating psoriasis, rheumatoid arthritis, and lupus vulgaris. A drug prototype feature for calcitriol, the active form of vitamin D, is included in Chapter 72.

Patients at risk for vitamin D deficiency include breastfed infants; older adults; people with limited sun exposure, dark skin, malabsorption disorders, or gastric bypass surgery; and women who wear head scarves (e.g., hijabs) and body coverings (e.g., burqas) for extended periods of time .

Mechanism of Action: Vitamin D is a fat-soluble vitamin that is found in food and that is also made by the body after exposure to ultraviolet (UV) rays from the sun. Sunlight is a significant source of vitamin D because UV rays trigger vitamin D synthesis in the skin. Vitamin D is readily absorbed from the GI tract and distributed in the lymph. The body stores vitamin D in the liver, skin, brain, spleen, and bones. About half of each vitamin D dose is excreted in bile but it may be stored in tissues for months.

Adverse Effects: Adverse effects of vitamin D therapy are uncommon at therapeutic doses. At higher doses possible adverse effects include fatigue, weakness, dizziness, ataxia, muscle and joint pain, hypotonia (infants), pruritus, headache, drowsiness, photophobia, or convulsions. GI symptoms include anorexia, nausea, vomiting, diarrhea, metallic taste, dry mouth, constipation, and abdominal cramps. Some patients present with anemia. Musculoskeletal symptoms include calcification of soft tissues in the kidneys, myocardium, lungs, or skin. Nephrotoxicity could occur with symptoms such as polyuria, polydipsia, nocturia, albuminuria, hematuria, and kidney failure. Vitamin D is rarely but possibly implicated in hypertension and some cardiac dysrhythmias. Chronic hypervitaminosis with vitamin D can occur in children, resulting in mental and physical retardation or suppression of linear growth.

Contraindications/Precautions: Precaution should be taken in patients with a known hypersensitivity to vitamin D, hypervitaminosis, hypercalcemia, hyperphosphatemia, renal osteodystrophy with hyperphosphatemia,

malabsorption syndrome, or decreased kidney function. Use cautiously in patients with coronary disease, arteriosclerosis (especially in older adults), history of kidney stones, biliary tract disease, or during lactation.

Drug Interactions: Consult with the healthcare provider if using mineral oil because it can deplete the supply of fat-soluble vitamins in the body. Cholestyramine may decrease the absorption of vitamin D. Patients should avoid OTC calcium supplements, other than those prescribed by the healthcare provider, because they may cause hypercalcemia. Oral corticosteroids can reduce calcium absorption and impair vitamin D metabolism.

Pregnancy: Category C. The safe use of vitamin D in amounts exceeding 400 international units (10 mcg) daily during pregnancy has not been established.

Recommended Intake: **RDA:** Children (ages 1 and above), men, and women until age 70 need 600 international units of vitamin D per day. Men and women ages 71 and older need 800 international units per day. The RDA during pregnancy and lactation is 600 international units per day.

Nursing Responsibilities: Key nursing implications for patients receiving vitamin D are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

PharmFACT

Indoor tanning has become increasingly popular with claims that it increases the level of vitamin D. However, most indoor tanning devices use UVA radiation, which is very inefficient at producing vitamin D in the skin (Ernst, Grimm, & Lim, 2015).

Vitamin E (Aquasol E, Vita-Plus E, Others)

Therapeutic Effects and Uses: Vitamin E has many therapeutic uses. It prevents cell membrane and protein damage, protects against blood clot formation by decreasing platelet aggregation, enhances vitamin A utilization, and promotes the normal growth and development and tone of muscles. As an antioxidant, vitamin E prevents the damaging effects of free radicals, which are highly reactive chemical structures that damage cell membranes and alter nuclear proteins. Free radicals are associated with various conditions such as aging and disease.

Vitamin E supplementation can reverse or prevent hemolytic anemia in premature neonates caused by vitamin E deficiency. It is also used to prevent retinopathy associated with vitamin E deficiency in neonates and to treat diseases with secondary erythrocyte membrane abnormalities (e.g., sickle cell disease and G6PD deficiency). Vitamin E is used as a supplement in malabsorption syndromes. Topical vitamin E is used for dry or chapped skin and minor skin disorders.

Vitamin E deficiency is rare. People with lipid-absorption disorders may have deficiencies because fats are required for vitamin E absorption. This includes people who have an inability to secrete bile.

Mechanism of Action: When fat absorption is adequate, 20% to 60% of vitamin E is absorbed across the GI tract. It enters blood through the lymph and is stored in adipose (fat) tissue. Vitamin E is metabolized in the liver and is eliminated primarily in bile. Vitamin E crosses the placenta.

Adverse Effects: No adverse reactions have been found to consuming vitamin E in food. With excessive supplementation, symptoms may include fatigue, headache, skeletal muscle weakness, nausea, diarrhea, intestinal cramps, thrombophlebitis, contact dermatitis, blurred vision, or abnormal bleeding. With toxic levels laboratory tests may reveal increased serum creatine kinase, cholesterol, and triglycerides; decreased serum thyroxine and triiodothyronine; increased urinary estrogens and androgens; and creatinuria.

Contraindications/Precautions: Vitamin E should be used with caution in bleeding disorders and thrombocytopenia or during pregnancy. Vitamin E can prolong the PT by inhibition of vitamin K–dependent clotting factors. Large doses may worsen iron deficiency anemia because it may impair the hematologic response to iron.

Drug Interactions: Mineral oil should be avoided because it can deplete fat-soluble vitamins. Cholestyramine may decrease absorption of vitamin E. Vitamin E may enhance the anticoagulant activity of warfarin.

Pregnancy: Category A (at RDA levels).

Recommended Intake: **RDA:** Although the nutrient requirements for vitamin E have traditionally been listed as international units, the FDA has mandated that this be changed to milligrams (mg) starting in 2018. From ages 1 to 13, the RDA ranges from 6 to 11 mg, and 15 mg for individuals ages 14 through adult. The RDA during pregnancy is 15 mg and during lactation 19 mg.

Nursing Responsibilities: Key nursing implications for patients receiving vitamin E are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Vitamin K (AquaMEPHYTON)

Therapeutic Effects and Uses: Vitamin K promotes the liver synthesis of clotting factors and is used in the

production of red blood cells (RBCs). It helps maintain healthy bones, assists in healing fractures, and minimizes osteoporosis. Vitamin K is the antidote for warfarin overdose. Vitamin K reverses hypoprothrombinemia secondary to the administration of PO antibiotics, quinidine, salicylates, sulfonamides, and excessive vitamin A, and secondary to inadequate absorption and synthesis of vitamin K (as in obstructive jaundice, biliary fistula, ulcerative colitis, intestinal resection, or prolonged hyperalimentation). Vitamin K is used as prophylaxis of and therapy for neonatal hemorrhagic disease.

Most people receive adequate amounts of this vitamin in their diets. Those at risk for deficiency include newborns not treated with vitamin K at birth and those with malabsorption disorders.

Mechanism of Action: The body makes most of its needed vitamin K through bacteria in the GI tract. Phytonadione (also called phylloquinone) is a fat-soluble substance that is chemically identical to naturally occurring vitamin K. It is readily absorbed in the intestinal lymph when bile is present. Vitamin K is essential for the hepatic biosynthesis of blood clotting Factors II, VII, IX, and X. Hemorrhage is usually controlled within 3 to 8 hours, with normal PT obtained in 12 to 14 hours after vitamin K administration. Phytonadione is concentrated briefly in the liver after absorption, crosses the placenta, and is secreted in the breast milk of nursing mothers. It is metabolized quickly in the liver and eliminated in the urine and bile.

Adverse Effects: Reported effects after PO dosing include headache, GI upset, paradoxical hypoprothrombinemia (in patients with severe liver disease), severe hemolytic anemia, hyperbilirubinemia, kernicterus, bronchospasm, and dyspnea. Possible pain at the injection site, hematoma and nodule formation, erythematous skin eruptions (with repeated injections), and peculiar taste sensations may occur. **Black Box Warning:** Severe reactions such as shock, anaphylaxis, and cardiac arrest have occurred when vitamin K is given by the intravenous (IV) or intramuscular (IM) route. These routes should be used only when subcutaneous or oral routes are not feasible.

Contraindications/Precautions: Caution should be used in patients with biliary tract disease, obstructive jaundice, or severe liver disease. Patients should be monitored for hypersensitivity to phytonadione, benzyl alcohol, or castor oil. Some interference may occur with diagnostic tests such as falsely elevated urine steroids.

Drug Interactions: Vitamin K decreases the anticoagulant effects of warfarin. Patients may have decreased absorption with the use of cholestyramine, colestipol, or mineral oil.

Pregnancy: Category C.

Recommended Intake: **RDA:** 30–75 mcg for ages 1–18, and 120 mcg for ages 19 and older. Values for pregnancy and lactation are 75–90 mcg.

Nursing Responsibilities: Key nursing implications for patients receiving vitamin K are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

CONNECTION Checkpoint 61.1

From what you learned in Chapter 38, describe how vitamin K reverses the therapeutic effects of warfarin (Coumadin). *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Water-Soluble Vitamins

61.6 Water-soluble vitamins include the B-complex vitamins and vitamin C.

The water-soluble vitamins are found in rich abundance in fresh fruits and vegetables. Unlike the fat-soluble vitamins, vitamin C and most B-complex vitamins are not stored to any great extent, and signs of deficiency may be noted quickly if they are omitted from the diet. Excessive intake of these vitamins is usually not harmful because they are rapidly excreted.

Thiamine: Vitamin B_1

Therapeutic Effects and Uses: Thiamine (vitamin B_1) functions as an essential coenzyme in the metabolism of carbohydrates and has a role in converting tryptophan to nicotinamide. Thiamine deficiency is called beriberi. Early symptoms of thiamine deficiency include anorexia, weight loss, and nervous system signs such as confusion, memory impairment, and depressed sensory and motor reflex functions. Severe beriberi can lead to heart failure and encephalopathy.

Because of its abundance in food, thiamine deficiency in the United States is uncommon. People at risk for deficiency include those with chronic alcohol dependence, chronic liver disease, human immunodeficiency virus (HIV) infection or diabetes; older adults; and patients following bariatric surgery. Therapy generally includes other members of the B-complex vitamins because thiamine deficiency rarely occurs alone. Thiamine is sometimes used in combination with other B vitamins to reduce depression and anxiety as well as to prevent motion sickness.

Mechanism of Action: Thiamine is necessary for the conversion of carbohydrates to energy and is essential in maintaining the proper functioning of the heart, nervous system, and muscles. Thiamine is absorbed from the GI

tract and widely distributed, and it is secreted in breast milk. This vitamin is eliminated in the urine.

Adverse Effects: Thiamine has few adverse effects. Excessive doses may cause a feeling of warmth, weakness, sweating, restlessness, tightness of the throat, angioneurotic edema, cyanosis, pulmonary edema, cardiovascular collapse, or hypotension after rapid IV administration. Other adverse effects may include GI hemorrhage, nausea, urticaria, and pruritus.

Contraindications/Precautions: There are no contraindications if the dosage is within the RDA.

Drug Interactions: Antibiotics such as erythromycin and azithromycin may decrease thiamine levels by altering intestinal flora.

Pregnancy: Category A; category C if doses are greater than the RDA.

Recommended Intake: **RDA:** 0.5–0.9 mg (children ages 1–13), 1.2 mg (males ages 14 and above), 1.0–1.1 mg (females ages 14 and above), and 1.4 mg during pregnancy and lactation.

Nursing Responsibilities: Key nursing implications for patients receiving thiamine (vitamin B_1) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Riboflavin: Vitamin B_2

Therapeutic Effects and Uses: Vitamin B_2, or riboflavin, is a component of coenzymes that participate in a number of different oxidation–reduction reactions. As with thiamine, a deficiency of riboflavin is most commonly observed in people with chronic alcoholism. Vegetarians, vegans, those who do not drink milk, and pregnant and lactating women are also at risk. Clinical symptoms of deficiency include digestive disturbances, headache, burning sensation of the skin (especially "burning" feet), cracking at the corners of the mouth (cheilosis), glossitis, seborrheic dermatitis (and other skin lesions), mental depression, corneal vascularization (with photophobia, burning and itchy eyes, lacrimation, roughness of eyelids), anemia, and neuropathy. Riboflavin therapy is used to prevent riboflavin deficiency and microcytic anemia and to supplement other B vitamins in the treatment of pellagra and beriberi.

Mechanism of Action: As a component of the flavoprotein enzymes, riboflavin works together with a wide variety of proteins to catalyze many cellular respiratory reactions by which the body derives its energy. The vitamin is readily absorbed from the GI tract. Little riboflavin is stored and excess amounts are excreted in urine.

Adverse Effects: Riboflavin is nontoxic. It may discolor urine bright yellow. In large doses, riboflavin may produce yellow-green fluorescence in urine, which can cause false elevations in certain determinations of urinary catecholamines.

Contraindications/Precautions: Unknown.

Drug Interactions: Unknown.

Pregnancy: Category A; category C if doses exceed the RDA.

Recommended Intake: **RDA:** 0.5–0.9 mg (children ages 1–13), 1.3 mg (males ages 14 and above), 1.0–1.1 mg (females ages 14 and above), and 1.4–1.6 mg (pregnancy and lactation).

Nursing Responsibilities: Key nursing implications for patients receiving riboflavin (vitamin B_2) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Niacin: Vitamin B_3

The primary use for niacin is for the medical management of elevated cholesterol levels in patients at risk for atherosclerotic disease. It may be used as monotherapy or in combination with other antihyperlipidemic drugs. Additional details about niacin are provided in Chapter 29.

Pyridoxine: Vitamin B_6

Therapeutic Effects and Uses: Pyridoxine is a coenzyme that participates in over 100 metabolic reactions in the body, most of them related to protein metabolism. Pyridoxine deficiency in uncommon in the United States and usually occurs concurrently with deficiencies of other B vitamins. Pyridoxine deficiency occurs with inadequate dietary intake due to alcoholism, drug-induced deficiency (e.g., isoniazid [INH], oral contraceptives), and congenital errors of metabolism (vitamin B_6–dependent convulsions or anemia). People with chronic kidney disease (CKD) or autoimmune disorders are also at risk for deficiency. Deficiency symptoms include nausea, vomiting, cheilosis, edema, and central nervous system (CNS) symptoms. Pyridoxine is administered to treat acute toxicity caused by overdosage of cycloserine, hydralazine, or INH; alcoholic polyneuritis; and sideroblastic anemia associated with high serum iron concentration. Pyridoxine has been used to manage many other conditions, including nausea and vomiting in radiation sickness and pregnancy, suppression of postpartum lactation, and diabetes; to decrease the symptoms of premenstrual syndrome (PMS); to minimize joint pain caused by some types of arthritis; and to treat carpal tunnel syndrome.

Mechanism of Action: Pyridoxine is usually available as part of a water-soluble complex of three closely related

compounds with vitamin B_6 activity. Pyridoxine is converted in the body to pyridoxal, a coenzyme that functions in protein, fat, and carbohydrate metabolism and in facilitating the release of glycogen from the liver and muscle. In protein metabolism, pyridoxine participates in many enzymatic transformations of amino acids and in the conversion of tryptophan to niacin and serotonin. It aids in energy transformation in the brain and nerve cells and is thought to stimulate heme production. Pyridoxine is readily absorbed from the GI tract. It is distributed and stored in the liver and crosses the placenta. Metabolism of this vitamin takes place in the liver. Pyridoxine is eliminated in urine.

Adverse Effects: Adverse events are few but the patient could experience paresthesias, slight flushing or feeling of warmth, temporary burning or stinging pain at the injection site, somnolence seizures (particularly following large parenteral doses), low folic acid levels, insomnia, or anxiety.

Contraindications/Precautions: Pyridoxine should be used with caution in patients with CKD, neonatal prematurity with renal impairment, or cardiac disease.

Drug Interactions: Use of INH, cycloserine, penicillamine, hydralazine, and oral contraceptives may increase pyridoxine requirements. This vitamin may reverse or antagonize the therapeutic effects of the antiparkinsonism drug levodopa because it reduces the amount of dopamine entering the brain by facilitating the breakdown of levodopa in peripheral circulation.

Recommended Intake: **RDA:** 0.5–1.0 mg (children ages 1–13), 1.3 mg (males ages 14–50), 1.9 mg (men over 50 years), 1.2–1.5 mg (females ages 14 and above), and 1.9–2.0 mg (pregnancy and lactation).

Pregnancy: Category A; category C if doses exceed the RDA.

Nursing Responsibilities: Key nursing implications for patients receiving pyridoxine (vitamin B_6) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

CONNECTION Checkpoint 61.2

From what you learned in Chapter 51, how does the antitubercular drug isoniazid affect levels of pyridoxine (vitamin B_6)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Folic Acid (Folate): Vitamin B_9

Therapeutic Effects and Uses: Folate and folic acid are forms of vitamin B_9. Folate is the form that is found naturally in food, whereas folic acid is the synthetic form of the vitamin found in supplements. Folate deficiency is rare in the United States. Those at increased risk for deficiency include people with alcohol dependence or malabsorption disorders and women of childbearing age or who are pregnant. Folic acid is used to treat folate deficiency, macrocytic anemia, and megaloblastic anemias, which are associated with inadequate dietary intake, alcoholism, primary liver disease, malabsorption syndromes, pregnancy, infancy, and childhood. Up to 80% of neural tube defects in newborns can be prevented with supplementation of folic acid prior to pregnancy.

Mechanism of Action: Vitamin B_9 is essential for the synthesis of nucleoproteins and the maintenance of RBCs, neurons, and proteins. It stimulates production of RBCs, white blood cells (WBCs), and platelets in patients with megaloblastic anemias. Folic acid counters folic acid deficiency, which can result in the production of defective deoxyribonucleic acid (DNA), leading to megaloblast formation and arrest of bone marrow maturation. Folic acid is readily absorbed in the proximal small intestine, is distributed to all body tissues, crosses the placenta in pregnancy, and is secreted in breast milk in lactating women. It is metabolized in the liver and excreted in urine.

Adverse Effects: The patient may feel warmth or flushing with IV doses. Although rare, the possible adverse effects include irritability, depression, loss of appetite, rash, itching, nausea, or dyspnea.

Contraindications/Precautions: Folic acid should not be used in patients with allergic sensitivity to B vitamins. It should be administered with caution if using folic acid alone to correct pernicious anemia or other vitamin B_{12} deficiency states as well as normocytic, refractory, aplastic, or undiagnosed anemia. Caution should be used with neonates. Folic acid can cause false low serum folate levels in patients who are receiving antibiotics such as tetracyclines.

Drug Interactions: Folic acid inhibitors such as methotrexate can antagonize the effects of folate therapy. Folic acid therapy increases the metabolism of phenytoin (Dilantin), possibly causing increased seizure activity.

Pregnancy: Category A.

Recommended Intake: The recommended intakes for folic acid are based on units called dietary folate equivalents (DFEs). These units reflect the fact that not all folic acid in food is absorbed or bioavailable. **RDA:** 150–300 DFE (children ages 1–13), 300–400 DFE (adults ages 14 and above), and 500–600 DFE (pregnancy and lactation).

Nursing Responsibilities: Key nursing implications for patients receiving folic acid (vitamin B_9) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Cyanocobalamin: Vitamin B_{12}

Therapeutic Effects and Uses: Cyanocobalamin is used to treat vitamin B_{12} deficiency and anemia due to malabsorption syndrome, such as in pernicious anemia; sprue; GI pathology, dysfunction, or surgery; fish tapeworm infestation; and gluten enteropathy. This drug is also used in vitamin B_{12} deficiency caused by increased physiologic requirements or inadequate dietary intake and in the vitamin B_{12} absorption (Schilling) test. It may be used to prevent and treat toxicity associated with sodium nitroprusside, to treat asthma, and possibly to aid in healing following surgery. A prototype drug feature for this vitamin is presented in Chapter 39.

Mechanism of Action: Vitamin B_{12} is a cobalt-containing B-complex vitamin that is essential for normal growth, cell reproduction, maturation of RBCs, synthesis of nucleoproteins, and maintenance of the nervous system (myelin synthesis). It is believed to be involved in protein and carbohydrate metabolism as well. Vitamin B_{12} deficiency results in megaloblastic anemia, dysfunction of the spinal cord with paralysis, and GI lesions. Intestinal absorption requires the presence of intrinsic factor in the terminal ileum. It is widely distributed and is principally stored in the liver, kidneys, and adrenals. It crosses the placenta and is excreted in breast milk. In metabolism this vitamin is converted in the tissues to active coenzymes and is enterohepatically cycled. Vitamin B_{12} is eliminated in urine in 48 hours.

Adverse Effects: Adverse effects are rare but may include the feeling of a swelling body, anaphylactic shock, peripheral vascular thrombosis, pulmonary edema, heart failure, mild transient diarrhea, unmasking of polycythemia vera (with correction of vitamin B_{12} deficiency), hypokalemia, itching, rash, flushing, severe optic nerve atrophy, and sudden death.

Contraindications/Precautions: Contraindications include a history of sensitivity to vitamin B_{12}, other cobalamins, or cobalt; early Leber's disease (hereditary optic nerve atrophy); and indiscriminate use in folic acid deficiency. Caution should be used in patients with heart disease, anemia, or pulmonary disease.

Drug Interactions: Alcohol, aminosalicylic acid, neomycin, and colchicine may decrease the absorption of PO cyanocobalamin. Chloramphenicol may interfere with the therapeutic response to cyanocobalamin.

Pregnancy: Category A; category C (parenteral).

Recommended Intake: **RDA:** 2.4 mcg/day for ages 14 and older, 2.6 mcg/day during pregnancy, and 2.8 mcg/day during lactation. **DRI:** 0.9–1.2 mcg/day for children (ages 1–13) and 2.4 mcg/day for adults (ages 14 and above).

Nursing Responsibilities: Key nursing implications for patients receiving cyanocobalamin (vitamin B_{12}) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Vitamin C: Ascorbic Acid

Therapeutic Effects and Uses: Vitamin C is essential for the synthesis and maintenance of collagen and intercellular ground substance of body tissues, blood vessels, cartilage, bones, teeth, skin, and tendons. It helps maintain the functions of the immune system for improved wound healing and increased resistance to infection. Vitamin C is used for both prophylaxis and treatment of scurvy and as a dietary supplement. Off-label uses include acidification of urine, prevention and treatment of cancer, treatment of idiopathic methemoglobinemia, and use as an adjuvant during deferoxamine therapy for iron toxicity. In megadoses vitamin C may possibly reduce the severity and duration of the common cold. It is used as an antioxidant in formulations of parenteral tetracycline and other drugs.

Mechanism of Action: Vitamin C is readily absorbed and widely distributed to body tissues. It crosses the placenta and is secreted in breast milk. Vitamin C is metabolized in the liver and eliminated rapidly in urine when the plasma level exceeds the renal threshold of 1.4 mg/dL. Unlike most mammals, humans are unable to synthesize ascorbic acid in the body; thus it must be consumed daily.

Adverse Effects: Possible adverse effects from large doses include nausea, vomiting, heartburn, diarrhea or abdominal cramps, acute hemolytic anemia, sickle cell crisis, headache, insomnia, urethritis, dysuria, crystalluria, hyperoxaluria, or hyperuricemia. With rapid IV administration temporary dizziness and soreness at the injection site may occur. Vitamin C may produce false-negative tests for occult blood in stools if taken within 48 to 72 hours of testing.

Contraindications/Precautions: Sodium ascorbate should not be used in patients on sodium restriction; calcium ascorbate is contraindicated in patients who are receiving digoxin (Lanoxin). Excessive doses should be avoided in patients with G6PD deficiency, hemochromatosis, thalassemia, sideroblastic anemia, or sickle cell disease, or in patients prone to gout or renal calculi.

Drug Interactions: Large doses may attenuate the hypoprothrombinemic effects of PO anticoagulants. Aspirin and other salicylates may inhibit ascorbic acid uptake by leukocytes and tissues, and ascorbic acid may decrease elimination of salicylates. Chronic high doses of ascorbic acid may diminish the effects of disulfiram.

Pregnancy: Category C.

Recommended Intake: **RDA:** 60 mg/day. **DRI:** 15–45 mg/day for children (ages 1–14) and 75–90 mg/day for adults (above age 14).

Nursing Responsibilities: Key nursing implications for patients receiving ascorbic acid (vitamin C) are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements.

Minerals

Minerals are essential substances that constitute about 4% of the body's weight and serve many diverse functions. Some are essential ions or electrolytes in body fluids; others are bound to organic molecules such as hemoglobin, phospholipids, or metabolic enzymes. Those minerals that function as critical electrolytes in the body, most notably sodium and potassium, are covered in detail in Chapter 33.

Because minerals are needed in very small amounts for human metabolism, a balanced diet will supply the necessary quantities for most patients. Like vitamins, excess amounts of minerals can lead to toxicity, and patients should be advised not to exceed the recommended doses. Mineral supplements are, however, indicated for certain disorders. Iron deficiency anemia is the most common nutritional deficiency in the world and is a common indication for iron supplements. Women at high risk for osteoporosis are advised to consume extra calcium, either in their diet or as a dietary supplement.

61.7 Macrominerals are inorganic substances needed in amounts of at least 100 mg per day for normal body functioning.

Macrominerals are major inorganic substances that must be consumed daily in amounts of 100 mg or higher. Included in this group are calcium, chloride, magnesium, phosphorus, potassium, sodium, and sulfur. Two of the body's most important minerals affecting fluid and electrolyte balance, sodium and potassium, are presented in Chapter 33, with prototype features for sodium bicarbonate, sodium chloride, and potassium chloride. Each macromineral is listed in Table 61.4 along with its RDA and function. Brief descriptions of some of the common macrominerals and their therapeutic uses are given next.

Calcium: Calcium is primarily stored in the teeth and bones to provide strength. Calcium may also be found in blood, muscle, and in the body fluid between cells. A consistent level of calcium is needed for vital body processes and

Table 61.4 Minerals: RDAs and Functions

Mineral	RDA (adults)	Function
Macrominerals		
Calcium	1.0–1.2 g	Forms bony matrix; regulates nerve conduction and muscle contraction
Chloride	1.8–2.3 g	Major anion in body fluids; part of gastric acid secretion
Magnesium	Men: 400–420 mg Women: 310–320 mg	Cofactor for many enzymes; necessary for normal nerve conduction and muscle contraction
Phosphorus	700 mg	Forms bone matrix; part of ATP and nucleic acids
Potassium	4.7 g	Necessary for normal nerve conduction and muscle contraction; principal cation in intracellular fluid; essential for acid–base and electrolyte balance
Sodium	1.2–1.5 g	Necessary for normal nerve conduction and muscle contraction; principal cation in extracellular fluid; essential for acid–base and electrolyte balance
Sulfur	Not established	Component of proteins, B vitamins, and other critical molecules
Microminerals		
Chromium	20–35 mcg	Potentiates insulin; necessary for proper glucose metabolism
Cobalt	0.1 mcg	Cofactor for vitamin B_{12} and several oxidative enzymes
Copper	900 mcg	Cofactor for hemoglobin synthesis
Fluoride	3–4 mg	Influences tooth structure and possibly affects growth
Iodide	150 mcg	Component of thyroid hormones
Iron	Men: 8 mg Women: 8–18 mg	Component of hemoglobin and some enzymes of oxidative phosphorylation
Manganese	1.8–2.3 mg	Cofactor in some enzymes of lipid, carbohydrate, and protein metabolism
Molybdenum	45 mg	Cofactor for certain enzymes
Selenium	55 mcg	Antioxidant cofactor for certain enzymes
Zinc	5–13 mg	Cofactor for certain enzymes, including carbonic anhydrase; needed for proper protein structure, normal growth, and wound healing

functions such as bone matrix construction, muscle contraction, hormone and enzyme secretion, hemostasis, and nerve conduction. When a calcium deficiency occurs, the patient may become irritable and restless, with muscular cramps, spasms, and cardiac abnormalities. Fractures may result from continued hypocalcemia. Calcium compounds are available for pharmacotherapy in many PO salts such as calcium carbonate, calcium citrate, calcium gluconate, or calcium lactate. IV preparations are administered in severe cases. Calcium salts are featured as a prototype drug for hypocalcemia and osteoporosis in Chapter 72.

Chloride: Chloride is a chemical that the human body needs for metabolism and to maintain acid–base balance. In the CNS the inhibitory actions of certain neurotransmitters rely on the entry of chloride into specific neurons. The amount of chloride in the blood is carefully controlled by the kidneys. Isolated imbalances of chloride are due to fluid, electrolyte, or acid–base imbalances. Chloride imbalances are corrected by treating the underlying pathology.

Magnesium: Magnesium is required for more than 300 biochemical reactions in the body. This mineral helps maintain normal muscle and nerve function, keeps cardiac rhythm steady, supports a healthy immune system, and maintains bone strength. The pharmacologic use of magnesium includes multiple pathologic conditions. For example, magnesium citrate is used for bowel evacuation, as is magnesium hydroxide, which can also be used as an antacid. Magnesium salicylate is used for the relief of pain and inflammation in rheumatoid arthritis. The mineral can also be used as a CNS depressant because magnesium sulfate is frequently used as an anticonvulsant in labor and delivery. Magnesium sulfate is featured as a drug prototype in Chapter 33.

Most recently, magnesium has been used to help regulate blood sugar levels, promote normal blood pressure, and assist in energy metabolism and protein synthesis. The metabolism of magnesium is important to insulin sensitivity and blood pressure regulation. Magnesium deficiency is common in people with diabetes. Several epidemiologic studies indicate that magnesium may play an important role in regulating blood pressure. Furthermore, magnesium assists in the metabolism of carbohydrates and may influence the release and activity of insulin, which is the hormone that helps control blood glucose (sugar) levels.

Phosphorus: Phosphorus, another essential macromineral, binds to calcium to form calcium phosphate in bones. In addition to playing a role in bone structure, phosphorus is a component of protein, adenosine triphosphate (ATP), and nucleic acids. Dietary sources of phosphorus are widely available; thus hypophosphatemia is most often seen in patients with severe malnutrition, intestinal malabsorption disorders, or kidney impairment that results in excess phosphorus loss in the urine. When serum phosphorus levels fall below 1.5 mEq/L, phosphate supplements are usually administered. Sodium phosphate and potassium phosphate are available for treating phosphorus deficiencies.

61.8 Microminerals are inorganic substances needed in amounts of at least 20 mg per day for normal body functioning.

Commonly called trace minerals, the **microminerals** are required daily in amounts of 20 mg or less. Although they are needed in minute amounts, their functions should not be underestimated. Profound illness may result with deficits of some of the microminerals. Each micromineral is listed in Table 61.4 along with its RDA and function. Brief descriptions of some of the common microminerals and their therapeutic uses are given next.

Fluoride: Fluoride, a trace mineral, is best known as the mineral that is helpful for bone and teeth health. Dental professionals may apply concentrated fluoride topically to the teeth to prevent cavities, especially in children. Many cities have added fluoride to the municipal water supply to improve dental health. Because high amounts of fluoride can be quite toxic to children, the use of fluoride-containing products should be closely monitored.

Iodide: Iodide is a micromineral needed to synthesize thyroid hormone. The most common source of dietary iodide is iodized salt. When dietary intake of iodide is low, hypothyroidism occurs and enlargement of the thyroid gland results. At high concentrations iodide suppresses thyroid function. Lugol's solution, a mixture containing 5% elemental iodine and 10% potassium iodide, is given to patients with hyperthyroid prior to thyroidectomy or during a thyrotoxic crisis. Sodium iodide is a drug that acts by rapidly suppressing the secretion of thyroid hormone and is indicated for patients who are having an acute thyroid crisis. Radioactive iodine (^{131}I) is given to destroy overactive thyroid glands (see Chapter 67). As an expectorant, the iodine ion increases mucous secretion formation in the bronchi and decreases viscosity of the mucus. Iodine salts such as iothalamate and diatrizoate are very dense and serve as diagnostic contrast agents in radiologic procedures of the urinary and cardiovascular systems.

Iron: Iron is essential to normal human physiology as an integral part of many proteins and enzymes that maintain good health. Iron is an essential component of proteins involved in oxygen transport; a deficiency limits oxygen delivery to cells, resulting in fatigue, poor work performance, and decreased immune function. It is also essential for the regulation of cell growth and differentiation. Dietary sources include meat, shellfish, nuts, and legumes.

Iron can be supplemented using various pharmacologic preparations, which often have ascorbic acid added to improve the absorption of PO iron. Generally, iron supplementation therapy is a PO therapy, and parenteral IV or IM iron therapy is given only when absorption is seriously compromised by illnesses or when the patient cannot swallow. A prototype drug feature for ferrous sulfate is presented in Chapter 39.

Zinc: Zinc is found in at least 100 enzymes and has a role in regulating nucleic acid synthesis as well as wound healing, bone formation, cell-mediated immunity, and male fertility. Sources of zinc include protein foods, beans, lentils, nuts, seeds, and whole-grain cereals. Zinc sulfate, zinc acetate, and zinc gluconate are available to prevent and treat deficiency states at doses of 60 to 120 mg/day. Lozenges that contain zinc can be purchased OTC for treating sore throats and cold symptoms.

Those at highest risk for zinc insufficiency include vegetarians, pregnant and lactating women, patients with alcohol dependence, older infants who are exclusively breastfed, and people with GI disorders.

CONNECTION Checkpoint 61.3

From what you learned in Chapter 39, what are the most common adverse effects experienced by patients taking iron salts such as ferrous sulfate by the oral route? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Vitamin or Mineral Supplements

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, neurologic, endocrine, hepatic, or renal disease. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations, alcohol use, or smoking. Be alert to possible drug interactions.
- Obtain a history of any current symptoms that may indicate vitamin deficiencies or hypervitaminosis (e.g., dry itchy skin, alopecia, sore and reddened gums or tongue, tendency to bleed easily or excessive bruising, nausea or vomiting, or excessive fatigue).
- Obtain a dietary history, noting adequacy of essential vitamins, minerals, and nutrients obtained from food sources.
- Note sunscreen use and amount of sun exposure.
- Obtain baseline weight and vital signs.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, hepatic and renal function studies, and ferritin and iron levels).
- Assess the patient's ability to receive and understand instructions. Include family or caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects dependent on the reason for the drug (e.g., symptoms of deficiency are diminished or absent).
- Continue monitoring vital signs and periodic laboratory values as appropriate.
- Assess for and promptly report adverse effects: nausea, vomiting, excessive fatigue, tachycardia, palpitations, hypotension, constipation, drowsiness, dizziness, disorientation, hyperreflexia, and electrolyte imbalances.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Treat the cause: If a definitive cause of vitamin or mineral deficiency is identified, correct the deficiency using natural sources of the nutrient where possible. Encourage an adequate diet to ensure sufficient intake of essential nutrients is enhanced. (The dietary history can assist in determining the cause of the symptoms and the adequacy of the patient's current diet to correct the deficiency. Natural food sources provide additional nutrients, fiber, and essential requirements not found in vitamin and mineral supplementation.)	• Review the dietary history with the patient and discuss food source options for correcting any deficiencies. Encourage the patient to adopt a healthy lifestyle of increased variety in the diet and limited or eliminated alcohol consumption. Provide for dietitian consultation as needed. • Assist the patient, family, or caregiver to become educated consumers, aware of the marketing of supplements that may not be required if diet is adequate. Provide educational pamphlets or web-based references to reputable sources as needed (e.g., NIH Office of Dietary Supplements).
Minimizing adverse effects: • Review the dietary and supplement history to correct any existing possibility for hypervitaminosis and adverse drug effects. (In the United States, hypervitaminosis from excessive vitamin and mineral intake is more common than deficiencies for most nutrients. Excessive intake of vitamins A, C, D, E, B_6, niacin, and folic acid may cause toxic effects.)	• Discuss the need for nutritional supplements if a normal diet is unable to supply these or if disease conditions (e.g., pernicious anemia) prevent absorption or utilization. • Discourage the overuse of supplementation and provide information on adverse effects and symptoms related to hypervitaminosis to watch for and report.
• Continue to monitor periodic laboratory work as needed. (Laboratory tests appropriate to the condition, e.g., pernicious anemia and hemoglobin [Hgb] and hematocrit [Hct] levels, will help to ensure that therapeutic effects are met. With mineral replacement, electrolytes should return to, and maintain, normal levels.)	• Instruct the patient on the need to return periodically for laboratory work.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor the use of fat-soluble vitamins (A, D, E, and K). Excessive intake may lead to toxic effects. (Fat-soluble vitamins are stored in the body and may accumulate and result in toxic levels. Monitor liver function studies and for symptoms such as nausea, vomiting, headache, fatigue, dry and itchy skin, blurred vision, or palpitations. Report any symptoms immediately.)	• Instruct the patient not to take additional or large amounts of fat-soluble vitamins unless instructed by the healthcare provider. • Encourage the patient to obtain fat-soluble vitamins from natural sources through a balanced diet whenever possible.
• Assess for pregnancy or the possibility of pregnancy. Assess storage availability for any prenatal vitamins kept in the house. (Folic acid supplementation has been demonstrated to reduce the incidence of neurologic birth defects, and adequate folic acid intake should begin ideally before conception. Excessive vitamin intake may have deleterious effects on the developing fetus and prenatal vitamin use should be monitored by the healthcare provider. Poisonings with vitamins and iron are common in children.)	• Provide education to women of childbearing age pertaining to folic acid and its potential usefulness in preventing neurologic-related birth defects. Encourage adequate intake of vitamin and folic acid–rich foods (e.g., fortified and enriched grains, cereals and bread, spinach, and liver) *prior* to conception. • Instruct the patient to keep prenatal vitamins in a secure location if young children are in the household to prevent unintentional ingestion and poisonings.
• Ensure adequate hydration if large doses of water-soluble vitamins are taken. (Water-soluble vitamins are not stored in the body but are excreted. Large doses of vitamins, particularly vitamin C, may cause adverse effects such as renal calculi.)	• Encourage the patient to increase fluid intake to 2 L/day, divided throughout the day.
• Monitor the use of mineral supplements. Excessive intake may lead to toxic effects. (Mineral toxicity is rare but may occur with excessive intake or underexcretion. Symptoms similar to Parkinson's disease, anemia, cirrhosis, dermatologic effects, hyper- or hypothyroidism, hair loss, or peripheral neuritis may signal mineral toxicity and should be reported to the provider for further testing.)	• Encourage the patient to obtain trace minerals from natural sources such as are found in a well-balanced, varied diet containing both locally grown and other produce. • Instruct the patient to consult the provider before taking large doses of any trace mineral and to report any unusual symptoms for further follow-up testing.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken with additional fluids. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 61

Key Concepts Summary

61.1 Although the importance of nutrition has been known for centuries, the specific vitamins were discovered in the 1900s.

61.2 Vitamins are essential for optimal health.

61.3 Government regulations and consumer knowledge about vitamins are limited.

61.4 The recommended dietary allowance is the dietary intake level that is sufficient to meet the nutrient requirements for most people.

61.5 Fat-soluble vitamins include vitamins A, D, E, and K.

61.6 Water-soluble vitamins include the B-complex vitamins and vitamin C.

61.7 Macrominerals are inorganic substances needed in amounts of at least 100 mg per day for normal body functioning.

61.8 Microminerals are inorganic substances needed in amounts of at least 20 mg per day for normal body functioning.

CASE STUDY: Making the Patient Connection

Remember the patient "Charlene Garrett" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Charlene Garrett is a 32-year-old mother of a 1-year-old baby girl. She returned to work part time 3 months ago as a special-education instructor working with a group of preschoolers with special needs. Her husband watches their daughter two evenings a week so that Charlene can resume work toward a master's degree in special education at the local university.

Lately Charlene has begun feeling more stressed and tired. It is almost the end of the semester and papers are due; the holidays arrive in another month and both sides of the family will be coming to visit; and they have delayed celebrating the baby's birthday this month so that the families can enjoy the celebration when they visit.

Charlene lives next door and asks you, a nurse and the "reference for the neighborhood," about vitamin therapy to help her through this stressful period and to increase her energy level. She tells you that she still has some prenatal vitamins and wonders if she should take them.

Critical Thinking Questions

1. What other assessment data might you want to gather from Charlene before recommending vitamin therapy?
2. Should Charlene take the prenatal vitamins? Why or why not?
3. What other recommendations would you give to Charlene regarding vitamin therapy?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Jerrod is a 16-year-old Hispanic youth with moderate to severe developmental disabilities and mental retardation. He is cared for by his mother in their home. Jerrod has been admitted for possible seizure activity after his mother reported that he began atypical twitching and jerking of the extremities. The mother reports that Jerrod was unresponsive to her commands throughout the episode, which lasted approximately 4 to 5 minutes.

On further questioning, Jerrod's mother discloses that until approximately 6 months ago he attended a day care center for individuals with disabilities. However, due to his increased unpredictable irritability and combative behavior, his mother feared Jerrod venturing outside of the home. Typically, Jerrod spends his days watching television in a dark room or staring endlessly at a fish tank. Additionally, Jerrod is extremely selective about food intake and refuses to consume any dairy products, eggs, fish, or cereals. His daily intake consists mostly of chicken tenders and French fries.

1. One notable laboratory finding is Jerrod's elevated calcium and phosphate levels. What vitamin deficiency is most likely present given these findings and the patient's previous history?
2. What adverse effects should you monitor in Jerrod once the vitamin supplement therapy is initiated?
3. What environmental changes would you recommend to Jerrod's caregivers?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A healthcare provider has ordered oral vitamin A (Aquasol A) supplements for a patient. The level of vitamin A may be increased if the patient is also taking:
    1. Vitamins D and E.
    2. Oral contraceptives.
    3. Mineral oil.
    4. Antibiotics.
2. Vitamin C (ascorbic acid) may cause a false-negative result in _____ if taken within 48 to 72 hours of testing.
3. Pyridoxine (vitamin B_6) may cause antagonistic drug effects for the patient taking:
    1. Isoniazid (INH).
    2. Oral contraceptives.
    3. Hydralazine (Apresoline).
    4. Antiparkinsonism drugs.

4. The nurse is teaching the patient about the need for adequate intake of zinc in the diet. The nurse will teach the patient to increase consumption of:
   1. Protein foods such as beans, lentils, and nuts.
   2. Vegetables such as leafy greens, carrots, and squash.
   3. Citrus such as grapefruit, oranges, and lemons.
   4. Cruciferous vegetables such as broccoli, cauliflower, and Brussels sprouts.

5. A nurse should anticipate the administration of vitamin K (AquaMEPHYTON) for which of the following patients? (Select all that apply.)
   1. A newborn infant
   2. The patient with visual disturbances
   3. The patient who received an overdose of certain oral anticoagulants
   4. The patient with hypothyroidism
   5. A teenager with chronic acne

6. The nurse would suspect a calcium deficiency in the patient exhibiting:
   1. Night blindness.
   2. Anemia.
   3. Muscle cramping and spasms.
   4. Bleeding abnormalities.

See Answers to Chapter Review in Appendix A.

Chapter 62
Enteral and Parenteral Nutrition

Chapter Outline

- Enteral Nutrition
  - Enteral Formulations
  - Elements of Enteral Nutrition
  - Complications of Enteral Therapy
  - Drug and Food Interactions
- Parenteral Nutrition
  - Components of Total Parenteral Nutrition Solutions
  - Complications of Parenteral Therapy
  - Drug and Food Interactions

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify conditions that may benefit from parenteral or enteral nutrition.
2. Compare and contrast enteral and parenteral methods of nutrition.
3. Distinguish among polymeric, elemental, semielemental, and modular formulas for enteral nutrition.
4. Identify the basic classes of nutrients contained in enteral formulas and their functions.
5. Identify the possible complications and adverse effects of enteral nutrition administration.
6. Describe the types of drug interactions that can occur when enteral nutrition formulas are given.
7. Explain the differences between delivering parenteral nutrition through a peripheral line versus a central line.
8. Describe the components of total parenteral nutrition solutions and the function of each element in attaining the body's daily requirements.
9. Describe the possible complications of parenteral nutrition therapy.
10. Identify drugs that may be incompatible with parenteral nutrition solutions.
11. Apply the nursing process to care for patients receiving enteral or parenteral nutrition.

Key Terms

elemental (monomeric) formulas, 1149
enteral nutrition (EN), 1148
modular formulas, 1149
parenteral nutrition, 1148
partial parenteral nutrition, 1152
peripheral parenteral nutrition (PPN), 1152
polymeric formulas, 1149
refeeding syndrome, 1151
semielemental (oligomeric) formulas, 1149
total parenteral nutrition (TPN), 1152

To maintain good health and to allow healing during periods of illness, the body needs to receive various nutrients in predetermined amounts or in combinations. The intake of sufficient amounts of amino acids (proteins), carbohydrates, fats, vitamins, and minerals can often be achieved by eating a well-balanced diet of foods and fluids. In some circumstances, however, the daily nutritional needs of the body may require supplementation. Furthermore, certain diseases and conditions prevent feeding by the normal oral (PO) route. This chapter examines the methods and types of products available for providing enteral and parenteral nutrition.

62.1 Nutritional supplementation is required for patients with certain medical conditions.

Ensuring that patients have the necessary nutritional intake for proper health and wellness is a primary responsibility of the nurse. This responsibility extends to all patients, regardless of age, condition, or disease status. Although healthy patients can maintain their required caloric and nutritional requirements by eating a balanced diet, certain disease states, such as the following, may require nutritional intervention:

- Severe infections, such as human immunodeficiency virus (HIV)
- States of malnutrition
- Bowel rest for inflammatory bowel disease and disorders of the gastrointestinal (GI) tract
- Coma
- Postsurgical complications
- Major burns and trauma
- Neuromuscular and central nervous system disorders
- Advanced age or premature birth
- Eating disorders
- Cancer-related chemotherapy or radiation therapy.

Although mechanical causes such as the inability to chew or swallow properly may limit caloric or nutritional intake, psychologic and social reasons also play a role in inadequate nutrition. For example, stress related to a hospitalization may alter a patient's normal eating habits or regimen. Unfamiliar foods and generalized malaise or fear associated with a patient's medical condition may also result in a decreased appetite. For the older patient, ill-fitting dentures or issues with dysphagia may lead to nutritional deficits. Younger patients may be on a fad diet with limited intake of specific nutrients or may engage in activities related to bulimia or anorexia.

Clinical nutritional support is utilized in all settings, including hospitals and extended or long-term care facilities, as well as in the individual patient's home. Pediatric patients are now provided various forms of nutritional support by specially trained providers at day care facilities and schools.

Malnutrition in hospitalized patients or residents of nursing homes may present as dry, flaky skin and hair loss. More serious complications of malnutrition may include delayed wound healing, muscle atrophy, impaired immune function, infection, and even death. Secondary complications may include peripheral edema caused by a reduction in plasma proteins and a decreased oncotic pressure.

62.2 Supplemental nutrition may be provided by the oral or parenteral route.

Two basic routes are used to administer nutritional support: enteral and parenteral. **Enteral nutrition (EN)** is used for patients who have a functioning GI tract but are unable to orally ingest an adequate amount of nutrients to meet their metabolic needs. **Parenteral nutrition** involves the administration of high-caloric nutrients via a central vein, such as the subclavian vein.

Before initiating any form of nutritional support therapy, the medical team of healthcare providers, dietitians, and nurses must thoroughly evaluate the patient and determine which is the best method of treatment. It is also important to examine which route of nutritional support will achieve the desired optimal result. Areas that must be addressed include the amount of weight lost by the patient, the percentage of meals consumed, the patient's albumin level, and the patient's overall health and appearance. Other factors to consider when planning nutritional support are the patient's primary diagnosis, the ability to swallow, any anticipated diagnostic testing and treatments (e.g., nothing by mouth [NPO] for more than 3 days), and the overall prognosis. Socioeconomic factors of convenience, feasibility, and cost play a role in the decision-making process as well.

Enteral Nutrition

62.3 Various methods are utilized to administer enteral feedings to the patient.

Enteral nutrition includes products that are administered via the GI tract, either PO or through a feeding tube. When the patient's condition permits, EN is best administered by the PO route. Administering nutrition this way allows the natural digestive process to occur and requires less direct nursing supervision. Oral administration requires cooperation of the patient to adhere to the feeding regimen and an ability to safely swallow substances.

If the patient is unable to swallow properly, a feeding tube is passed either through the nose to the GI tract or surgically inserted directly into the stomach or small intestine. A nasogastric (nose to stomach) tube is more commonly used for short-term therapy and is often inserted by the nurse. If the patient displays symptoms of decreased gastric motility, a nasoduodenal or nasojejunal tube may be inserted by the healthcare provider. If therapy is expected to last longer than 4 weeks, surgical or percutaneous endoscopic insertion of a gastrostomy or jejunostomy tube may be appropriate. A percutaneous endoscopic gastrostomy (PEG) tube remains the preferred route for long-term therapy and is usually better tolerated than a nasogastric tube.

An advantage of providing nutritional support via a feeding tube is that the amount of enteral solution can be precisely controlled and measured, and calories can be recorded. Contraindications to total enteral nutrition include peritonitis, intestinal obstruction, intractable vomiting, paralytic ileus, intractable diarrhea, and GI ischemia.

Enteral Formulations

62.4 Several types of liquid nutrition formulas are commercially available for enteral feedings.

Enteral solutions differ according to the various nutrients, the caloric values, and the osmolality of the solutions. The four basic groups of solutions for EN are as follows:

- **Polymeric formulas** contain various mixtures of intact proteins, lipids, and carbohydrates and are considered the most common type of enteral preparation. Typical composition includes 30% fat, 50% to 55% carbohydrate, and 15% to 20% protein. These formulas are used for patients who are generally undernourished but have a fully functioning GI tract. Polymeric formulas include blenderized diets and meal replacement formulas. Blenderized diets are generally high-residue, highly viscous products. Meal replacement formulas are either milk based or lactose free. These preparations are nutritionally complete, generally meet the recommended dietary allowance (RDA) for vitamins and minerals (see Chapter 61), and are palatable for oral ingestion. Examples include Osmolite and Promote.
- **Elemental (monomeric) formulas** include products that are usually lactose free and contain only a small percentage (1–3%) of calories from fats. The nutrient building blocks are broken down into small subunits (such as individual amino acids) that are able to be absorbed without the aid of digestive enzymes. These formulas are used for patients who have malabsorption disorders. Examples include Criticare HN and Vivonex T.E.N.
- **Semielemental (oligomeric) formulas** contain slightly larger molecules than those in elemental products, such as small peptides that require little or no digestion and are easily absorbed into the body. They contain a higher percentage of fats than elemental products but they are in the form of medium-chain triglycerides (MCTs) that can be directly absorbed by the intestine without digestive enzymes or bile salts. They are used in patients with digestive disorders such as malabsorption syndrome, partial bowel obstruction, inflammatory bowel disease, short bowel syndrome, bowel fistulas, and antibiotic- or radiation-induced intestinal damage. Because there is little stimulation of digestive secretions, these products are also useful for patients with chronic pancreatitis. Oligomeric formulas are more expensive than polymeric preparations, with the main caloric source coming from carbohydrates. They are usually low in fat, which allows for rapid gastric emptying, and many of these preparations are designed for administration directly into the intestines. Flavor packets are available to improve the taste, but they are generally unpalatable and best suited for tube feedings. Examples of oligomeric products include Pepti-2000, Vital HN, Peptamen, and Subdue.
- **Modular formulas** or disease-specific supplements contain nutrients that are designed to meet a specific nutrient deficiency or disease state. For example, protein modules can be utilized to meet the extra nitrogen needs of patients with burns or severe trauma. Other conditions include chronic kidney disease (CKD), hepatic failure, pulmonary disease, and a specific genetic enzyme deficiency. They are not designed to meet 100% of a patient's nutritional needs.

Elements of Enteral Nutrition

62.5 Most enteral nutrition formulas contain four basic classes of nutrients.

There are many different enteral products, each containing various amounts of nutritional substances. The four basic nutrient classes and their functions are discussed next.

Carbohydrates: Carbohydrates are the major source of energy in the diet and function to spare body protein, prevent ketosis, and regulate blood glucose levels. Carbohydrate sources in enteral formulas must be soluble, digestible, and have a low osmolality. Commonly used sources of carbohydrates include corn syrup solids, hydrolyzed corn starch, maltodextrin, and other glucose polymers. Some special formulas include various types of fiber, fructose, and fructo-oligosaccharides. Simple sugars, such as sucrose, glucose, dextrose, and lactose, enhance the palatability of the oral preparations but increase the product's osmolality. These simple sugars retain water in the intestinal tract and can therefore promote diarrhea in the patient. The percentage of total calories derived from carbohydrates varies from 30% to 90%, depending on the particular preparation and the specific condition it was designed to treat. Most available EN products do not contain lactose and thus should not pose a problem for patients experiencing lactose intolerance.

Proteins: Proteins are essential to the diet because they support cellular growth as well as maintain and repair body tissues. They may be delivered as intact proteins, partially digested (hydrolyzed) proteins, or free amino acids. The selection of a particular protein product is based on the patient's medical condition and his or her ability to absorb the protein. Soy protein and caseinates are common sources of intact proteins and are found in polymeric formulas. Oligomeric formulas contain enzymatically hydrolyzed casein or whey. Elemental formulas contain free amino acids. Proteins may make up approximately 4% to 32% of the total calories of enteral formulas, depending on the specific product. Products that are designed for patients with CKD may contain no protein, whereas patients who are receiving immune-enhancing formulas may receive as much as 80 g of protein per 1000 kcal.

Lipids: Lipids provide an isotonic, high-caloric source of energy for the body. Soybean and corn oil are common lipid sources, and canola and safflower oils are also available. Long-chain triglycerides provide essential fatty acids, limit the osmolality, and enhance the palatability of the product. The fat content of the enteral product can vary from 1% to 55% of the total calories. Products that are designed for patients with glucose intolerance or pulmonary disease are generally high in fat, whereas products that are designed for patients with intestinal malabsorption contain lower amounts of total fat.

Other nutrients: Most commercially prepared enteral formulas are fortified with vitamins and minerals. When given in adequate volume, they provide most of the elements needed to maintain body functioning. However, the volume required to provide the RDA varies greatly among the numerous products available to the consumer. Fiber such as cellulose and pectin is added to enteral formulas to improve stool consistency but can create complications in patients who are fluid restricted or have delayed GI motility. Because most enteral formulas do not provide enough water in solution to maintain adequate hydration, additional free water (water without solutes) is needed to meet the minimum fluid requirements.

Complications of Enteral Therapy

62.6 Total enteral nutrition can predispose the patient to various complications.

Total enteral nutrition therapy poses a risk of mechanical complications such as aspiration, gastroesophageal reflux, diarrhea, metabolic and electrolyte disturbances, and procedural-related problems, such as tube clogging, migration, and dislodgment. Localized infections and sepsis are also potential problems during treatment. The most serious complications are related to potential electrolyte or fluid imbalances from the tube feeding solution or lack of supplementation, or to mechanical complications such as aspiration and nasal or esophageal irritation and damage.

Aspiration: The most serious potential complication for patients receiving enteral feedings is tracheobronchial aspiration of gastric contents. Symptoms of aspiration may include dyspnea, tachypnea, wheezing, rales, tachycardia, agitation, and cyanosis. Aspiration of a small amount of enteral formula may not produce immediate symptoms, but a subsequent fever may suggest the development of aspiration pneumonia. The risk for aspiration is increased if the patient is fed while lying flat or if the patient is unconscious. The head of the bed should be elevated at least 30 degrees during the administration of the feeding and should remain elevated for at least 30 minutes after the feeding. The nurse should check for gastric residual volume by gently aspirating the stomach contents before administering the next feeding, or every 4 to 6 hours if the patient is on a continuous infusion. Other risk factors for aspiration include a diminished gag reflex, neurologic injury, gastroesophageal reflux, and the use of large-bore feeding tubes.

Nausea and vomiting: A small percentage of patients who receive enteral tube feedings experience nausea and vomiting, which increase the risk of aspiration. The most common cause for this problem is delayed gastric emptying. If this cause is suspected, the following steps should be considered:

- Reduce the doses of opioid or other medications that slow GI motility.
- Switch to a low-fat preparation.
- Administer the feeding at room temperature.
- Reduce the rate of administration.

- Administer a promotility medication such as metoclopramide (Reglan).
- Consider antiemetic medications if gastric residues are low yet nausea persists.

Diarrhea: One of the major problems in patients who require tube feeding is diarrhea, which is commonly due to the rapid administration of the feeding, high-caloric solutions, or bacterial contamination of the feeding formula or equipment. A patient who develops diarrhea while receiving EN should be evaluated for *Clostridium difficile*, which usually results secondary to antibiotic therapy. Drugs that contain magnesium, such as antacids, may contribute to the problem of diarrhea, as well as drugs containing sorbitol, liquid cimetidine (Tagamet), and various multivitamin preparations. Diarrhea frequently coincides with the initiation of the enteral treatments because many of the medications that had been given by the intravenous (IV) route are changed to the PO route when enteral feeding is begun. If diarrhea develops during enteral therapy, the following should be considered:

- Add fiber, such as psyllium (see Chapter 60).
- Switch to a formula containing fiber.
- Decrease the rate of infusion.
- Dilute the solution.
- Administer an antidiarrheal drug.
- If *C. difficile* is confirmed, administer an appropriate antibiotic.

Metabolic complications: **Refeeding syndrome** can occur when nutritional support, including EN therapy, is introduced to severely malnourished patients. This syndrome consists of metabolic complications, such as dehydration, electrolyte imbalances, and hyperglycemia. In severe cases, nervous system complications such as confusion, seizures, and coma may occur.

Careful monitoring can minimize or prevent metabolic complications. To prevent refeeding syndrome, those at high risk should first be identified, including patients with anorexia nervosa, kwashiorkor, chronic alcohol abuse, prolonged fasting, and prolonged IV hydration. Any electrolyte abnormalities should be corrected before starting nutritional support therapy, and vital signs, intake and output (I&O), and laboratory values should all be carefully monitored.

Clogged feeding tube: Tube clogging is more likely to occur with the use of intact protein and highly viscous products. Routine flushing of the feeding tube with 20 to 30 mL of warm water every 4 hours during continuous feedings and before and after each intermittent feeding and drug administration can prevent most clogs. Aseptic technique should be utilized in order to minimize formula contamination, and extreme care should be maintained when administering medications via the feeding tube (Table 62.1).

Various methods are used to unclog a blocked feeding tube. The first is to instill warm water via a syringe, using slight manual pressure. If this fails, a sodium bicarbonate solution may be instilled in order to break down the clog. Pancrelipase (Creon, Pancreaze, Zenpep) crushed and instilled along with the sodium bicarbonate solution and left in place up to an hour may also break down the clog. These techniques may be repeated two to three times. If the tube remains clogged, the primary healthcare provider should be contacted.

Interrupted infusions: In the hospitalized patient, EN is sometimes interrupted for various diagnostic tests and procedures. These may include feedings held due to drug–food incompatibilities, hemodialysis treatment, "NPO after midnight" orders for surgery or procedures, physical

Table 62.1 Drug Administration Guidelines with Enteral Feedings

The following are guidelines for administering medications to patients who are receiving enteral nutrition:
• If the patient is able to take medications by mouth, the PO route is preferred over administration through the tube.
• Alternate routes of administration (IV, intramuscular [IM], rectal, sublingual, or transdermal) should be considered for certain medications that cannot be crushed, are not available in liquid form, or which repeatedly clog or block the tubing.
• Sterile technique is usually not required when administering enteral feedings or medications. Sterile technique, however, may be required for severely immunocompromised patients.
• Check the compatibility of the medication with the tube feeding formula first before administering it through the tube.
• If a tablet is to be administered through the feeding tube, check with the pharmacist first to make sure that crushing the medication will not alter its effectiveness. Then crush the tablet into a fine powder and mix it with warm water before administering. Enteric-coated drugs are never crushed and alternative formulations or a different drug may need to be ordered.
• For individual doses of most medications, the tube should be flushed with at least 30 mL of water before and after administration. This will clear the tube for the drug delivery, facilitate the transport of the drug to the intestine, and indicate if the tube is patent.
• When several medications are to be administered, all medications should be given separately and the feeding tube flushed with at least 5 mL of water after each one.
• Most drugs in elixir form are hypertonic. Highly concentrated drug solutions or suspensions should be diluted with at least 60 mL of water before administration in order to decrease gastric mucosal irritation and to prevent osmotic diarrhea.
• Medications should never be added directly to the feeding formula. This may result in a decrease in the potency of the medication as well as a decrease in the stability of the feeding formula.
• For most medications enteral feedings should be stopped for at least 15 min before and after the administration of a drug.

or occupational therapy sessions, transportation from the unit, or GI intolerance (diarrhea, nausea, vomiting). When frequent interruptions are expected, recalculating the goal flow rate on a 22- or 23-hour basis instead of 24 hours may be more practical.

Drug and Food Interactions

62.7 Most medications that are administered orally can also be delivered to the patient via an enteral tube.

Medications that are delivered via an enteral tube must be in a liquid form (elixir or suspension), or finely crushed and dissolved in a liquid vehicle. Drugs that must not be crushed or dissolved are enteric-coated pills, time release forms, sublingual medications, and bulk-forming laxatives. If a tablet must be administered through the feeding tube, the nurse should check with the pharmacist to make sure that crushing the medication will not alter its effectiveness.

When liquid forms of drugs are mixed with enteral preparations, physical incompatibilities can cause the mixture to thicken and clog the feeding tube. Hyperosmolar liquid medications can also be poorly tolerated by the GI tract, resulting in abdominal distention and cramping, vomiting, and diarrhea. Both of these problems can be avoided by simply flushing the feeding tube with water and by diluting the medication first with warm water before instilling it into the feeding tube.

Enteral feeding products are usually delivered as a constant infusion and contain high concentrations of proteins and certain metals such as calcium, magnesium, and iron. These important nutrients can bind with certain medications, hindering the bioavailability of the drug and, in turn, reducing the total delivered dose of the medication. The fluoroquinolone antibiotics, such as ciprofloxacin (Cipro), are a frequently prescribed class of drugs that can interact with these metals. The effectiveness of liquid phenytoin (Dilantin) is often reduced by the drug's ability to bind with proteins in the enteral formula, resulting in subtherapeutic levels of the medication. Likewise, therapeutic levels of warfarin (Coumadin) may also be affected due to protein binding and the presence of vitamin K in the feeding preparation. Holding the enteral feeding for 1 hour before and after an antibiotic dose and 2 hours before and after giving phenytoin or warfarin will help minimize the drug's interaction with the enteral feeding. Table 62.2 lists the various drugs that interact with enteral formulas.

CONNECTION Checkpoint 62.1

From what you learned in Chapter 3, explain why drugs that have an enteric coating and those that are extended release should not be crushed and used in enteral feeding. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Table 62.2 Interaction of Drugs with Enteral Formulas

Interaction with Enteral Formula	Drugs
Physically incompatible	Antacids, cimetidine (Tagamet), dicyclomine (Bentyl), Dimetapp elixir, iron preparations, KCl liquid, MCT oil, Robitussin, thioridazine (Mellaril)
Increased osmolality	digoxin (Lanoxin), furosemide (Lasix), methyldopa (Aldomet), phenytoin (Dilantin), theophylline
Decreased drug effect	carbamazepine (Tegretol), ciprofloxacin (Cipro), digoxin, lithium, levodopa (L-dopa), phenytoin, theophylline, warfarin (Coumadin)

Parenteral Nutrition

62.8 Parenteral nutrition is used when patients are unable to tolerate enteral feedings.

Parenteral nutrition is utilized for patients who are unable to eat or tolerate any form of EN or when there is inadequate oral intake to meet nutritional needs. It is frequently given to patients with severe GI disorders such as diseases of the small bowel (Crohn's disease, fistulas, adhesions, postoperative ileus), necrotizing pancreatitis, hyperemesis gravidarum (maternity patients), and pediatric patients with congenital anomalies or prolonged diarrhea. It is also used for patients with demonstrated undernutrition (less than 50% of the metabolic needs met for more than 7 days) as well as patients with AIDS, cancer chemotherapy or radiation-induced enteritis, burns, severe trauma, or anorexia.

Total parenteral nutrition (TPN), or hyperalimentation**,** will provide the patient with all the calories, glucose, protein, fats, minerals, and trace elements needed by the body to sustain growth and to promote weight gain and wound healing. **Partial parenteral nutrition** lacks at least one essential element, usually fats or lipids, and supplies only part of the patient's daily nutritional requirements. Because these parenteral solutions are so concentrated, they can cause irritation and thrombosis of peripheral veins; therefore, a central venous catheter is usually required. Common central venous catheter sites include the subclavian and the internal jugular veins, and peripherally inserted central catheters (PICC lines) are often inserted in patients who require home therapy with TPN. TPN is always administered using an infusion pump in order to precisely monitor the amount of solution given. Figure 62.1 shows the locations of a central venous catheter for TPN therapy.

Peripheral parenteral nutrition (PPN) is used when a central vein cannot be accessed or when a central venous catheter is not appropriate for the patient. These situations

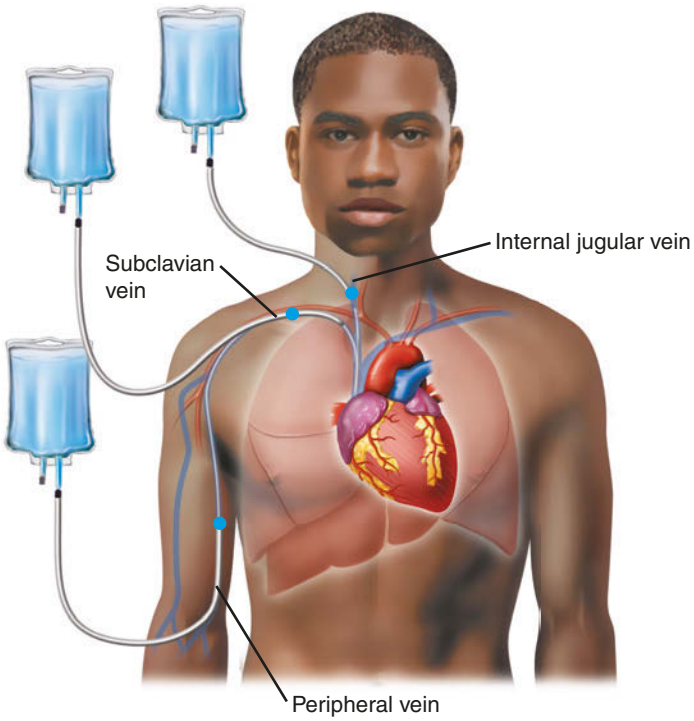

Figure 62.1 Routes of administration for parenteral nutrition.

may include patients in whom the subclavian vein is inaccessible due to scar tissue from repeated IV punctures or in patients with extensive trauma, severe burns, or cancer in the region of the upper torso or chest. These patients may be relatively healthy with only a slight nutritional deficit that cannot be met with enteral therapy. PPN is considered a temporary measure until a central venous catheter can be placed, and the solution administered is usually lower in osmolality than the solution delivered through a central venous catheter. PPN is advantageous because fewer risks are associated with the catheter placement, care of the infusion site is simpler, and the complications associated with hyperosmolar solutions can be avoided.

Problems associated with PPN include the need for several large peripheral veins, because the catheter site is routinely rotated to prevent infection. The vein must also be able to accommodate the larger sized venous catheter. PPN is associated with a high risk of phlebitis and is therefore reserved for patients with robust veins.

PharmFACT

When assessing undernourished patients for potential enteral therapy, the nurse should consider that the lack of dietary intake may be caused by drugs that cause bleeding gums (anticoagulants), altered taste (captopril), candidiasis (broad-spectrum antibiotics), or nausea and vomiting (antineoplastics and many other drugs) (Dawodu, 2015).

Components of Total Parenteral Nutrition Solutions

62.9 The basic total parenteral nutrition solution consists of carbohydrates, lipids, amino acids, electrolytes, minerals, and vitamins.

TPN solutions may be modified daily based on the patient's laboratory results, the underlying disorder, the rate of metabolism, and other factors. Like the enteral products, the basic components include carbohydrates, lipids, amino acids (proteins), electrolytes, minerals, and vitamins.

Carbohydrates: Carbohydrates and lipids are the primary sources of calories for the patient on TPN. Dextrose is the most common carbohydrate source because it is inexpensive and readily available from cornstarch, beet, or cane sugar. The RDA of carbohydrates for adult patients ranges from 25 to 35 kcal/kg. When administered through a central line, the concentration of dextrose in the TPN solution usually comprises 25% to 35% of the overall solution.

When dextrose is administered as the primary calorie source (without lipids added), hyperglycemia can occur. Because insulin is required for dextrose utilization, a combination of dextrose and lipids may help reduce the risk of hyperglycemia and the patient's need for supplemental insulin injections. Dextrose increases the metabolic rate and the production of carbon dioxide, which may increase the demands placed on the patient's respiratory system. The addition of lipids will also decrease this risk. Abruptly stopping the TPN solution can result in hypoglycemia due to the continued release of endogenous insulin. This problem can be avoided by substituting a dextrose 10% solution until the new TPN solution bag is available, or by gradually tapering the solution over a 24-hour period when discontinuing parenteral therapy.

CONNECTION Checkpoint 62.2

From what you learned in Chapter 36, what are the primary indications for an infusion of dextrose in water (D_5W)? Why should a patient with severe heart failure not receive D_5W? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Lipids: Unlike amino acids and concentrated dextrose solutions, fat emulsions are isotonic, which means that they can be infused through either a peripheral or central line. They are often a requirement for patients who are receiving TPN therapy for longer than 5 days. Currently available lipid preparations are produced from either safflower oil (Liposyn) or soybean oil (Intralipid). The principal fatty acids used in these preparations are linoleic, linolenic, oleic, palmitic, and stearic acids.

Fat emulsions can be hazardous for patients with liver disease, pulmonary disease, anemia, or blood coagulation disorders, with the most common adverse effect being hyperlipidemia. Fat emboli and death can occur when lipids are administered to premature, preterm, or low-birth-weight infants.

Amino acids: Amino acids are needed by the body to synthesize proteins, to conserve lean body mass, and to help promote wound healing. The RDA for infants and children ranges from 1.4 to 2.5 g/kg per day, whereas adults require 0.8 to 1 g/kg daily. Essential amino acids cannot be produced by the body, whereas nonessential amino acids can be synthesized from a nitrogen source, such as ammonium salts or urea. Amino acids must be closely monitored in patients with CKD, because the blood urea nitrogen (BUN) level can become elevated. For the patient with liver failure, the administration of amino acids may result in hepatic coma due to the liver's inability to process nitrogen.

Electrolytes and minerals: Electrolytes, including sodium, potassium, magnesium, calcium, phosphorus, chloride, and acetate, can be added to the TPN formula as salts. Specific electrolyte amounts are ordered daily by the healthcare provider, based on preexisting deficiencies and the patient's current medical condition. To prevent interactions between specific elements and crystallization of the solution, the pharmacist should add the electrolytes.

Trace mineral mixtures typically contain copper, chromium, manganese, selenium, and zinc and are commercially available to meet the specific nutritional needs of the patient. Trace minerals are metabolic cofactors that are essential for the proper functioning of several enzyme systems.

Although it is routine to monitor electrolyte levels, serum levels of the trace minerals are generally not monitored. Trace mineral administration should be decreased or withheld in patients with a limited capacity to excrete them. For example, selenium and chromium should not be used in patients with CKD, whereas copper and manganese should be withheld in patients with severe hepatic disease.

Vitamins: Vitamins are essential components of the TPN regimen. Most commercially prepared vitamin formulas can be given on alternate days in order to meet the patient's need for both fat-soluble vitamins as well as the water-soluble vitamins, and they can be added to the existing TPN solution. Vitamin K is usually administered weekly by subcutaneous or IM injection.

CONNECTION Checkpoint 62.3

Vitamin K is used as an antidote for overdose from a coagulation modifier. From what you learned in Chapter 38, what is the specific coagulation modifier and what would be the symptoms of an overdose from that drug? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Complications of Parenteral Therapy

Despite improvements made in the delivery of parenteral nutrition during the past decade, patients may encounter certain problems during TPN therapy. It is important for the nurse to assess the TPN solution prior to hanging the bag for any signs of cloudiness, particles, or a change in color. If lipids have been added to the bag, then the nurse should assess for fat globules or separation of the lipids from the solution. If any of the above conditions are noted, the nurse should replace the solution with a different container of solution.

Other patient-specific complications can be classified as mechanical, metabolic, or infectious in nature. Selected complications of TPN therapy are summarized in Table 62.3.

62.10 As with enteral therapy, patients who are receiving parenteral nutrition therapy can experience various complications.

Regular monitoring is important during TPN therapy. The patient's individual nutritional requirements should be reviewed regularly, taking into account the patient's current condition, drug therapy, nutritional status, concurrent treatments (e.g., hemodialysis), response to TPN, and supporting laboratory data.

Mechanical complications: Improper or incorrect placement of the catheter can result in subclavian artery puncture, pneumothorax, hemothorax, carotid artery injury, thromboembolism, catheter malposition, brachial plexus injury, subcutaneous emphysema, endocarditis, cardiac arrhythmias and tamponade, and phrenic nerve paralysis. Venous thrombosis is the most common problem and is associated with significant morbidity rates. Signs of venous thrombosis include distended neck veins as well as swelling of the face and arm on the side of the IV catheter.

Metabolic complications: Metabolic complications of parenteral nutrition therapy fall into two broad categories: early or late complications. Early complications can usually be anticipated and include fluid volume overload, refeeding syndrome, and various electrolyte and mineral imbalances. Hypertriglyceridemia can lead to pancreatitis and altered pulmonary function if left untreated. The early complications can be prevented by carefully monitoring the patient and adjusting the composition of the TPN formula or the rate of infusion.

Late metabolic complications are less predictable and may be caused by the exacerbation of preexisting conditions, inadequate solution composition, or failure to monitor the patient adequately. Late complications can include fatty acid, mineral, and vitamin deficiencies and metabolic bone disease or bone demineralization, which may develop in patients who receive TPN for periods extending beyond 3 months. Although the exact mechanism is not known, metabolic bone disease can cause severe pain in the lower

Table 62.3 Selected Complications of Total Parenteral Nutrition

Complication	Cause	Symptom
Mechanical		
Pneumothorax	Puncture of the pleural cavity by the catheter during insertion.	Sharp chest pain, decreased breath sounds
Hemothorax	Catheter damages a vein with blood entering the chest cavity.	Same as above
Hydrothorax	Catheter perforates a vein, releasing TPN solution into the chest. Clot in the subclavian vein.	Same as above
Venous thrombus	IV tubing is disconnected. Catheter is not clamped. Infusion cap fell off.	Distended neck veins, swelling of the face and arm
Air embolism	Same as above	Cough, shortness of breath, chest pain, and cyanosis
Metabolic		
Hyperglycemia	Fluid is infused too quickly. Insufficient insulin coverage.	Nausea, headache, weakness, thirst, increased blood glucose level
Hypoglycemia	Fluid stopped abruptly. Too much insulin administered.	Pallor, cold clammy skin, increased pulse, headache, tremors, blurred vision
Fluid overload	Increased IV rate. Fluid shifts from the cellular to the vascular space due to hyperosmolar solution.	Cough, dyspnea, distended neck veins, rales, weight gain
Infection		
Sepsis	Poor aseptic technique when the catheter is inserted. Contamination of the catheter when changing tubing or when the TPN solution is mixed. Contamination when dressing is changed.	Fever, chills, tachycardia, drainage from the insertion site, lethargy, increased white blood cells (WBCs), positive blood cultures

extremities and the back. The only known treatment is to temporarily or permanently discontinue the TPN infusion. Hepatic steatosis (fatty liver) and gallbladder complications (cholelithiasis and cholecystitis) are also late complications of TPN therapy.

Infectious complications: Parenteral nutrition therapy creates a chronic breach in the patient's physiologic line of defense. The IV infusion system from the solution container to the tip of the catheter may serve as a source for the introduction of bacterial or fungal organisms into the patient's bloodstream. The healthcare provider inserting the venous catheter, the pharmacist mixing the TPN solution, or the nurse hanging the IV bag or changing the central venous catheter dressing may inadvertently contaminate the patient's "lifeline."

Peripheral IV lines are at high risk for infection and infiltration, and the site of the peripheral line should be changed, if possible, every 48 hours in order to eliminate that risk. Unfortunately, severely debilitated patients often have few robust veins available for selection, necessitating the eventual placement of a central line.

Strict asepsis should be maintained when changing the IV tubing and dressings at the IV insertion site. TPN is an excellent medium for the growth of organisms; thus most TPN solutions are prepared by the pharmacist with the use of a laminar airflow hood. Whenever possible, the central line should be used exclusively for the infusion of the TPN solution. Other preventive measures to reduce the patient's risk for infection include the following:

- Change the dressing routinely (every 48–72 hours, per institutional policy) or when it becomes soiled, wet, or loose. The caregiver should wear a mask and gloves while changing the dressing.
- Extend the application of antimicrobial solution (e.g., iodine) at least 1 inch beyond the edges of the final dressing.
- Place a sterile sponge over the catheter, then cover with an occlusive, waterproof dressing.
- Inspect the site for signs of tenderness, redness, edema, loose sutures, or any bleeding or drainage.
- Change the TPN tubing every 24 hours with the first bag of the day. A 0.22-micron inline filter should be used to reduce the introduction of bacteria from the TPN solution.
- Avoid the use of the TPN catheter for central venous pressure (CVP) monitoring or the administration of IV medications or blood products.

Drug and Food Interactions

62.12 Certain drugs are incompatible and should not be added to parenteral nutrition solutions.

The major issue associated with the addition of medications to the parenteral formula is the potential for drug incompatibilities. A significant risk is that of a precipitate forming in the solution but being obscured by the opaque fat emulsion. Therefore, drug additions to the TPN solution should never be undertaken unless sufficient data exist to ensure the stability of the solution. Medications that are routinely added to parenteral preparations and are physiologically stable in solution are the H_2-receptor antagonists, such as ranitidine (Zantac) and insulin.

When there is no other option but to administer a medication through the same access site as the TPN, it is best to use a separate lumen in a multilumen catheter to avoid the potential for incompatibility. The use of a Y site or piggyback drug delivery has helped to decrease the risk of drug compatibility problems. Flushing the IV line prior to and after the medication administration, along with temporarily turning off the TPN infusion during the drug administration for 15 to 30 minutes, will help lower the possibility of interactions.

Drugs with demonstrated physical incompatibilities with TPN include ampicillin, tetracycline, and amphotericin B. For administration of these medications, a second IV line should be sought. Medications that have a decreased therapeutic drug effect when given to patients who are receiving TPN with lipids include kanamycin and warfarin. It is important for the nurse to always check with the pharmacist to confirm compatibility and drug effectiveness when administering TPN with any medication.

CONNECTION Checkpoint 62.4

From what you learned in Chapter 59, to what drug class does ranitidine belong? Why would it be added to TPN solutions? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: Community-Oriented Practice

Home Care of Patients on Total Parenteral Nutrition Therapy

Patients may be sent home on TPN. The patient and the patient's family should have the opportunity to practice the procedure for delivering TPN therapy while they are in the hospital setting under the supervision of the nurse.

Review the procedure for the storage of the solution. Instruct the patient to keep the containers refrigerated and to allow the container to come to room temperature before administering the solution. Instruct the patient never to warm the TPN in the microwave or the oven. Advise the patient to check the expiration date, label of contents, and the appearance of the solution. The patient should not use the solution if the TPN is cloudy, discolored, or has solid pieces floating in it. The solution should not be used if any separation (oil and water) is visible. The patient should check the integrity of the bag by gently squeezing it in order to detect any leakage.

The dressing should be changed at least every 2 days. Teach the patient, family, or caregiver how to use aseptic technique when changing the dressing. The supplies for the dressing and the infusion should be kept in a clean, dry place when not in use. The IV site should be inspected for any signs of swelling, redness, or drainage, which should be reported to the healthcare provider immediately. Demonstrate to the family how to irrigate the catheter and how to change the bags and the tubing. Instruct the patient about the various settings of the infusion pump, paying particular attention to reviewing what to do if the alarm goes off during the infusion. Review the local Environmental Protection Agency (EPA) policy regarding the proper disposal of used syringes and IV equipment.

Explain that the patient should be weighed daily, and that the patient's I&O should be closely monitored. Ask the family to observe the patient for signs of edema. Demonstrate how to check the glucose level and ensure that all supplies needed are available. Review the potential complications of TPN, such as chills, fever, dyspnea, chest pain, coughing, reaction to lipid infusion, air embolism, nausea, vomiting, and hypo- or hyperglycemia. Instruct the patient never to stop the TPN infusion without conferring first with the healthcare provider. Recommend that the family keep the telephone numbers of the healthcare provider, the nursing service, and the community emergency services readily available in case an emergency or other need should arise. Whenever possible, provide written instructions for the patient and family to use as a reference before the patient is discharged.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Enteral and Parenteral Nutrition

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, neurologic, endocrine, hepatic, or renal disease. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, and herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Obtain a dietary history, noting the ability to swallow, eat, and take adequate fluids.
- Obtain baseline height, weight, and vital signs.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, BUN, hepatic and renal function studies, total protein, serum albumin, lipid profile, serum iron levels).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., weight is maintained, electrolytes, glucose, proteins, and lipid levels remain within normal limits).
- Continue monitoring vital signs and periodic laboratory values as appropriate.
- Weigh daily at the same time each day and record.
- Assess for and promptly report adverse effects: fever, nausea, vomiting, tachycardia, palpitations, hypotension, dyspnea, drowsiness, dizziness, disorientation, hypo- or hyperglycemia, and electrolyte imbalances.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Assess the patient's ability to take oral nutrition during replacement nutrition and encourage small PO feedings if allowed. (Supplementation with PO feedings may be allowed if enteral or parenteral nutrition will be used short term. Encouraging small amounts of PO intake will help the patient maintain normal salivation and ability to perform activities of daily living [ADLs] during the time of replacement nutrition.)	• If allowed, encourage the patient to maintain small, frequent PO intake, or have the family or caregiver assist the patient with PO nutrition and hydration.
• Provide water between feedings or each time a new enteral feeding amount is added with continuous feedings. If the patient is unable to take fluids PO, provide additional water through the enteral tube in addition to amounts used to flush the tube. Monitor skin turgor and oral mucous membranes. (Additional water will assist in maintaining adequate dilution of concentrated feedings and replenish body water. Decreased skin turgor and dry mucous membranes may indicate dehydration and the need for additional water.)	• Encourage the patient to consume small amounts of water if allowed, assisted by the family or caregiver as needed. • Teach the patient, family, or caregiver to monitor for dry mouth or lips, dry skin, or tenting of the skin as signs that insufficient water is being given.
Minimizing adverse effects: • Monitor vital signs, particularly temperature, throughout nutrition replacement. Assess all access sites (e.g., gastric tube insertion site, IV cannula, tubing, or port sites) frequently for redness, streaking, swelling, or drainage. Report any fever, chills, malaise, or changes in mental status immediately. (Nutritional replacement solutions contain high glucose, protein, and lipid sources that may serve as a reservoir for infection. Tube insertion and access sites may also serve as points of entry for infection.)	• Instruct the patient, family, or caregiver to immediately report any fever, chills, unusual changes to the insertion site, or changes in level of consciousness to the healthcare provider.
• Use aseptic technique with all insertion-site dressing changes, and refrigerate opened enteral solutions until approximately 30 min before using or as per agency protocol. Follow agency guidelines on the length of time solutions and equipment are allowed to remain in use and change accordingly. (Insertion sites are at high risk for development of infection and must be monitored frequently. Solutions must be refrigerated to inhibit bacterial growth.)	• Explain the rationale for all dressing and equipment monitoring and changes. • Teach appropriate technique (aseptic or clean) to the family or caregiver if the nutrition is to be continued at home. Follow with demonstration and then teach-back until the family or caregiver is comfortable with the routine. • Provide written instructions on the frequency of bag, tubing, and solution changes.
• Monitor blood glucose levels. Observe for signs of hyperglycemia or hypoglycemia and obtain capillary glucose levels as ordered. (Blood glucose levels may be affected if the nutrition feeding is stopped or the rate is reduced, or dependent on other medications the patient takes. Supplemental insulin may be required.)	• Instruct the patient on the need for frequent glucose monitoring. Teach the patient, family, or caregiver to promptly report signs of hyperglycemia (excessive thirst, copious urination, insatiable hunger) or hypoglycemia (nervousness, irritability, and dizziness). • Instruct the patient, family, or caregiver in the technique to monitor capillary glucose, followed by teach-back, if the patient is to continue nutrition replacement at home.
• Monitor for signs of fluid overload. (Solutions are hypertonic and can create fluid shifting with resulting decreased intravascular fluid. Monitoring for a noticeable increase in the pulse rate and quality, changes in blood pressure from the baseline, dyspnea, or edema will assist in noting adverse effects quickly.)	• Instruct the patient, family, or caregiver to immediately report shortness of breath, heart palpitations, swelling, decreased urine output, dizziness, disorientation, or confusion.
• Monitor renal status. (I&O ratio, daily weight, and laboratory studies such as serum creatinine and BUN should be monitored to assess renal function.)	• Instruct the patient on home therapy to weigh self daily at the same time each day and record. An increase or loss in weight of over 1 kg (2 lb) per 24 h should be reported to the healthcare provider. Immediately report any edema or dyspnea.
• Monitor for signs of venous thrombosis on the same side as the IV catheter. (Venous thrombosis may occur in or around the catheter tubing. Signs and symptoms include the inability to obtain blood on aspiration from the catheter, inability to run fluids through the catheter, neck vein distention, and facial and neck edema on the side of the catheter. The infusion should be stopped and the provider immediately contacted).	• Instruct the patient, family, or caregiver to immediately report a stoppage in the infusion, neck vein distention, or swelling of the face or neck on the side of the IV placement.
• Assess for appropriate enteral tube placement before administering any feeding. Assess for residual amount by aspiration prior to beginning a new enteral feeding if continuous or by bolus. Hold the feeding if the amount returned is 50% or greater of the last bolus feeding or 2 times the hourly amount given by continuous feeding and contact the healthcare provider. Flush the tube with adequate amounts of warm water before and after each bolus feeding or every 2–4 h with continuous feedings or as per agency protocol. (Proper tube insertion should be confirmed radiographically before any feeding is initiated. Dependent on agency policy, confirmation of placement by observing the characteristics of the gastric aspirate or pH may be used. If any doubt exists about placement, hold the feeding and alert the healthcare provider to obtain an x-ray to confirm the placement site. Excessive residual amounts may indicate decreased absorption of the feeding or other conditions and increase the risk of aspiration. Return aspirated amounts unless agency policy requires otherwise.)	• Explain the rationale for checking tube placement prior to each feeding to the patient, family, or caregiver. If home enteral therapy is ordered, teach the patient, family, or caregiver the appropriate methods for checking placement prior to feeding, tube flushing, and aspiration technique for residual amounts. Follow with demonstration and then teach-back until the family or caregiver feels comfortable with the technique.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Assess lung sounds every 4 h or per agency protocol. Immediately report any dyspnea, lung congestion, or changes in sputum to the healthcare provider. Maintain the head of the bed at a 30-deg angle or greater per agency policy for patients on enteral feedings. (Keeping the head of the bed elevated may help prevent regurgitation and aspiration.)	• Teach the patient, family, or caregiver to keep the patient in a semi-upright position and to immediately report dyspnea or lung congestion.
• Assess bowel sounds every 4 h, whenever a new amount of feeding is added to continuous feedings, before each feeding, or per agency protocol. Assess for and report diarrhea, especially if profuse, watery, or containing blood or mucus. (Diarrhea or constipation may occur with enteral feedings. Patients on enteral feeding, particularly with elemental formulas, are at increased risk of *C. difficile*–associated diarrhea [CDAD] or from other pathogens.)	• Teach the patient, family, or caregiver to report diarrhea or constipation to the healthcare provider. Immediately report any diarrhea that is profuse, watery, or contains blood or mucus.
• Review all PO medications the patient is to receive for appropriateness to be given via enteral tube. Contact the healthcare provider for alternative forms when necessary. (PO medications may be crushed for administration via enteral tube in most cases. Enteric-coated, sustained release, gel capsules, and others may not be crushed and an alternative form or drug may be required.)	• Instruct the patient, family, or caregiver to review any new medication ordered with the provider who has ordered the enteral feeding to ensure appropriateness for administration via the enteral tube.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the enteral feedings, appropriate amount and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of enteral therapy.
Patient self-administration of drug therapy: • When administering the feeding, instruct the patient, family, or caregiver in the proper administration of feeding, e.g., that it is taken with additional fluids. (Utilizing time during nurse administration of feedings helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate administration needs. • The patient, family, or caregiver is able to provide teach-back on appropriate administration of the nutritional feeding and the care of access and insertion sites and tubes prior to home use.

Understanding Chapter 62

Key Concepts Summary

62.1 Nutritional supplementation is required for patients with certain medical conditions.

62.2 Supplemental nutrition may be provided by the oral or parenteral route.

62.3 Various methods are utilized to administer enteral feedings to the patient.

62.4 Several types of liquid nutrition formulas are commercially available for enteral feedings.

62.5 Most enteral nutrition formulas contain four basic classes of nutrients.

62.6 Total enteral nutrition can predispose the patient to various complications.

62.7 Most medications that are administered orally can also be delivered to the patient via an enteral tube.

62.8 Parenteral nutrition is used when patients are unable to tolerate enteral feedings.

62.9 The basic total parenteral nutrition solution consists of carbohydrates, lipids, amino acids, electrolytes, minerals, and vitamins.

62.10 As with enteral therapy, patients who are receiving parenteral nutrition therapy can experience various complications.

62.11 Certain drugs are incompatible and should not be added to parenteral nutrition solutions.

CASE STUDY: Making the Patient Connection

Remember the patient "Christopher Jones" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Christopher Jones is a 62-year-old man with a long-standing history of diabetes, the past 20 years as an insulin-dependent diabetic. During the past few months, Christopher has been having increasing difficulty eating. At first he noticed that he felt full almost immediately and then nausea began in waves, eventually resulting in vomiting. He began to lose weight and had trouble controlling his blood glucose levels, experiencing more frequent bouts of hypoglycemia. He visited his healthcare provider, and after an upper GI series, esophagogastroduodenoscopy, and a gastric emptying study, Christopher was diagnosed with gastroparesis diabeticorum. His provider has told him that it is most likely due to his diabetes and may be temporary. He has been started on a prokinetic drug (metoclopramide [Reglan]) and erythromycin in an attempt to increase gastric emptying.

The provider inserted a jejunostomy tube for feedings until the outcomes of drug therapy can be determined. Christopher has returned to the provider's office for his first postoperative visit and will need teaching about his feeding tube.

Critical Thinking Questions

1. Christopher wants to know if he can still eat foods "normally." Give a rationale for your answer.
2. Christopher does not know how to take care of his feeding tube and wants to know if any special care is required. What would you teach him?
3. Create a list of potential complications to which Christopher and his family should be alerted.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Misty Moore is a 36-year-old woman who was admitted to the hospital with a complete bowel obstruction, multiple abdominal adhesions, and a flare-up of Crohn's disease. She stands 5 ft 5 in. and weighs 65 kg (143 lb). Her usual weight is 75 kg (165 lb). Her past medical condition includes Crohn's disease since age 16, as well as a 10-year history of type 2 diabetes. Exploratory surgery is scheduled to remove the diseased portion of her small bowel as well as to perform lysis of the adhesions, which occurred as a result of her previous bowel operations. Because of her depleted nutritional state and the 10% drop in her weight, nutritional support is indicated. Her GI tract is not expected to be accessible for at least 10 to 14 days.

1. What type of nutritional support do you think will be ordered for Misty? Why?
2. Considering the patient's condition, what metabolic problem would you suspect she is at risk for developing?
3. How can the risk of developing this problem be reduced?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. To meet his nutritional goals, the patient is placed on enteral feedings via a nasogastric (NG) tube. Which intervention should the nurse perform in order to ensure that the patient is maintaining a proper fluid balance?
    1. Weigh the patient every other day.
    2. Maintain a strict record of intake and output, and flush the nasogastric tube once a day.
    3. Provide additional free water in addition to that used for irrigating the tube.
    4. Assess the skin around the tube insertion site for any drainage or irritation.
2. Before hanging a bag of total parenteral nutrition, the nurse checks the various components of the solution. Which elements would the nurse expect to see on the solution label? (Select all that apply.)
    1. Electrolytes
    2. Diuretic
    3. Trace minerals
    4. Isophane (NPH) insulin
    5. Multivitamins

3. The nurse is making rounds at the beginning of the shift and notes that the patient's total parenteral nutrition bag is empty. Which solution should the nurse hang until the total parenteral nutrition solution can be properly prepared and delivered to the nursing unit?
   1. 5% dextrose in water (D_5W)
   2. 5% dextrose in Ringer's lactate (D_5RL)
   3. 5% dextrose in 0.9% sodium chloride (D_5NS)
   4. 10% dextrose in water ($D_{10}W$)

4. The patient has been discharged home on total parenteral nutrition therapy. When making the home visits, which assessments should the home care nurse closely monitor?
   1. Temperature and blood pressure
   2. Temperature and weight
   3. Pulse and blood pressure
   4. Pulse and weight

5. The nurse is preparing to hang a lipid solution and notes that fat globules are visible at the top of the bag. Which action should be taken?
   1. Roll the solution container gently.
   2. Shake the solution container vigorously.
   3. Run the solution container under warm water.
   4. Obtain a different container of solution.

6. The patient who is receiving enteral nutrition via a PEG tube suddenly spikes a fever of 38.6°C (101.5°F). The nurse notifies the healthcare provider who orders the solution and tubing to be changed immediately. Preventive measures to limit the risk of infection from enteral feedings include which of the following? (Select all that apply.)
   1. Refrigerate unused portions of feeding.
   2. Hang a feeding solution no longer than 4 hours.
   3. Wash feeding bags and tubes before reusing.
   4. Use plain water to irrigate the tube between feedings.
   5. Maintain sterile technique whenever initiating a new feeding solution.

Chapter 63
Weight Reduction Strategies and the Pharmacotherapy of Obesity

Chapter Outline

- Etiology of Obesity
- Pathogenesis of Obesity
- Measurement of Obesity
- Nonpharmacologic Therapies for Obesity
- Pharmacotherapy of Obesity
  - Lipase Inhibitors
    PROTOTYPE *Orlistat (Alli, Xenical), p. 1168*
  - Anorexiants
- Adjuncts to Obesity Therapy

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify genetic and lifestyle factors that contribute to obesity.
2. Explain how energy imbalances can cause weight gain or loss.
3. Describe the role of the hypothalamus in regulating appetite.
4. Explain how leptin and brain neurotransmitters regulate appetite.
5. Describe how obesity is measured.
6. Outline the major components of a successful weight management program.
7. Identify several weight loss agents that were removed from the market due to their adverse effects.
8. Describe the nurse's role in the pharmacologic management of obesity.
9. For each class shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
10. Apply the nursing process to care for patients receiving antiobesity therapy.

Key Terms

adipocytes, 1164
appetite, 1164
body mass index (BMI), 1164
leptin, 1164
satiety, 1164
satiety center, 1164

Americans spend about $60 billion each year in attempts to lose weight. In the majority of cases, people experience little long-term success in sustaining weight loss. Obesity is closely associated with increased health risks that include premature death, hypertension (HTN), hyperlipidemia, diabetes mellitus, heart disease, sleep apnea, osteoarthritis, and some cancers. In addition, the healthcare costs associated with treating obesity-related illness in the United States are estimated to be $193 billion per year. This chapter examines the etiology, pathogenesis, and treatment of obesity.

Etiology of Obesity

63.1 Genetic and lifestyle factors contribute to the etiology of obesity.

Obesity is a growing epidemic in the United States: More than 36% of the adult population over age 20 is obese. Along with the increase in adult obesity, infant and childhood obesity have also become concerns. About 17% of children and adolescents are now considered obese. Both these percentages have doubled or tripled since the mid-1970s. The trend is expected to continue, because studies have shown that those who were obese as children are more likely to be obese as adults.

Despite considerable research, the specific causes of obesity have not been identified. The etiology is likely a complex combination of genetic, lifestyle, and physiologic factors. In a few cases, weight gain can be attributed to medical conditions, the most common being hypothyroidism. Certain rare disorders of the hypothalamus can also cause overeating. Drugs such as corticosteroids clearly cause weight gain.

PharmFACT

Although obesity is increasing in the total population, the incidence is not uniform. The highest incidences (35% or higher) in adults are in Alabama, Louisiana, Mississippi, and West Virginia. The lowest incidences (less than 25%) are in California, Colorado, Hawaii, Massachusetts, Montana, and Utah (Centers for Disease Control and Prevention, 2016).

Studies of family histories and twins support a strong genetic component to obesity. Researchers have identified a few genetic mutations that lead to obesity, although these are rare and do not contribute significantly to the extent of obesity currently observed in the population. While a family history does not cause someone to be obese, it predisposes that individual to weight gain. The predisposition is best overcome by preventing weight gain. This is particularly important in identifying children at risk of adult obesity and implementing interventions aimed at prevention.

Lifestyle factors play a key role in the development of obesity, the two most obvious factors being diet and physical activity. The fundamental shift in obesity levels in the past three decades is likely due to the consumption of high-fat, calorie-dense diets combined with sedentary lifestyles.

Various theories have been proposed about the relationship between specific dietary practices and obesity, many of which are fueled by fad diets rather than research. While it is certainly true that the body metabolizes and stores carbohydrates, lipids, and proteins differently, no specific dietary nutrient limitation has been clearly demonstrated to prevent obesity or to result in more sustainable weight loss.

Despite the ongoing debate on the "best" diet, the fact remains that body weight is largely determined by energy (calorie) balance. Simply stated, if the number of calories consumed equals the number of calories expended, the individual will maintain (balance) body weight at the current level. Changes in weight occur when there is an energy imbalance. For example, an imbalance of as little as 10 surplus calories per day can lead to a 1-lb weight gain each year. While this seems insignificant, if the imbalance persists over several decades it can lead to obesity in older adults. Of course, this calculation also holds true for losing weight, but few people are patient enough to wait an entire year to lose a single pound.

Therefore, to lose weight people have to expend more calories than they consume. In terms of weight loss or gain, the source of the calories, carbohydrates, proteins, or lipids probably does not matter. Of course, the source is indeed important in terms of overall health and wellness, and the medical community continues to debate which of the energy sources (carbohydrate, protein, or lipid) contributes the most to adult obesity.

The second half of the energy equation is energy expenditure. Physical activity expends calories and can result in either prevention of weight gain or a faster loss of weight. The most successful diet plans always combine a reduction in calories with an increase in physical activity.

Pathogenesis of Obesity

63.2 Appetite is regulated by the satiety center in the hypothalamus and is influenced by various hormones.

Hunger occurs when the hypothalamus recognizes the levels of certain chemicals (glucose) or hormones (insulin) in the blood. Hunger is a normal physiologic response that drives people to seek nourishment. Appetite is somewhat different than hunger. **Appetite** is a psychologic response that drives food intake based on associations and memory. For example, people often eat not because they are experiencing hunger, but because it is a particular time of day or because they find the act of eating pleasurable or social. The psychologic feeling of fullness or satisfaction following a meal is called **satiety**. The degree of satiety is directly recognized by a region of the hypothalamus known as the **satiety center**.

CONNECTION Checkpoint 63.1

The hypothalamus is part of the limbic system of the brain. From what you learned in Chapter 17, what are the primary functions of the limbic system? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

In addition to glucose and insulin, another substance that regulates hunger and weight balance is **leptin**, a hormone secreted by **adipocytes** (fat cells). Adipocytes are metabolically active cells that are central to overall weight gain (and loss). After adipocytes have stored a certain amount of fat, they notify the brain of their energy status by secreting leptin. Leptin then binds to receptors in the satiety center in the hypothalamus, signaling the brain that the body now has sufficient energy stores. Body temperature (thermogenic) and energy expenditure increase. The body now "feels full"; leptin thus serves as a natural appetite suppressant.

It would seem that administering leptin would be a natural method for suppressing appetite and promoting weight loss. However, patients who are obese already have high levels of leptin circulating in the blood. Leptin receptors in these patients appear to have become desensitized and developed resistance to the satiety effects of leptin. The unfortunate result is an increase in appetite. At this time, the experimental administration of leptin does not have any effect on obesity.

Binding of the leptin receptors in the hypothalamus creates a signal cascade that leads to the secretion of a number of different hormones. Of primary interest is the action of neuropeptide Y (NPY), a hormone concentrated in the hypothalamus that has been associated with increased appetite. When the adipocytes are full, the hypothalamus inhibits NPY release, thus decreasing appetite. Unfortunately, experimental drugs that block NPY receptors have not been found to promote weight loss in patients with obesity.

Another important finding in the pathogenesis of obesity is the role of neurotransmitters in appetite suppression. Activation of certain subreceptors of the neurotransmitter serotonin (5-HT_{1B} and 5-HT_{2C}) reduces appetite and the consumption of calories at meals. In addition, activation of alpha_1- or beta_2-adrenergic receptors and the release of norepinephrine seem to decrease appetite. Antiobesity drugs are currently available that promote the release of these neurotransmitters.

Lipids are the most energy-dense nutrients for fueling long-term metabolic processes; more calories can be obtained from lipids than from any other molecule. While the body can store only small amounts of protein and carbohydrate, fat stores are nearly unlimited. The ability of adipocytes to increase in size and store a nearly unlimited quantity of fat is likely a consequence of evolutionary adaptation. For most of human history, starvation has been a major cause of death, and hard physical activity was necessary to survive. Those who had more efficient lipid-storage capacity survived the times of famine. Although starvation is still a problem in parts of the world, it is no longer a major cause of death in developed countries. Unfortunately, human metabolic systems are still programmed for low-fat diets, combined with lots of physical exercise. What was once a survival mechanism becomes a liability when individuals consume a high-fat diet and choose a sedentary lifestyle.

Measurement of Obesity

63.3 Obesity is measured by using the body mass index and waist circumference.

Obesity is defined by several different measures. In simple terms, obesity is being more than 20% above the ideal weight. The ideal weight fluctuates depending on the individual's gender, height, and general build.

The most commonly accepted measurement of obesity is the **body mass index (BMI)**. BMI is determined by dividing body weight (in kilograms) by the square of height (in meters). In adults, a BMI of 25 to 29 kg/m^2 indicates the individual is overweight. Obesity is defined by a BMI of 30 kg/m^2 and above. Figure 63.1 illustrates a simple graph of BMI for estimating obesity. BMI measurement is not accurate in athletes due to the higher proportion of muscle to fat in these individuals.

Another clinical measure of obesity is waist circumference, as measured by a simple tape measure. Waist circumference values of 80 cm (32 in.) for women and 94 cm (37 in.) for men are associated with increased health risk. Waist measurements greater than 88 cm (35 in.) for women and

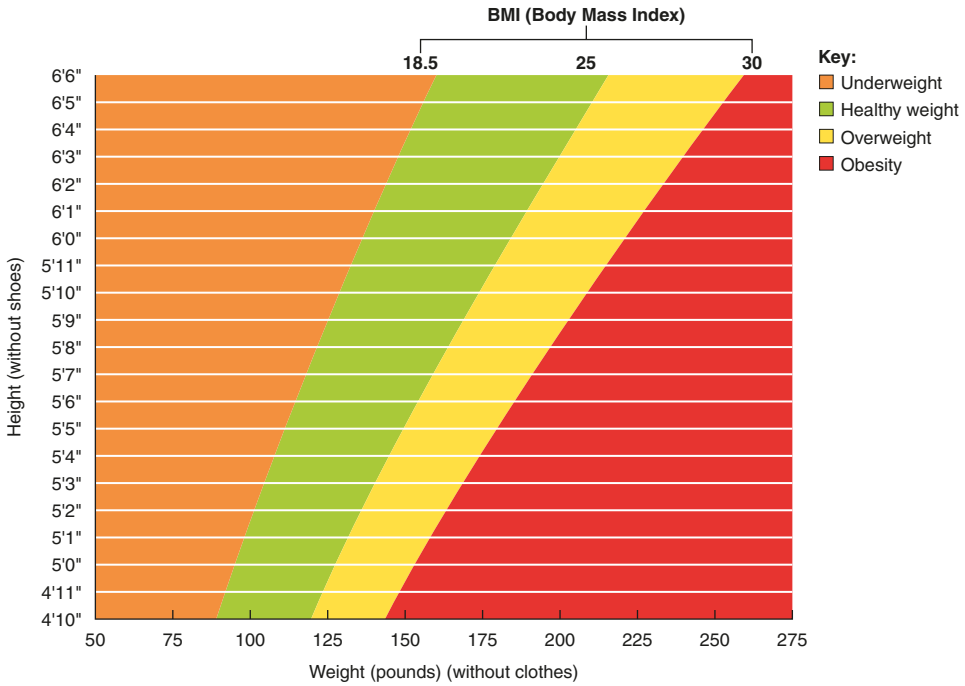

Figure 63.1 Calculation of body mass index. To determine your BMI, find the value for your height on the left and follow this line to the right until it intersects with the value for your weight on the bottom axis. The area in the graph where the two points intersect is your BMI.

From *Nutrition: An Applied Approach* (4th ed.), by J. J. Thompson and M. Manore, 2015. Reprinted and Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, NJ.

102 cm (40 in.) for men have the greatest health risks. Waist circumference correlates well with BMI and also provides an estimate of abdominal (visceral) fat, which is more strongly associated with health risk than fat stored in other regions of the body.

PharmFACT

Obesity rates vary considerably by ethnic group and gender. From 2013 to 2014, the highest rates of obesity in adults over age 20 were found in Mexican-American women (51%) and non-Hispanic Black women (57%). The lowest rates were found in Asian men and women (both 12%) (National Center for Health Statistics, 2016).

Nonpharmacologic Therapies for Obesity

63.4 Nonpharmacologic treatment of obesity should be attempted prior to initiating pharmacotherapy.

Prior to initiation of drug therapy, the healthcare provider and patient must first attempt to achieve weight management through nonpharmacologic means. This involves making three major lifestyle changes: diet, exercise, and behavior modification. To obtain successful, sustained weight loss, lifestyle changes can be physically and emotionally demanding for a patient who is obese.

Choosing a sustainable nutritional plan (diet) is often the biggest hurdle for patients. Although it may have taken decades or longer to become obese, no one wants to take decades to lose weight. Weight loss schemes and fad diets that claim rapid weight loss while making few changes in dietary habits are very attractive to patients with obesity who are desperate to lose weight. The nurse should assist patients in setting realistic goals and steer them away from fad diets that may be unhealthy as well as unsuccessful. Severe restriction of any of the food groups—proteins, carbohydrates, or lipids—is not necessary or recommended by most nutritionists. The initial weight loss goal should be to lose 10% of the baseline weight, although smaller, progressive steps may be needed in patients who are accustomed to consuming 2 to 6 times the recommended daily calorie values. Weight loss of 0.5 to 1 kg (1 to 2 lb) per week is usually a physically safe and realistic goal.

Exercise is an essential component of any weight management program. Many patients with obesity, however, have chronic health problems that could impact an exercise program, the most common being diabetes, HTN, and heart disease. The patient should receive a thorough medical workup to be certain there are no physical contraindications to starting an exercise program. The patient who is obese should begin with very modest exercise goals and proceed to more challenging physical activity under the guidance of a healthcare provider. Exercise should be combined with calorie restriction because

increased physical activity, by itself, is not an efficient method for losing weight.

Behavior modification is another essential component of successful weight management programs. The patient likely became obese due to poor eating habits and behaviors, which must be changed for the remainder of the individual's life. For patients with extreme obesity, the weight loss program will extend a year or longer; therefore, support groups should be encouraged. Breaking learned habits of eating is challenging and relapses always occur. Support groups can provide valuable help in adjusting to new lifestyle patterns.

Patients should be cautioned about taking over-the-counter (OTC) supplements that claim to promote weight loss. Many contain vitamins and minerals that can be obtained through a healthy diet, while others contain herbs and botanicals that have never been tested for weight loss. These products are costly as well as potentially dangerous. The U.S. Food and Drug Administration (FDA) has posted a warning that certain weight loss products contain hidden ingredients not included on their label (FDA, 2017). Over 3 dozen products were found to be tainted, most with sibutramine, a controlled substance removed from the market for safety reasons (see Section 63.5). Several products contained fluoxetine (an antidepressant) and sildenafil (a drug for erectile dysfunction).

Bariatric surgery is an option for patients with extreme obesity who have a BMI over 30 and who have been unsuccessful in conventional weight loss programs. The most common types of bariatric surgery involve placing a gastric band around the stomach, creating a smaller stomach (sleeve gastrectomy), or bypassing the stomach altogether. These operations create a smaller region for food storage so less food is consumed at each meal. Most patients having obesity surgery experience significant weight loss: 40% to 70% of their excess weight within 1 year. Although some patients eventually regain weight, most of the weight loss is maintained. The bariatric surgeries require strict adherence to dietary recommendations and vitamin and mineral supplementation to maintain health.

Pharmacotherapy of Obesity

63.5 Drugs used for weight management affect appetite or the absorption of fats.

Because of the prevalence of obesity in society and the difficulty most patients experience maintaining weight management plans for extended periods, drug manufacturers have long sought to develop safe drugs that induce sustainable weight loss. The quest for the "magic weight loss pill," however, has been very disappointing. Indeed, many of the prescription weight loss products have been discontinued due to health concerns. A brief history of these discontinued products is included because the nurse may still receive questions from patients regarding their use.

In the 1970s, amphetamine and dextroamphetamine (Dexedrine) were widely prescribed to reduce appetite. Although these drugs have strong appetite-suppressant actions, their effects are short lived due to the development of tolerance, which leads to the use of higher and higher doses. Although methamphetamine and dextroamphetamine are still available, they have high abuse potential and are rarely used for the therapy of obesity. A new formulation of amphetamine (Evekeo) was approved by the U.S. Food and Drug Administration (FDA) in 2015 for obesity treatment. Amphetamine is featured as a prototype central nervous system (CNS) stimulant in Chapter 24.

CONNECTION Checkpoint 63.2

Methylphenidate (Ritalin) is an amphetamine-like drug. From what you learned in Chapter 24, what are the primary indications for amphetamine and methylphenidate? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

In the 1990s, the combination of fenfluramine and phentermine (Fen-Phen) was found to be effective at promoting weight loss. However, fenfluramine was subsequently removed from the market because it causes heart valve defects. Phentermine is still used as an adjunct to weight loss (see Section 63.7).

Two OTC appetite suppressants were widely used to promote weight loss in the 1980s and 1990s. Phenylpropanolamine, which was also used as a decongestant in cold remedies, was removed from the market in 2000 due to an increased incidence of strokes and adverse cardiac events. Until 2004, alternative weight loss products contained ephedra alkaloids, but these have also been removed from the market due to an increased incidence of adverse cardiovascular events.

Rimonabant (Acomplia, Zimulti) was the first of a new class of antiobesity drugs known as cannabinoid receptor (CB1) blockers. The CB1 receptors are primarily found in the brain, and their activation is responsible for the psychoactive effects of marijuana. Overeating activates CB1 receptors in the CNS; blocking them reduces appetite. Tobacco has a similar effect on cannabinoid receptors; thus, rimonabant was also used to promote tobacco cessation. Although approved in 2006, concerns about adverse effects, especially depression and suicidal ideation, prevented the drug from being marketed in the United States. Approval was subsequently withdrawn.

From 2007 until 2010, sibutramine (Meridia) was approved for the adjunctive treatment of obesity. The drug was able to produce a 5% to 10% loss of body weight within 6 to 12 months of treatment. Although well tolerated by

most patients, sibutramine was found to produce an unacceptable incidence of serious cardiac events and stroke and was voluntarily removed from the market.

Given all these pharmacologic disappointments, current pharmacologic strategies for weight management focus on two sites of action. The lipase inhibitors act by reducing the absorption of fats in the small intestine. The approved antiobesity drugs produce only modest effects, and pharmacotherapy must be combined with a calorie-restricted diet. The appetite suppressants (also called anorexiants or anorectics) act centrally by increasing the amounts of norepinephrine, serotonin, and dopamine in the regions of the brain that affect appetite. Current drugs used as adjuncts in the treatment of obesity are shown in Table 63.1.

63.6 Lipase inhibitors cause weight loss by interfering with the absorption of fats.

One strategy to reduce weight is to block the absorption of dietary fats. Most of the accumulated fat in patients is derived from dietary sources.

Chemical digestion of lipids occurs through the enzymatic action of pancreatic lipase, which splits dietary triglycerides into glycerol and free fatty acids. Once absorbed, the fatty acids can be recombined with glycerol and stored

Table 63.1 Drugs for Treating Obesity

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
amphetamine (Evekeo)	PO: 30 mg/day in divided doses	*Agitation, blurred vision, dizziness, tremor, insomnia, restlessness, HTN* Psychoses, tachycardia, drug abuse, dependence
benzphetamine	PO: 25–50 mg 1–3 times daily	*Agitation, blurred vision, dizziness, tremor, insomnia, restlessness, HTN* Psychoses, ischemic cardiac events, drug abuse, dependence
bupropion and naltrexone (Contrave)	PO: Begin with 1 tablet in wk 1 (90 mg bupropion/8 mg naltrexone); increase by 1 tablet/day each subsequent wk until maintenance dose of 2 tablets bid is achieved by wk 4	*Nausea, constipation, headache, vomiting* Suicidal behavior, seizures, HTN, liver impairment, hypoglycemia
diethylpropion (Tenuate)	PO (regular release): 25 mg tid PO (extended release): 75 mg once daily	*Vomiting, diarrhea, dry mouth, changes in libido, nervousness, dizziness* Dysrhythmia, HTN, psychotic episodes, euphoria
liraglutide (Saxenda)	Subcutaneous: Start with 0.6 mg once daily and gradually increase to 3 mg daily	*Nausea, diarrhea, constipation, vomiting, headache, dyspepsia, fatigue, dizziness* Thyroid tumors, acute pancreatitis, acute gallbladder disease, serious hypoglycemia, suicidal behavior
lorcaserin (Belviq)	PO (regular release): 10 mg bid PO (extended release): 20 mg once daily	*Headache, dizziness, fatigue, nausea, dry mouth, constipation, and hypoglycemia (in patients with diabetes)* Serotonin syndrome, valvular heart disease, euphoria, suicidal thoughts, priapism
methamphetamine (Desoxyn)	PO: 5 mg 30 min before each meal	*Agitation, blurred vision, dizziness, tremor, insomnia, restlessness, HTN* Psychoses, tachycardia, drug abuse, dependence
orlistat (Alli, Xenical)	PO: 60–120 mg with each meal containing fat	*Flatus with discharge, fatty or oily stool, increased defecation, and fecal urgency or incontinence* Hepatic toxicity, increased renal oxalate
phendimetrazine (Bontril)	PO (regular release): 35 mg bid or tid PO (extended release): 105 mg once daily	*Restlessness, insomnia, dry mouth* Valvular heart disease, pulmonary HTN, psychoses
phentermine (Adipex-P, Suprenza)	PO (capsule): 37.5 mg daily PO (orally disintegrating tablet): 15–37.5 mg daily	*Paresthesia, dizziness, dysgeusia, insomnia, constipation, dry mouth* Fetal toxicity, increased heart rate, suicidal behavior, acute myopia, glaucoma, mood and sleep disorders, cognitive impairment, metabolic acidosis
phentermine and topiramate (Qsymia)	PO: 3.75–15 mg phentermine and 23–92 mg topiramate once daily in the morning	*Paraesthesia, dizziness, dysgeusia, insomnia, constipation, dry mouth* Suicidal behavior, fetal toxicity, increased heart rate, metabolic acidosis, cognitive impairment

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTIONS: Complementary and Alternative Therapies

Green Tea and Weight Loss

Description

Green tea is a natural substance made from the leaves of the plant *Camellia sinensis*, which is native to mainland China but is cultivated worldwide. There are many varieties and types of green tea.

History and Claims

In China, green tea has been used for thousands of years for ceremonial functions as well as to treat a diverse variety of ailments. In modern times, the health effects of green teas have focused on improving cardiovascular function, weight loss, and preventing cancer. Some research has examined the role of green tea for improving symptoms or treatment of neurodegenerative diseases such as multiple sclerosis, Parkinson's disease, and Alzheimer's disease.

Standardization

Green tea extracts contain large amounts of catechins (also called polyphenols), a group of chemicals that have strong antioxidant properties as well as antihypertensive, anti-inflammatory, antiproliferative, antithrombogenic, and lipid-lowering effects. Green tea itself contains caffeine, although this is sometimes removed during processing. Extracts are sometimes standardized to percent polyphenols, which varies widely from 14% to 98%, depending on the product. Some products report the amount of epigallocatechin gallate (EGCG), which is the most abundant catechin in green tea extracts.

Evidence

The administration of green tea extract has been shown to decrease body weight. Epidemiologic studies suggest that those who consume green tea have a lower percentage of body fat and lower BMIs than non–tea drinkers. In a randomized, double-blind trial of 115 women with central (abdominal) obesity, weight loss and decreases in BMI and waist circumference were observed after 12 weeks of high-dose green tree extract treatment. This study also demonstrated a consistent trend of decreased total cholesterol and decreased LDL plasma levels (Chen, Liu, Chiu, & Hsu, 2016).

in adipocytes. Attempts to produce antiobesity drugs that block lipid absorption have resulted in one approved drug: orlistat (Alli, Xenical).

PROTOTYPE DRUG **Orlistat (Alli, Xenical)**

Classification **Therapeutic:** Antiobesity drug
Pharmacologic: Lipase inhibitor

Therapeutic Effects and Uses: Approved in 1999, orlistat is indicated for the treatment of obesity in combination with a reduced-calorie diet and exercise. Orlistat is indicated for patients with a BMI of 30 or greater, or a BMI of 27 or greater if the patient has other risk factors such as HTN, hyperlipidemia, or diabetes. This drug produces only a modest weight reduction compared to placebos.

The prescription form of orlistat (Xenical) is available at 120 mg and is given three times daily, during or up to 1 hour after a meal containing fat. An OTC dosage form (Alli) is approved at 60 mg taken a maximum of 3 times daily. Orlistat is effective only if taken with meals containing lipids; the dose may be omitted if the meal contains no fat. Orlistat is not approved for individuals under age 12 (Xenical) or age 18 (Alli).

Mechanism of Action: Orlistat inhibits pancreatic lipase and acts by blocking lipid absorption in the gastrointestinal (GI) tract. It primarily lowers the absorption of free fatty acids but also has an effect on cholesterol absorption. The decreased lipid absorption lowers calories and promotes weight loss. Orlistat inhibits fat absorption by approximately 30%.

Pharmacokinetics:

Route(s)	PO
Absorption	Minimal absorption
Distribution	Not distributed; remains in the GI tract; does not cross the placenta; is not secreted in breast milk
Primary metabolism	Wall of the GI tract
Primary excretion	Feces
Onset of action	24–48 h
Duration of action	Half-life: 1–2 h

Adverse Effects: Some of the adverse effects of orlistat are directly related to its inhibition of lipid absorption. As more lipids reach the large intestine, flatus with discharge, oily stool, and fecal urgency are common, especially during the first 4 weeks of therapy. To avoid serious adverse GI effects, patients should restrict their fat intake. Rare cases of liver toxicity have been reported with this drug.

Contraindications/Precautions: Orlistat should be used with caution in patients with cholestasis because the drug inhibits gallbladder contractions. Orlistat is contraindicated for patients who have a known cause of obesity, such as hypothyroidism, and in patients with severe

malabsorption disorders. The drug is contraindicated in patients with anorexia nervosa or bulimia because it may worsen these disorders. Orlistat is contraindicated during pregnancy because the benefits of weight loss do not outweigh the potential risks to the fetus.

Drug Interactions: Because orlistat inhibits the absorption of the lipid-soluble vitamins A, D, and E, a supplement containing these vitamins should be taken at least 2 hours before or after a dose of orlistat. Vitamin K levels may decrease in patients taking orlistat, which can affect anticoagulation produced by warfarin. Orlistat decreases the absorption of cyclosporine and the two drugs should not be used concurrently. Orlistat may also decrease the absorption of warfarin (Coumadin); therefore, coagulation values in these patients should be monitored closely.
Herbal/Food: Unknown.

Pregnancy: Category X.

Treatment of Overdose: Overdose with orlistat is not a clinical problem because the effects of the drug are rapidly reversible.

Nursing Responsibilities:

- Obtain a complete health history including allergies, drug history, and possible drug interactions.
- Perform a physical assessment including vital signs and apometric measurements such as BMI and body weight.
- Assess laboratory values as indicated to determine hepatic and renal function.
- Consult a dietitian to prepare and educate the patient on the recommended nutritional intake.
- Administer the drug during or up to 1 hour after a meal containing fat. Omit the dose if eating a meal that does not contain fat or if a meal is skipped.
- Monitor weight and BMI; closely monitor people with diabetes for hypoglycemia.
- Monitor prothrombin time (PT) and international normalized ratio (INR) if the patient is taking warfarin. Assess for signs of vitamin K deficiency such as bruising or prolonged oozing from minor cuts.
- Monitor blood pressure frequently, especially in patients with preexisting HTN.
- Assess for medications that can interact with orlistat such as warfarin, cyclosporine, pravastatin, diabetes drugs, and fat-soluble vitamin supplements such as A, D, E, and K. Vitamin deficiencies can occur, causing changes in eyesight, hair, and skin.

Lifespan and Diversity Considerations:

- Assess the older adult's diet, medication history, and alcohol intake. Vitamin deficiency may occur as a

CONNECTIONS: Preparing for Advanced Practice

Obesity in Primary Care

Case

Sydney is a 42-year-old woman with obesity who has a 9-year history of type 2 diabetes. She comes to the clinic with her husband, Frank, with complaints of fatigue, difficulty losing weight, and lack of motivation. Her depression screening is negative. On physical exam, her height is 1.5 m (5 ft 2.5 in.) and her weight is 124 kg (275 lb) with a BMI of 50.3 kg/m^2. Her blood pressure is 160/88 mmHg. The remaining physical findings are normal. During her first visit, she was counseled on a low-calorie, high protein, low-fat, and low-carbohydrate diet, and was asked to exercise at least 5 times a week. She was also instructed on behavioral triggers and coping mechanisms. At her 4-week follow-up appointment, she had lost 2.7 kg (6 lb) and her blood pressure was down to 126/85 mmHg. She did not seem happy with that and insisted that she be prescribed the diet pill that her sister was given. Her diet and exercise plan was reviewed and it was recommended that she continue with the diet and exercise plan for another 6 weeks. Although she seemed frustrated and asked why her sister did not have to do all of this, she agreed to the plan. At her 6-week follow-up appointment she was down an additional 4 pounds! The diet and exercise plan was continued, and because the lifestyle plan had been followed and Sydney had shown positive lifestyle changes, she was started on phentermine/topiramate (Qsymia) for appetite suppression, and canagliflozin (Invokana) was added to her medication regimen to help with glucose control. Sydney returned 6 weeks later with increased energy and was ecstatic with her 12-pound weight loss. Her blood pressure and blood sugar were also well controlled and she let us know that she has reduced her snacking. Is this treatment plan appropriate for Sydney?

Discussion

The U.S. Preventive Services Task Force (USPSTF) recommends that clinicians screen all adults for obesity. Lifestyle and behavioral changes are considered first-line therapies and it is important for patients to maintain them for sustained weight management. Diet and exercise should remain the gold standard of care; however, recent studies suggest that the addition of pharmacotherapy may increase the likelihood that patients will achieve weight loss (more than or equal to 5% of initial weight), as compared with brief counseling alone (Carvajal, Wadden, Tsai, Peck, & Moran, 2013). Healthcare providers should consider adding pharmacologic management to weight loss treatment plans and, with the new evidence, should feel safe in prescribing these medications.

result of normal physiologic changes related to aging and nutrient absorption, alcohol use, or medication. Medication interactions may be impaired further with the use of orlistat. Supplementation may be required.

Patient and Family Education:

- Take a daily multivitamin containing fat-soluble vitamins at least 2 hours before or after orlistat.
- Adverse GI effects are common but typically resolve after 4 weeks of therapy.
- Avoid high-fat meals to minimize adverse GI effects. Distribute fat calories over three main meals daily. Do not skip meals.
- Monitor weight several times weekly. If diabetic, monitor blood glucose carefully following any weight loss.
- Expect that certain adverse effects can occur such as stomach discomfort, an increased number of stools, loss of control of defecation, gas released with bowel movements, oily stools, or the urgent desire to defecate.
- Increase physical activity as tolerated and approved by the healthcare provider.
- Provide the healthcare provider with a list of all drugs and supplements currently taken because orlistat can interact with other drugs and vitamins.
- Immediately notify the healthcare provider of any known or suspected pregnancy.

Drugs Similar to Orlistat (Alli, Xenical)

Orlistat is the only lipase inhibitor indicated for obesity.

63.7 Anorexiants are drugs used to induce weight loss by suppressing appetite and hunger.

A second strategy to reduce weight is to block parts of the nervous system responsible for recognizing and reacting to hunger. All the anorexiants have the potential to produce serious adverse effects; thus their use is limited to short-term therapy. Like the lipase inhibitors, anorexiants are prescribed for patients with a BMI of at least 30 or greater, or a BMI of 27 or greater if the patient has other risk factors such as HTN, hyperlipidemia, or diabetes.

Bupropion and naltrexone (Contrave): In 2014, the FDA approved Contrave for the short-term pharmacotherapy of obesity. Bupropion is also approved as an atypical antidepressant and naltrexone as an opioid agonist. Contrave reduces appetite by increasing dopamine activity and blocking opioid receptors in the brain. Contrave should be discontinued after 4 months if a weight loss of less than 5% is observed. The drug carries a black box warning that it may cause suicidal behavior. It is pregnancy category X.

Liraglutide (Saxenda): Liraglutide was initially approved in 2010 for type 2 diabetes. Subsequently, it was approved in 2014 for weight management in patients with obesity who have a comorbid condition such as HTN or diabetes. Like other anorexiants it should be used with a reduced-calorie diet and increased physical activity. Liraglutide is a glucagon-like peptide-1 (GLP-1) receptor agonist. GLP-1 helps to regulate appetite by increasing feelings of satiety. Liraglutide has the potential to produce serious adverse effects such as pancreatitis, hypoglycemia, and gallbladder disease. The drug is pregnancy category X and carries a black box warning that it may cause thyroid tumors.

Lorcaserin (Belviq): In 2012, Lorcaserin was approved for weight loss when combined with a reduced-calorie diet and increased exercise. It is believed to act by activating serotonin receptors in the hypothalamus, causing increased satiety. If a 5% weight loss has not occurred after 12 weeks of therapy, it is recommended that the drug be discontinued. Safety and effectiveness in patients younger than age 18 has not been established. Lorcaserin does produce euphoria in some patients; thus it has some potential for abuse (Schedule IV). This drug is contraindicated during pregnancy because the benefits of weight loss do not outweigh the potential risks to the fetus.

Sympathomimetic amines (SAs): The SAs are the oldest drugs for treating obesity. The prototype for this group is amphetamine. Adderall, commonly used to treat attention-deficit/hyperactivity disorder (ADHD), is a 75:25 mixture of dextroamphetamine and levoamphetamine. Evekeo, indicated for weight loss and ADHD, is a 50:50 mixture of the two amphetamines. Other SAs approved for weight management include phentermine, phendimetrazine, methamphetamine, benzphetamine, and diethylpropion. For effective weight loss, the SAs should be combined with a calorie-restriction plan and a physical exercise regimen.

All of the SAs are CNS stimulants with the ability to suppress appetite. All are controlled substances that can cause physiologic and psychologic dependence. Methamphetamine is a Schedule II drug that carries a black box warning regarding its high potential for abuse. Typical weight loss is less than 0.5 kilogram (1 pound) per week and the effects tend to diminish over time due to tolerance. The SAs have limited clinical usefulness because they are only for short-term therapy (several weeks), whereas successful treatment of obesity may require years. Long-term therapy, or abuse, may cause HTN, cardiac abnormalities, bipolar illness, and other psychoses.

CONNECTION Checkpoint 63.3

Orlistat may decrease the absorption of fat-soluble vitamins. From what you learned in Chapter 61, describe the types of effects that could result from deficiencies in the fat-soluble vitamins A and D. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Adjuncts to Obesity Therapy

63.8 Artificial sweeteners and fat substitutes are sometimes used as adjuncts to weight management programs.

A primary component of any weight management program is reduction of caloric intake. In an attempt to reduce total calories, many people have turned to artificial sweeteners and fat substitutes.

Artificial sweeteners include saccharin (Sweet'N Low®, Sugar-Twin®), aspartame (NutraSweet®, Equal®), acesulfame (ACK, Sweet One®, Sunett®), and sucralose (Splenda®). These agents are 200 to 600 times sweeter than table sugar, or sucrose, and thus less quantity is needed for sweetening food and beverages. Artificial sweeteners are regulated by the FDA because they are classified as food additives. Safety studies suggest that these substances are safe when used in usual amounts. Consumers should be aware that "sugar-free" foods that contain artificial sweeteners may have just as many calories and have a higher fat content than regular foods. Patients who have diabetes or are pregnant should consult with their healthcare providers before consuming artificial sweeteners.

Stevia (Truvia) is a genus of a plant in the sunflower family from which natural sweeteners are extracted. More than 30 times sweeter than sucrose, stevia is recognized by the FDA as a dietary supplement, not as a food additive. It has gained wide acceptance as an artificial sweetener in the United States. Stevia has a bitter taste when used in large amounts. Safety concerns have caused it to be banned in several countries.

Fats give food a smooth texture as well as calories. It is easy to identify fat-free or low-fat foods because they generally lack the taste and texture of normal fat. Fat substitutes attempt to simulate the texture of normal fat without the calories or effects of raising lipid levels in the blood. Olestra is a popular fat substitute that consists of a sucrose molecule surrounded by fatty acids. It has the appeal of fat but passes through the digestive tract undigested. It offers zero calories and zero fat but has the unpleasant adverse effects of loose stools and anal leakage. It is primarily restricted to use in snack foods. Simplesse® is a second fat substitute. It is derived from natural whey protein and is used in baked goods and dairy products. Many other products are under development.

Do artificial sweeteners and fat substitutes actually help patients lose weight? The answer depends on the dietary habits of the consumer. Certainly, drinking a liter of a regular soft drink gives one many more calories than drinking the same amount of a diet soft drink. Likewise, eating 8 ounces of potato chips using olestra gives fewer calories and fat than eating 8 ounces of regular chips. However, patients with serious weight problems should probably make better food choices than soft drinks and chips. A few studies have suggested that the body compensates by craving sucrose and high-fat meals. Note that the FDA has evaluated these food additives only for safety, not for their effectiveness in maintaining or losing body weight. Just as there are no miracle pills for weight loss, there are no miracle foods that will promote weight loss. The answer lies in the simple rules of limiting calorie intake, proper nutrition, and exercise.

Understanding Chapter 63

Key Concepts Summary

63.1 Genetic and lifestyle factors contribute to the etiology of obesity.

63.2 Appetite is regulated by the satiety center in the hypothalamus and is influenced by various hormones.

63.3 Obesity is measured by using the body mass index and waist circumference.

63.4 Nonpharmacologic treatment of obesity should be attempted prior to initiating pharmacotherapy.

63.5 Drugs used for weight management affect appetite or the absorption of fats.

63.6 Lipase inhibitors cause weight loss by interfering with the absorption of fats.

63.7 Anorexiants are drugs used to induce weight loss by suppressing appetite and hunger.

63.8 Artificial sweeteners and fat substitutes are sometimes used as adjuncts to weight management programs.

CASE STUDY: Making the Patient Connection

Remember the patient "Rosemary Goodman" at the beginning of this chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Rosemary, a 58-year-old woman, has just had her annual physical examination with the nurse practitioner. She was shocked to learn that she has gained just under 13.6 kg (30 lb) since her office visit 2 years ago, 7.7 kg (17 lb) in the last year alone. She went through menopause 2 years ago and thought that some of the mild edema and resulting weight gain she experienced around the time of her menses was over. Rosemary has always been under or at normal weight except for the last office visit. At the time she was going through a personally stressful time and was not concerned about the weight gain. She works in an office as a financial manager, spending most of her day at her desk. Although she tries to take lunchtime walks, on most days there is just too much to do in the office.

The rest of her physical examination was unremarkable except for a borderline hypertensive blood pressure reading of 138/82 mmHg. Her height is 1.6 m (5 ft 6 in.), and she now weighs 79.5 kg (175 lb). She states that she "watches what she eats" and normally eats three meals per day: a hurried breakfast of "something from the local fast-food place" on the drive to work, a sandwich at her desk or "whatever the rest of the office is ordering from take-out" for lunch, and a "regular dinner" at home with her husband. On the evenings when her husband is not home for dinner, Rosemary picks up something at the local supermarket from the prepared food aisle. She also enjoys a glass of wine with dinner. When the nurse and Rosemary add up the approximate number of calories she consumes, the average total is over 2000 per day. Rosemary is upset and asks the nurse about weight loss strategies.

Critical Thinking Questions

1. Rosemary asks about diet pills because her mother used to take them on occasion. What would you tell her about the availability of these drugs today?
2. Rosemary would like to try orlistat (Alli), which she has noticed on the shelf in the supermarket. What does Rosemary need to know about orlistat before deciding to take it? What teaching does she need about taking orlistat?
3. What factors have contributed to Rosemary's weight gain during the past 2 years? What general health teaching would be appropriate for Rosemary to aid her in her weight reduction?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Kathryn is a 52-year-old woman who has been grossly overweight for more than 15 years. In that time she has tried many diets, exercise regimens, diet clubs, and drug therapies but all to no avail. She weighs 143 kg (315 lb) and has a BMI of 48. Her healthcare provider has prescribed orlistat (Xenical). She informs you that she has tried diet pills in the past. She has heard that amphetamines cause people terrible problems and is fearful that she will become dependent on orlistat or experience serious complications.

1. How would you address Kathryn's fears about diet drugs and the use of orlistat (Xenical)?
2. How is prescription strength orlistat different from the OTC dosage? What adverse effects may occur at the higher dosage?
3. What effect does orlistat have on vitamin absorption? If Kathryn's provider prescribes a multivitamin, what should Kathryn know about taking it?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient is prescribed lorcaserin (Belviq) for the treatment of obesity and is concerned about the risks involved with the drug. Which of the following should the nurse include when teaching this patient?
    1. If less than a 5% weight loss has been achieved after 3 months, a different weight loss regimen may be needed.
    2. There is no need to worry about any long-term effects if they do not occur when the drug is taken.
    3. Begin to see a cardiologist monthly until any cardiovascular risk has been ruled out.
    4. Contact the drug company about follow-up programs.

2. A patient asks the provider about a prescription for phentermine (Adipex-P) for obesity. Which of the following would be considered a contraindication for the use of this drug?
   1. Extreme obesity
   2. A history of type 2 diabetes managed with oral antidiabetic drugs
   3. A history of hypertension managed with beta blockers
   4. Pregnancy

3. The patient has been started on orlistat (Xenical). The nurse would teach this patient to take this medication:
   1. Once in the morning.
   2. When a feeling of hunger is noticed.
   3. Before daily exercise.
   4. Just prior to each meal containing fats.

4. While taking orlistat (Alli), the nurse would instruct the patient to do which of the following?
   1. Drink at least 2 to 3 liters of diet soda per day.
   2. Always wear sunscreen when outdoors or when exposed to direct sunlight.
   3. Rise slowly from a sitting or supine position.
   4. Take a daily vitamin supplement containing fat-soluble vitamins.

5. A nurse is instructing a patient taking orlistat (Xenical) about adverse effects of the medication. Which symptoms indicate the presence of an expected adverse effect?
   1. Flatus with discharge and oily stool
   2. Heartburn and dyspepsia
   3. Constipation with fecal impaction
   4. Nausea with projectile vomiting

6. Which of the following measures is used to assess the presence of obesity? (Select all that apply.)
   1. Body weight
   2. Body mass index
   3. Waist circumference
   4. Treadmill test
   5. Buoyancy analysis

Chapter 64
Review of the Endocrine System

Chapter Outline

- Overview of the Endocrine System
- Hormone Receptors
- Negative Feedback Mechanisms
- Hormone Pharmacotherapy

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the general structure and functions of the endocrine system.
2. Compare and contrast the nervous and endocrine systems in the control of homeostasis.
3. Explain circumstances in which hormone receptors may be up-regulated or down-regulated.
4. Through the use of a specific example, explain the concept of negative feedback in the endocrine system.
5. Explain the three primary types of stimuli that regulate hormone secretion.
6. Identify indications for hormone pharmacotherapy.

Key Terms

down-regulation, 1177
endocrine system, 1177
hormones, 1177
negative feedback, 1179
replacement therapy, 1180
target cells, 1177
up-regulation, 1177

Like the nervous system, the endocrine system is a major controller of homeostasis. Whereas a nerve exerts instantaneous control over a single muscle fiber or gland, a hormone from the endocrine system may affect all body cells and take as long as several days to produce an optimal response. Hormonal balance is kept within a narrow range: Too little or too much of a hormone can produce profound physiologic changes. This chapter reviews endocrine anatomy and physiology and its relevance to pharmacotherapy. For a more detailed review of the endocrine system, the student should refer to an anatomy and physiology textbook.

Overview of the Endocrine System

64.1 The endocrine system controls homeostasis through the secretion of hormones.

The **endocrine system** consists of glands that secrete **hormones**, chemical messengers released in response to a change in the body's internal environment. The role of hormones is to maintain homeostasis in the body. For example, when the level of glucose in the blood rises above normal, the pancreas secretes insulin to return glucose levels to normal. The various endocrine glands and their hormones are illustrated in Figure 64.1.

After secretion from an endocrine gland, hormones enter the blood and are transported throughout the body. Compared to the nervous system, which reacts to body changes within milliseconds, the endocrine system responds relatively slowly. A few hormones, such as epinephrine, act within seconds, whereas others, such as testosterone, may take several days or even months to produce noticeable changes. Although slower in onset, the effects of hormones have a longer duration than those of the nervous system.

Hormone Receptors

64.2 Hormones must bind to specific receptors to cause physiologic changes.

The cells affected by a hormone are called its target cells. **Target cells** have specific protein receptors on their plasma membrane that bind to the hormone. For some hormones, the receptors are in the cytoplasm or nucleus of the target cell. Once binding occurs, a change is produced in the cell, resulting in an action that is characteristic for the hormone. For example, when epinephrine binds to receptors on smooth muscle cells, they contract. When prolactin binds to secretory cells in the breast, milk production occurs.

Although a hormone travels throughout the body via the circulation, it only affects cells that have receptors for that specific hormone. Epinephrine does not affect breast secretory cells, because these cells have no epinephrine receptors. Prolactin does not cause muscular contraction because smooth muscle cells do not have prolactin receptors. This concept is illustrated in Figure 64.2.

In some cases, the target cells for a hormone are limited and specific. For example, the only receptors for thyroid-stimulating hormone are in the thyroid gland. However, some hormones, such as insulin and cortisol, have receptors on nearly every cell in the body; thus, these hormones have widespread effects.

The number of protein receptors for a hormone is dynamic and changes with the needs of the body. Cells can create more receptors on their plasma membrane to capture hormone molecules as they pass by, a process called **up-regulation**. This may occur if the cell is receiving signals that a hormone action is needed, such as the need for production of more breast milk or additional secretion of thyroid hormone. Once the hormone is up-regulated (secreted in large quantities), the cell no longer needs to capture every hormone molecule so it makes fewer receptors on its surface, a process called **down-regulation**. Receptors are very efficient at capturing hormone molecules; although most hormones are secreted only in small amounts, they produce profound changes.

Down-regulation has important implications for pharmacotherapy. When a hormone is administered as pharmacotherapy for long periods, the body recognizes an abundance of the hormone, and cells will down-regulate the number of receptors for that hormone. This causes a desensitization of the target cells; that is, they are less responsive to the effects of the hormone. When therapy is discontinued, the cells will need time, usually several days, to synthesize more protein receptors and adjust to the new hormone level.

It is important to understand that the amount of hormone secreted by an endocrine gland is only partially responsible for the therapeutic response. Other critical components include the number of receptors and their sensitivity. During pharmacotherapy, increasing the dose of a hormone will produce little additional pharmacologic effect if all the receptors are already occupied, or if they are no longer sensitive to the hormone.

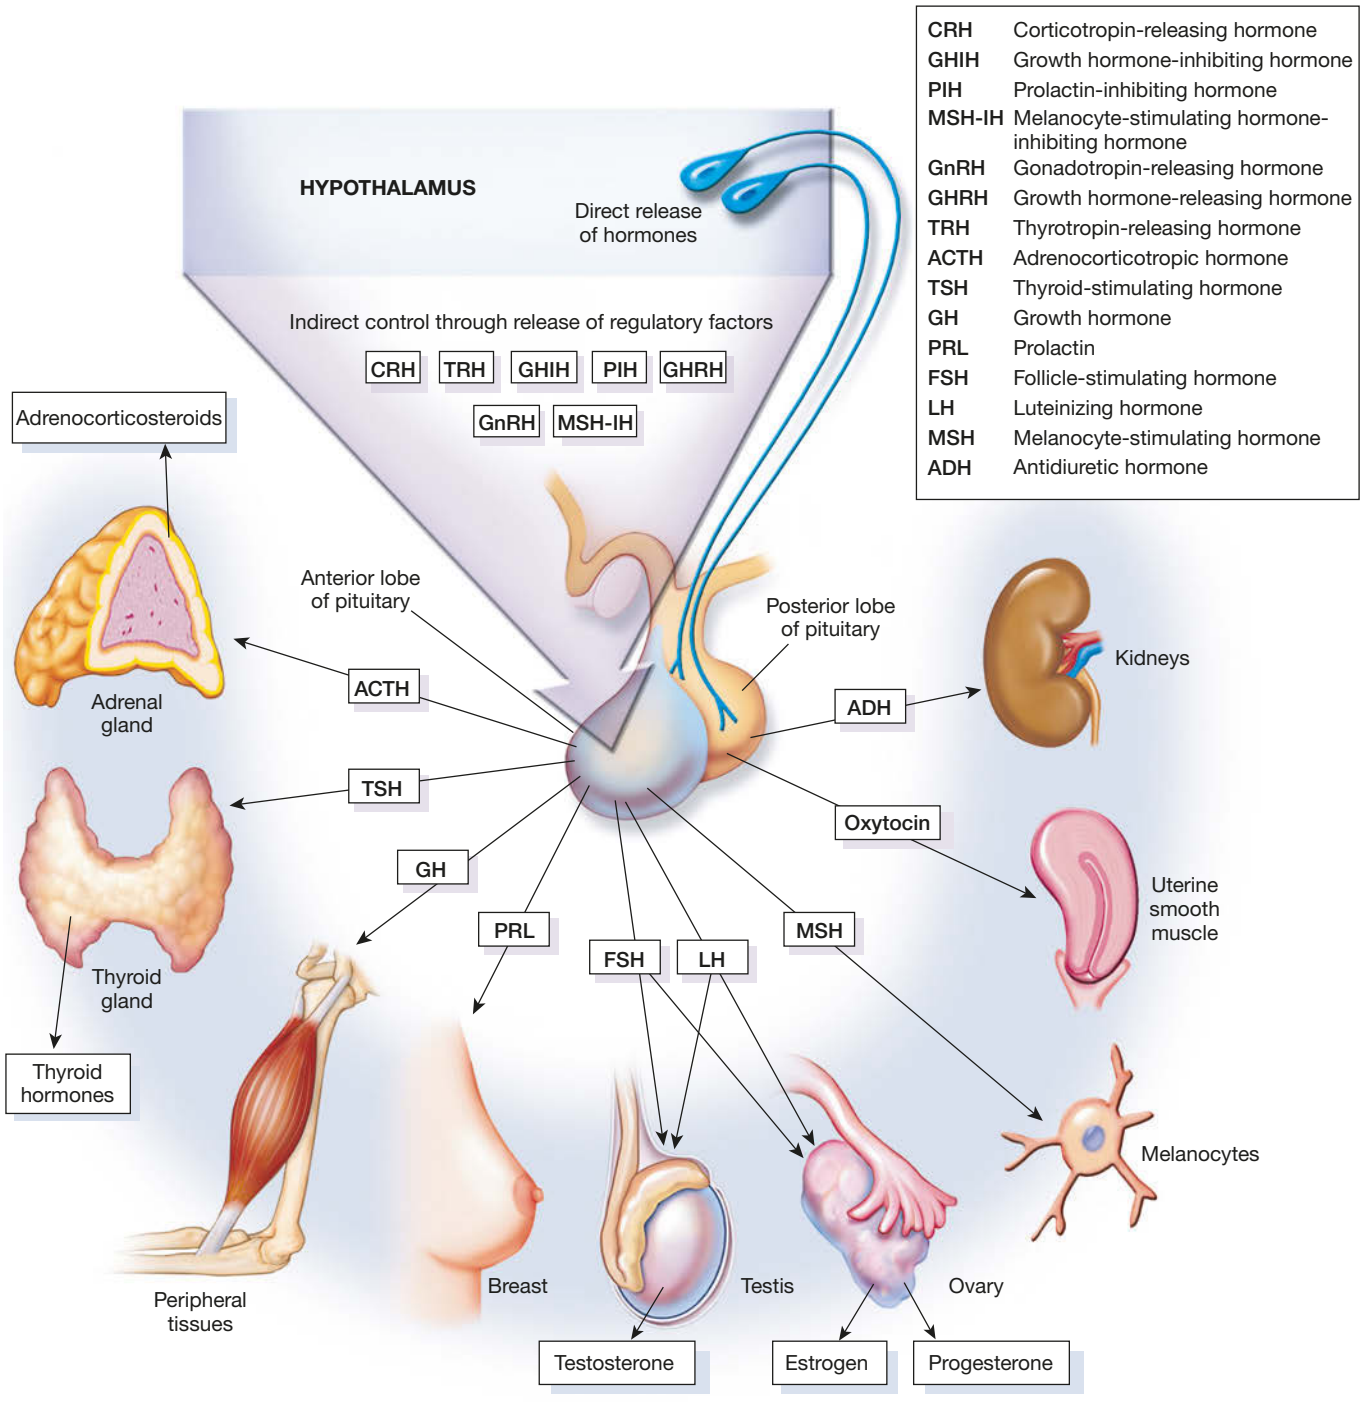

Figure 64.1 Hormones and the endocrine system.

PharmFACT

Although it does not appear in most textbooks as an endocrine organ, adipose tissue secretes hormones that affect energy balance. Endocrine-disrupting chemicals, called obesogens, have been discovered that alter normal adipose tissue endocrine secretions and could possibly lead to obesity (Janesick & Blumberg, 2016).

Negative Feedback Mechanisms

64.3 Most hormone action is regulated through negative feedback.

Because hormones can produce profound effects on the body, their secretion and release is carefully regulated by several levels of control. The most important mechanism is

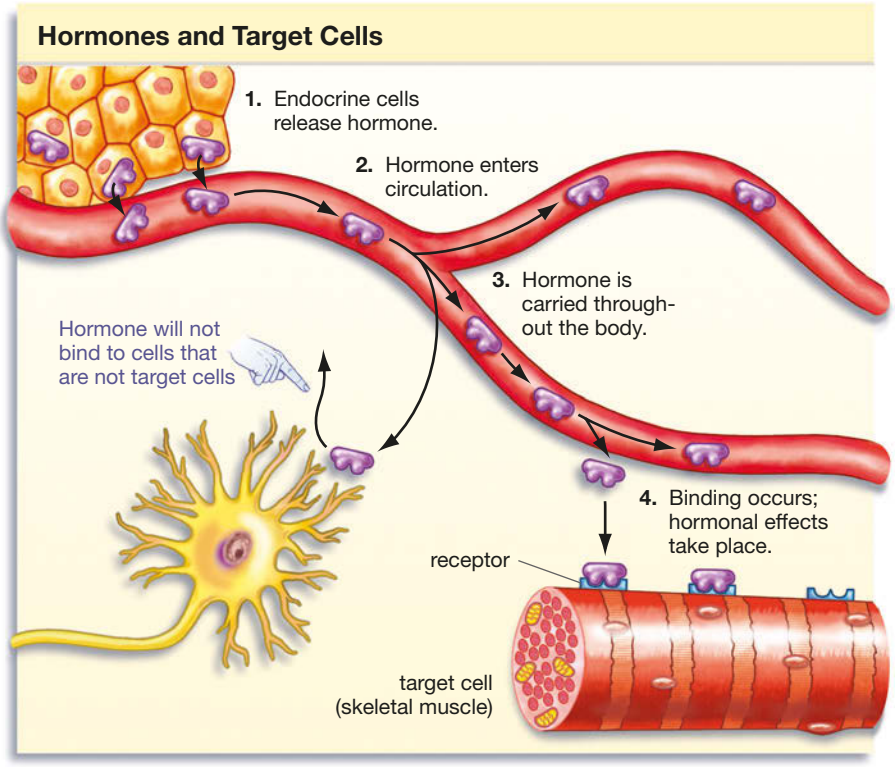

Figure 64.2 Hormones and their target cells.
From *Biology: A Guide to the Natural World*, 5th ed., by D. Krogh, 2011. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

negative feedback, which is illustrated in Figure 64.3. A hormone causes an output or action in its target cell or tissue. As the level of a hormone rises, so does the hormone's action. The increased output or action is monitored by sensors. Once homeostasis is restored, the sensor signals the endocrine tissue to stop secreting the hormone; that is, the target tissue provides negative feedback.

Depending on the specific hormone, the negative feedback mechanism may be based on three primary types of stimuli: neuronal, humoral, and hormonal. In some cases, regulation involves multiple stimuli. The various hormones and their regulation are summarized in Table 64.1.

Neuronal stimuli: A few hormones are regulated by nerve impulses. The best example is epinephrine, which is released when a neuronal impulse from the sympathetic nervous system reaches the adrenal medulla. Another example is the release of oxytocin from the pituitary gland.

Humoral stimuli: Some endocrine glands sense the levels of specific substances in the blood and release the hormone when the substance rises above or falls below the normal range. For example, pancreatic islet cells can sense the level of glucose in the blood. If glucose levels become too high, insulin is secreted. Another example is the release of parathyroid hormone when blood calcium levels fall.

Hormonal stimuli: In the endocrine system, it is common for one hormone to control the secretion of another

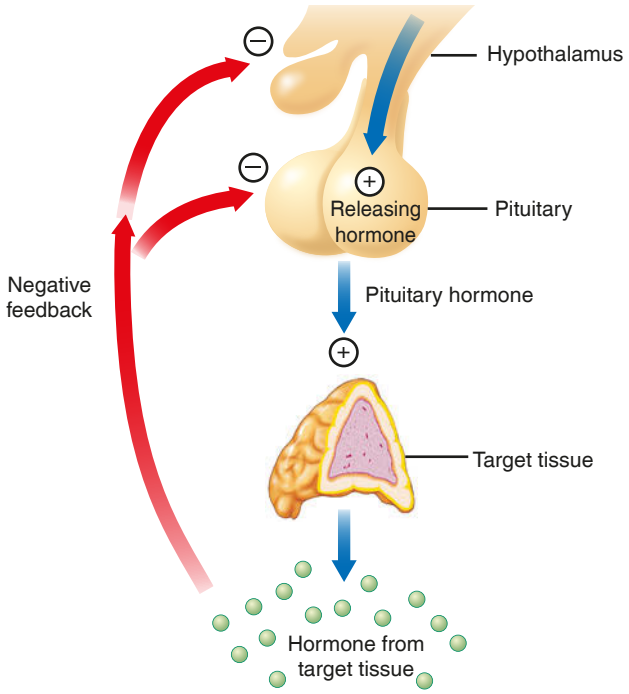

Figure 64.3 Negative feedback mechanism.

hormone. In some cases, the sequence involves three hormones. For example, thyrotropin-releasing hormone (TRH, from the hypothalamus) stimulates thyroid-stimulating hormone (TSH, from the pituitary), which causes the release of thyroid hormone (TH, from the thyroid gland).

Table 64.1 Selected Hormones and Their Regulation

		REGULATION	
Hormone	**Target Organ(s) and Action**	**Stimulation**	**Inhibition**
Adrenocorticotropic hormone (ACTH)	Adrenal cortex: stimulates release of glucocorticoids	Corticotropin-releasing hormone	Negative feedback from corticosteroids
Aldosterone	Kidneys: promotes reabsorption of sodium and water	Renin-angiotensin-aldosterone pathway, decreased blood volume, hypotension	Increased blood volume or hypertension
Antidiuretic hormone (ADH)	Kidneys: increases water reabsorption	Increased osmolarity of blood or decreased blood volume	Adequate hydration
Corticosteroids (glucocorticoids)	Most tissues: increases protein breakdown and glucose metabolism, provides resistance to stress, suppresses inflammation and immune response	Adrenocorticotropic hormone (ACTH)	Negative feedback from corticosteroids
Follicle-stimulating hormone (FSH)	Ovaries: promotes maturation of ovarian follicles and estrogen production Testes: increases sperm production	Gonadotropin-releasing hormone (GnRH)	Negative feedback from estrogen (women) or testosterone (men)
Growth hormone (GH)	Most tissues, including bone, muscle, liver: stimulates growth and mobilizes lipids	Growth hormone-releasing hormone (GHRH)	Negative feedback from GH or growth hormone-inhibiting hormone (GHIH)
Insulin	Most tissues: promotes movement of glucose into cells, lowers blood glucose, decreases glycogen synthesis, and increases lipogenesis and protein synthesis	Hyperglycemia	Hypoglycemia
Luteinizing hormone (LH)	Ovaries: stimulates ovulation and production of estrogen Testes: produces testosterone	Gonadotropin-releasing hormone (GnRH)	Negative feedback from estrogen and progesterone (women) or testosterone (men)
Oxytocin	Uterus: stimulates contractions Breasts: ejects milk	Stretching of uterus or infant suckling	Lack of stretching of the uterus or discontinuation of breastfeeding
Parathyroid hormone	Kidneys, gastrointestinal tract, bone: increases calcium levels in blood	Hypocalcemia	Hypercalcemia
Prolactin	Breasts: promotes lactation	Prolactin-releasing hormone	Prolactin-inhibiting hormone
Thyroid hormone	Most tissues: increases basal metabolic rate and growth	Thyroid-stimulating hormone	Negative feedback from thyroid hormone

In a loop typical of the endocrine system, the last hormone in the pathway (TH) provides negative feedback to shut off secretion of the initial hormone (TRH).

CONNECTION Checkpoint 64.1

From what you learned in Chapter 15, identify indications for epinephrine pharmacotherapy. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hormone Pharmacotherapy

64.4 Hormone pharmacotherapy is indicated for a diverse variety of conditions.

The goals of hormone pharmacotherapy vary widely. In many cases, a hormone is administered as **replacement therapy** for patients who are unable to secrete sufficient quantities of their own endogenous hormones. Examples of replacement therapy include the administration of thyroid hormone after the thyroid gland has been surgically removed, supplying insulin to patients whose pancreas is not functioning, or administering growth hormone to children with short-stature disorder. The pharmacologic goal of replacement therapy is to supply the same physiologic, low-level amounts of the hormone that would normally be present in the body. Selected endocrine disorders and their drug therapy are summarized in Table 64.2.

Some hormones are used in cancer chemotherapy to shrink the size of hormone-sensitive tumors. For example, certain breast cancers are strongly dependent on estrogen for their growth. Giving the "opposite" hormone, testosterone, will shrink the tumor. In a similar manner, estrogen is used to shrink the size of testicular cancer, which is dependent on testosterone for its growth. Exactly how these hormones produce their antineoplastic action is largely unknown. When hormones are used as antineoplastics, their doses far exceed physiologic levels normally present in the body. Hormones are nearly always used in combination with other antineoplastic medications.

Another goal of hormonal pharmacotherapy may be to produce an exaggerated response that is part of the normal action of the hormone. Administering hydrocortisone

Table 64.2 Selected Endocrine Disorders and Their Pharmacotherapy

Gland	Hormone(s)	Disorder	Drug Therapy Examples
Adrenal cortex	Corticosteroids	Hypersecretion: Cushing's syndrome	ketoconazole (Nizoral) and mitotane (Lysodren)
		Hyposecretion: Addison's disease	hydrocortisone, prednisone
Gonads	Ovaries: estrogen	Hyposecretion: menstrual and metabolic dysfunction	conjugated estrogens and estradiol
	Ovaries: progesterone	Hyposecretion: dysfunctional uterine bleeding	medroxyprogesterone (Provera, others) and norethindrone
	Testes: testosterone	Hyposecretion: hypogonadism	testosterone
Pancreatic islets	Insulin	Hyposecretion: diabetes mellitus	insulin and oral antidiabetic drugs
Parathyroid	Parathyroid hormone	Hypersecretion: hyperparathyroidism	surgery (no drug therapy)
		Hyposecretion: hypoparathyroidism	vitamin D and calcium supplements
Pituitary	Antidiuretic hormone	Hyposecretion: diabetes insipidus	desmopressin (DDAVP, Stimate) and vasopressin
		Hypersecretion: syndrome of inappropriate antidiuretic hormone (SIADH)	conivaptan (Vaprisol) and tolvaptan (Samsca)
	Growth hormone	Hyposecretion: small stature	somatropin (Genotropin, others)
		Hypersecretion: acromegaly (adults)	octreotide (Sandostatin)
	Oxytocin	Hyposecretion: delayed delivery or lack of milk ejection	oxytocin (Pitocin)
Thyroid	Thyroid hormone (T_3 and T_4)	Hypersecretion: Graves' disease	propylthiouracil (PTU) and ^{131}I
		Hyposecretion: myxedema (adults), cretinism (children)	thyroid hormone and levothyroxine (T_4)

to suppress inflammation takes advantage of the normal action of the corticosteroids but at higher amounts than would normally be present in the body. Hydrocortisone is indicated for acute inflammatory disorders such as lupus or rheumatoid arthritis. As another example, supplying estrogen or progesterone at specific times during the uterine cycle can prevent ovulation and pregnancy. In this example, the patient is given natural hormones; however, they are taken at a time when levels in the body are normally low.

Endocrine pharmacotherapy also involves the use of "antihormones." These hormone antagonists block the actions of endogenous hormones. For example, propylthiouracil (PTU) is given to block the effects of an overactive thyroid gland. Tamoxifen is given to block the actions of estrogen in estrogen receptor–dependent breast cancers (see Chapter 57).

CONNECTION Checkpoint 64.2

Glucocorticoids, or corticosteroids, are important drugs in treating inflammation. From what you learned in Chapter 42, explain their role in treating autoimmune disease. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Understanding Chapter 64

Key Concepts Summary

64.1 The endocrine system controls homeostasis through the secretion of hormones.

64.2 Hormones must bind to specific receptors to cause physiologic changes.

64.3 Most hormone action is regulated through negative feedback.

64.4 Hormone pharmacotherapy is indicated for a diverse variety of conditions.

Chapter 65
Hypothalamic and Pituitary Drugs

Chapter Outline

- Functions of the Hypothalamus
- Functions of the Pituitary Gland
- Pharmacotherapy of Growth Hormone Disorders

  Growth Hormone Analogs

  PROTOTYPE *Somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Saizen, Serostim, Zorbtive), p. 1188*

  Growth Hormone Antagonists

  PROTOTYPE *Octreotide (Sandostatin), p. 1190*
- Pharmacotherapy of Antidiuretic Hormone Disorders

  PROTOTYPE *Desmopressin (DDAVP, Noctiva, Stimate), p. 1194*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the principal actions of the hormones secreted by the hypothalamus and pituitary gland.
2. Identify indications for hypothalamic hormone therapy.
3. Explain the pharmacotherapy of growth hormone disorders in children and adults.
4. Explain the pharmacotherapy of antidiuretic hormone disorders.
5. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
6. Apply the nursing process to the care of patients receiving pharmacotherapy for disorders of the hypothalamus and pituitary gland.

Key Terms

acromegaly, 1190
anterior pituitary gland, 1185
diabetes insipidus (DI), 1194
dwarfism, 1186
gigantism, 1190
growth hormone (GH), 1186
insulin-like growth factor (IGF), 1186
posterior pituitary gland, 1185
short stature, 1187
syndrome of inappropriate antidiuretic hormone (SIADH), 1194
tropic hormones, 1185

In the specialty of endocrinology, understanding the complex relationship between the hypothalamus and pituitary gland is important because these organs regulate so many homeostatic functions. For example, the two organs collaborate to secrete hormones that control functions of the gonads, adrenal glands, thyroid gland, kidneys, and the milk-producing tissues of the breast. The functioning of these two glands serves as the control center that provides integration between the nervous and endocrine systems. This chapter examines drugs that directly affect the functions of the hypothalamus and pituitary gland.

Functions of the Hypothalamus

65.1 The hypothalamus controls many diverse body processes and secretes hormones that influence pituitary function.

Roughly the size of an almond, the hypothalamus lies in the center of the diencephalon of the brain, just superior to the brainstem. The general purpose of the hypothalamus is to maintain homeostasis. To achieve this, the hypothalamus receives input from numerous vital regions of the nervous system, recognizes imbalances, and makes adjustments to bring the body back to homeostasis. Examples of the multiple and diverse functions of this organ include control of body temperature, thirst, appetite, fatigue, circadian rhythms, anger, and the rate of overall body metabolism. The hypothalamus also controls vital functions of the autonomic nervous system such as heart rate, vasoconstriction, digestion, and sweating. For the purposes of this chapter, only the endocrine functions of the hypothalamus are presented.

Every hormone has target cells that possess receptors for that specific hormone. For the hormones secreted by the hypothalamus, there is only one target organ: the pituitary gland. All hypothalamic hormones travel by the blood a short distance to the pituitary, which lies immediately below the hypothalamus. Upon reaching their receptors, the hypothalamic hormones simply increase or decrease the release of hormones by the pituitary gland. Because of this, hormones from the hypothalamus are called releasing hormones or inhibiting hormones. The major hypothalamic hormones and their actions on the pituitary gland are given in Table 65.1.

There are very few indications for the administration of hypothalamic hormones. Rather than give hypothalamic hormones, it is more effective (and less expensive) to administer pituitary hormones or the secretions of a target endocrine organ such as thyroid hormone, estrogen, testosterone, or corticosteroids.

Table 65.1 Hormones Secreted by the Hypothalamus and Pituitary Glands

Hypothalamic Hormone	Pituitary Hormone	Target Organ	Principal Actions
Corticotropin-releasing hormone (CRH)	Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Stimulates release of corticosteroids
Gonadotropin-releasing hormone (GnRH)	Follicle-stimulating hormone (FSH)	Ovaries, testes	Stimulates release of estrogen and ovarian follicle development in women, and sperm production in men
	Luteinizing hormone (LH)	Ovaries, testes	Triggers ovulation and secretion of estrogen and progesterone in women, increases testosterone secretion in men
Growth hormone-inhibiting hormone (GHIH) Growth hormone-releasing hormone (GHRH)	Growth hormone (GH)	Most body cells	Regulates growth and development of bones, muscles, cartilage, organs; general body metabolism
None	Melanocyte-stimulating hormone (MSH)	Skin	Stimulates pigmentation
Prolactin-inhibiting hormone (PIH) Prolactin-releasing hormone (PRH)	Prolactin	Mammary glands	Regulates lactation
Thyrotropin-releasing hormone (TRH)	Thyroid-stimulating hormone (TSH)	Thyroid gland	Stimulates release of thyroid hormone

Table 65.2 Hypothalamic Medications

Drug	Action	Indication
cetrorelix (Cetrotide)	GnRH antagonist	Female infertility
degarelix (Firmagon)	GnRH antagonist	Advanced prostate cancer
ganirelix	GnRH antagonist	Female infertility
goserelin (Zoladex)	GnRH analog	Men: Stage 2 prostate cancer and palliation of advanced prostate cancer
histrelin (Supprelin LA, Vantas)	GnRH analog	Palliation of advanced prostate cancer (Vantas) and treatment of precocious puberty (Supprelin LA)
leuprolide (Eligard, Lupron, Viadur)	GnRH analog	Men (Eligard, Viadur): palliation of advanced prostate cancer Women (Lupron): endometriosis and leiomyomata
nafarelin (Synarel)	GnRH analog	Precocious puberty
triptorelin (Trelstar)	GnRH analog	Palliation of advanced prostate cancer

The hypothalamic hormones that do have clinical applications are analogs or antagonists of gonadotropin-releasing hormone (GnRH). Initially the effect of the GnRH analogs is to increase the production of interstitial cell-stimulating hormone (in men) or follicle-stimulating hormone (in women), which increases the secretion of sex hormones. With continued therapy, however, the pituitary becomes insensitive to the effects of GnRH, and the production of sex hormones falls to near castration levels. Indications for these drugs are shown in Table 65.2. Doses and additional information may be found in Chapters 57 and 69.

CONNECTION Checkpoint 65.1

Target tissues can up-regulate or down-regulate the number of receptors for a specific hormone. From what you learned in Chapter 64, which of the two processes occurs when a hormone is administered as pharmacotherapy for long periods? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Functions of the Pituitary Gland

65.2 The pituitary gland secretes hormones that control many diverse body functions.

Although the pituitary gland is often referred to as the "master gland," its function is largely controlled by releasing or inhibiting hormones from the hypothalamus. The pituitary gland is divided into anterior and posterior lobes, which have very different structures and functions.

The **anterior pituitary gland** (adenohypophysis) comprises glandular tissue that manufactures and secretes hormones that control major body functions and systems. Four of these are called **tropic hormones**, a term that refers to the ability of these hormones to regulate the secretory actions of other endocrine glands. The anterior pituitary hormones are synthesized and stored in the pituitary until they receive a message from the hypothalamus. The message from the hypothalamus is usually to *enhance* the release of hormones, as is the case for growth hormone-releasing hormone (GHRH), thyrotropin-releasing hormone (TRH), prolactin-releasing hormone (PRH), corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). Two of the hypothalamic secretions, growth hormone-inhibiting hormone (GHIH) and prolactin-inhibiting hormone (PIH), *prevent* the release of pituitary hormones.

The **posterior pituitary gland** (neurohypophysis), by contrast, consists of nervous tissue and is basically an extension of the hypothalamus. It secretes two hormones: antidiuretic hormone (ADH) and oxytocin. These hormones are manufactured in the hypothalamus and travel down neurons to the posterior pituitary where they are stored until factors stimulate their release. The primary stimulus causing ADH secretion is an increased serum osmolality, or a high concentration of solutes in the blood. Oxytocin release is stimulated by touch receptors in the nipples of lactating women. Pharmacotherapy with oxytocin is presented in Chapter 69.

Regulation of hormone levels is an essential function because too little or too much of any of these endocrine secretions can cause profound symptoms. Many are controlled by negative feedback loops. As circulating levels of a hormone rise above normal, a message is sent to the hypothalamus, pituitary, or other endocrine gland to shut down the manufacture and secretion of the hormone. This prevents excess hormone levels. When hormones are administered as drug therapy, they can influence this normal negative feedback mechanism. One of the most important examples of this phenomenon is the negative feedback suppression of the adrenal glands caused by administration of corticosteroid medications. The student should review the information on negative feedback in Chapter 64 before proceeding.

Because of the widespread effects of the hormones secreted and controlled by the hypothalamus and pituitary glands, disorders of these glands are quite complex. In

general, the pathologies of endocrine glands can be categorized as causing hypofunction or hyperfunction of the particular gland. Pituitary disorders can be the result of tumors, surgery, radiation therapy, infection, injury, infarction (loss of blood supply), or bleeding (hemorrhage) in the area. Congenital defects may also result in absent or impaired function of a hormone, or the lack of an enzyme necessary for hormone production.

Pharmacotherapy of Growth Hormone Disorders

65.3 Growth hormone deficiency in adults and children can be treated by administering recombinant growth hormone.

Growth hormone (GH), also called somatotropin or somatropin, is produced and secreted by the anterior pituitary gland. This hormone was once believed to be of importance only during periods of active growth, but it is now recognized that adults produce nearly as much GH as children. Although its major targets are bone and skeletal muscle, GH stimulates many types of body cells to increase in size and replicate. It is considered an anabolic (tissue-building) hormone. The primary effects of GH, illustrated in Figure 65.1, are as follows:

- Increases length and width of bone
- Stimulates cartilage growth
- Stimulates the growth and development of most visceral and endocrine organs, skeletal and cardiac muscle, and skin and connective tissue
- Enhances cellular uptake of amino acids and increased protein synthesis
- Breaks down adipose tissue to release fatty acids for use as fuel
- Decreases use of glucose; impairs glucose tolerance and induces insulin resistance in peripheral tissues.

Many of the effects of GH are dependent on **insulin-like growth factor (IGF)**, a family of peptides that promote cartilage and bone growth. IGFs are produced in the liver and are released when hepatic cells become activated by GH. Secretion of GH fluctuates during the day, peaking 1 to 4 hours following the onset of sleep. These nighttime bursts in GH are greater in children than in adults.

The overall regulation of serum GH levels resides in the hypothalamus, with the secretion of GHRH and GHIH. A large number of secondary factors, such as exercise and sleep, influence the release of GH, and these are listed in Table 65.3.

In children, GH deficiency results in dwarfism. **Dwarfism** is associated with normal birth length followed by a slowing of the growth rate. These children have normal intelligence, short stature, immature facial features, obesity,

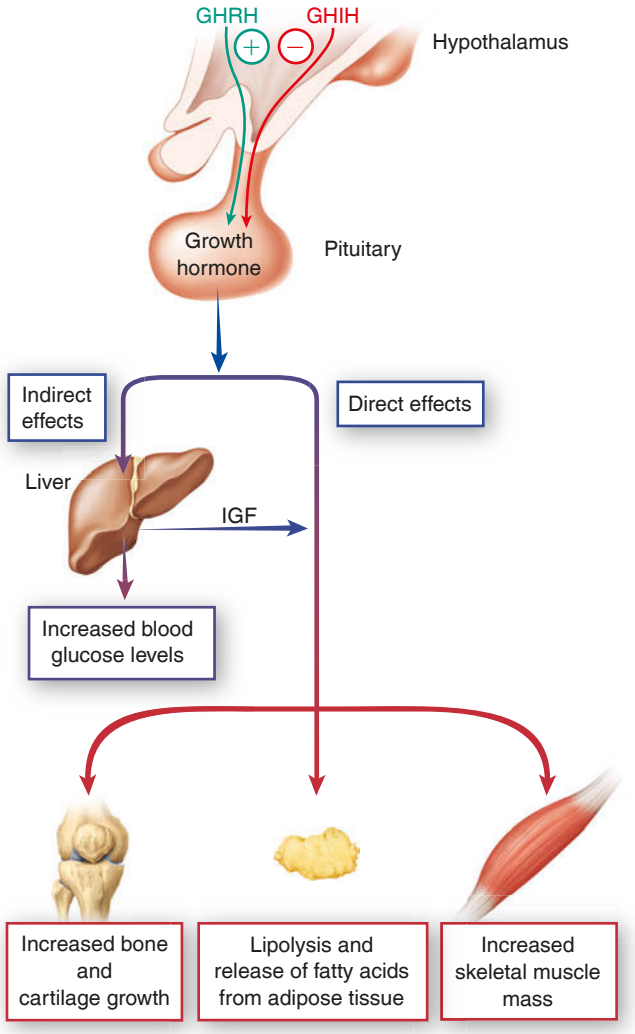

Figure 65.1 Physiologic and pharmacologic effects of growth hormone.

Table 65.3 Selected Factors Affecting the Release of Growth Hormone

Factors Increasing Release of GH	Factors Decreasing Release of GH
Amino acids: leucine, arginine	Beta-adrenergic agonists
Androgens and estrogens	Carbohydrate-rich diet
Clonidine	Cortisol
Elevated body temperature	Free fatty acids
Gamma-hydroxybutyrate	Increased serum glucose level
Growth hormone-releasing hormone (GHRH)	Obesity
Hypoglycemia, fasting, starvation	Somatostatin (GHIH)
L-dopa	
Stress, trauma	
Vigorous exercise	

and delayed skeletal maturation. In this context, **short stature** is defined as well below the fifth percentile for age and gender, or more than two standard deviations below the mean (average) height for age and gender. Acquired GH deficiency develops later in childhood and can be caused by a hypothalamic-pituitary tumor or an infection. Children who have been severely neglected or emotionally deprived can develop a psychosocial dwarfism, with poor growth, a potbelly, and poor nutritional habits. GH levels often return to normal once the child is removed from the dysfunctional environment.

When GH deficiency is the cause of short stature, replacement therapy is the preferred treatment. Until 1985, GH was obtained from the pituitary glands of human cadavers, a practice that was halted following the deaths of several recipients who developed Creutzfeldt–Jakob disease. GH is now obtained using recombinant DNA technology. GH obtained through recombinant technology is called somatropin. Doses for the GH analogs are listed in Table 65.4.

Therapy with recombinant GH is expensive, with a cost of approximately $50,000 per inch of growth. The hormone is administered subcutaneously, several times a week during the period of active growth, and therapy may continue until adulthood. Females with Turner's syndrome and children with chronic kidney disease (CKD) may also be treated with GH. Often, treatment with GH produces only modest gains in final adult height, but these gains are considered beneficial to the psychologic well-being of the patient.

Adult GH deficiency is associated with reduced muscle mass, increased cardiovascular mortality, central adiposity and increased visceral fat, insulin resistance, and dyslipidemia. This hormonal deficiency may develop during adulthood, or it may be a continuation of childhood deficiency. Several forms of recombinant human GH

Table 65.4 Drugs Acting on the Pituitary Gland and Target Tissues

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
bromocriptine (Cycloset, Parlodel)	PO (Cycloset): 0.8 mg daily, increased weekly to achieve 1.6–4.8 mg daily PO: 1.25–2.5 mg/day for 3 days, then increase dose every 3–7 days to 30–60 mg/day	*Orthostatic hypotension, nausea, vomiting, fatigue, dizziness, headache* Shock, acute MI, cerebral ischemia, confusion, agitation, psychosis
desmopressin (DDAVP, Noctiva, Stimate)	IV/subcutaneous: 2–4 mcg in 2 divided doses PO: 0.2–0.4 mg/day Intranasal: 1 spray in either right or left nostril 30 min before bedtime	*Headache, nasal congestion or irritation, nausea* Water intoxication, coma, thromboembolic disorder, hyponatremia
lanreotide (Somatuline Depot)	Subcutaneous: 60–120 mg q4wk	*Pain at the injection site, nausea, vomiting, diarrhea, itching* Gallstones, abdominal pain, bradycardia, hyper- or hypoglycemia
mecasermin (Increlex)	Subcutaneous: 0.04–0.08 mg/kg bid. Must be administered within 20 min of a meal or snack (max: 0.12 mg/kg bid)	*Injection-site reaction, iron deficiency anemia, goiter, antibody development, headache, hypertrophy of tonsils* Hypoglycemia, increased intracranial pressure
octreotide (Sandostatin)	Subcutaneous/IV: 100–600 mcg/day in 2–4 divided doses; after 2 wk may switch to IM depot, 20 mg q4wk	*Nausea, vomiting, diarrhea, headache, flushing, injection-site pain, cholelithiasis* Dysrhythmia, worsening heart failure, sinus bradycardia
pasireotide (Signifor LAR)	IM: 40 mg once q4wk	*Diarrhea, cholelithiasis, hyperglycemia, QT prolongation, bradycardia* Diabetes
pegvisomant (Somavert)	Subcutaneous: 40 mg loading dose, then 10 mg/day (max: 30 mg/day)	*Nausea, diarrhea, injection-site pain, flulike symptoms* Liver damage, elevated transaminase levels
somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Saizen, Serostim, Zorbtive)	Subcutaneous (Humatrope): 0.006 mg/kg daily (max: 0.0125 mg/kg/day) Subcutaneous (Serostim): Weight more than 55 kg: 6 mg at bedtime; 45–55 kg: 5 mg at bedtime; 35–45 kg: 4 mg at bedtime; less than 35 kg: 0.1 mg/kg at bedtime Child: Subcutaneous (Genotropin): 0.16–0.24 mg/kg/wk in 6–7 divided doses Norditropin: 0.024–0.034 mg/kg 6–7 times/wk	*Pain at injection site, hyperglycemia, arthralgia, myalgia, abdominal pain, otitis media, headache, bronchitis, hypothyroidism, HTN, flulike symptoms* Severe respiratory impairment in patients with severe obesity and Prader-Willi syndrome, diabetes, pancreatitis, scoliosis of the spine, papilledema, intracranial tumor
vasopressin	IM/subcutaneous: 5–10 units aqueous solution 2–4 times/day IV: 0.2–0.4 units/min up to 1 unit/min	*Tremor, pallor, nausea, vomiting, water retention, intoxication* Angina, acute MI, gangrene, anaphylaxis, cardiac arrest

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

formulations (Humatrope and Genotropin) have been approved for use in adults with body-wasting–type disorders. Treatment can result in increased lean body mass, decreased fat mass, increased bone mineral density, and decreased lipid levels.

Human GH has been abused for its anabolic effects. Athletes have used the drug to build muscle, increase strength, and maintain less body fat. It has also been called an antiaging drug because it promotes younger looking skin, improved memory, and reduced wrinkles. The administration of GH for these purposes is illegal, and prolonged use may lead to long-term adverse effects in patients. Despite potential adverse health effects, products advertised as "human growth hormone supplements" are readily marketed without a prescription. These do not contain any GH (which must be administered parenterally) but instead contain a mixture of oral (PO) supplements that are claimed to stimulate the pituitary gland. The safety and effectiveness of these products have not been evaluated adequately.

PROTOTYPE DRUG **Somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Saizen, Serostim, Zorbtive)**

Classification **Therapeutic:** Human growth hormone
Pharmacologic: Pituitary hormone

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1987, somatropin is prepared through recombinant DNA technology and is identical to endogenous human GH. It is available in several different formulations that vary by dose and regimen. The preferred route of administration is subcutaneous, although some forms may be given via the intramuscular (IM) route. GH produces growth of long bones in children prior to epiphyseal closure. The gain in growth is very rapid at the initiation of therapy but slows over time. Treatment may continue until the desired height is achieved, epiphyseal closure occurs, or the patient fails to respond to treatment. If treatment does not result in growth, it is stopped, and the diagnosis is reevaluated. The metabolic effects of the drug include increased protein synthesis, reduced carbohydrate utilization, and increased use of fatty acids for energy.

GH is used in the management of a number of growth-related disorders, including the following:

- Growth failure in children due to GH deficiency or Prader-Willi syndrome
- Growth failure in children due to CKD (Nutropin)
- Short stature associated with Turner's syndrome (Genotropin, Humatrope, Norditropin, Nutropin)
- Adult GH deficiency (Genotropin, Humatrope, Norditropin, Nutropin, Saizen)
- Acquired immunodeficiency syndrome (AIDS) wasting, cachexia, and severe thermal injuries (Serostim)
- Short bowel syndrome in patients receiving specialized nutrition support (Zorbtive).

Although the various brand-name products of GH have the same effectiveness, they differ in potency and are not interchangeable. Some are available in prefilled syringes, whereas others are longer acting. The nurse should check the package insert for specific dosing instructions.

Mechanism of Action: Somatropin has the same amino acid sequence as endogenous human GH and produces the same effects as the naturally occurring form of the hormone. The effects of GH are mediated by IGF.

Pharmacokinetics:

Route(s)	Subcutaneous, IM
Absorption	Well absorbed following injection
Distribution	Distributed to highly perfused organs (liver, kidneys); circulates bound to GH binding protein
Primary metabolism	Hepatic; some metabolism in kidneys
Primary excretion	Renal
Onset of action	Peak action variable: days to weeks
Duration of action	Half-life: 3.8–5 h

Adverse Effects: Adverse effects of somatropin include hyperglycemia and insulin resistance, which is made worse in patients with preexisting diabetes mellitus. It can also cause hypothyroidism. Edema of the hands and feet, headache, and hypertension (HTN) often occur initially but may resolve with continued therapy. Joint pain, muscle aches, and pain at the injection site are common. Carpal tunnel syndrome may occur with use of Serostim. Development of antibodies to GH may rarely occur. Hypercalciuria, possibly asymptomatic, may occur in the first few months of therapy.

Contraindications/Precautions: Somatropin is contraindicated for use in patients with closed epiphyses. It is also contraindicated in patients with severe obesity, respiratory impairment, or sleep apnea due to potentially fatal respiratory impairment. Somatropin should not be used in patients with intracranial tumor due to the risk for increased growth or recurrence of tumor. The drug is contraindicated in patients who are sensitive to glycerin. Somatropin should be used with caution in patients with severe renal or hepatic disease due to reduced clearance, and in patients with diabetes mellitus due to

hyperglycemia and insulin resistance. It should be used with caution in pregnant or lactating patients because safety has not been established.

Drug Interactions: Corticosteroids interfere with the bone growth–promoting action of GH; thus, the two should not be given concurrently. Concurrent use with anabolic steroids, androgens, estrogens, or thyroid hormone may increase the rate of epiphyseal closure. Patients receiving insulin should be monitored carefully because somatropin decreases the actions of insulin. **Herbal/Food:** Unknown.

Pregnancy: Category B or C, depending on the specific formulation.

Treatment of Overdose: Overdose with somatropin has not been reported.

Nursing Responsibilities: Key nursing implications for patients receiving somatropin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Growth Hormone.

Drugs Similar to Somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Saizen, Serostim, Zorbtive)

Mecasermin is the only other drug that has actions similar to GH.

Mecasermin (Increlex): Approved in 2005, mecasermin is a solution of IGF produced through recombinant DNA technology. This drug is identical to endogenous IGF and therefore has the same actions as GH. Mecasermin is indicated for two specific indications: the long-term treatment of growth failure in children with severe primary IGF deficiency, or for those who have developed neutralizing antibodies to GH. It is not intended to be used for any other forms of GH deficiency. It should not be used in adults after the epiphyses have closed. Adverse effects include hypoglycemia, local and systemic hypersensitivity, and tonsillar hypertrophy. Rare adverse effects include intracranial HTN, slipped capital epiphysis, and progression of scoliosis. Mecasermin use should be monitored carefully in patients taking insulin

CONNECTIONS: Preparing for Advanced Practice

Traumatic Brain Injury and Hormones

Case

Emma was a 17-year-old promising young soccer player. During her junior year in high school she spent weekends traveling to soccer tournaments, and she was being recruited by colleges around the country. Emma was being seen for her annual sports physical examination. Her only concerns were her lack of height and that she often felt tired. At 1.5 meters (5 ft 1 in.) she had not grown since she was 12 years old. Her family history showed that her father was nearly 1.8 meters (6 feet) tall, her mother was 1.7 meters (5 ft 10 in.), and both sets of grandparents were above average height. Emma did not smoke or drink alcohol, and denied using any illicit drugs. She had a history of three mild head injuries that she acquired while playing soccer. In fact, she was diagnosed twice with mild concussions 3 months apart when she was 12 years old. On physical examination, she displayed minimal breast tissue growth and was only at Tanner stage III. Other than the slow development, her physical examination was unremarkable. As a result of the history of head injuries and her small stature and unusual growth pattern, blood testing for hormone levels was done. The results showed that Emma had GH deficiency, adrenal insufficiency, and hypothyroidism.

Emma was started on growth hormone, cortisol, and replacement thyroid hormone, and on her annual sports physical examination 1 year later she had grown an additional 8.9 cm (3.5 in.). She feels less tired and is excited to have been offered the opportunity to play soccer at the local university. Is Emma's case unusual at such a young age?

Discussion

Traumatic brain injury (TBI) is a form of acquired brain injury that occurs when a sudden trauma causes damage to the brain. In Emma's case, it occurred after a soccer ball hit her in the head. Symptoms of a TBI can be mild, moderate, or severe, depending on the extent of damage to the brain. When minor head injuries occur back to back it can cause compounding effects. Young athletes have been found to be both more susceptible to concussions than older athletes and more likely to get these compounding effects (Rose, Weber, Collen, & Heyer, 2015).

Research has shown that TBI, even when mild, can have a negative effect on pituitary function, which can cause low levels of several hormones (Lauzier et al., 2014). Problems that can occur soon after a head injury or be delayed include the following:

- Adrenal insufficiency occurs when the adrenal glands do not make enough hormones. Symptoms include weight loss, fatigue, vomiting, dehydration, and low blood pressure. Adrenal insufficiency can be life threatening if not treated.
- Diabetes insipidus occurs when the pituitary does not make enough antidiuretic hormone (ADH). Symptoms include frequent urination and extreme thirst.
- Hypothyroidism results when the levels of thyroid hormone in the body are insufficient. Symptoms include fatigue, constipation, weight gain, irregular menstrual periods, and cold intolerance.
- Growth hormone deficiency occurs when the body's level of growth hormone is insufficient. In adults, this leads to increased fat, loss of muscle and bone, and decreased energy; in children, growth problems and small stature.

or oral antidiabetic drugs because mecasermin can increase the actions of these medications. This drug is pregnancy category C.

65.4 Overproduction of growth hormone in adults can be treated by administering growth hormone antagonists.

Excessive GH secretion that occurs prior to puberty and the sealing of epiphyseal plates of the long bones results in **gigantism**, or unusual tallness. Gigantism is rare due to early recognition of the cause of the oversecretion: a benign pituitary adenoma. GH excess in children is usually treated with surgery as soon as the disorder is diagnosed.

Excessive GH secretion in adults causes a condition known as **acromegaly**. Excess levels of GH stimulate the secretion of IGFs from the liver, which then produce the clinical manifestations of the disorder. Because the epiphyseal plates are closed in adults, bones become deformed rather than elongated with this disorder. The onset is gradual, with enlargement of the bones of the hands, feet, face, and skull, a broad nose, protruding lower jaw, and slanting forehead. The cartilage of the larynx enlarges, deepening the voice. Spinal changes can lead to kyphosis. Arthralgias and degenerative arthritis may occur, and enlargement of organs, including the heart, can result in an early death due to atherosclerosis. Metabolic changes lead to insulin resistance and impaired glucose tolerance. Treatment may consist of a combination of surgery, radiation therapy, and pharmacotherapy to suppress GH secretion and correct metabolic abnormalities. Doses of the GH antagonists are listed in Table 65.4.

PROTOTYPE DRUG **Octreotide (Sandostatin)**

Classification **Therapeutic:** Growth hormone antagonist; antidiarrheal
Pharmacologic: Somatostatin

Therapeutic Effects and Uses: Approved in 1988, octreotide, which is also called somatostatin, is a long-acting peptide that mimics the actions of GHIH. Octreotide is effective in both children and adults with GH excess. To treat acromegaly, the drug is initially given 3 times daily by the subcutaneous route. A long-acting IM form (Sandostatin LAR Depot) is available that reduces dosing to every 4 weeks.

Although GHIH is primarily secreted by the hypothalamus, small amounts are also secreted by the stomach, intestine, and pancreas. Thus, in addition to its effect of blocking GH secretion in the anterior pituitary, octreotide suppresses the release of multiple gastrointestinal (GI) hormones, including gastrin, cholecystokinin (CCK), secretin, vasoactive intestinal peptide, insulin, and glucagon. This has resulted in its use in treating multiple secretory and bleeding conditions of the intestinal tract. Because it stimulates the absorption of fluid and electrolytes from the GI tract and prolongs intestinal transit time, it is approved to treat severe diarrhea and flushing episodes associated with metastatic carcinoid tumors or vasoactive intestinal peptide tumors. Octreotide inhibits enzymes that cause vasodilation, decreases hepatic and GI blood flow, and reduces hepatic-portal venous pressure. These properties make the drug useful in treating portal HTN and upper GI bleeding caused by esophageal varices. It is also used off-label to reduce the output from pancreatic and other GI fistulas.

Mechanism of Action: Octreotide produces the same effects as the natural hormone somatostatin to suppress secretion of GH. It also suppresses secretion of serotonin, pancreatic peptides, gastrin, vasoactive intestinal peptides, secretin, motilin, insulin, and glucagon.

Pharmacokinetics:

Route(s)	Subcutaneous or IM (depot formulation)
Absorption	Absorbed rapidly following subcutaneous injection
Distribution	May cross the placenta; may be secreted in breast milk; 65% bound to lipoproteins
Primary metabolism	Liver
Primary excretion	Renal
Onset of action	15–30 min (subcutaneous); 60 min (IM)
Duration of action	12 h; half-life: 1.5 h

Adverse Effects: The most common adverse effects of octreotide are related to the GI system: nausea, vomiting, diarrhea, abdominal discomfort, development of gallstones, and elevated liver enzymes. The nausea, vomiting, and abdominal pain diminish with continued therapy. It can also cause headache, fatigue, flushing, and edema. Because hypoglycemia or hyperglycemia can develop with long-term use, an adjustment in insulin doses in patients with diabetes may be necessary. It can also cause cardiac dysrhythmias, heart failure, and chest pain. Pain at the injection site is very common.

Contraindications/Precautions: Octreotide is contraindicated in patients who are sensitive to it. It is used with caution in patients with CKD, liver disease, cardiac disease, diabetes, and hypothyroidism. Because the drug can cause cholelithiasis, biliary obstruction, or cholecystitis, it should be used cautiously in patients with preexisting gallbladder disease. In addition, it is used with caution in older adult patients due to a significantly longer half-life and delayed clearance; dose adjustments are necessary for these patients.

Drug Interactions: Octreotide may decrease cyclosporine levels and may alter the absorption of other drugs and nutrients because it slows intestinal motility. Concurrent administration of octreotide with PO antidiabetic drugs or insulin can produce hypoglycemia. Additive bradycardia may occur when administered with cardiac drugs such as beta blockers and calcium channel blockers. Concurrent use of octreotide with antidiarrheals and opioids can lead to severe constipation, intestinal obstruction, or paralytic ileus. **Herbal/Food:** Octreotide decreases the absorption of dietary fat and vitamin B_{12}.

Pregnancy: Category B.

Treatment of Overdose: Overdose with octreotide has not been reported.

Nursing Responsibilities:

- Assess baseline height and weight and monitor regularly to determine drug effectiveness.
- Assess baseline and periodic electrocardiograms (ECGs) because the drug may cause bradycardia and other dysrhythmias.
- Assess baseline and periodic vitamin B_{12} levels because the drug can reduce the absorption of this vitamin. Recommend supplementation as needed.
- Assess baseline and periodic hepatic and biliary function tests because this drug may cause or aggravate existing gallbladder disease.
- Administer octreotide by subcutaneous injection as the preferred route, alternating among the recommended sites between the abdomen, thigh, and buttock. Allow the solution to reach room temperature before administering.
- Monitor serum glucose levels frequently because this drug can cause hypoglycemia and may require adjustments in insulin dose.
- Monitor the patient's cardiac status, thyroid function, and electrolyte balance.

Lifespan and Diversity Considerations:

- Monitor all laboratory studies and other diagnostic testing more frequently in the older adult because normal physiologic changes related to aging may increase the risk of adverse effects.
- Because genetic, individual variations may affect the results of drug therapy, monitor ethnically diverse populations more frequently to ensure optimal therapeutic effects and minimize adverse effects.

Patient and Family Education:

- Administer the drug between meals and at bedtime to minimize adverse GI effects. Rotate injection sites, and use the preferred sites for injections: the abdomen, thigh, or buttock.
- Reconstitute the drug gently, and avoid shaking the vial to prevent damaging the drug. Allow the solution to come to room temperature prior to injecting and refrigerate any unused solution. Discard any discolored solution or if particulate matter is present.
- Immediately report to the healthcare provider any yellowing of skin or the whites of the eyes, sharp right upper abdomen pain, nausea, or vomiting, because these may indicate the development of liver or gallbladder disease.
- Report changes in bowel habits, either diarrhea or constipation, or abdominal pain that is severe or that lasts more than 2 days.
- Be aware that treatment is expensive, and therapy may be prolonged.
- Immediately notify the healthcare provider of any known or suspected pregnancy.
- Do not breastfeed during drug therapy without approval of the healthcare provider.

Drugs Similar to Octreotide (Sandostatin)

Drugs with similar actions to octreotide include bromocriptine, lanreotide, pasireotide, and pegvisomant.

Bromocriptine (Cycloset, Parlodel): Approved in 1978, bromocriptine is a PO drug that is classified as a dopamine agonist. Dopamine itself is not used for acromegaly due to an unacceptable incidence of adverse effects. Bromocriptine inhibits the secretion of GH as well as prolactin from the pituitary. It is primarily indicated for Parkinson's disease and infertility caused by prolactin excess, but it has been used in combination with octreotide in children with GH excess. In 2009, the FDA approved bromocriptine (Cycloset) as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus.

The most common dose-limiting adverse effects are psychologic reactions including confusion, agitation, hallucinations, paranoid delusions, or nightmares. Other adverse effects include orthostatic hypotension, headache, nausea, vomiting, anorexia, or rash on the face and arms. Bromocriptine interferes with lactation and should not be used during breastfeeding. It is a pregnancy category B drug.

Lanreotide (Somatuline Depot): Approved in 2007, lanreotide is a somatostatin analog indicated for the treatment of patients with acromegaly who have not responded to radiation therapy or who are unable to undergo surgical treatment. The drug lowers levels of GH, thus improving symptoms related to acromegaly. Lanreotide is a depot formulation that requires dosing only once per month. It is available in prefilled syringes and is delivered by deep subcutaneous injection. Adverse effects associated with lanreotide include pain at the injection site, nausea and vomiting,

diarrhea, gallstones, skin reactions such as itching, bradycardia, and changes in blood glucose levels (either hyper- or hypoglycemia). This drug is pregnancy category C.

Pasireotide (Signifor LAR): Pasireotide is a somatostatin analog given once monthly by IM injection. The drug was approved in 2012 for Cushing's disease, which is caused by a tumor of the adrenal gland that secretes excess adrenocorticotropic hormone (ACTH). Its indications were extended in 2014 for acromegaly in patients for which surgical treatment is not an option. The formulation for Cushing's disease (Signifor) is not interchangeable with that for acromegaly (Signifor LAR). The most common side effects are diarrhea and cholelithiasis. Hyperglycemia and diabetes may become severe during therapy. Pasireotide also prolongs the QT interval. This drug is pregnancy category C.

Pegvisomant (Somavert): Approved in 1997, pegvisomant is a specific GH receptor antagonist, making it very effective for acromegaly. The drug is structurally very similar to GH, although when it binds to GH receptors, it causes no cellular response. The multiple polyethylene glycol (PEG) molecules attached to the drug prolong its half-life and allow for once-daily dosing. It is administered subcutaneously once daily and is supplied as a powder for reconstitution. Adverse effects include nausea, vomiting, elevated liver enzymes, angina, chest pain and myocardial infarction (MI), HTN, flulike syndrome, and injection-site pain. Patients with diabetes should be monitored regularly to avoid hypoglycemia. Therapy for this drug is expensive and is continued indefinitely. It is a pregnancy category B drug.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Growth Hormone

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, GI, hepatic, or kidney disease, diabetes, pregnancy, or breastfeeding. Obtain a growth and development related history including congenital conditions such as Prader-Willi syndrome. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, alcohol use, or smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, hepatic and renal function studies, thyroid hormone panels, insulin-like growth factor-1 [IGF-1], IGF binding protein [IGFBP]).
- Obtain baseline height, weight, and vital signs. Obtain radiologic assessment of epiphyseal plates if ordered.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects dependent on the reason the drug is given (e.g., measurable increase in height, improved nutritional intake, weight).
- Continue periodic monitoring of CBC, electrolytes, glucose, hepatic and renal function studies, and thyroid and GH panels.
- Continue monitoring vital signs, height, and weight.
- Assess for adverse effects: nausea, vomiting, diarrhea, headache, peripheral edema, elevated serum glucose, joint pain, or muscle aches. Patients with diabetes should promptly report consistent elevations in glucose.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor height and weight at each clinical visit. Report lack of growth to the provider. (Lack of growth after a period of consistent growth may indicate the development of antibodies against GH or closure of the epiphyseal plates.)	• Teach the patient, family, or caregiver to measure and record height and weight weekly and bring the record to each clinical visit. • Instruct the patient on the need to return periodically for laboratory work. • Advise the patient, family, or caregiver of the cost of the drug before beginning therapy. Explore the ability to maintain drug therapy for the duration of the treatment prescribed. Assess financial concerns and provide appropriate social service referrals as needed.
Minimizing adverse effects: • Monitor for any reports of muscle, joint, or bone pain, particularly in the knee or hip, or any changes in gait. (Carpal tunnel syndrome may occur, especially with Serostim. Avascular necrosis is an adverse drug effect of GH. Increasing or severe pain in joints or changes in gait should be reported promptly for follow-up evaluation.)	• Instruct the patient, family, or caregiver to report any changes in walking, discomfort or pain in knee or hip joints, bone pain, or consistent muscle pain over joint areas to the healthcare provider.
• Monitor glucose levels, particularly in patients with diabetes. Report consistent elevations to the healthcare provider. (GH may cause increases in glucose level. Patients with diabetes may need alterations in their normal medication routines if hyperglycemia occurs.)	• Instruct the patient on the need to return periodically for laboratory work. • Teach patients with diabetes to monitor capillary glucose levels more frequently during therapy. Report any consistent elevations in blood glucose to the healthcare provider.
• Continue to monitor vital signs, especially pulse and blood pressure for patients with existing cardiac disease. Monitor daily weight, output, lung sounds, and for peripheral edema. (Fluid retention with an increased intravascular volume, HTN, and peripheral edema may occur in early therapy but should resolve over time. Immediately report any continuing or worsening symptoms to the healthcare provider.)	• Instruct the patient to immediately report pounding headache, dizziness, palpitations, or syncope. • Teach the patient, family, or caregiver how to monitor pulse and blood pressure as appropriate. Ensure the proper use and functioning of any home equipment obtained. • Instruct the patient on how to monitor urine output if ordered, and provide measuring equipment as needed. Have the patient keep a record of daily weight and output and bring the record to each clinical visit.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Periodically monitor urine calcium levels, especially in the first few months of therapy. Report any flank pain, GI symptoms, or dysuria to the healthcare provider. (Hypercalciuria may occur in early therapy, sometimes without symptoms. Renal calculi are a possible adverse effect.)	• Instruct the patient on the need to return periodically for laboratory work.
• Continue to monitor nutritional and fluid intake. (Wasting syndromes caused by conditions such as AIDS or CKD may result in nutritional deficits and dehydration until the drug therapy is effective. Dietary consultation may be required to reach and maintain optimal nutrition.)	• Encourage increased fluid intake, up to 2 L/day if allowed, taken in frequent small amounts. • Encourage small, high-calorie, nutrient-dense meals rather than large infrequent meals. • Obtain a dietary consult if the patient requests or if malnutrition is severe.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., during the evening meal, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Reconstitute the parenteral drug exactly per package directions and do not shake the vial; gently rotate it to avoid breaking down the drug. Follow the manufacturer's instruction if an automated pen injector (e.g., Nutropin) is used.
	  • Store any unused reconstituted solutions in the refrigerator; do not freeze the solution. Discard any discolored solution or if particulate matter is present.
	  • Administer GH drugs in the evening to mimic the body's natural rhythms.
	  • Administer subcutaneous injections in the abdomen, buttock, or thigh areas, rotating injection sites. Do not use gluteal sites for children under the age of 2; these muscles are not well developed until the child has been walking for a year or more.

Pharmacotherapy of Antidiuretic Hormone Disorders

65.5 Pharmacotherapy is used to treat deficient or excess secretion of antidiuretic hormone.

It is essential for the amount of fluid in the body to be maintained within narrow limits. Loss of large amounts of water leads to dehydration, a serious condition that can lead to shock and death. Too much body fluid leads to congestion, edema, and water intoxication. Antidiuretic hormone (ADH) is one of the most important means the body uses to maintain fluid balance homeostasis. For a complete discussion of fluid balance and the drugs used as fluid replacement agents, see Chapter 33.

The hypothalamus senses fluid balance by recognizing the osmolarity of the blood. Osmolarity is the number of dissolved particles, or solutes, in a fluid. As water is lost, the osmolality, or concentration of the blood, increases and the hypothalamus directs the posterior pituitary gland to release ADH. This hormone acts on the renal tubules to enhance water reabsorption. The increased amount of water in the body reduces serum osmolality to normal levels and ADH secretion stops. Other factors stimulating release of ADH include hypotension, decreased fluid volume, dehydration, pain, nausea, and vomiting. Factors inhibiting ADH release include decreased serum osmolality and increased fluid volume. Many drugs also affect ADH release, as listed in Table 65.5. ADH is also called vasopressin because it has the ability to cause vasoconstriction at high doses.

Table 65.5 Drugs Interacting with Antidiuretic Hormone

Drugs Stimulating ADH Secretion	Drugs Inhibiting ADH Secretion
acetaminophen	alcohol
anesthetics	beta-adrenergic agonists
barbiturates	chlorpromazine
carbamazepine	demeclocycline
chlorpropamide	heparin
corticosteroids	lithium
diuretics	norepinephrine
tricyclic antidepressants	opioids
	phenytoin

CONNECTION Checkpoint 65.2

In addition to ADH, the renin-angiotensin-aldosterone system (RAAS) is essential for maintaining fluid balance. From what you learned in Chapter 31, how does the RAAS affect sodium and water balance? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

A deficiency in ADH results in **diabetes insipidus (DI)**, a condition characterized by the production of large volumes of very dilute urine, usually accompanied by increased thirst. DI may be either nephrogenic or neurogenic. Nephrogenic DI is caused by the inability of the kidneys to respond to ADH. Drugs, such as lithium (Eskalith), or electrolyte disturbances can cause nephrogenic DI. Because nephrogenic DI results from an inability to respond to ADH, replacement therapy is not effective.

Neurogenic or central DI results from a lack of adequate production or secretion of ADH in the brain. The etiology of neurogenic DI can be genetic or acquired following head injury, surgery, tumors, infections, or vascular lesions of the region. The preferred drug for treating chronic neurogenic DI is desmopressin (DDAVP). Chlorpropamide, a hypoglycemic drug, can be used to stimulate ADH release in partial neurogenic DI. Paradoxically, both forms of DI respond in part to thiazide diuretics such as hydrochlorothiazide.

The primary symptoms of DI are polyuria and polydipsia (excessive thirst). Extremely large volumes of fluid (up to 30 L/day) may be ingested and the urine will be very dilute. The intense thirst and frequent urination usually keep patients awake during the night. Failure to ensure adequate fluid intake will result in hypovolemia and dehydration due to the large renal water loss.

Excess secretion of ADH is the cause of the **syndrome of inappropriate antidiuretic hormone (SIADH)**, a condition characterized by marked fluid retention, elevated urine osmolality, low serum osmolality, and sodium loss in the urine. SIADH may occur as a transient or chronic condition. The resulting hyponatremia and water retention cause muscle cramps, weakness, headache, apprehension, nausea, vomiting, and lethargy, progressing to stupor and coma. Treatment involves fluid restriction and diuretics such as mannitol or furosemide (Lasix) to remove excess fluid. Conivaptan (Viprostol) and tolvaptan (Samsca) are vasopressin receptor antagonists that promote renal water excretion and increased serum sodium levels in patients with SIADH. The antibiotic demeclocycline (Declomycin) is a tetracycline used off-label to treat SIADH due to its ability to cause diuresis through the inhibition of ADH-induced water reabsorption in the tubules and collecting ducts of the kidneys. In severe cases, IV infusion of a hypertonic sodium chloride solution may be necessary to raise serum osmolality.

PharmFACT

Diabetes insipidus is uncommon with a prevalence of 3 cases per 100,000 people. Thirty percent of the cases are idiopathic with no identifiable cause (Khardori, 2017).

PROTOTYPE DRUG Desmopressin (DDAVP, Noctiva, Stimate)

Classification **Therapeutic:** Antidiuretic hormone replacement, drug for nocturia
Pharmacologic: Pituitary hormone

Therapeutic Effects and Uses: Approved in 1978, desmopressin is a synthetic analog of human ADH that has a longer duration of action than the natural hormone. It controls the acute symptoms of polyuria and polydipsia in patients with neurogenic DI but not nephrogenic diabetes insipidus. For DI, the PO route is preferred, although IV and subcutaneous forms are available for SIADH.

Desmopressin has vasoconstrictor activity that causes contraction of smooth muscle in the vascular system, uterus, and GI tract. It produces fewer vasoconstrictive effects than natural vasopressin. Desmopressin also produces an increase in plasma Factor VIII and von Willebrand's factor and is thus indicated for the management of bleeding in patients with hemophilia A and von Willebrand's disease (type I). Desmopressin is available in IV and intranasal (Stimate) forms for these indications. The use of desmopressin in treating coagulation disorders is presented in Chapter 38. This drug is the most effective pharmacologic intervention for controlling enuresis (bedwetting) in children. For enuresis, desmopressin is administered 1 hour before bedtime in children age 6 or older, for up to 6 months. In 2017, an intranasal form (Noctiva) was approved to treat nocturnal polyuria in adults who awaken at least 2 times per night to void.

Mechanism of Action: Desmopressin increases the permeability of renal collecting tubules to water, thereby increasing the reabsorption of water. It produces vasoconstriction of blood vessels at higher doses. The vasoconstriction produced is greatest in portal vessels and less in cerebral, coronary, pulmonary, and peripheral vessels. Desmopressin enhances GI motility and tone through contraction of smooth muscle in the GI tract.

Pharmacokinetics:

Route(s)	Subcutaneous, IV, PO
Absorption	5% through GI mucosa
Distribution	Small amount may cross the blood–brain barrier; secreted in breast milk
Primary metabolism	Metabolized rapidly by the liver
Primary excretion	Renal
Onset of action	PO: 1 h, with a peak at 4–7 h; IV: 1 min with a peak at 30 min; intranasal: 30 min with a peak of 1.5 h
Duration of action	PO: 8–20 h; IV: 3 h

Adverse Effects: Desmopressin can cause water intoxication. Early signs include drowsiness, headache, and listlessness, progressing to convulsions and coma. Other adverse effects include transient headache, nausea, mild abdominal pain and cramping, facial flushing, HTN, or pain or swelling at the injection site. A rare adverse effect of desmopressin is a severe allergic reaction or anaphylaxis (IV administration). Tolerance to the effects of desmopressin develops when it is administered more frequently than every 48 hours or by the IV route. The intranasal route may cause local irritation, rhinitis, and congestion. **Black Box Warning:** Noctiva may cause hyponatremia, which can be severe and even life threatening.

Contraindications/Precautions: Desmopressin is contraindicated in patients with nephrogenic DI. It is used with caution in patients with coronary artery disease, HTN, and in patients with a history of hyponatremia or thrombi. The drug is contraindicated in patients with CKD because the drug can worsen fluid retention and overload. Young children and the older adult should be treated with caution because these patients are more prone to water intoxication and hyponatremia.

Drug Interactions: Increased antidiuretic action can occur with carbamazepine, chlorpropamide, and nonsteroidal anti-inflammatory drugs (NSAIDs). Decreased antidiuretic action can occur with lithium, alcohol, heparin, and epinephrine. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: In case of overdose, or if water intoxication develops, symptomatic treatment with diuretics is recommended.

Nursing Responsibilities: Key nursing implications for patients receiving desmopressin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antidiuretic Hormone.

Drugs Similar to Desmopressin (DDAVP, Noctiva, Stimate)

The only drug that is similar to desmopressin is vasopressin.

Vasopressin: A synthetic analog of antidiuretic hormone, vasopressin is given IM or subcutaneously for central or neurogenic DI. Approved in 1941, it has a shorter duration of action than desmopressin and a more pronounced vasoconstrictor action, which can result in serious adverse effects.

Because vasopressin is a potent vasoconstrictor, it is given IV as an alternative to epinephrine for many off-label indications. These include bleeding from esophageal varices or the upper GI tract, cardiac arrest, and the treatment of severe hypotension or shock. Vasopressin may precipitate MI or angina. It may cause water intoxication. When used for its vasopressor effects, possible adverse effects include tissue necrosis and gangrene. Vasopressin is a pregnancy category C drug.

CONNECTION Checkpoint 65.3

Desmopressin is used to treat von Willebrand's disease, the most common inherited coagulation disorder. From what you learned in Chapter 38, what is the function of von Willebrand's factor? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: Treating the Diverse Patient

Gender Differences in Desmopressin Dose for Nocturia in Adults

Although nocturnal enuresis is commonly considered a childhood condition, it occurs in the adult population as well. Excessive fluid intake and alcohol use are known causative factors. Increasing age and female gender are risk factors for desmopressin-induced hyponatremia, secondary to fluid retention. It has been shown that women have a higher sensitivity to vasopressin in the kidneys, which leads to a fivefold higher risk of hyponatremia for women over age 50 than men. Berges, Höfner, Gedamke, and Oelke (2014) concluded that equivalent doses of desmopressin resulted in lower overall efficacy in men compared to women and that the standard dose of 0.1 and 0.4 mg daily does not increase the risk of developing hyponatremia in men. Additional large-scale clinical trials need to be conducted to verify and determine appropriate doses for men and women.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antidiuretic Hormone

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, GI, hepatic or kidney disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, or smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., urine and serum osmolality, urine specific gravity, serum protein, CBC, electrolytes, hepatic and renal function studies).
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects dependent on the reason the drug is being given (e.g., diuresis slows and urine output and serum osmolality return to normal, bleeding stops or slows).
- Continue periodic monitoring of urine and serum osmolality, urine specific gravity, CBC, electrolytes, serum protein, hepatic and renal function studies.
- Continue monitoring vital signs and weight.
- Assess for adverse effects: nausea, vomiting, diarrhea, headache, nasal congestion, or rhinitis. Immediately report drowsiness, dizziness, lethargy, hypotension or HTN, tachycardia, dysrhythmias, or angina to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • For patients with DI, monitor urine output, urine and serum osmolality, and urine specific gravity for return to normal limits. If given for nocturnal enuresis, have the patient or family keep a diary of sleep patterns, noting any bedwetting. (Urine output, osmolality, and specific gravity should return to normal limits. Bedwetting should decrease or stop.)	• Teach the patient, family, or caregiver to measure and record height and weight weekly and bring the record to each clinical visit. • Instruct the patient on the need to return periodically for laboratory work. • Instruct the patient to monitor output (provide measuring equipment as needed) and to keep a record of daily weight and output. • Teach the patient, family, or caregiver to keep a diary of nighttime sleep habits and any bedwetting. Limit oral fluids within 4 h of bedtime. Bring the record to each clinical visit. • Advise the patient of the cost of the drug before beginning therapy. Explore the ability to maintain drug therapy for the duration of the treatment prescribed. Assess financial concerns and provide appropriate social service referral as needed.
Minimizing adverse effects: • Continue to monitor vital signs, especially pulse and blood pressure for patients with existing cardiac disease. ECGs may be ordered periodically for patients with a history of dysrhythmias. Monitor daily weight, urine output, level of consciousness (LOC), lung sounds, and for peripheral edema. (Fluid retention secondary to antidiuretic hormone treatment may lead to increased intravascular volume, HTN, and water intoxication.)	• Instruct the patient to immediately report pounding headache, dizziness, palpitations, or syncope. • Teach the patient, family, or caregiver how to monitor pulse and blood pressure as appropriate. Ensure proper use and functioning of any home equipment obtained. • Instruct the patient to monitor urine output (provide measuring equipment as needed) and to keep a record of daily weight and urine output. • Instruct the patient, family, or caregiver to immediately report any drowsiness, dizziness, lethargy, or decreased LOC to the healthcare provider.
• Continue to monitor laboratory studies, especially serum sodium levels and osmolality. (DI or water retention triggered by the use of ADH replacement may result in alterations in serum sodium and osmolality. **Lifespan:** Normal physiologic changes may place the older adult at greater risk for adverse effects related to electrolyte or fluid changes.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor for and immediately report signs of peripheral ischemia, HTN, or angina. (Vasoconstriction caused by vasopressin may cause cardiac or peripheral ischemia, angina, or infarction.)	• Instruct the patient to immediately report any chest pain, pain or numbness in toes or fingers, or cramping when walking to the healthcare provider.
• Monitor nasal passages. Report any excoriation or bleeding. (Long-term intranasal ADH therapy may cause nasal irritation and ulceration.)	• Teach the patient to report nasal congestion, irritation, increase in nasal discharge, or bleeding to the healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, the appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient or caregiver in proper self-administration of the drug, e.g., during the evening meal, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Direct nasal sprays high into the nasal cavity rather than back to the nasopharynx. Do not shake a nasal spray before using; gently rotate it.
	  • Store any unused solutions in the refrigerator. Nasal sprays may be kept at room temperature but avoid excessive heat over 26.7°C (80°F). Discard any discolored solution or if particulate matter is present.

Understanding Chapter 65

Key Concepts Summary

65.1 The hypothalamus controls many diverse body processes and secretes hormones that influence pituitary function.

65.2 The pituitary gland secretes hormones that control many diverse body functions.

65.3 Growth hormone deficiency in adults and children can be treated by administering recombinant growth hormone.

65.4 Overproduction of growth hormone in adults can be treated by administering growth hormone antagonists.

65.5 Pharmacotherapy is used to treat deficient or excess secretion of antidiuretic hormone.

CASE STUDY: Making the Patient Connection

Remember the patient "Raj" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented in this chapter, answer the critical thinking questions that follow.

Raj, an 8-year-old boy, was referred to the pediatric endocrinology clinic for evaluation of his short stature. He had been healthy and developmentally normal until 3 years ago. Since that time, his growth has been extremely slow—in fact, almost imperceptible. On his initial examination, Raj's weight and height were 17 kg (37.4 lb) and 108 cm (42.5 in.), respectively. His height standard deviation score was –4.0 with a body mass index of 14.6. The remainder of his physical examination was normal.

When the pediatrician reviewed the results of hormonal tests with Raj's parents, everyone was relieved to find out that, although there is a problem, it is not due to a tumor or other life-threatening disorder. Raj has a congenital deficiency in GH, and the pediatrician discusses replacement therapy with the parents. They agree that Raj should have this therapy and want to start it as soon as possible. Somatropin (Humatrope) has been ordered. As the nurse working with Raj and his family, address each of the following questions.

Critical Thinking Questions

1. What teaching will you need to provide to Raj's parents regarding drug therapy for his disorder?
2. Raj's father states, "I hope my health insurance will cover this medication." What would you say in response to this comment?
3. The parents ask about the adverse effects that might occur with this therapy. How would you respond?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Edward Keithy, a 10-year-old boy, and his parents visit the pediatrician's office where you are a nurse. The parents are concerned with Edward's continuing nocturnal enuresis, or nighttime bedwetting. Increasingly, they see this condition as adversely affecting his self-image, self-esteem, and psychosocial well-being. Edward tells you that he is reluctant to take part in sleepovers at his friends' houses or to attend camping trips with his scouting troop.

1. What type of pharmacotherapy do you anticipate for Edward?
2. What information will Edward and his parents need as part of patient drug teaching?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A teaching plan for a parent whose child is receiving somatropin (Nutropin) should include what important information?
   1. The patient must adhere to therapy to prevent mental retardation.
   2. The medication cannot be given orally; it can be given only parenterally.
   3. If growth hormone is begun in adolescence, it can add up to 15 cm (6 in.) in height.
   4. Growth hormone therapy requires frequent blood work.

2. Which of the following findings would the nurse consider to be effects of somatropin? (Select all that apply.)
   1. Increase in the length and width of long bones
   2. Organ, muscle, and connective tissue growth
   3. Increased synthesis of proteins
   4. Lowering of serum glucose levels
   5. Increase in fat deposits around the abdomen

3. The patient with neurogenic diabetes insipidus is being started on an oral dose of desmopressin (DDAVP). Which instruction should the nurse include in the teaching plan?
   1. Use the drug only if urine output is excessive.
   2. Use twice the prescribed dose if you miss a dose.
   3. Obtain and record your weight each morning.
   4. Use an NSAID such as ibuprofen if leg cramping occurs during walking.

4. A patient with metastatic colon cancer is experiencing bowel-related complications of the cancer and treatment. Octreotide (Sandostatin) has been ordered. The nurse will anticipate which therapeutic effect from this drug?
   1. Decrease in the number of diarrheal stools per day
   2. Slowing of the metastatic spread of the cancer
   3. Increase in lean body mass and fat deposits
   4. Episodes of hypo- or hyperglycemia

5. Prior to starting a patient on octreotide (Sandostatin) for control of esophageal varices, the nurse will obtain the patient's past health history. If present, what condition might indicate the need to verify the order with the prescriber?
   1. Glaucoma
   2. Alcoholism
   3. Chronic obstructive pulmonary disease (COPD)
   4. Diabetes

6. Which of the following assessment findings would indicate that therapeutic goals have been achieved for a patient with diabetes insipidus being treated with desmopressin (DDAVP)?
   1. Decreasing signs of dehydration
   2. Increasing pulse and urine output
   3. Decreasing urine specific gravity
   4. Decreasing hyperglycemia

Chapter 66
Pharmacotherapy of Diabetes Mellitus

Chapter Outline

- Physiology of Serum Glucose Control
- Pathophysiology of Diabetes Mellitus: Types of Diabetes
- Symptoms and Diagnosis of Diabetes
- Complications of Diabetes Mellitus

  PROTOTYPE *Glucagon (GlucaGen), p. 1205*
- Insulin Therapy

  PROTOTYPE *Human Regular Insulin (Humulin R, Novolin R), p. 1209*
- Antidiabetic Drugs for Type 2 Diabetes

  Sulfonylureas

  PROTOTYPE *Glyburide (DiaBeta, Glynase), p. 1215*

  Biguanides

  PROTOTYPE *Metformin (Glucophage, Glumetza, Others), p. 1217*

  Meglitinides

  PROTOTYPE *Repaglinide (Prandin), p. 1218*

  Thiazolidinediones

  PROTOTYPE *Rosiglitazone (Avandia), p. 1219*

  Alpha-Glucosidase Inhibitors

  PROTOTYPE *Acarbose (Precose), p. 1220*

  Incretin Therapies

  PROTOTYPE *Sitagliptin (Januvia), p. 1221*
- Miscellaneous Antidiabetic Drugs

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain how blood glucose levels are maintained within narrow limits by insulin and glucagon.
2. Compare and contrast the etiology and pathogenesis of type 1, type 2, and gestational diabetes.
3. Describe the signs and diagnosis of diabetes.
4. Describe the acute complications of diabetes.
5. Identify the chronic complications of diabetes.
6. Compare and contrast the pharmacotherapy of the different types of diabetes.
7. For each type of insulin, identify the onset of action, peak action and duration of action, administration routes, when it is given related to meals, compatibility with other insulins, and adverse effects.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to the care of patients receiving pharmacotherapy for diabetes.

type 1 diabetes, 1202
type 2 diabetes, 1202

It is estimated that over 29 million people in the United States have diabetes mellitus, with more than 8 million of those being undiagnosed. Diabetes is one of the leading causes of death in the United States. Mortality has risen in recent years, causing some public health officials to refer to it as an epidemic. Diabetes can lead to serious acute and chronic complications, including heart disease, stroke, blindness, kidney failure, and amputations. Because nurses frequently care for patients with diabetes, it is imperative that they thoroughly understand the disorder, its treatment, and possible complications. There is an unrelated disorder, diabetes insipidus, which results from a deficiency of antidiuretic hormone (see Chapter 65). When the term *diabetes* is used in this chapter, it is referring to diabetes mellitus.

Physiology of Serum Glucose Control

66.1 Serum glucose is maintained within a narrow range by the hormones insulin and glucagon.

Because diabetes is essentially a disorder of carbohydrate metabolism, it is important to understand the way the body obtains, metabolizes, and stores glucose. Of all the different molecules available, the body prefers to use glucose as its primary energy source. The brain relies almost exclusively on glucose for its energy needs because it is unable to synthesize glucose and it will exhaust its supply after just a few minutes of activity. Most other tissues can use fatty acids and proteins for energy production, if necessary, but they too prefer to use glucose. One of the most important roles of the liver and pancreas is to regulate the body's carbohydrate fuel supply so that all tissues of the body have sufficient energy to perform their functions.

Although the normal range for serum glucose is considered to be 60 to 100 mg/dL, it is usually tightly regulated by the body to remain between 80 and 90 mg/dL. Two pancreatic hormones contribute to maintaining a stable serum glucose level: **insulin**, which acts to decrease blood glucose levels, and glucagon, which acts to increase blood glucose levels.

Following a meal, glucose is rapidly absorbed from the gastrointestinal (GI) tract, and serum levels rise. Some of the glucose is taken up by cells and used for immediate energy needs, but about two thirds is stored in liver and muscle cells as glycogen, the storage form of glucose. When glucose levels fall between meals, glycogen is broken down in a process called **glycogenolysis**, and glucose is released into the bloodstream. Maintaining a stable serum glucose level is simply a matter of storing glucose during times of excess, and returning it to the bloodstream in times of deficiency. The importance of maintaining this delicate balance, however, cannot be overstated. Too much glucose or too little glucose can have lethal consequences.

Following a meal, the pancreas recognizes the rising serum glucose levels and releases insulin. Without insulin, glucose is not able to enter cells of the body. The cells may be surrounded by high amounts of glucose but they are unable to use it until insulin arrives. It may be helpful to visualize insulin as a transporter or "gatekeeper." When present, insulin swings open the gate, transporting glucose inside cells—if there is no insulin, there is no entry. The physiologic actions of insulin are summarized as follows:

- It promotes the entry of glucose into cells.
- It provides for the storage of glucose, as glycogen.
- It inhibits the breakdown of fat and glycogen.
- It increases protein synthesis and inhibits **gluconeogenesis**, which is the production of new glucose from noncarbohydrate molecules.

Insulin is produced in beta cells of the pancreas known as islets of Langerhans, whereas alpha cells in the pancreas secrete glucagon. Glucagon maintains stable blood glucose levels between meals and during periods of fasting and has actions that are opposite to those of insulin. It removes glucose from its storage in the liver and sends it to the blood (glycogenolysis), raising serum glucose within minutes.

The level of glucose in the blood regulates the release of both insulin and glucagon. A hypoglycemic state (low serum glucose) stimulates the release of glucagon and inhibits the release of insulin, whereas a hyperglycemic state (high serum glucose) has the opposite effect: It stimulates the release of insulin and inhibits the release of glucagon. The physiologic dynamics of insulin and glucagon release are shown in Figure 66.1.

Additional factors that decrease blood glucose levels are fasting, exercise, and alcohol. Factors that increase blood glucose levels include stress from infection, injury, or surgery, which triggers release of the epinephrine and norepinephrine; large meals or overconsumption of carbohydrates; growth hormone; and corticosteroids.

PharmFACT

According to the American Diabetes Association (ADA, 2017), the incidence of diabetes mellitus in the United States is as follows:

- 1 in every 400 children and adolescents has diabetes.
- 9.4% of all people 20 years or older have diabetes.
- 25% of all people 65 years or older have diabetes.
- 1.5 million new cases of adult diabetes are diagnosed each year.

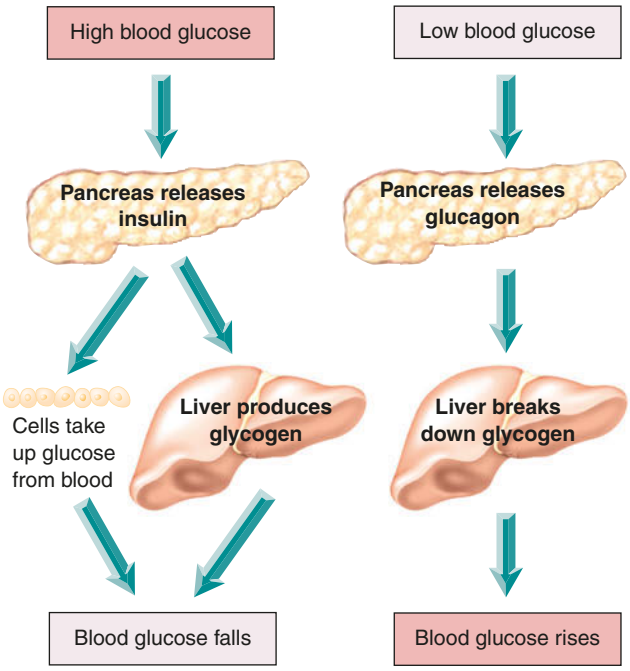

Figure 66.1 Insulin, glucagon, and blood glucose.

Pathophysiology of Diabetes Mellitus: Types of Diabetes

66.2 Type 1 diabetes is characterized by insufficient insulin synthesis by the pancreas, whereas type 2 diabetes is characterized by insulin resistance in the target cells.

Diabetes mellitus is a metabolic disorder characterized by an imbalance between insulin availability and insulin need. The two primary forms of diabetes are called type 1 and type 2. There are significant differences between the two types in terms of pathophysiology and disease management. A third form of the disease occurs during pregnancy and is known as gestational diabetes.

Type 1 diabetes results from an absolute lack of insulin secretion due to destruction of pancreatic beta cells. The destruction of beta cells is believed to result from a combination of autoimmune, genetic, and environmental factors. Type 1 is the less common form of diabetes, accounting for only 5% to 10% of all patients with the disorder. It is seen most frequently among children and young adults, but it may occur at any age.

Because of the lack of sufficient insulin in patients with type 1 diabetes, glucose cannot enter cells and fatty acids are used as the primary energy source. Metabolic by-products of lipid metabolism known as ketones accumulate in the blood, producing diabetic ketoacidosis (DKA), a dangerous and potentially life-threatening condition (see Section 66.4).

Patients with type 1 diabetes must receive insulin therapy to survive. In the past, type 1 was called juvenile or insulin-dependent diabetes. Although these terms are still in use, they do not accurately reflect the nature of the disease.

Type 2 diabetes is the more common form of the disorder, representing 90% to 95% of people with diabetes. The primary physiologic characteristic of type 2 diabetes is hyperglycemia, caused by a relative deficiency of insulin. The disorder is characterized by **insulin resistance**, a condition in which cells become unresponsive to insulin due to a defect in insulin receptor function. The pancreas may be secreting sufficient amounts of insulin but target cells do not recognize it.

As cells become increasingly resistant, blood glucose levels rise and the pancreas responds by secreting even more insulin. Eventually, the hypersecretion of insulin leads to beta cell exhaustion and, ultimately, to beta cell death. As type 2 diabetes progresses, it becomes a disorder characterized by insufficient insulin levels as well as insulin resistance. The activity of insulin receptors can be increased by exercise, which lowers the level of circulating insulin. In fact, adhering to a healthy diet and regular exercise have been shown to reverse insulin resistance and to delay or prevent the development of type 2 diabetes.

Eighty percent of people with type 2 diabetes are overweight, and the degree of obesity directly affects the degree of insulin resistance. In particular, individuals with

Table 66.1 Comparison of Type 1 and Type 2 Diabetes Mellitus

Diabetes Mellitus	Type 1	Type 2
Cause	Destruction of beta cells causing lack of insulin	Insulin resistance in target cells; insulin deficiency may develop
Incidence	5–10%	90–95%
Age at onset	Children, young adults, usually younger than 35 years	Usually older than 35 years but incidence increasing in children
Symptom onset	Rapid	Gradual
Body weight	Usually underweight	Usually overweight or obese
Symptoms	Polyuria, polydipsia, polyphagia, weight loss	Same as type 1, plus blurred vision, fatigue, recurrent infections
Ketosis	Often present with poor control	Infrequent
Pharmacologic treatment	Insulin replacement	Oral antidiabetes drugs with or without insulin

upper body obesity (central or visceral obesity) are at increased risk for developing insulin resistance and type 2 diabetes. Although most patients with type 2 diabetes are older, this disease is increasingly being diagnosed in adolescents with obesity. Risk factors for type 2 diabetes are a family history of diabetes, obesity, and race and ethnicity. Hispanics/Latinos, non-Hispanic African Americans, and Asian Americans are at increased risk for type 2 diabetes (ADA, 2015). Other risk factors are age older than 45 years; a history of elevated fasting serum glucose levels or impaired glucose tolerance; hypertension (HTN); low levels of high-density lipoproteins; triglycerides above 250 mg/dL; and a history of gestational diabetes or delivery of a baby over 9 pounds, or both. Table 66.1 compares and contrasts type 1 and type 2 diabetes.

Most patients with type 2 diabetes do not require insulin administration, at least initially; their condition can be managed with oral antidiabetic drugs. Type 2 diabetes was formerly called adult-onset diabetes and non–insulin-dependent diabetes, but these are not accurate descriptions of the disorder because it occurs in children and may require insulin administration.

Gestational diabetes is a condition resulting from glucose intolerance with an onset, or first recognition, during pregnancy. This is a serious disorder that puts both the woman and fetus at risk for complications and so requires careful management during pregnancy. In addition, women who develop gestational diabetes are at increased risk for developing diabetes 5 to 10 years after delivery. It occurs most frequently in women with a family history of diabetes, a history of stillbirth or spontaneous abortion, a previous large-for-gestational-age baby, women who are obese or of advanced maternal age, women who have had five or more pregnancies, or women who are members of a high-risk population (Hispanic, Native American, Asian, or African American). If careful nutritional management combined with an approved exercise plan is unable to normalize serum glucose levels, insulin therapy is initiated. Traditionally, oral antidiabetic drugs have not been used for gestational diabetes due to concerns regarding potential teratogenicity; however, the results of research may change that practice in the future.

Symptoms and Diagnosis of Diabetes

66.3 The classic signs and symptoms of diabetes include polyuria, polydipsia, and polyphagia.

The classic triad of signs and symptoms for either type of diabetes is known as the three "polys": **polyuria**, excessive urine production; **polydipsia**, excessive thirst; and **polyphagia**, excessive appetite.

Glucose is one of the body's most valuable energy molecules, and nondiabetic patients excrete very little. As glucose levels rise in the blood in patients with diabetes, however, the kidneys are unable to reabsorb the large amounts passing through the renal tubules, so glucose is eliminated in the urine (glucosuria). Glucose molecules create increased osmotic pressure in body fluids, pulling water along with it; thus, osmotic diuresis (polyuria) occurs. The glucose increases osmotic pressure in the bloodstream, pulling water out of tissue cells and causing cellular dehydration. This triggers thirst and causes the individual to increase fluid intake (polydipsia). The excess hunger (polyphagia) occurs primarily with type 1 diabetes, when nutrient stores become too depleted to meet the body's energy needs and weight is lost. Other signs and symptoms include blurred vision, fatigue, paresthesias, and skin infections. Nocturia, secondary to the polyuria, may occur.

Although symptomology is important for recognizing the possibility of diabetes, many patients with the disease have no symptoms. Laboratory tests are required for proper diagnosis. The primary blood tests for diagnosing diabetes are the **fasting plasma glucose (FPG) test**, **oral glucose tolerance test (OGTT)**, and **hemoglobin A1C test**.

- FPG: obtained following a fast of at least 8 hours. A value of 126 mg/dL or higher indicates diabetes.
- OGTT: A loading dose of 75 g of glucose is ingested and the plasma glucose level is obtained 2 hours later. A value of 200 mg/dL or higher indicates diabetes.
- A1C: As serum glucose increases, more glucose becomes bound to hemoglobin. A value of 6.5% or higher indicates diabetes. The advantage of the A1C test is that it does not require fasting and it provides an average measure of glucose control over the 8 to 12 weeks prior to the test.

Home monitoring of blood glucose is now commonplace and enables the patient with diabetes to maintain tighter control of glucose levels. Fingerstick testing involves placing a drop of capillary blood on a test strip, which is then read by a glucose meter.

Most patients who develop type 2 diabetes go through a period of impaired glucose tolerance referred to as **prediabetes**. In prediabetes, serum glucose levels are elevated but are not high enough to be diagnosed as diabetes. This condition increases the risk for developing diabetes, heart disease, and stroke. Prediabetes may result from impaired fasting glucose or impaired glucose tolerance, or both. Progression from prediabetes to diabetes is not inevitable. Careful management of nutrition, regular exercise, and weight management may prevent or delay progression to diabetes. Patients with prediabetes should be monitored on an annual basis for the potential development of diabetes and to evaluate the degree of success in managing comorbid conditions such as HTN, hyperlipidemia, and obesity.

Obesity-related insulin resistance can lead to **metabolic syndrome**, a cluster of biochemical changes that place the patient at increased risk for developing diabetes, heart disease, peripheral vascular disease, and stroke. Again, weight loss, exercise, and nutritional management enable people with this syndrome to delay or prevent the progression to type 2 diabetes. According to the American Heart Association (AHA, 2016), metabolic syndrome is diagnosed by the presence of three or more of the following:

- Central (visceral) obesity, with waist circumference more than 88 cm (35 in.) for women or more than 102 cm (40 in.) for men
- Serum triglycerides equal to or greater than 150 mg/dL
- High-density lipoprotein (HDL) cholesterol less than 50 mg/dL in women or less than 40 mg/dL in men (or receiving drug therapy for hyperlipidemia)
- Blood pressure more than 130/85 mmHg (or receiving drug therapy for HTN)
- Fasting plasma glucose equal to or greater than 100 mg/dL (or receiving drug therapy for hyperglycemia).

Complications of Diabetes Mellitus

66.4 Acute complications of diabetes include diabetic ketoacidosis, hyperosmolar hyperglycemic state, and hypoglycemia.

Although most patients experience chronic diabetes, which develops over many years, acute episodes may occur suddenly in those with uncontrolled or poorly controlled diabetes. Diabetic ketoacidosis, hyperosmolar hyperglycemic state (HHS), and hypoglycemia are the three primary acute conditions. The chronic complications are discussed in Section 66.5.

Diabetic ketoacidosis (DKA) is an acute condition that occurs primarily in patients with type 1 diabetes. The three major disturbances that occur with DKA are hyperglycemia, metabolic acidosis, and osmotic diuresis. DKA typically develops over several days with symptoms such as polyuria, polydipsia, nausea, vomiting, and severe fatigue, progressing to stupor and eventual coma. The patient may report having abdominal pain or tenderness, and the breath has a fruity smell as the lungs attempt to remove volatile ketoacids. As the acidosis worsens, Kussmaul's respirations may develop, with an increased rate and depth of respirations. Tachycardia and hypotension occur in response to dehydration and fluid depletion.

DKA may be the first presenting symptoms of an individual previously undiagnosed with diabetes. Treatment includes fluid replacement to improve circulating blood volume and tissue perfusion, normalization of blood glucose levels, and correction of electrolyte imbalances and metabolic acidosis. Insulin therapy is begun, usually with an IV loading dose, followed by a continuous low-dose infusion. Serum glucose levels must be lowered gradually because too rapid a drop can cause a fluid shift back into the cells that can lead to cerebral edema. Although DKA is a very serious disorder, the mortality rate for this complication has been reduced to less than 5% with proper treatment.

CONNECTION Checkpoint 66.1

From what you learned in Chapter 33, what is the clinical definition of acidosis? What is the preferred drug for reversing metabolic acidosis? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hyperosmolar hyperglycemic state (HHS) is a serious, acute complication of diabetes that carries a mortality rate of 20% to 40%. HHS is generally seen in people with type 2 diabetes and is characterized by extreme hyperglycemia (above 600 mg/dL), hyperosmolarity (above 310 mOsm/L) with dehydration, the absence of ketoacidosis, and central nervous system (CNS) dysfunction. The typical patient is older, obese, and has comorbid medical problems, such as heart failure or chronic kidney disease (CKD). The elevated serum glucose levels and increased osmolarity produce a large osmotic diuresis with marked dehydration, confusion, and lethargy. Other possible neurologic symptoms are seizures, hemiparesis, abnormal reflexes, aphasia, and visual disturbances. Symptoms can progress to stupor and coma. Tachycardia and hypotension result from fluid depletion and poor tissue perfusion. Acidosis may develop, caused by an accumulation of lactic acid rather than ketoacids.

The onset of HHS is gradual and, because of the neurologic manifestations, may be mistaken for a stroke in older adults. Treatment consists of careful fluid replacement while avoiding cerebral and pulmonary edema and correction of electrolyte imbalances, particularly potassium. Low-dose insulin is given by continuous IV infusion to slowly lower glucose levels to 250 to 300 mg/dL. Seizure precautions should be instituted, and hemodynamic monitoring should be used in these critically ill patients. The nurse should closely monitor intake and output, blood pressure, heart rate, lung sounds, weight, peripheral pulses, and neurologic status. Finally, the underlying cause of the episode should be investigated and treated as needed.

Hypoglycemia, or abnormally low serum glucose, occurs most often in patients improperly treated with insulin and may occur during therapy with some oral antidiabetic drugs. The manifestations of hypoglycemia result from changes in mental status and by the activation of the sympathetic nervous system. Because the brain relies on a continuous supply of glucose, falling glucose levels may lead to headache, difficulty concentrating, confusion, and behavioral changes, progressing to seizures and coma. The sympathetic nervous system activation results from the body's attempt to increase serum glucose by the release of catecholamines (epinephrine and norepinephrine). These catecholamines cause symptoms that include tachycardia, anxiety, sweating, and the constriction of surface vessels, leading to cool, clammy skin. Acute hypoglycemia is considered a medical emergency, and if prolonged or severe, can lead to brain damage or death.

The symptoms of hypoglycemia may have a very rapid onset. Patients who have had diabetes for an extended time may develop hypoglycemic unawareness, which is the inability to recognize symptoms. Some drugs, such as beta-adrenergic blockers, interfere with the sympathetic symptoms of hypoglycemia, making it more difficult for the patient to recognize the condition and for the body to correct the low glucose levels.

Factors that cause hypoglycemia in patients with diabetes include errors in insulin dosage, failure to eat at regular intervals, increased exercise, medication adjustments, or changes in the insulin injection site. Alcohol consumption can lead to hypoglycemia by decreasing gluconeogenesis. The treatment for hypoglycemia is always glucose, given in a concentrated source of 15 to 20 g. This can be repeated as necessary, while taking care not to overtreat the patient and cause hyperglycemia. If the individual is unconscious, or unable to swallow safely, a small amount of glucose gel or spray can be administered to the buccal mucosa. Intravenous (IV) glucose is immediately effective in treating hypoglycemia and glucagon may be administered.

PROTOTYPE DRUG Glucagon (GlucaGen)

Classification **Therapeutic:** Antihypoglycemic drug
Pharmacologic: Pancreatic hormone

Therapeutic Effects and Uses: Glucagon is used for the emergency treatment of severe hypoglycemia in patients with diabetes who are unconscious or unable to eat sugar or drink a sweetened beverage. It is also used for radiographic studies to relax the smooth muscle of the GI tract. GlucaGen is obtained through recombinant DNA technology and is identical in structure to human glucagon.

Glucagon can be given intramuscularly (IM), subcutaneously, or IV. It will raise serum glucose levels in 10 to 20 minutes. Because glucagon raises glucose levels by stimulating breakdown of stored glycogen, it is not effective in patients who experience hypoglycemia due to starvation, because their glycogen stores are depleted.

From 1930 to 1950, massive doses of insulin were administered to agitated psychiatric patients with serious mental illnesses to induce seizures and coma, a procedure called insulin shock therapy. Upon administration of glucose or glucagon, the patient awakened in a more sedated state. Although glucagon is still approved by the U.S. Food and Drug Administration (FDA) for this purpose, this inhumane practice was discontinued when antipsychotic drugs were discovered in the 1950s.

Mechanism of Action: Glucagon increases glucose levels by increasing glycogenolysis; therefore, its actions are dependent on the presence of adequate liver glycogen stores. Glucagon stimulates the uptake of amino acids, increases their conversion to glucose (gluconeogenesis), and promotes lipolysis in the liver, with the release of fatty acids and glycerol.

Pharmacokinetics:

Route(s)	IM, IV, subcutaneous
Absorption	Easily absorbed IM or subcutaneous
Distribution	Throughout plasma
Primary metabolism	Liver, plasma, and kidneys
Primary excretion	Renal and through the bile
Onset of action	IV: 5–20 min; IM: 30 min; subcutaneous: 30–45 min
Duration of action	1–1.5 h

Adverse Effects: Glucagon is well tolerated. Adverse effects include nausea, vomiting, hypersensitivity reactions, transient changes in blood pressure (either hypotension or HTN), tachycardia, hyperglycemia, and hypokalemia.

Contraindications/Precautions: Glucagon is contraindicated in patients sensitive to protein compounds, in

patients with depleted glycogen stores, or in patients with insulinoma or pheochromocytoma. It is used with caution in patients with coronary artery disease because it may affect blood pressure, heart rate, and myocardial oxygen demand.

Drug Interactions: Glucagon increases serum glucose and will antagonize the effects of antidiabetic drugs. Beta-adrenergic blockers will inhibit the glucose-elevating effect of glucagon and will also increase the risk of blood pressure or heart rate adverse effects associated with glucagon. **Herbal/Food:** None known.

Pregnancy: Category B.

Treatment of Overdose: An overdose can cause hyperglycemia, which may be treated with insulin, IV fluids, and monitoring of electrolytes.

Nursing Responsibilities:

- Assess the patient's blood glucose level before, during, and after glucagon administration.
- Reconstitute the dry powder of glucagon with the diluent supplied by the manufacturer. Gently roll the vial to mix the drug but do not shake the vial. If glucagon fails to cause a response, IV glucose must be given.
- Administer supplemental oral carbohydrates once consciousness has been achieved to restore glycogen levels and prevent secondary hypoglycemia.
- Instruct the patient on the proper use of the GlucaGen emergency kit.

Lifespan and Diversity Considerations:

- Calculate pediatric dosages carefully. In general, children under the age of 6 require one half the adult dose.

Patient and Family Education:

- Immediately report signs of impending hypoglycemia such as headache, difficulty concentrating, confusion, seizures, palpitations, nervousness, sweating, and cool, clammy skin to the healthcare provider.
- At the first signs of hypoglycemia, eat sugar or other carbohydrate because this may eliminate the need to administer glucagon. Follow any carbohydrate with a protein source for longer lasting effects.
- Do not mix the GlucaGen solution with the powder until it is ready to be used. Discard any unused portion.
- Wear a medical alert bracelet or jewelry that identifies your medical condition and its treatment.

Drugs Similar to Glucagon (GlucaGen)

There are no drugs similar to glucagon.

66.5 Serious complications of chronic diabetes include neuropathy, nephropathy, retinopathy, and vascular disease.

Most patients with type 2 diabetes experience no symptoms of their illness for many years, perhaps even decades. There may be no acute symptoms to motivate the patient to seek medical care. However, while years may pass without symptoms, the effects of uncontrolled blood glucose levels are progressively producing major, irreversible changes on body systems, especially the nervous and circulatory systems.

Teaching patients about the long-term consequences of untreated diabetes can be a major challenge for the nurse. When diagnosed at an asymptomatic stage, it is difficult to convince patients to make radical changes to their lifestyle and to spend money on prescriptions when they do not feel ill. Patients must clearly understand that if they delay treatment until symptoms appear, it will likely be too late to prevent serious, chronic complications. Intensive management of blood glucose levels has been found to dramatically reduce the incidence of long-term complications of diabetes.

Neuropathies are common, affecting an estimated 60% to 70% of people with diabetes. Diabetic neuropathies affect both the somatic and autonomic nervous systems. Somatic neuropathies include paresthesias, numbness, tingling and pain, motor weakness, and muscle wasting. Autonomic neuropathies include postural hypotension, altered GI functioning including gastroparesis, or gastric atony, diarrhea, altered genitourinary functioning with difficulty voiding or erectile dysfunction, and possible cranial nerve impairment. Intensive management of blood glucose has been shown to reduce the occurrence of neuropathies.

Diabetic nephropathy is the leading cause of end-stage renal disease, which affects patients with both type 1 and type 2 diabetes. Most commonly, the renal glomeruli are damaged, and progressive loss of kidney function leads to eventual renal failure. Comorbid conditions that put the patient at high risk for nephropathy include HTN, poor glucose control, smoking, and hyperlipidemia.

Diabetic retinopathy is the leading cause of acquired blindness in the United States. Thirty years after the onset of diabetes, almost all people with type 1 diabetes, and over 60% of those with type 2 diabetes, show some degree of retinopathy (Bhavsar, 2017). Regular eye examinations are important for everyone who has diabetes.

Diabetes is a major risk factor for the development of vascular disease, including premature atherosclerosis, which leads to coronary artery disease, cerebrovascular disease, and peripheral vascular disease. Heart disease and stroke account for about 65% of deaths in individuals with diabetes. Preventive measures are directed toward reducing risk factors: control of blood pressure, smoking cessation, lowering of lipid levels, and optimal glucose control. In addition, antiplatelet drugs are often indicated.

Foot ulcers occur in patients with diabetes due to peripheral neuropathies and poor circulation. Neuropathies may impair sensation, so a small area of irritation may go unnoticed. Vascular insufficiency and elevated glucose levels inhibit healing of the ulcer. If the ulcer becomes infected, it is often resistant to treatment and can ultimately result in the need for amputation. Diabetes is the leading cause of nontraumatic amputations.

Insulin Therapy

66.6 Insulin is the cornerstone of therapy for patients with type 1 and gestational diabetes.

Because patients with type 1 diabetes are severely deficient in insulin production, insulin replacement therapy is required to survive. Insulin is also required for those with type 2 diabetes who are unable to manage their blood glucose levels with diet, exercise, and oral antidiabetic drugs. Among adults diagnosed with diabetes, 14% take only insulin, 15% take insulin with oral antidiabetic drugs, 57% take oral antidiabetic drugs only, and 14% take neither insulin nor antidiabetic drugs (ADA, 2015).

The pharmacologic goal for patients with type 1 diabetes is to administer insulin as replacement therapy in normal physiologic amounts. Because insulin secretion varies greatly in response to daily activities, pharmacotherapy must be carefully planned in conjunction with proper meal planning and lifestyle habits. The desired outcome of insulin therapy is to prevent the long-term consequences of diabetes by maintaining blood glucose levels strictly within the normal range.

The fundamental principle to remember about insulin therapy is that the right amount of insulin must be available to cells when glucose is present in the blood. Administering insulin when glucose is not available can lead to hypoglycemia and, possibly, coma. This situation occurs when a patient administers insulin correctly but skips a meal. The insulin is available to cells, but glucose is not. In another example, the patient participates in strenuous exercise. The insulin may have been administered on schedule, and food eaten, but the active muscles quickly use up all the glucose in the blood, and the patient becomes hypoglycemic. Patients with diabetes who engage in competitive sports need to consume food or sports drinks just prior to and during the activity to maintain their blood glucose at normal levels. The nurse plays a key role in helping patients plan their meals, activities, and insulin dosages correctly. Figure 66.2 illustrates the management of type 1 diabetes and correct timing of the insulin dose with meals.

Many types of insulin are available, differing in their source, time of onset, and peak effect and duration of action. Almost all insulin today is human insulin obtained through recombinant DNA technology. Pharmacologists have modified human insulin to create certain pharmacokinetic

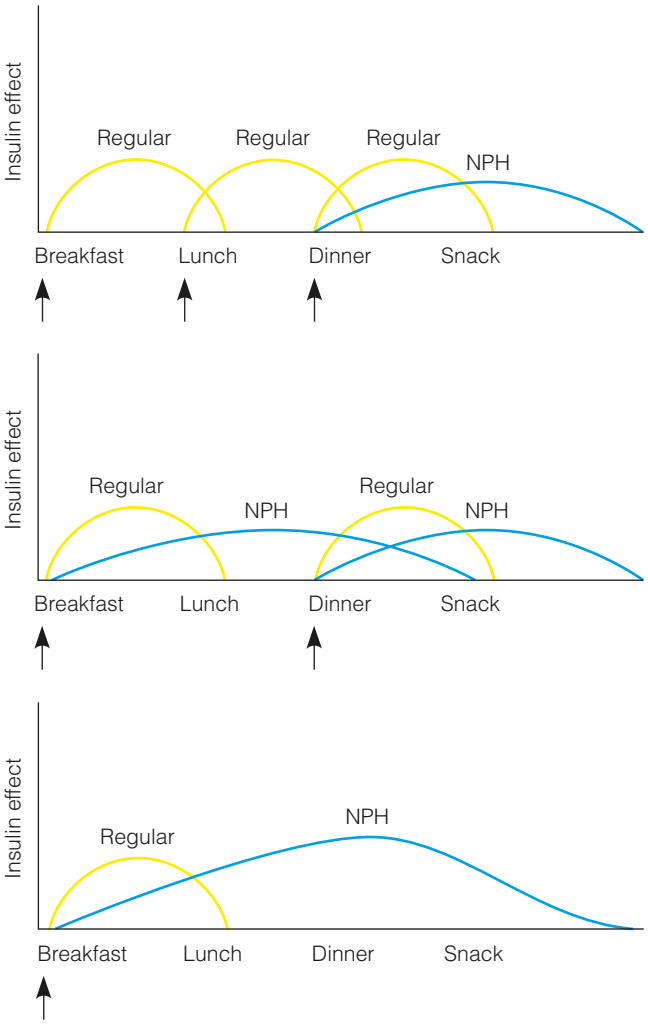

Figure 66.2 Insulin regimens.

advantages, such as a more rapid onset of action (Humalog) or a more prolonged duration of action (Lantus). These modified forms are called insulin *analogs*. It is important for nurses and patients to know the time of peak action of any insulin, because that is when the risk for hypoglycemic adverse effects is greatest. The different types of insulins available are listed in Table 66.2.

Doses of insulin are highly individualized for the precise control of blood glucose levels in each patient. Because the GI tract destroys insulin, it must be given by injection. Some patients require two or more injections daily for proper diabetes management. For ease of administration, two different compatible types of insulin may be mixed, using a standard method, to obtain the desired therapeutic effects. Some of these combinations are marketed in cartridges containing premixed solutions. A long-acting insulin may be taken daily to provide a basal blood level, with a supplemental rapid-acting insulin given shortly before a meal.

Rapid- or regular-acting insulin can be used in continuous subcutaneous infusion devices, often called insulin pumps. An infusion set, which holds a syringe of the drug, delivers

Table 66.2 Types of Insulin: Actions and Administration

Drug	Action	Onset	Peak	Duration	Administration and Timing	Compatibility
Insulin aspart (NovoLog)	Rapid	15 min	1–3 h	3–5 h	Subcutaneous: 5–10 min before meal	Can give with NPH; draw aspart up first, give immediately
Insulin degludec (Tresiba)	Long	Gradual	9 h	To 42 h	Subcutaneous: once daily, any time of day	Do not mix with any other insulin
Insulin detemir (Levemir)	Long	Gradual	6–8 h	To 24 h	Subcutaneous: 1–2 times daily	Do not mix with any other insulin
Insulin glargine (Basaglar, Lantus, Toujeo)	Long	Gradual: begins at 1.1 h	No peak	To 24 h	Subcutaneous: once daily, same time each day	Do not mix with any other insulin
Insulin glulisine (Apidra)	Rapid	15–30 min	1 h	3–4 h	Subcutaneous: 15 min before meal	Can give with NPH; draw glulisine up first, give immediately
Insulin lispro (Humalog)	Rapid	5–15 min	0.5–1 h	3–4 h	Subcutaneous: 15 min before or immediately after a meal	Can give with NPH; draw lispro up first, give immediately
Insulin regular (Humulin R, Novolin R)	Short	30–60 min	2–4 h	5–7 h	Subcutaneous: 30–60 min before meal; IV	Can mix with NPH, sterile water, normal saline; do not mix with glargine
Isophane insulin suspension (Humulin N, NPH)	Intermediate	1–2 h	4–12 h	18–24 h	Subcutaneous: mix (cloudy)	Can mix with aspart, lispro, reg; do not mix with glargine

insulin from the pump to a needle anchored in the subcutaneous tissue of the abdomen. The infusion set is replaced after 2 to 3 days, at which time the injection site should be moved, at least 2 inches away from the old site. Many providers recommend checking blood glucose levels within 3 to 4 hours of replacement to ensure the system is working properly. The pump is programmed to release small subcutaneous doses of insulin into the abdomen at predetermined intervals, with larger boluses administered manually at mealtime if necessary. Most pumps contain an alarm that reminds patients to take their insulin. They are generally worn on a belt or tucked into a pocket. Figure 66.3 shows an insulin pump.

The primary adverse effect of insulin therapy is overtreatment; insulin may remove too much glucose from the blood, resulting in hypoglycemia. This may occur when a patient with type 1 diabetes has more insulin in the blood than is needed to balance the amount of circulating blood glucose. Hypoglycemia may occur when the insulin level peaks, during exercise, when the patient receives too much insulin due to a medication error, or if the patient skips a meal. Some of the symptoms of hypoglycemia are the same as those of DKA. Those that differ and help to determine that a patient is hypoglycemic include pale, cool, and moist skin, with blood glucose less than 50 mg/dL and a sudden onset of symptoms. Left untreated, severe hypoglycemia may result in death.

Other adverse effects of insulin include injection-site reactions, generalized urticaria, and swollen lymph glands. Some patients will experience Somogyi phenomenon, a rapid decrease in blood glucose, usually during the night, which stimulates the release of hormones that elevate blood glucose (epinephrine, cortisol, and glucagon), resulting in an elevated morning blood glucose level. Administration of insulin above the patient's normal dose may produce a rapid rebound hypoglycemia. The hormone glucagon is administered as a replacement therapy for some patients with diabetes when they are in a hypoglycemic state and have impaired glucagon secretion.

Figure 66.3 Insulin pump.
Courtesy of Ace Stock Limited/Alamy Stock Photo.

Patients with diabetes who forget their insulin dose face equally serious consequences. Again, remember the fundamental principle of insulin pharmacotherapy: The right amount of insulin must be available to cells when glucose is present in the blood. Without insulin present, glucose from a meal can build up to high levels in the blood, causing hyperglycemia and possible coma. Proper planning and teaching by the nurse are essential to achieve successful outcomes and maximize patient adherence with therapy.

Insulin Adjunct

Pramlintide (Symlin) is an antihyperglycemic drug approved in 2005 that is used along with insulin in patients with type 1 or type 2 diabetes who are not able to achieve glucose control by the use of insulin alone. The drug is a synthetic analog of amylin, a natural hormone released by the beta cells of the pancreas at the same time as insulin. Its natural function is to act synergistically with insulin in glycemic control. The therapeutic actions of pramlintide are to slow gastric emptying time, reduce postprandial glucagon secretion, and increase satiety, thereby leading to reduced calorie intake. Pramlintide is administered subcutaneously immediately prior to major meals using a premeasured disposable injector called a SymlinPen. It cannot be mixed with insulin, and it must be injected into a different site than insulin. When initiating treatment, rapid- or short-acting insulin doses are usually reduced by 50%. Adverse effects include nausea, vomiting, abdominal pain, headache, dizziness, fatigue, coughing, allergic reaction, or arthralgia. The drug carries a black box warning that severe hypoglycemia may occur during therapy. Hypoglycemia may be prolonged and severe, usually occurring within 3 hours following an injection.

PROTOTYPE DRUG **Human Regular Insulin (Humulin R, Novolin R)**

Classification **Therapeutic:** Antidiabetic drug, pancreatic hormone
Pharmacologic: Short-acting hypoglycemic drug

Therapeutic Effects and Uses: Human regular insulin is used to maintain blood glucose levels within normal limits. The primary effects of human regular insulin are promotion of cellular uptake of glucose, amino acids, and potassium; promotion of protein synthesis, glycogen formation and storage, and fatty acid storage as triglycerides; and conservation of energy stores by promoting the utilization of glucose for energy needs and inhibiting gluconeogenesis. Indications for insulin include the following:

- As monotherapy to lower blood glucose levels in patients with type 1 diabetes
- In combination with oral antidiabetic drugs in patients with type 2 diabetes
- For the emergency treatment of DKA or hyperosmolar hyperglycemic state
- For gestational diabetes.

Because regular insulin is short acting, it is most often used in combination with intermediate- or long-acting insulin to achieve 24-hour glucose control. Nondiabetic indications for insulin include stimulation of growth hormone secretion in the evaluation of growth hormone deficiency and the treatment of hyperkalemia to promote a shift of potassium into cells.

Mechanism of Action: Regular insulin is identical to endogenous insulin. Insulin decreases blood glucose levels by increasing cellular uptake of glucose and stimulating storage of glucose as glycogen; it also inhibits the release of glucagon.

Pharmacokinetics:

Route(s)	Subcutaneous; IV (only regular insulin can be given IV); inhalation
Absorption	Rapidly absorbed following subcutaneous injection; absorption time can vary by site of injection
Distribution	Throughout extracellular fluids
Primary metabolism	Hepatic
Primary excretion	Liver and kidneys
Onset of action	Subcutaneous: 30–60 min; IV: 15 min
Duration of action	6–10 h

Adverse Effects: The most common adverse effect of insulin therapy is hypoglycemia. Rebound hyperglycemia (Somogyi phenomenon) may occur. Irritation at injection sites may occur, including lipohypertrophy, the accumulation of fat in the area of injection. This effect is lessened with rotation of injection sites. Weight gain is a possible adverse effect. Because insulin facilitates the intracellular uptake of potassium, hypokalemia is possible.

Contraindications/Precautions: Insulin is used with caution in pregnancy, CKD, fever, and thyroid disease and among infants, children, and older adults. Insulin should not be administered to patients with hypoglycemia. Patients with hypokalemia should be monitored carefully because insulin may worsen this condition.

Drug Interactions: Caution must be used when insulin is concurrently administered with drugs that can produce hypoglycemia, including sulfonylureas, meglitinides, beta-adrenergic blockers, salicylates, anabolic steroids, monamine oxidase inhibitors (MAOIs), and alcohol. Several drugs can antagonize the glucose-lowering effects of insulin including dextrothyroxine, corticosteroids, epinephrine or norepinephrine, furosemide, and thiazide diuretics. Angiotensin-converting enzyme (ACE) inhibitors increase insulin sensitivity and may enhance the hypoglycemic effects of insulin. Many other drugs can influence blood glucose and the nurse should consult current drug references when treating patients who take high insulin doses or who have unstable diabetes. **Herbal/Food:** Garlic, chromium, black cohosh, bitter melon, bilberry, and ginseng may potentiate the hypoglycemic effects of insulin. Cocoa and rosemary may have a hyperglycemic effect.

Pregnancy: Insulin glargine is pregnancy category C; other forms of insulin are category B.

Treatment of Overdose: An overdose of insulin can cause profound hypoglycemia, which is treated with a

concentrated source of glucose (dextrose), such as D_5W or glucagon, by the parenteral route.

Nursing Responsibilities: Key nursing implications for patients receiving regular insulin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Insulin.

Drugs Similar to Human Regular Insulin (Humulin R, Novolin R)

Many types of insulin are available. They are categorized by their onset of action and duration of action, as given in Table 66.2. Premixed formulations of insulin, such as Humulin 70/30, are also available. This type contains 70% NPH insulin and 30% regular insulin, so it can be given before a meal to help control postprandial glucose while also providing longer coverage of insulin needs. Other combination insulins include Humalog 75/25, Humulin 50/50, Novolin 70/30, and NovoLog 70/30. The characteristics of selected insulin combinations are shown in Table 66.3.

Insulin aspart (NovoLog): Insulin aspart is a rapid-onset drug, with a structure very similar to that of endogenous insulin. Insulin aspart has a more rapid onset of action than regular insulin, acting within about 15 minutes when given subcutaneously. Because insulin aspart acts rapidly, injections should be made 5 to 10 minutes before meals. It also has a short duration of action, 3 to 5 hours when compared to regular insulin. Because of its short duration, insulin aspart is usually given in combination with an intermediate- or long-acting form of insulin. Insulin aspart is available in 10-mL vials and 3-mL prefilled cartridges.

Insulin degludec (Tresiba): Insulin degludec is a newer long-acting insulin analog approved in 2015 for both type 1 and type 2 diabetes. Because it has a long duration of up to 42 hours, it may be taken at any time of day, regardless of meals. It is administered by the subcutaneous route. Ryzodeg 70/30 is a mixture of insulin degludec and insulin aspart, a rapid-acting human insulin analog.

Insulin detemir (Levemir): Insulin detemir is a long-acting insulin with a slow onset and dose-dependent duration of action. Detemir may be given once or twice a day, depending on the dose, which is individualized to the patient. At low doses (0.2 unit/kg), effects persist about 12 hours. At higher doses (0.4 unit/kg), effects last 20 to 24 hours. Because of its slow onset and prolonged duration, insulin detemir is used to provide basal glycemic control. It is not injected before meals to control postprandial hyperglycemia. It cannot be mixed with any other type of insulin and is only given by subcutaneous injection. Insulin detemir is supplied in 10-mL vials, 3-mL cartridges, a 3-mL pen, and a 3-mL InnoLet dosing device. The InnoLet dosing injection device is disposable and has an easy-to-read dial, large push button for injection, and audible clicks that indicate each unit injected.

Insulin glargine (Basaglar, Lantus, Toujeo): Insulin glargine is a recombinant insulin analog that exhibits constant, long-duration insulin activity. It has no defined peak effect and provides for the maintenance of steady blood levels, leading to a lowered risk of hypoglycemia. Insulin glargine allows for once-daily dosing as basal insulin coverage. Although it can be given without regard to meals, it should be given at the same time each day to provide consistent blood levels. It cannot be mixed with any other type of insulin and is only given by subcutaneous injection. Insulin glargine may also help improve the lipid profiles and A1C levels of type 2 diabetes when added to therapy.

Insulin glulisine (Apidra): Insulin glulisine has a 10- to 15-minute onset and a short duration of 3 to 5 hours. Because of its rapid onset, the drug should be administered no sooner than 15 minutes before eating and no later than 20 minutes after starting a meal. Apidra is given only by subcutaneous injection.

Insulin lispro (Humalog): Insulin lispro is a rapid-acting analog of regular insulin, with effects beginning within 15 to 30 minutes of subcutaneous injection. Insulin lispro acts faster than regular insulin but has a shorter duration of action, 5 hours or less. Because of its rapid onset, insulin lispro should be administered immediately before eating, or shortly after eating. It is intended to help control the rise in blood glucose brought on by a meal and is normally given concurrently with an intermediate- or long-acting drug that provides a basal coverage of insulin. It is a clear insulin and does not require mixing prior to injecting. Lispro is often used with insulin infusion pumps and cannot be given IV.

Table 66.3 Premixed Insulin Combinations

Drug	Description	Onset (min)	Peak (h)	Duration (h)	Adverse Effects
Humalog Mix 75/25	75% insulin lispro protamine/ 25% insulin lispro	15–60	1–6.5	Up to 24	*Pain and swelling at injection site* Hypoglycemia, DKA
Humulin 50/50	50% NPH insulin/ 50% regular insulin	30–60	2–5.5	Up to 24	
Humulin 70/30	70% NPH insulin/30% regular insulin	30–60	1.5–16	Up to 36	
Novolin 70/30	70% NPH insulin/ 30% regular insulin	30–60	2–12	Up to 36	
NovoLog Mix 70/30	70% insulin aspart protamine/ 30% insulin aspart	15–60	1–4	Up to 24	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Isophane insulin (Humulin N, NPH): Isophane insulin is the only intermediate-acting insulin. It has a slower onset of action (1 to 4 hours) than regular insulin and a duration of action of up to 18 to 24 hours. It is used to provide a basal level of insulin coverage between meals and at night. NPH insulin is normally administered 30 minutes before the first meal of the day, but in some instances a second, smaller dose is taken before the evening meal or at bedtime. Many patients are prescribed insulin that is premixed, such as 70% NPH with 30% regular or rapid acting. NPH is a cloudy suspension and requires mixing prior to drawing up a dose. NPH can be given with aspart, lispro, or regular insulin, but it cannot be mixed with glargine insulin. When mixed with another type of insulin, NPH should be drawn up after the other insulin, and the mixture should be administered immediately. The term *NPH* stands for neutral protamine Hagedorn. Hans Christian Hagedorn was a scientist who developed the drug in the 1920s.

Antidiabetic Drugs for Type 2 Diabetes

66.7 Antidiabetic drugs from multiple classes are used to treat type 2 diabetes.

The six primary classes of antidiabetic drugs used to treat type 2 diabetes are differentiated by their chemical structures and their mechanisms of action. Drug classes prescribed for patients with type 2 diabetes include alpha-glucosidase inhibitors, biguanides, incretin enhancers, meglitinides, sulfonylureas, and thiazolidinediones. An additional group includes miscellaneous drugs from other classes. All the

CONNECTIONS: Lifespan Considerations

Diabetes in the School Setting

Caring for the school-age child with diabetes in a school setting requires teamwork among the parents or caregiver, school nurse, school staff, the child's healthcare provider, and, most often, the child. For each child, an individual diabetes medical management plan (DMMP) should be established that addresses all aspects of the diabetes care. The ADA (2014) recommends the following specific instructions be included in each child's DMMP:

- Blood glucose monitoring instructions, including the frequency and circumstances for requiring monitoring. Provision should be made for privacy during testing or insulin administration if the child, parents, or caregiver desires.
- Information on insulin injections, if used, to include type(s) of insulin, dose, times for administration, storage, and provider permission for adjustments in insulin dosage if needed.
- Information on meals and snacks, including scheduling, the need for the child to be able to eat prn (as needed) to prevent hypoglycemia, and content and calories of a school lunch.
- Symptoms and treatment for hypoglycemia and hyperglycemia. Specific levels of training should be provided to school personnel based on whether they will administer basic, intermediate, or advanced treatment in caring for the child.
- Information on participation in physical activity.
- Emergency plans for emergency evacuation, shelter-in-place, or school lockdowns.

By establishing a DMMP, routine daily care as well as emergency contingencies can be addressed. When all participants work as a team, a child with diabetes can participate fully and safely in the school setting.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Insulin
Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including endocrine, cardiovascular, hepatic, or kidney disease; pregnancy; or breastfeeding. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain a history of current symptoms, duration and severity, and other related signs or symptoms (e.g., paresthesias of hands or feet). Assess feet and lower extremities for possible injury, infection, or ulcerations.
- Obtain a dietary history including caloric intake if on an ADA diet, number of meals and snacks per day. Assess fluid intake and type of fluids consumed.
- Obtain baseline vital signs, height, and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, A1C level, lipid profile, osmolality, and hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., glucose levels remain within normal limits, electrolytes and osmolality remain normal, A1C level demonstrates adequate glucose control).
- Assess for and report promptly any adverse effects: signs of hypoglycemia (e.g., nausea, paleness, sweating, diaphoresis, tremors, irritability, headache, light-headedness, anxiety, decreased level of consciousness) and hyperglycemia (e.g., flushed, dry skin, polyuria, polyphagia, polydipsia, drowsiness, glycosuria, ketonuria, acetone-breath), lipodystrophy, infection.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Depending on the severity of hyperglycemia, blood glucose levels should return gradually to normal.)	• Teach the patient to report any return of original symptoms. • Teach the patient the symptoms of hyper- and hypoglycemia to observe for and instruct the patient to check the capillary glucose level routinely and if symptoms are present. Promptly report any noticeable symptoms and concurrent capillary glucose level to the healthcare provider.
• Administer insulin correctly and per the schedule ordered (e.g., routine dosing with or without additional sliding-scale coverage). Plan insulin administration and peak times around mealtimes. (Maintaining a steady level of insulin with mealtimes arranged to match peak insulin activity will assist in maintaining a steady blood glucose level.)	• Teach the patient, family, or caregiver appropriate administration techniques for all types of insulin used, followed by return demonstration until the patient or caregiver is comfortable with the technique and able to perform correctly. • Teach the patient, family, or caregiver the importance of peak insulin levels and the need to ensure that adequate food sources are consumed to avoid hypoglycemia. Provide written materials for future reference whenever possible.
• Ensure that dietary needs are met based on the need to lose, gain, or maintain current weight and glucose levels. Consult with the dietitian as needed. Limit or eliminate alcohol use. (Adequate caloric, protein, carbohydrate, and fat amounts support an insulin regimen for glucose control. Activity and lifestyle will also be factored into dietary management. As alcohol is metabolized, it can raise and then precipitously lower blood sugar, increasing the risk of hypoglycemia.)	• Review current diet, lifestyle, and activity level with the patient. Arrange a dietitian consult based on the need to alter diet or food choices. Teach the patient to limit or eliminate alcohol use. If alcoholic beverages are consumed, limit to one per day, and consume along with a complete meal to ensure that food intake balances alcohol metabolism.
Minimizing adverse effects: • Continue to monitor capillary glucose levels. Hold insulin dose if blood sugar is less than 70 mg/dL or per parameters as ordered, and contact the healthcare provider for further orders. (Daily glucose levels, especially before meals, will assist in maintaining adequate control of blood glucose and aid in assessing the appropriateness of current insulin types and dosages.)	• Instruct the patient on blood glucose monitoring the appropriate techniques to obtain capillary blood glucose levels, followed by return demonstration, and when to contact the healthcare provider (e.g., glucose less than 70 mg/dL). Monitor use and ensure proper functioning of all equipment to be used at home.
• Continue to monitor periodic laboratory work: CBC, electrolytes, glucose, A1C level, lipid profile, osmolality, hepatic and renal function studies. (Periodic monitoring of laboratory work assists in determining glucose control and the need for any change in insulin amounts and assesses for complications. A1C level provides a measure of glucose control over several months' time.)	• Instruct the patient on the need to return periodically for laboratory work.
• Assess for symptoms of hypoglycemia, especially around the time of insulin peak activity. If symptoms of hypoglycemia are noted, provide a quick-acting carbohydrate source (e.g., juice or other simple sugar), and then check capillary glucose level. Report to the healthcare provider if glucose is less than 70 mg/dL or as ordered. If mealtime is not immediate, provide a longer acting protein source to ensure that hypoglycemia does not recur. (Hypoglycemia is especially likely to occur around peak insulin activity, especially if food sources are inadequate. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hypoglycemia. Providing a quick-acting carbohydrate source and then checking the capillary glucose level will ensure that glucose does not decrease further while locating the glucose testing equipment. When in doubt, treating symptoms for suspected hypoglycemia is safer than allowing further decreases in glucose and possible loss of consciousness with adverse effects. Small additional amounts of carbohydrates will not dramatically increase blood sugar if testing shows a hyperglycemic episode.)	• Teach the patient to always carry a quick-acting carbohydrate source in case symptoms of hypoglycemia occur. If unsure whether symptoms indicate hypo- or hyperglycemia, treat as hypoglycemia and then check capillary glucose. If symptoms are not relieved in 10–15 min, or if blood sugar is below 70 mg/dL (or parameters as ordered), immediately notify the healthcare provider.
• Monitor blood glucose more frequently during periods of illness or stress. (Insulin needs may increase or decrease during periods of illness or stress. Frequent monitoring during these times helps to prevent hypoglycemia and ensures adequate glucose control.)	• Instruct the patient to check glucose levels more frequently when ill or under stress. Stress may increase insulin needs because the stress response can cause glycogenolysis. Illness, especially associated with anorexia, nausea, or vomiting, may decrease insulin needs. Notify the healthcare provider if unable to eat normal meals during periods of illness or stress for possible change in insulin dose.
• Encourage increased activity and exercise, but monitor blood glucose before and after exercise and begin any new or increased exercise routine gradually. Continue to monitor for hypoglycemia for up to 48 h after exercise. (Exercise assists muscles to use glucose more efficiently and increases insulin receptor sites in the tissues, lowering the blood sugar. Benefits of exercise and lowered blood sugar may continue for up to 48 h, increasing the risk of hypoglycemia during this time. Frequent monitoring helps to prevent hypoglycemia and ensures adequate glucose control.)	• Teach the patient the benefits of increased activity and exercise and to begin any new routine or increase in exercise gradually. Exercise should occur an hour after a meal or after a 10- or 15-g carbohydrate snack to prevent hypoglycemia. If exercise is prolonged, small frequent carbohydrate snacks can be consumed every 30 min during exercise to maintain blood sugar. • Instruct the patient to check glucose levels more frequently before, during, and after exercise.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Rotate insulin administration sites weekly. If the patient is hospitalized, use sites that have been less used or are difficult for the patient to reach. Insulin pump subcutaneous catheters should be changed every 2–3 days or as recommended by the healthcare provider. (Rotating injection sites weekly helps to prevent lipodystrophy. Use caution if using a new site, especially if the previous site used by the patient exhibits signs of lipodystrophy. Insulin in an unused site may absorb more quickly than in a site with lipodystrophy or tissue changes, resulting in hypoglycemia. Insulin pump subcutaneous catheters should be changed every 2–3 days to prevent infections at the site of insertion.)	• Instruct the patient on the need to rotate insulin injection sites on a weekly basis to prevent tissue damage or to rotate subcutaneous catheter sites (insulin pumps) every 2–3 days.
• Ensure proper storage of insulin to maintain maximum potency. (Unopened insulin may be stored at room temperature, but avoid direct sunlight and excessive heat. Opened insulin vials may be stored at room temperature for up to 1 month. If noticeable change in solution occurs or if precipitate forms, discard the vial.)	• Teach the patient methods for proper storage of insulin and for storage during travel.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and any special requirements of the medication therapy (e.g., insulin needs during exercise or illness). • Instruct the patient to carry a wallet identification card and wear medical identification jewelry indicating diabetes.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of the drug followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs including:
	  • Proper preparation of insulin: Rotate vials gently between the palms and do not shake; if insulins are mixed, draw up the quickest acting insulin and then the longer acting one if insulins are compatible; insulin glargine or insulin detemir should not be mixed with any other type of insulin; use the appropriate syringe (100 unit) unless small amounts of insulin are ordered, then obtain syringes with smaller volumes to ensure accurate dosing.
	  • Proper subcutaneous injection techniques: selection and cleansing of the site with rotation every week, injecting at 90-deg angle, and applying a pad to the site after injection but not massaging the site.
	  • Proper use of all equipment: blood glucose monitoring equipment, insulin pump.

CONNECTIONS: Patient Safety

Incorrect Insulin Dose

A patient with diabetes has 30 units of Humulin R (regular) insulin ordered for the morning dose. There are several patients with diabetes on the unit and the nurse has given many doses of insulin that morning. The nurse prepares the insulin but draws up Humalog 30 units instead. The patient begins experiencing symptoms of hypoglycemia within 15 minutes and is treated successfully.

What errors occurred and how could they be prevented in the future?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

medications used to treat type 2 diabetes require some degree of pancreatic insulin secretion. These antidiabetic medications are not effective in treating type 1 diabetes because these patients have a total lack of insulin secretion.

Treatment goals recommended by the American Association of Clinical Endocrinologists (AACE) and the American College of Endocrinology (2015) are designed to target an A1C level of 6.5% or less with an FPG of less than 110 g/dL. In general, all of the antidiabetic drugs are similar in their ability to lower A1C levels in the short term. There are some differences, however, in long-term control. For example, drugs in the thiazolidinedione class appear to maintain glycemic control for 5 to 6 years, while the sulfonylureas peak at 6 months and slowly decline in efficacy. The adverse effects observed for each class differ: Some cause hypoglycemia, whereas others cause weight gain or GI complaints such as diarrhea. Because there is no perfect drug for type 2 diabetes, choice of therapy is guided by the experiences of the prescriber and the results achieved by the individual patient. A comparison of the antidiabetic drug classes is presented in Table 66.4. Doses of the individual medications are listed in Table 66.5.

Therapy for type 2 diabetes is usually initiated with a single drug. The AACE recommends metformin as the initial therapy for most patients with type 2 diabetes (AACE & American College of Endocrinology, 2015). If glycemic control is not achieved with monotherapy, a second medication is added to the therapeutic regimen. Failure to achieve

Table 66.4 Summary of Antidiabetic Drug Classes

Drug	Action(s)	Nursing Considerations
Alpha-Glucosidase Inhibitors	Interfere with carbohydrate breakdown and absorption; act locally in the GI tract with little systemic absorption	Common GI effects; hypoglycemia can occur if combined with another oral drug; if this occurs, treat with glucose, not sucrose; take with meals
Biguanides	Decrease production and release of glucose from the liver; increase cellular uptake of glucose; lower lipid levels; promote weight loss	Common GI adverse effects; risk for lactic acidosis (rare); avoid alcohol; low risk for hypoglycemia
Incretin Enhancers	Slow the breakdown of insulin, keeping it circulating in the blood longer; slow the rate of digestion, which increases satiety	Well tolerated; minor nausea, vomiting, and diarrhea; some weight loss is likely; low risk for hypoglycemia
Meglitinides	Stimulate insulin release	Can cause hypoglycemia, GI effects; well tolerated; administer shortly before meals
Sulfonylureas	Stimulate insulin release; decrease insulin resistance	Can cause hypoglycemia, GI disturbances, rash; cross sensitivity with sulfa drugs and thiazide diuretics; possible disulfiram response with alcohol
Thiazolidinediones	Decrease production and release of glucose from the liver; increase insulin sensitivity in fat and muscle tissue	Can cause fluid retention and worsening of heart failure; therapeutic effects take several weeks to develop

Table 66.5 Antidiabetic Drugs for Type 2 Diabetes

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Alpha-Glucosidase Inhibitors		
acarbose (Precose)	PO: 25–100 mg tid (max: 300 mg/day)	*Flatulence, diarrhea, abdominal distention* Hypoglycemia (tremors, palpitations, sweating)
miglitol (Glyset)	PO: 25–100 mg tid (max: 300 mg/day)	
Biguanide		
metformin immediate release (Glucophage, Riomet) extended release (Fortamet, Glucophage XR, Glumetza)	PO: 500 mg bid or 850 mg once daily; increase to 1000–2550 mg in 2–3 divided doses/day (max: 2.55 g/day) Glumetza: 1000–2000 mg once daily (max: 2 g/day) Glucophage XR: 500 mg once daily (max 2 g/day) Fortamet: 1000 mg once daily (max: 2.5 g/day)	*Flatulence, diarrhea, nausea, anorexia, abdominal pain, bitter or metallic taste, decreased vitamin B12 levels* Lactic acidosis
Incretin Mimetics (GLP-1 Receptor Agonists)		
albiglutide (Tanzeum)	Subcutaneous: 30–50 mg once weekly	*Nausea, vomiting, diarrhea, headache, nervousness* Hypoglycemia (tremors, palpitations, sweating), antibody formation, pancreatitis, CKD (exenatide), thyroid tumors (liraglutide, albiglutide)
dulaglutide (Trulicity)	Subcutaneous: 0.75–1.5 mg once weekly	
exenatide (Byetta)	Subcutaneous: 5–10 mcg bid 60 min prior to morning and evening meals	
liraglutide (Victoza)	Subcutaneous: 0.6–1.8 mg once daily, any time of day	
lixisenatide (Adlyxin)	Subcutaneous: 10–20 mcg once daily prior to morning meal	
Incretin Enhancers (DPP-4 Inhibitors)		
alogliptin (Nesina)	PO: 25 mg once daily	*Headache, upper respiratory and urinary tract infections* Hypoglycemia (tremors, palpitations, sweating), anaphylaxis, peripheral edema, exfoliative dermatitis, Stevens–Johnson syndrome
linagliptin (Tradjenta)	PO: 5 mg once daily	
saxagliptin (Onglyza)	PO: 2.5–5 mg once daily	
sitagliptin (Januvia)	PO: 100 mg once daily	
Meglitinides		
nateglinide (Starlix)	PO: 60–120 mg tid, 1–30 min prior to meals	*Flulike symptoms, upper respiratory infection, back pain* Hypoglycemia (tremors, palpitations, sweating), anaphylaxis, pancreatitis
repaglinide (Prandin)	PO: 0.5–4 mg bid–qid, 1–30 min prior to meals (max: 16 mg/day)	
Sulfonylureas, First Generation		
chlorpropamide (Diabinese)	PO: 100–500 mg/day (max: 750 mg/day)	*Nausea, heartburn, dizziness, headache, drowsiness* Hypoglycemia (tremors, palpitations, sweating), cholestatic jaundice, blood dyscrasias
tolazamide (Tolinase)	PO: 100–500 mg 1–2 times/day (max: 1 g/day)	
tolbutamide (Orinase)	PO: 250–1500 mg 1–2 times/day (max: 3 g/day)	
Sulfonylureas, Second Generation		
glimepiride (Amaryl)	PO: 1–4 mg/day (max: 8 mg/day)	*Nausea, heartburn, dizziness, headache, drowsiness* Hypoglycemia (tremors, palpitations, sweating), cholestatic jaundice, blood dyscrasias
glipizide (Glucotrol)	PO: 2.5–20 mg 1–2 times/day (max: 40 mg/day)	
glyburide (DiaBeta) glyburide micronized (Glynase)	PO: 1.25–10 mg 1–2 times/day (max: 20 mg/day) PO: 0.75–12 mg 1–2 times/day (max: 12 mg/day)	

Table 66.5 Antidiabetic Drugs for Type 2 Diabetes (*continued*)

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Thiazolidinediones		
pioglitazone (Actos)	PO: 15–30 mg/day (max: 45 mg/day)	*Upper respiratory infection, myalgia, headache, edema, weight gain* Hypoglycemia (tremors, palpitations, sweating), hepatotoxicity, bone fractures, heart failure, MI
rosiglitazone (Avandia)	PO: 4–8 mg 1–2 times/day (max: 8 mg/day)	
Miscellaneous Drugs		
bromocriptine (Cycloset)	PO: 0.8–4.8 mg/day upon awakening	*Nausea, fatigue, dizziness, vomiting, and headache* Hypotension, psychosis, drowsiness
canagliflozin (Invokana)	PO: 100 mg once daily (max: 300 mg/day) taken before first meal	*Female genital mycotic infections, urinary tract infection, and nasopharyngitis* Hypotension, CKD, hyperkalemia, hypoglycemia
dapagliflozin (Farxiga)	PO: 5–10 mg once daily in the morning, with or without food	
empagliflozin (Jardiance)	PO: 10–25 mg once daily in the morning, with or without food	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

glycemic control with two oral hypoglycemic drugs suggests the need for insulin to be added to the regimen.

Many fixed-dose combination products are available for the treatment of people with type 2 diabetes. The main advantage of taking a combination drug is that it is more convenient than taking two separate drugs and may improve adherence to the therapeutic regimen. Combination products are indicated for patients who fail to adequately control glucose levels with the use of a single drug. Doses for selected combination products are listed in Table 66.6.

Sulfonylureas

The first oral antidiabetic drug class available, sulfonylureas are divided into first- and second-generation categories. Although drugs from both generations are equally effective at lowering blood glucose, the second-generation drugs exhibit fewer drug–drug interactions.

The sulfonylureas act by stimulating the release of insulin from pancreatic islet cells and by increasing the sensitivity of insulin receptors on target cells. The most common adverse effect is hypoglycemia, which is usually caused by taking too much medication or not eating enough food. Hypoglycemia from these drugs may be prolonged and require administration of dextrose to return serum glucose to normal levels. Other adverse effects include weight gain, hypersensitivity reactions, GI distress, and hepatotoxicity. When alcohol is taken with sulfonylureas, some patients experience an uncomfortable disulfiram-like reaction, with flushing, palpitations, and nausea.

PROTOTYPE DRUG Glyburide (DiaBeta, Glynase)

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: Sulfonylurea

Therapeutic Effects and Uses: Approved in 1984, glyburide is a second-generation sulfonylurea used to lower blood glucose levels in patients with type 2 diabetes. Glyburide can be used alone or in combination with another oral hypoglycemic drug. It should be used only if diet and exercise have proven ineffective in controlling the elevated blood glucose levels.

Table 66.6 Selected Combination Oral Antidiabetic Drugs*

Trade-Name Drug	Generic Drug Combination	Route and Adult Dose (Maximum Dose Where Indicated)
Actoplus Met	pioglitazone/metformin	PO: 15 mg/500–850 mg bid (regular release) or 15–30 mg/1000 mg once daily (extended release)
Avandamet	rosiglitazone/metformin	PO: 4 mg/1000 mg daily in divided doses
Duetact	pioglitazone/glimepiride	PO: Start with 30 mg/2 mg once daily (max: 45 mg/8 mg daily)
Glucovance	glyburide/metformin	PO: 1.25–5 mg/250–500 mg once or twice daily with a meal (max: 20 mg/2000 mg daily)
Janumet	sitagliptin/metformin	PO: Starting dose 50 mg/500 mg bid (regular release) or 100 mg/1000 mg once daily (extended release) (max: 100 mg/2000 mg/day)
Jentadueto	linagliptin/metformin	PO: 2.5 mg/500–1000 mg bid (regular release) or 5 mg/1000 mg once daily (extended release) with meals
Kazano	alogliptin/metformin	PO: 12.5 mg/500 mg bid with meal
Oseni	alogliptin/pioglitazone	PO: 25 mg/15 mg once daily with or without food
PrandiMet	repaglinide/metformin	PO: 1 mg/500 mg bid, 15 min before meals (max: 10 mg/2500 mg daily)
Qtern	dapagliflozin/saxagliptin	PO: 10 mg/5 mg once daily with morning meal
Synjardy	empagliflozin/metformin	PO: 12.5 mg/1000 mg bid with meals (regular release) or 25 mg/2000 mg once daily with morning meal (extended release)

* Dosage levels are determined individually according to patient response and glycemic laboratory results.

Two types of glyburide are available: the conventional form (DiaBeta) and a micronized form (Glynase). Glynase allows for lower doses, compared to the conventional forms. Glucovance is a combination product that contains glyburide and metformin.

Mechanism of Action: Glyburide stimulates the release of insulin from pancreatic beta cells and increases the sensitivity of peripheral tissues to insulin. The stimulation of insulin release relies on some residual beta cell functioning; therefore, the drug is not effective for type 1 diabetes.

Pharmacokinetics:

Route(s)	Oral (PO)
Absorption	Readily absorbed following PO administration
Distribution	Distributed widely to body tissues, with greatest concentrations in liver, kidneys, and intestines; crosses the placenta
Primary metabolism	Extensive hepatic metabolism
Primary excretion	Equal in urine and feces
Onset of action	15–60 min
Duration of action	Up to 24 h

Adverse Effects: The primary adverse effect of glyburide is hypoglycemia. Patients at increased risk for hypoglycemia include those with CKD or hepatic insufficiency, those consuming an improper diet, and patients who are older or malnourished. Excessive exercise or alcohol consumption also increases the risk for hypoglycemia. Other adverse effects of therapy include heartburn, nausea, vomiting, diarrhea, pruritus, erythema, urticaria, photosensitivity, and blurred vision. Rare, though serious, adverse effects include hepatotoxicity, cholestatic jaundice, aplastic anemia, leukopenia, thrombocytopenia, and agranulocytosis.

Contraindications/Precautions: Glyburide is contraindicated in patients with a known sensitivity to sulfa drugs or thiazide diuretics because sulfonylureas are chemically similar to sulfa drugs. It is contraindicated as the primary treatment for type 1 diabetes, diabetic coma, or DKA. The drug is used with caution in patients with CKD or hepatic disease because the drug may accumulate to toxic levels. If used during pregnancy, glyburide should be discontinued at least 1 month before delivery because newborns exposed to sulfonylureas may develop severe hypoglycemia lasting several days.

Drug Interactions: Using alcohol with glyburide can cause hypoglycemia or hyperglycemia and has resulted in a disulfiram-type response, with severe nausea, vomiting, flushing, and palpitations. Drugs that can increase hypoglycemia when taken with glyburide are oral anticoagulants, MAOIs, probenecid, sulfonamides, chloramphenicol, oxyphenbutazone, phenylbutazone, salicylates, and clofibrate. Increased risk of hyperglycemia can occur with use of rifampin and thiazides. **Herbal/Food:** Ginseng, garlic, black cohosh, juniper berries, fenugreek, coriander, or dandelion root can cause hypoglycemia.

Pregnancy: Category C.

Treatment of Overdose: Treatment is the same as for acute hypoglycemia: A concentrated source of glucose is administered.

Nursing Responsibilities: Key nursing implications for patients receiving glyburide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Glyburide (DiaBeta, Glynase)

First-generation sulfonylureas are typically less potent, require larger doses, have a shorter duration of action, and require more frequent dosing than the second-generation sulfonylureas. Thus, the second-generation drugs are more widely prescribed.

First-generation sulfonylureas:

Chlorpropamide (Diabinese): Approved in 1958, chlorpropamide is the longest acting of the first-generation sulfonylureas, with a duration of action of 24 to 72 hours. In addition to treating type 2 diabetes, an unlabeled use is the treatment of neurogenic diabetes insipidus. Rarely, it can produce an antidiuretic effect, with resulting hyponatremia, water intoxication, and edema. Due to the long half-life of the drug (36 hours), hypoglycemia can be severe and prolonged. It is a pregnancy category C drug.

Tolazamide (Tolinase): Approved in 1965, tolazamide is structurally related to tolbutamide but is 5 times more potent. It is taken once daily with breakfast. It can also be used in patients who fail to respond to other sulfonylureas. It is a pregnancy category C drug.

Tolbutamide (Orinase): Tolbutamide is a short-acting sulfonylurea, with a duration of 6 to 12 hours, given once or twice daily after meals. Approved in 1957, it has been used in patients being treated with insulin who have failed to respond to other sulfonylureas. It is a pregnancy category C drug.

Second-generation sulfonylureas:

Glimepiride (Amaryl): Approved in 1995, glimepiride can be used alone or in combination with insulin for patients with type 2 diabetes. It is most often given once a day with the first meal of the day. More recently, glimepiride is included in a fixed-dose combination with pioglitazone (Duetact). Because of the increased risk for myocardial infarction (from rosiglitazone and pioglitazone), the fixed-dose combinations contain a black box

warning regarding the increased risk for heart failure and myocardial infarction.

Glipizide (Glucotrol): Approved in 1984, glipizide is available in a standard tablet form and an extended release (XL) tablet, which should not be crushed or chewed. In addition to treating patients with type 2 diabetes who are unable to achieve glucose control with diet alone, it can be used for short-term therapy for those who normally can control their glucose levels by diet. Once-a-day dosing is given 30 minutes before the first meal of the day.

CONNECTION Checkpoint 66.2

Glyburide combined with alcohol can cause a disulfiram reaction. From what you learned in Chapter 27, what causes the symptoms of the disulfiram reaction and what are common symptoms of this reaction? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Biguanides

Metformin (Glucophage) is the only drug in this class. It is a preferred drug for managing type 2 diabetes because of its effectiveness and safety.

PROTOTYPE DRUG **Metformin (Glucophage, Glumetza, Others)**

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: Biguanide

Therapeutic Effects and Uses: Approved in 1994, metformin lowers blood glucose levels in patients with type 2 diabetes who are unable to control glucose levels by diet and exercise. It can be used alone or in combination with sulfonylureas, alpha-glucosidase inhibitors, or insulin. It is approved for use in children ages 10 and older. Several formulations of metformin are available:

- **Regular release tablets.** Administered once or twice daily, absorption is decreased with food, and the peak plasma level is 2.5 hours.
- **Solution (Riomet).** Administered once or twice daily, absorption is slightly increased with food, and the peak plasma level is 2.3 hours.
- **Extended release (Fortamet, Glucophage XR, and Glumetza).** These are long-duration systems in which metformin is slowly released from a semipermeable membrane (Fortamet), gel (Glucophage XR), or gastric-retentive technology (Glumetza). Administered once daily, absorption is significantly increased with food, and the peak plasma level is 6 to 8 hours.

Metformin reduces fasting and postprandial glucose levels. Because it does not promote insulin release, it does not cause hypoglycemia, which is a major advantage of the drug. The drug actions do not depend on stimulating insulin release, so it is able to lower glucose levels in patients who no longer secrete insulin. In addition to lowering blood glucose levels, it lowers triglyceride levels, lowers total and low-density lipoprotein (LDL) cholesterol levels, and promotes weight loss.

Metformin is used off-label to treat women with polycystic ovary syndrome. Women with this syndrome have insulin resistance and high serum insulin levels. Metformin reduces insulin resistance, which in turn lowers insulin and androgen levels, thus restoring normal menstrual cycles and ovulation.

Mechanism of Action: Metformin reduces blood glucose levels by multiple mechanisms. The drug reduces gluconeogenesis, thereby suppressing hepatic production of glucose. In addition, the drug decreases the intestinal reabsorption of glucose and increases the cellular uptake of glucose.

Pharmacokinetics:

Route(s)	PO (regular release tablets, solution, and extended release preparations)
Absorption	Approximately 50–60% of a dose reaches systemic circulation; extended release forms are absorbed very slowly
Distribution	Distributed to most tissues; crosses the placenta; secreted in breast milk; not protein bound
Primary metabolism	Not metabolized
Primary excretion	Kidneys
Onset of action	Less than 1 h; peak action: 1–3 h
Duration of action	12 h (regular release); 24 h (extended release)

Adverse Effects: The most common adverse effects that occur in 30% of patients taking metformin are GI related and include nausea, vomiting, abdominal discomfort, metallic taste, diarrhea, anorexia, and moderate weight loss. It may also cause headache, dizziness, agitation, and fatigue. Unlike the sulfonylureas, metformin rarely causes hypoglycemia or weight gain. **Black Box Warning:** Lactic acidosis is a rare, though potentially fatal, adverse effect of metformin therapy. The risk for lactic acidosis is increased in patients with CKD or any condition that puts them at risk for increased lactic acid production, such as liver disease, severe infection, excessive alcohol intake, shock, or hypoxemia.

Contraindications/Precautions: Metformin is contraindicated in patients with severe CKD, because the drug can rise to toxic levels. It is also contraindicated in patients with heart failure, liver failure, history of lactic acidosis, concurrent serious infection, or with any condition

that predisposes the patient to hypoxemia. It is contraindicated for 2 days prior to, and 2 days after, receiving IV radiographic contrast. Metformin is used with caution in patients with anemia, diarrhea, vomiting, dehydration, fever, gastroparesis, or GI obstruction; in older adults; and in those with hyperthyroidism, pituitary insufficiency, or trauma; or during pregnancy and lactation. Safety in children under age 10 has not been established.

Drug Interactions: Alcohol increases the risk for lactic acidosis and should be avoided. Captopril, furosemide, and nifedipine may increase the risk for hypoglycemia. Use with IV radiographic contrast may cause lactic acidosis and CKD. The following drugs may decrease renal excretion of metformin: amiloride, cimetidine, digoxin, dofetilide, midodrine, morphine, procainamide, quinidine, ranitidine, triamterene, trimethoprim, and vancomycin. Acarbose may decrease blood levels of metformin. Use with other antidiabetic drugs potentiates hypoglycemic effects. **Herbal/Food:** Metformin decreases the absorption of vitamin B_{12} and folic acid. Garlic and ginseng may increase hypoglycemic effects.

Pregnancy: Category B.

Treatment of Overdose: For overdose or development of lactic acidosis, hemodialysis can be used to correct the acidosis and remove excess metformin.

Nursing Responsibilities: Key nursing implications for patients receiving metformin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Metformin (Glucophage, Glumetza, Others)

Metformin is the only biguanide available.

Meglitinides

The meglitinides act by stimulating the release of insulin from pancreatic islet cells in a manner similar to that of the sulfonylureas. Both drugs in this class have short durations of action of 2 to 4 hours. Their efficacy is equal to that of the sulfonylureas, and they are well tolerated. Hypoglycemia is the most common adverse effect.

PROTOTYPE DRUG Repaglinide (Prandin)

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: Meglitinide

Therapeutic Effects and Uses: Approved in 1997, repaglinide is used to lower blood glucose levels in patients with type 2 diabetes as an adjunct to diet and exercise. It may be used alone or in combination with metformin or a thiazolidinedione.

Because repaglinide is rapidly absorbed, it should be taken shortly before each meal. It is effective in lowering postprandial glucose levels and in reducing A1C levels but has little effect on fasting glucose levels. It undergoes almost no renal excretion, and so it can be used in patients with CKD.

Mechanism of Action: Repaglinide lowers glucose levels by stimulating insulin release from pancreatic beta cells. Patients must have some ability to secrete insulin for the drug to be effective.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed following PO administration
Distribution	98% protein bound
Primary metabolism	Hepatic (CYP3A4)
Primary excretion	90% in feces
Onset of action	15–30 min; peak: 1 h
Duration of action	4 h

Adverse Effects: Repaglinide is generally well tolerated; the most common adverse effect is hypoglycemia. Other adverse effects include nausea, vomiting, diarrhea, and dyspepsia. Headache, paresthesias, upper respiratory infections, sinusitis, rhinitis, or bronchitis may also occur.

Contraindications/Precautions: Repaglinide is contraindicated in people with type 1 diabetes or DKA. It should be used with caution in patients with hepatic impairment, during pregnancy or lactation, in older adults, or in those with systemic infection, surgery, or trauma. Its safety in children has not been established.

Drug Interactions: Drugs that induce hepatic CYP3A4 enzyme such as barbiturates, carbamazepine, rifampin, and pioglitazone may increase repaglinide metabolism and cause hyperglycemia. Drugs that inhibit CYP3A4 such as erythromycin, ketoconazole, and miconazole inhibit repaglinide metabolism and may potentiate hypoglycemia. Gemfibrozil may increase risk for hypoglycemia. Use with isophane insulin may cause myocardial ischemia. **Herbal/Food:** The concurrent intake of grapefruit juice inhibits metabolism and may result in increased repaglinide levels and hypoglycemia. Garlic and ginseng may increase hypoglycemic effects.

Pregnancy: Category C.

Treatment of Overdose: During overdose, provide symptomatic therapy and a concentrated source of glucose for hypoglycemia, preferably by the IV route.

Nursing Responsibilities: Key nursing implications for patients receiving repaglinide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Repaglinide (Prandin)

The only other meglitinide is nateglinide.

Nateglinide (Starlix): Approved in 2000, nateglinide has actions and uses similar to those of repaglinide. It is used alone or in combination with metformin for managing glucose levels in patients with type 2 diabetes who have not achieved glycemic control through diet and exercise. It is not effective for type 1 diabetes. Like repaglinide, it is given 5 to 20 minutes before meals. An important difference between these drugs is that nateglinide is primarily excreted by the kidneys, so it should be used with caution in patients with CKD. Like repaglinide, nateglinide is well tolerated and hypoglycemia is usually mild. The drug is pregnancy category C.

Thiazolidinediones

The thiazolidinediones (TZDs), or glitazones, reduce blood glucose by decreasing insulin resistance and inhibiting hepatic gluconeogenesis. Optimal lowering of blood glucose may require 3 to 4 months of therapy. The most common adverse effects are fluid retention, headache, and weight gain. Hypoglycemia does not occur with drugs in this class. Because of their tendency to promote fluid retention, thiazolidinediones are contraindicated in patients with serious heart failure or pulmonary edema.

PROTOTYPE DRUG **Rosiglitazone (Avandia)**

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: Thiazolidinedione

Therapeutic Effects and Uses: Approved in 1999, rosiglitazone is used to lower blood glucose levels in patients with type 2 diabetes as an adjunct to diet and exercise. It can be used as monotherapy or in combination with metformin, a sulfonylurea, or insulin. It is effective in lowering fasting glucose and A1C levels. Optimal therapeutic effects take several weeks to occur.

Mechanism of Action: Rosiglitazone lowers blood glucose levels by increasing cellular sensitivity to insulin, thereby reducing insulin resistance. In addition, it decreases gluconeogenesis by the liver.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Greater than 99% protein bound
Primary metabolism	Hepatic (CYP2C8)
Primary excretion	Primarily renal, with approximately 25% in feces
Onset of action	Within 1 h; peak: 1 h
Duration of action	12–24 h

Adverse Effects: Rosiglitazone is generally well tolerated. The most prominent adverse effect is edema, including macular edema. Anemia, headache, back pain, fatigue, diarrhea, upper respiratory infection, or sinusitis may occur. The drug can also raise serum lipid levels, including HDL cholesterol, triglycerides, and LDL cholesterol. It is recommended that baseline liver function tests be obtained prior to initiating treatment, and then assessed every 3 to 6 months. Patients should be informed of the signs of liver damage (nausea, fatigue, dark urine, jaundice) as well as the signs of heart failure (dyspnea, weight gain, edema, fatigue) while taking rosiglitazone. Research has also raised the concern of increased fracture risk among women taking drugs in this class. **Black Box Warning:** Drugs in this class can cause or worsen heart failure due to increased fluid retention. In addition, rosiglitazone may increase the risk of myocardial infarction (MI).

Contraindications/Precautions: Rosiglitazone is contraindicated in people with severe heart failure, liver disease, or elevated liver enzymes and during pregnancy or lactation. Its safety in children has not been established. Rosiglitazone is contraindicated in patients with type 1 diabetes or DKA.

Drug Interactions: Inducers of hepatic CYP2C8 such as rifampin may decrease the effects of rosiglitazone. Inhibitors of CYP2C8 such as azole antifungals, fluvoxamine, gemfibrozil, and trimethoprim may elevate rosiglitazone plasma levels and increase the risk for adverse reactions. Concurrent use of rosiglitazone with insulin can increase edema and the risk for heart failure and myocardial ischemia. Other antidiabetic drugs, angiotensin II receptor antagonists, and gemfibrozil can increase the hypoglycemic effects. Use of rosiglitazone with nitrates is not recommended due to the potential for myocardial ischemia. Thiazide diuretics, phenothiazines, and atypical antipsychotic drugs can decrease the hypoglycemic effects of rosiglitazone by increasing blood glucose levels. **Herbal/Food:** Garlic and ginseng can increase the risk for hypoglycemia if used with rosiglitazone. Cocoa and rosemary may decrease the therapeutic effect and have a hyperglycemic effect.

Pregnancy: Category C.

Treatment of Overdose: Standard treatment for hypoglycemia is initiated during overdose, along with symptomatic treatment of edema or fluid overload.

Nursing Responsibilities: Key nursing implications for patients receiving rosiglitazone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Rosiglitazone (Avandia)

The only other drug in this class is pioglitazone.

Pioglitazone (Actos): Approved in 1999, pioglitazone has actions and uses similar to those of rosiglitazone. It is rapidly

absorbed following PO administration, with peak effects occurring within 7 days of beginning therapy. Pioglitazone can decrease serum levels of oral contraceptives and can cause nonovulating premenopausal women to resume ovulation; therefore, a reliable form of contraception is recommended. Excessive alcohol consumption may affect glycemic control. Hepatic function should be assessed for a baseline and periodically thereafter as with rosiglitazone. Pioglitazone has been associated with an increased risk for bladder, prostate, and pancreatic cancer. The drug carries the same black box warnings regarding heart failure and myocardial ischemia as rosiglitazone. The drug is pregnancy category C.

Alpha-Glucosidase Inhibitors

The alpha-glucosidase inhibitors act by blocking enzymes in the small intestine responsible for breaking down complex carbohydrates into monosaccharides. Because carbohydrates must be in the monosaccharide form to be absorbed, digestion of glucose is delayed. These drugs have minimal adverse effects, with the most common being GI related, such as abdominal cramping, diarrhea, and flatulence. Although alpha-glucosidase inhibitors do not produce hypoglycemia when used alone, hypoglycemia may occur when these drugs are combined with insulin or a sulfonylurea.

PROTOTYPE DRUG **Acarbose (Precose)**

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: Alpha-glucosidase inhibitor

Therapeutic Effects and Uses: Approved in 1995, acarbose lowers blood glucose levels in individuals with type 2 diabetes who cannot adequately manage glucose levels by diet and exercise alone. It may be used alone or in combination with a sulfonylurea, metformin, or insulin. By slowing the breakdown and absorption of carbohydrates, the rise in postprandial glucose level is reduced. A1C level is lowered as well.

Mechanism of Action: Acarbose lowers glucose levels by interfering with carbohydrate absorption from the GI tract. It acts locally in the GI tract to inhibit the enzyme responsible for carbohydrate breakdown.

Pharmacokinetics:

Route(s)	PO
Absorption	Only 2% absorbed (low absorption is desired because the drug acts locally in the GI tract); some metabolites are absorbed
Distribution	Acts locally in the digestive tract
Primary metabolism	Metabolized in the GI tract by intestinal bacteria and digestive enzymes
Primary excretion	Primarily in feces, 30% in urine
Onset of action	Peak: 1 h
Duration of action	2–4 h

Adverse Effects: The most common adverse effects of acarbose are diarrhea, flatulence, abdominal distention, borborygmi, anemia (iron deficiency), urticaria, and erythema. The GI-related effects may diminish as therapy progresses; however, they will worsen if the patient does not adhere to the prescribed diabetic diet. Hypoglycemia may occur if acarbose is combined with other hypoglycemic drugs. If hypoglycemia does develop, it must be treated with glucose and not sucrose (table sugar), because the drug inhibits the absorption of sucrose. Acarbose may cause elevation of liver enzymes (plasma transaminases), although liver damage has not been reported, but levels return to normal following drug withdrawal.

Contraindications/Precautions: Acarbose is contraindicated in patients with inflammatory bowel disease, bowel obstruction, or colon ulcers and in those predisposed to bowel obstructions. It is used with caution in patients with GI distress or liver disorders and during pregnancy or lactation. Safety in children has not been established.

Drug Interactions: Use with sulfonylureas may increase the risk for hypoglycemia. Drugs that cause hyperglycemia such as thiazide diuretics, corticosteroids, phenothiazines, estrogens, phenytoin, or isoniazid may decrease the effectiveness of acarbose. **Herbal/Food:** Ginseng, garlic, black cohosh, juniper berries, aloe, or dandelion root can cause hypoglycemia. Cocoa and rosemary have a hyperglycemic effect and may decrease the therapeutic effect of acarbose.

Pregnancy: Category B.

Treatment of Overdose: Unlike the sulfonylureas, overdose with acarbose will not cause hypoglycemia. Abdominal pain, flatulence, and diarrhea are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving acarbose are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Acarbose (Precose)

The only other drug in this class is miglitol.

Miglitol (Glyset): Approved in 1996, miglitol is an alpha-glucosidase inhibitor used as monotherapy or in combination with other antidiabetic drugs for the pharmacotherapy of type 2 diabetes. It acts by delaying the conversion of complex carbohydrates to monosaccharides (glucose), thereby lessening the rise in postprandial serum glucose levels. Like

acarbose, the drug must be present in the intestine at the same time the carbohydrates are being digested; thus, the drug must be taken with a meal. The adverse effects are similar with the notable exception of not causing increased liver enzymes. Acarbose and miglitol both act locally in the intestine, although miglitol is completely absorbed and has the potential to produce systemic effects. Overdose does not cause hypoglycemia. The drug is pregnancy category B.

Incretin Therapies

66.8 Incretin therapies offer a different approach to treating type 2 diabetes.

Incretins are hormones released by the mucosa of the small intestine in response to meals. The most important incretin is glucagon-like peptide (GLP-1), which acts rapidly to produce the following effects:

- Increase in the amount of insulin secreted by the pancreas
- Decrease in the amount of glucagon secreted by the pancreas
- Delay in gastric emptying (slow glucose absorption)
- Decrease in food intake by increasing the level of satiety.

Two groups of drugs have been developed that can influence incretin release. The first activates the GLP-1 receptor, causing essentially the same glucose-lowering actions as the natural hormone. Albiglutide (Tanzeum), exenatide (Byetta), liraglutide (Victoza), and lixisenatide (Adlyxin) are synthetic drugs that *mimic* the action of incretin, thus they are called incretin mimetics or GLP-1 receptor agonists. They are all administered by the subcutaneous route, although albiglutide offers the advantage of once-weekly dosing.

The second class of drugs that *enhance* incretin actions are the dipeptidyl peptidase 4 (DPP-4) inhibitors. Alogliptin (Nesina), linagliptin (Tradjenta), saxagliptin (Onglyza), and sitagliptin (Januvia) prevent the breakdown of incretins, allowing the hormone levels to rise and produce a greater response. These incretin enhancers are given orally and are effective at lowering blood glucose with few adverse effects. They work well with other antidiabetic drugs and do not cause hypoglycemia.

PROTOTYPE DRUG **Sitagliptin (Januvia)**

Classification **Therapeutic:** Antidiabetic drug
Pharmacologic: DPP-4 inhibitor, incretin enhancer

Therapeutic Effects and Uses: Approved in 2006, sitagliptin is an oral incretin enhancer that is used to help lower glucose levels in patients with type 2 diabetes who are unable to achieve normal glucose levels with diet and exercise alone. The drug is used as adjunct therapy along with diet and exercise and can be administered as monotherapy or in combination with other oral antidiabetic drugs.

The actions of sitagliptin are glucose dependent: They occur only in the presence of elevated serum glucose, and so the risk for hypoglycemia is reduced. Sitagliptin has the added benefit of increasing satiety, or the feeling of fullness following a meal, resulting in a lower calorie intake and improved weight control. Sitagliptin lowers both fasting and postprandial glucose levels. Janumet is a fixed-dose combination drug containing sitagliptin and metformin.

Mechanism of Action: Sitagliptin inhibits DPP-4, the enzyme responsible for breaking down incretins. Inhibition of DPP-4 reduces the destruction of incretins. Levels of incretin hormones increase, thus decreasing blood glucose levels in patients with type 2 diabetes.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Approximately 38% protein bound
Primary metabolism	20% metabolized in the liver by CYP3A4 and CYP2CB
Primary excretion	Renal
Onset of action	30–60 min; peak: 1–4 h
Duration of action	Half-life: 12 h

Adverse Effects: Sitagliptin is well tolerated by most patients and adverse effects are generally not serious. Possible adverse effects include headache, diarrhea, nasopharyngitis, and upper respiratory infection. Allergic skin reactions and anaphylaxis have been reported. As monotherapy, sitagliptin does not cause hypoglycemia; however, when used concurrently with a sulfonylurea or insulin, hypoglycemia may occur.

Contraindications/Precautions: Sitagliptin is contraindicated in type 1 diabetes and DKA. It is used with caution in patients with CKD, in older adults, or during pregnancy and lactation. Safety for children under age 18 has not been established.

Drug Interactions: Sitagliptin may increase digoxin levels. **Herbal/Food:** Cocoa and rosemary may decrease the therapeutic effect and have a hyperglycemic effect.

Pregnancy: Category C.

Treatment of Overdose: Overdose is treated symptomatically. If used in combination with other glucose-lowering drugs and hypoglycemia occurs, a concentrated source of glucose should be administered by the IV route.

Nursing Responsibilities: Key nursing implications for patients receiving sitagliptin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Type 2 Diabetes.

Drugs Similar to Sitagliptin (Januvia)

Other incretin modulators include the GLP-1 agonists albiglutide, dulaglutide, exenatide, liraglutide, and lixisenatide, and the DPP-4 inhibitors alogliptin, linagliptin, and saxagliptin.

Albiglutide (Tanzeum): Albiglutide is a GLP-1 receptor agonist, approved in 2014 to improve glycemic control in adults with type 2 diabetes mellitus. It is not used for patients with type 1 diabetes mellitus or as first-line therapy for those unable to control blood glucose through diet and exercise. Although it must be administered by the subcutaneous route, it has the advantage of once-weekly dosing and may be given without regard to meals or time of day. It is packaged as a single-dose pen for ease of administration. The drug carries a black box warning that it may increase the risk for thyroid gland tumors. It is contraindicated in patients with a health or family history of thyroid tumors or multiple endocrine neoplasia syndrome type 2. Acute pancreatitis has occurred in some patients taking this medication. This drug is pregnancy category C.

Alogliptin (Nesina): One of the newer DPP-4 inhibitors, alogliptin was approved in 2013 for patients who are unable to control their blood glucose through exercise and diet alone. The drug works by the same mechanism and has the same effectiveness and side effects as the other DPP-4 inhibitors. When approving alogliptin, the FDA simultaneously approved two fixed-dose combinations of alogliptin with metformin (Kazano) and pioglitazone (Oseni). Kazano carries a black box warning due to the possibility of lactic acidosis (from metformin), and Oseni due to the possibility of heart failure (from pioglitazone). Alogliptin is pregnancy category B.

Dulaglutide (Trulicity): One of the newer drugs in this class, dulaglutide was approved in 2014 as an adjunct to diet and exercise in improving glycemic control in patients with type 2 diabetes. Given by the subcutaneous route once weekly, dulaglutide is a GLP-1 receptor agonist that causes increased insulin release by the pancreas. The drug may be used alone or in combination with metformin. Actions and side effects are the same as other GLP-1 agonists such as albiglutide. Like albiglutide, dulaglutide carries a black box warning that it may increase the risk for thyroid gland tumors and thus is contraindicated in patients with a history of thyroid tumors or multiple endocrine neoplasia syndrome type 2. This drug is pregnancy category C.

Exenatide (Byetta): Exenatide was approved in 2005 for patients with type 2 diabetes who are unable to achieve adequate glycemic control following metformin or sulfonylurea monotherapy. A GLP-1 receptor agonist, exenatide mimics the actions of the incretin hormones normally secreted by the intestines, which slow the absorption of glucose. It is effective in lowering fasting and postprandial glucose levels and causes a consistent, slow weight loss. A disadvantage of exenatide is that it must be given twice daily by the subcutaneous route, within 60 minutes before the morning and evening meals. It is available as a pen injector. Adverse effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and gastroesophageal reflux. It can also cause nervousness, dizziness, and diaphoresis. Like sitagliptin, it does not cause hypoglycemia. The drug is pregnancy category C.

Linagliptin (Tradjenta): Approved in 2011, linagliptin is a DPP-4 inhibitor. The drug is well tolerated and has the same actions and adverse effects as sitagliptin. One potential advantage over the other DPP-4 inhibitors is that linagliptin is excreted through the liver rather than the kidneys. This allows the drug to be used in patients with significant CKD. In 2012 a fixed-dose combination of linagliptin with metformin (Jentadueto) was approved. Jentadueto carries a black box warning that patients may be at risk for lactic acidosis from accumulation of metformin. The drug is pregnancy category B.

Liraglutide (Victoza): Approved in 2010 for glycemic control in patients with type 2 diabetes mellitus, liraglutide is a GLP-1 receptor agonist. Like exenatide, liraglutide is effective at reducing A1C levels as well as decreasing appetite and producing a desirable weight loss. An advantage over exenatide is that it can be given once daily. Because of its positive effects on weight loss, liraglutide (Saxenda) was subsequently approved for chronic weight management. Although Victoza and Saxenda have the same active ingredient, Saxenda is approved only for weight management. Liraglutide is well tolerated, with the most common adverse effects being headache, nausea, diarrhea, and anti-liraglutide antibody formation. Hypoglycemia is not a problem with monotherapy, but it may occur if used in combination with other antidiabetic drugs. Pancreatitis has been reported with other incretin enhancers and may also occur in patients taking liraglutide. Like albiglutide, the drug carries a black box warning about the possibility of thyroid tumors. Patients with a personal or family history of thyroid cancer should not take this drug. In 2016, the FDA approved Xultophy, a combination containing liraglutide and insulin degludec for type 2 diabetes. Liraglutide is pregnancy category C.

In postmarket reviews following its initial approval, research determined that use of liraglutide reduced the rates of cardiovascular deaths and other adverse cardiovascular events. In 2017, the FDA added a new indication for liraglutide: to reduce the risk of major cardiovascular events in adult patients with type 2 diabetes mellitus and high cardiovascular risk.

Lixisenatide (Adlyxin): Approved in 2016, lixisenatide is one of the newest GLP-1 receptor agonists. It is administered once daily by subcutaneous injection for glycemic

control in patients with type 2 diabetes. Its actions, effectiveness, and safety are similar to other incretin mimetics. Common side effects include nausea, vomiting, headache, diarrhea, dizziness, and hypoglycemia. In 2016, the FDA also approved Soliqua, a combination containing lixisenatide and insulin glargine for type 2 diabetes. Lixisenatide does not have a pregnancy category but the manufacturer recommends that the drug only be given to pregnant patients if the potential benefits outweigh the potential risks to the fetus.

Saxagliptin (Onglyza): Saxagliptin is a DPP-4 inhibitor approved in 2009 to improve glycemic control in patients with type 2 diabetes. The drug is well tolerated and has the same actions and adverse effects as sitagliptin. Kombiglyze XR is a fixed-dose combination of saxagliptin and metformin. Qtern is a combination of saxagliptin with dapagliflozin. Saxagliptin is pregnancy category B.

Miscellaneous Antidiabetic Drugs

A few miscellaneous drugs play minor roles in treating type 2 diabetes. Bromocriptine (Cycloset) is an older drug that was approved for a new indication, treating type 2 diabetes, in 2009. Bromocriptine is a dopamine receptor agonist but its mechanism for improving glycemic control is not known. The drug is also approved for acromegaly, Parkinson's disease, and hyperprolactinemia. Common adverse effects include nausea, fatigue, dizziness, vomiting, and headache.

In 2013, the FDA approved canagliflozin (Invokana), the first in a new class of drugs called the sodium-glucose cotransporter (SGLT) inhibitors. Inhibiting the SGLT in the kidney allows more glucose to leave the blood and be excreted via the urine. This drug has the advantage of promoting weight loss; however, it is contraindicated in patients with chronic kidney disease. The added glucose in the urine serves as a substrate for bacterial and fungal growth, thus increasing the frequency of mycotic infections of the urinary tract and genitalia. Canagliflozin is pregnancy category C. Two additional drugs in this class, dapagliflozin (Farxiga) and empagliflozin (Jardiance), were approved in 2014 and have very similar actions and adverse effects.

In postmarket reviews following its initial approval, research determined that use of empagliflozin rapidly reduced the rates of cardiovascular deaths and hospitalizations due to heart failure. In 2016, the FDA added a new indication for empagliflozin: to reduce the risk of cardiovascular death in adult patients with type 2 diabetes mellitus and cardiovascular disease.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Type 2 Diabetes

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including endocrine, cardiovascular, hepatic, or kidney disease; pregnancy; or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain a history of current symptoms, duration and severity, and other related signs or symptoms (e.g., paresthesias of hands or feet). Assess feet and lower extremities for possible ulcerations.
- Obtain a dietary history including caloric intake and number of meals and snacks per day. Assess fluid intake and type of fluids consumed.
- Obtain baseline vital signs, height, and weight.
- Evaluate appropriate laboratory findings (e.g., CBC, electrolytes, glucose, A1C level, lipid profile, hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., glucose levels remain within normal limits, A1C levels demonstrate adequate glucose control).
- Continue periodic monitoring of hepatic function studies.
- Assess for and report promptly any adverse effects appropriate to the type of oral drug: signs of hypoglycemia (e.g., nausea, paleness, sweating, diaphoresis, tremors, irritability, headache, light-headedness, anxiety, or decreased level of consciousness) most commonly associated with sulfonylureas and meglitinides, and hyperglycemia (e.g., flushed or dry skin, polyuria, polyphagia, polydipsia, drowsiness, glycosuria, ketonuria, or acetone breath), gastric upset, diarrhea, infection, edema.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Depending on the severity of hyperglycemia, supplemental insulin may be needed for blood glucose levels to return gradually to normal.)	• Teach the patient to report any return of original symptoms. • Teach the patient the symptoms of hyper- and hypoglycemia to observe for and to check capillary glucose level routinely and if symptoms are present. Promptly report any noticeable symptoms and concurrent capillary glucose level to the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Ensure that dietary needs are met based on the need to lose, gain, or maintain current weight and glucose levels. Consult with the dietitian as needed. Limit or eliminate alcohol use. (Adequate caloric protein, carbohydrate, and fat amounts support the oral hypoglycemic regimen for glucose control. Activity and lifestyle will also be factored into dietary management. As alcohol is metabolized, it can raise and then precipitously lower blood glucose, raising the risk of hypoglycemia. Patients on sulfonylureas should avoid or eliminate alcohol entirely because a disulfiram-like reaction with severe nausea, vomiting, and potential hypotension may result.)	• Review current diet, lifestyle, and activity level with the patient. Arrange a dietitian consult based on the need to alter diet or food choices. Teach the patient to limit or eliminate alcohol use. If alcoholic beverages are consumed, limit to one per day and consume along with a complete meal to ensure food intake balances alcohol metabolism. • Instruct patients on sulfonylureas (e.g., glyburide) to avoid or eliminate alcohol use.
Minimizing adverse effects: • Continue to monitor capillary glucose levels. Check with the healthcare provider before giving an oral hypoglycemic if blood sugar is less than 70 mg/dL or per the parameters as ordered by the healthcare provider. (Daily glucose levels, especially before meals, will assist in maintaining adequate control of blood glucose and aid in assessing the appropriateness of current drug therapy.)	• Instruct the patient on appropriate blood glucose monitoring techniques to obtain capillary blood glucose levels, followed by return demonstration, and when to contact the healthcare provider (e.g., glucose less than 70 mg/dL). Monitor use and ensure proper functioning of all equipment to be used at home.
• Continue to monitor periodic laboratory work: CBC, electrolytes, glucose, A1C level, lipid profile, hepatic and renal function studies. (Periodic monitoring of laboratory work assists in determining glucose control and the need for any change in medication and assesses for complications. A1C levels provide a measure of glucose control over several months' time. Sulfonylureas may cause hepatotoxicity. Biguanides may cause lactic acidosis. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hepatotoxicity.)	• Instruct the patient on the need to return periodically for laboratory work. • Teach patients on sulfonylureas to immediately report any nausea, vomiting, yellowing of the skin or sclera, abdominal pain, light or clay-colored stools, or darkening of urine to the healthcare provider. • Teach patients on biguanides to immediately report any drowsiness, malaise, decreased respiratory rate, or general body aches to the healthcare provider.
• Assess for symptoms of hypoglycemia. If symptoms are noted, provide a quick-acting carbohydrate source (e.g., juice or other simple sugar), and then check capillary glucose level. Report to the healthcare provider if glucose is less than 70 mg/dL or as ordered. If mealtime is not immediate, provide a longer acting protein source to ensure that hypoglycemia does not recur. (Hypoglycemia is especially likely to occur if the patient is taking sulfonylureas or meglitinides, although it may occur with other types of oral antidiabetic drugs, especially if food sources are inadequate. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hypoglycemia. Providing a quick-acting carbohydrate source and then checking the capillary glucose level will ensure glucose does not decrease further while locating the glucose testing equipment. When in doubt, treating symptoms for suspected hypoglycemia is safer than allowing further decreases in glucose and possible loss of consciousness with adverse effects. Small additional amounts of carbohydrates will not dramatically increase blood sugar if testing shows a hyperglycemic episode.)	• Teach the patient to always carry a quick-acting carbohydrate source in case symptoms of hypoglycemia occur. If unsure whether symptoms indicate hypo- or hyperglycemia, treat as hypoglycemia and then check capillary glucose. If symptoms are not relieved in 10–15 min, or if blood sugar is below 70 mg/dL (or the parameters as ordered), immediately notify the healthcare provider.
• Monitor blood glucose more frequently during periods of illness or stress. (Blood glucose levels may increase or decrease during periods of illness or stress. Frequent monitoring during these times helps to prevent hypoglycemia and ensures adequate glucose control.)	• Instruct the patient to check glucose levels more frequently when ill or under stress. Stress may increase blood glucose because the stress response can cause glycogenolysis. Supplemental insulin may be required if oral antidiabetic drugs do not adequately control the blood sugar. Illness, especially associated with anorexia, nausea, or vomiting, may decrease the need for an oral hypoglycemic drug. Notify the healthcare provider if unable to eat normal meals during periods of illness or stress for possible change in drug regimen.
• Encourage increased activity and exercise, but monitor blood glucose before and after exercise and begin any new or increased exercise routine gradually. Continue to monitor for hypoglycemia for up to 48 h after exercise. (Exercise assists muscles to use glucose more efficiently and increases insulin receptor sites in the tissues, lowering the blood sugar and assisting with weight control. Benefits of exercise and lowered blood sugar may continue for up to 48 h, increasing the risk of hypoglycemia during this time. Frequent monitoring helps to prevent hypoglycemia and ensures adequate glucose control.)	• Teach the patient the benefits of increased activity and exercise and to begin any new routine or increase in exercise gradually. • Instruct the patient to check glucose levels more frequently before and after exercise.
• Monitor for hypersensitivity and allergic reactions. Continue to monitor the patient throughout therapy. (Anaphylactic reactions are possible although rare. As sensitivity occurs, reactions may continue to develop.)	• Teach the patient to immediately report any itching, rashes, swelling, particularly of the face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing.
• Assess for pregnancy or the possibility of pregnancy. (Some oral antidiabetic drugs are category C and must be stopped during pregnancy. Due to the increasing metabolic needs of pregnancy, supplemental insulin or switching to insulin coverage may be required for the duration of the pregnancy.)	• Teach female patients of childbearing age to monitor for pregnancy and alert the healthcare provider if pregnant or if pregnancy is suspected to discuss medication needs.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor for edema, blood pressure, and lung sounds in patients taking thiazolidinediones. (Drugs such as rosiglitazone may cause edema and worsening of heart failure.)	• Instruct the patient to immediately report any edema of the hands or feet, dyspnea, or excessive fatigue to the healthcare provider.
• Monitor for hypoglycemia more frequently in patients on concurrent beta-blocker therapy. (Beta blockers antagonize the action of some oral antidiabetic drugs and may mask the symptoms of a hypoglycemic episode, allowing the blood sugar to drop lower before it is perceived.)	• Teach patients on concurrent beta-blocker therapy to monitor capillary blood glucose more frequently and to check blood glucose if minor changes in overall feeling are perceived (e.g., minor agitation or anxiety, slight tremors).
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and any special requirements of medication therapy (e.g., drug needs during exercise or illness). • Instruct the patient to carry a wallet identification card and wear medical identification jewelry indicating diabetes.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of drug. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs, including:
	  • Timing of doses: Most oral antidiabetic drugs are taken once or twice a day. For drugs given once a day, take approximately 30 min before the first meal of the day. Alpha-glucosidase inhibitors (e.g., acarbose) should be taken with meals.
	  • Insulin requirements: While patients with type 2 diabetes produce some insulin, insulin injections may be required in addition to the oral antidiabetic drug on occasion. This does not necessarily signal a worsening of the disease condition but may be a temporary need.

Understanding Chapter 66

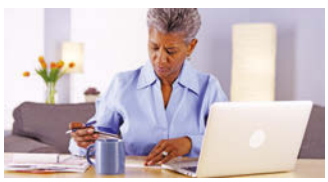
Key Concepts Summary

66.1 Serum glucose is maintained within a narrow range by the hormones insulin and glucagon.

66.2 Type 1 diabetes is characterized by insufficient insulin synthesis by the pancreas, whereas type 2 diabetes is characterized by insulin resistance in the target cells.

66.3 The classic signs and symptoms of diabetes include polyuria, polydipsia, and polyphagia.

66.4 Acute complications of diabetes include diabetic ketoacidosis, hyperosmolar hyperglycemic state, and hypoglycemia.



66.5 Serious complications of chronic diabetes include neuropathy, nephropathy, retinopathy, and vascular disease.

66.6 Insulin is the cornerstone of therapy for patients with type 1 and gestational diabetes.

66.7 Antidiabetic drugs from multiple classes are used to treat type 2 diabetes.

66.8 Incretin therapies offer a different approach to treating type 2 diabetes.

CASE STUDY: Making the Patient Connection

Remember the patient "Eileen Douglas" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Eileen is a 54-year-old woman who works full time as an art teacher in a local high school. She also teaches art courses on the weekends at the local senior center. She visited her healthcare provider last week for her annual physical examination and to update her TB screening (PPD) for the coming school year. The office called her back this morning and requested that she make an appointment to return tomorrow to discuss the results of her laboratory

tests. Her serum glucose level was elevated at 224 mg/dL and she will need further testing to rule out type 2 diabetes.

Eileen has follow-up testing with the results of a fasting serum glucose level at 131 mg/dL and a 2-hour 75-g oral glucose test of 242 mg/dL. A diagnosis of new-onset type 2 diabetes is confirmed. Eileen expresses disbelief and tells you, the nurse, "I can't believe it! I watch what I eat; I don't eat a lot of sugar, cookies, or candy. I drink only diet soda. I don't have any of the symptoms you hear about. And no one in my family has ever had diabetes." A health history and the results of Eileen's recent physical examination confirm overall good health. Her height is 1.7 meters (5 ft 6 in.) and her weight is 79.5 kg (175 lb) with a BMI of 28.2 kg/m^2, placing her in the "overweight" category. Vital signs, physical examination, and all other laboratory work are within acceptable limits. Eileen admits that she has been thirstier lately, "But it's summertime and I always drink more when it's hot." She has also been urinating more frequently but attributes that to her increased fluid intake.

Eileen's provider will start her on glyburide (DiaBeta) and metformin (Glucophage) and will recheck her serum glucose in 1 month. In the meantime, she is to begin capillary blood glucose testing before meals and at bedtime, and bring her log to the next visit. She is given dietary instructions and you will be providing instruction on her medications.

Critical Thinking Questions

1. Why are two oral antidiabetic drugs prescribed for Eileen?
2. What essential teaching does Eileen need about her glyburide (DiaBeta) and metformin (Glucophage)?
3. Eileen asks why she is not being started on insulin. Why is insulin not being used at this time?
4. Eileen tells you that she occasionally enjoys a glass of wine with her dinner and wants to know if this is allowed. How will you answer?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Nicholas Jefferson is 8 years old and has just been diagnosed with type 1 diabetes. After increasing symptoms during the past month, he was hospitalized for continuous nausea, vomiting, and gradually increasing lethargy. His parents report that during the past month or two, Nicholas has had blurry vision and has been thirsty and hungry constantly. He has been eating frequently but does not seem to be gaining any weight. They also tell you that on several occasions, Nicholas has wet the bed, which is very unusual for him. On admission, his serum glucose level is 420 mg/dL with a urine sample positive for glucose and ketones. Nicholas is to remain NPO and will be started on an IV with 0.45 normal saline for fluid replacement, given an IV bolus of insulin, and then started on an insulin drip at 0.5 unit per hour. Glucose levels are to be checked every hour using fingerstick blood samples, and serum blood glucose samples are to be drawn every 4 hours. The IV insulin drip is to be discontinued when Nicholas's blood glucose level is 240 mg/dL and subcutaneous insulin will be started at that time.

1. What type of insulin do you anticipate using for the IV bolus dose and IV drip?
2. Why do you think the insulin IV will be stopped when the blood glucose level is 240 mg/dL and not at the normal level of 70 to 100 mg/dL?
3. What essential teaching will Nicholas and his family need at this time?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient with type 1 diabetes will use a combination insulin that includes NPH and regular insulins. The nurse is explaining the importance of knowing the peak times for both insulins. Why is this important information for the patient to know?
    1. The patient will be able to estimate the time for the next injection of insulin based on these peaks.
    2. The risk of a hypoglycemic reaction is greatest around the peak of insulin activity.
    3. It is best to plan activities or exercise around peak insulin times for the best utilization of glucose.
    4. Additional insulin may be required at the peak periods to prevent hyperglycemia.
2. Before administering a morning lispro insulin (Humalog) injection, which activity should the nurse perform? (Select all that apply.)
    1. Obtain a morning urine sample for glucose and ketones.
    2. Check the patient's fingerstick glucose level.

3. Ensure that breakfast trays are present on the unit and the patient may eat.
4. Obtain the patient's pulse and blood pressure.
5. Assess for symptoms of hypoglycemia.

3. The nurse would consider which of the following assessment findings as adverse effects to metformin therapy?

1. Hypoglycemia
2. Gastrointestinal distress
3. Lactic acidosis
4. Weight loss

4. A patient was started on rosiglitazone for type 2 diabetes. He tells the nurse that he has been taking it for 5 days, but his glucose levels are unchanged. What is the nurse's best response?

1. "You should double the dose. That should help."
2. "You need to give the drug more time. It can take several weeks before it becomes fully effective."
3. "You will need to add a second drug since this one has not been effective."
4. "You most likely require insulin now."

5. A young woman calls the clinic and reports that her mother had an insulin reaction and was found unconscious. The young woman gave her a glucagon injection 20 minutes ago, and her mother woke up but is still groggy and "does not make sense." What should the nurse tell the daughter?

1. "Let her wake up on her own, then give her something to eat."
2. "Place some hard candies in her mouth."
3. "Just let her sleep. People are sleepy after hypoglycemic episodes."
4. "Give her another injection and call the paramedics."

6. The nurse explains the benefit of using the long-acting insulin glargine (Lantus) over other insulins. What will the nurse tell the patient about this insulin?

1. It does not need to be administered by injection.
2. It can be given by intramuscular or subcutaneous injection.
3. It does not require blood glucose monitoring.
4. It has no definite peak but maintains a steady state of insulin in the body.

Chapter 67
Pharmacotherapy of Thyroid Disorders

Chapter Outline

- Physiology of the Thyroid Gland
- Diagnosis of Thyroid Disorders
- Pathophysiology of Hypothyroid Disorders
- Pharmacotherapy of Hypothyroid Disorders

  PROTOTYPE *Levothyroxine (Levothroid, Levoxyl, Synthroid, Unithroid), p. 1233*
- Pathophysiology of Hyperthyroid Disorders
- Pharmacotherapy of Hyperthyroid Disorders

  PROTOTYPE *Propylthiouracil (PTU), p. 1238*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the functions of thyroid hormone.
2. Explain the negative feedback control of thyroid function.
3. Explain how thyroid disorders are diagnosed.
4. Describe the pathophysiology of thyroid disorders.
5. Describe the pharmacotherapy of thyroid disorders.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to the care of patients receiving pharmacotherapy for thyroid disorders.

Key Terms

thyrotropin-releasing hormone (TRH), 1230
thyroxine (T_4), 1230
thyroxine-binding globulin (TBG), 1230
tri-iodothyronine (T_3), 1230

The thyroid gland affects the function of virtually every organ of the body. It synthesizes and secretes hormones that increase overall body metabolism and protein synthesis. Adequate secretion of these hormones is also necessary for normal growth and development in infants and children, including mental development and attainment of sexual maturity. The thyroid also affects functions of the cardiovascular, respiratory, gastrointestinal (GI), and neuromuscular systems. Thyroid disorders are common, affecting women 5 to 10 times more often than men. This chapter presents the pharmacotherapy of thyroid imbalances.

Physiology of the Thyroid Gland

67.1 Thyroid hormones contain iodine and stimulate the basal metabolic rate of nearly all tissues.

The thyroid gland lies on both sides of the trachea just below the larynx. The gland contains two distinct types of endocrine cell types: follicular cells and parafollicular cells. Follicular cells produce, store, and secrete thyroid hormone. Parafollicular cells produce calcitonin, a hormone totally unrelated to the structure or function of thyroid hormone. Calcitonin regulates calcium metabolism and is used as a drug in the pharmacotherapy of osteoporosis (see Chapter 72).

Thyroid hormone actually consists of two distinct hormones: **tri-iodothyronine (T_3)** and **thyroxine (T_4)**. Both T_3 and T_4 are synthesized from the amino acid tyrosine and iodine; the subscript numeral refers to the number of iodine molecules each hormone contains. Because the two have very similar actions, they are usually considered a single hormone.

When secreted into the bloodstream, more than 99% of T_3 and T_4 is bound to **thyroxine-binding globulin (TBG)**, a plasma protein manufactured by the liver. Any condition that causes decreased amounts of plasma proteins, such as protein malnutrition or liver impairment, can lead to a larger percentage of free thyroid hormone, with subsequent symptoms of hyperthyroidism.

Most circulating thyroid hormone is in the form of T_4. Upon entering target cells, however, T_4 is converted in peripheral tissues to T_3, which is three to five times more biologically active. This offers an additional level of control (tissue level) of thyroid hormone function.

The two thyroid hormones are metabolized by the liver and excreted by the kidneys, with small amounts excreted in the stool. Iodine is conserved in the process and returned to the thyroid gland for the production of more hormone molecules. Therefore, only a small daily intake of iodine is needed to meet the demands of the thyroid gland. High amounts of iodine are found in shellfish, but the main dietary source is the use of iodized salt. Thyroid hormones are the only known use for iodine in the body.

Thyroid hormone stimulates the basal metabolic rate of all tissues except the brain, anterior pituitary, spleen, lymph nodes, testes, and lungs. In the presence of large amounts of thyroid hormone, the basal metabolic rate of cells can increase by 60% to 100%. This increases the oxidation of energy sources (glucose, fats, and proteins), which in turn increases oxygen consumption and generates large amounts of heat. The rapid metabolic rate increases the body's demands for vitamins. Thyroid hormone affects GI function and motility, appetite, and body weight. Thyroid hormone increases the number of $beta_1$- and $beta_2$-adrenergic receptors and enhances their affinity to catecholamines (norepinephrine, epinephrine, and dopamine). The increase in sympathetic activity leads to increased heart rate and force of contraction, cardiac output, and cardiac demands for oxygen. Thyroid hormones also stimulate the secretion of growth hormone and are therefore essential for the normal growth and development of the skeletal and nervous systems. Thyroid hormone affects reflexes, thought processes, and overall level of consciousness (LOC). Signs and symptoms of thyroid hormone deficiency and excess are presented in Sections 67.3 and 67.5, respectively.

The secretion of thyroid hormone is regulated by the hypothalamus and anterior pituitary gland through a negative feedback loop, as shown in Figure 67.1. When blood levels of thyroid hormone are low, the hypothalamus secretes **thyrotropin-releasing hormone (TRH)**. Secretion of TRH

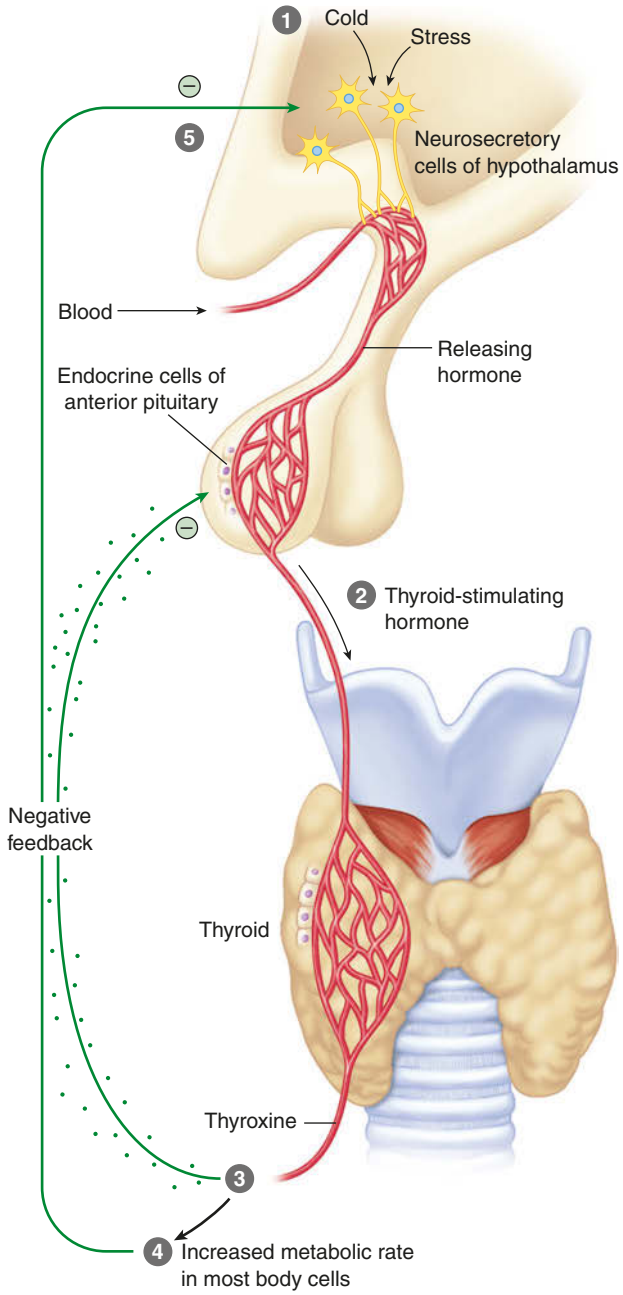

Figure 67.1 Feedback mechanisms of the thyroid gland.

stimulates the anterior pituitary to secrete **thyroid-stimulating hormone (TSH)**. TSH then stimulates the thyroid to produce and secrete T_3 and T_4. As blood levels of free, unbound thyroid hormone increase, negative feedback suppresses the secretion of TSH and TRH. High levels of iodine can also cause a temporary decrease in thyroid activity that can last for several weeks. One of the strongest stimuli for increased thyroid hormone production is exposure to cold.

Disorders of the thyroid result from a hypofunction or hyperfunction of the thyroid gland. Hormonal imbalances may occur due to disease within the thyroid gland itself or be caused by abnormalities of the pituitary or hypothalamus.

Thyroid disorders can be due to a congenital defect, or they may develop later in life. They may have an insidious or sudden onset. An increase in the size of the thyroid gland is referred to as a **goiter**. This can occur with normal, high, or low levels of thyroid hormone. Goiters may be diffuse, involving the entire gland, or nodular. When they become considerably enlarged, the goiter can compress the trachea and esophagus, causing difficulty swallowing, a choking sensation, and possibly inspiratory stridor (abnormal high-pitched sounds when breathing). They may also compress the superior vena cava, causing distention of the neck veins and facial edema.

Diagnosis of Thyroid Disorders

67.2 An accurate diagnosis of thyroid hormone dysfunction is based on the patient's symptoms and the results of diagnostic tests.

Because the thyroid gland is located close to the skin surface, palpation of the thyroid gland is conducted for routine screening of enlargements and nodules. Serum laboratory tests for T_3, T_4, and TSH are commonly used for diagnosis, as listed in Table 67.1. TSH is the preferred laboratory value for diagnosing and monitoring the progression of thyroid disease. Primary hypothyroidism is characterized by a low serum T_4 level and an elevated TSH level.

Abnormal laboratory values must be carefully evaluated because a number of conditions, including stress in

Table 67.1 Serum Values for Thyroid Function Tests*

Thyroid Test	Reference Value	Hypothyroid	Hyperthyroid
T_3 (serum)	80–220 ng/dL	Decreased	Increased
Free T_4	0.8–1.8 ng/dL	Decreased	Increased
Total T_4	4.5–12.5 mcg/dL	Decreased	Increased
TSH (serum)	0.5–5.5 microinternational units/mL	Increased	Decreased
Antithyroglobulin antibody (TgAb)	Less than 20 international units/mL	–	–
Thyroid peroxidase antibody (TPOAb)	Less than 9.0 international units/mL	–	–

* Reference values vary somewhat among different laboratories.

critically ill adults, can affect TSH and T_4 levels. In addition, these laboratory values are influenced by abnormalities in serum protein levels because both T_3 and T_4 are heavily protein bound. Any condition that affects protein levels requires careful analysis of these test results.

To identify the presence of autoimmune disorders, antibodies to thyroglobulin or thyroid peroxidase are measured. Individuals without thyroid disease generally have minimal or none of these antibodies in their blood. However, most patients with Hashimoto's thyroiditis or Graves' disease will show elevated levels of antithyroid antibody titer. In the case of Hashimoto's, the elevated antibodies may lead to hypothyroidism; for Graves' disease, however, the elevated antibodies may indicate hyperthyroidism. Patients with other autoimmune disorders such as systemic lupus erythematosus or rheumatoid arthritis may have elevated antibody values without thyroid disease.

The diagnostic tool of choice for detecting malignancy of a thyroid nodule is the fine needle biopsy. Ultrasonography can be used to assess masses, cysts, and enlargement of the thyroid gland. The radioactive iodine uptake test measures the rate of iodine uptake by the thyroid gland after administration of ^{123}I tracer. This test can detect areas of increased and decreased function. Computed tomography (CT) and magnetic resonance imaging (MRI) scans can be used to determine tracheal compression or pressure on neighboring structures caused by thyroid gland enlargement.

An accurate diagnosis of thyroid hormone dysfunction is essential. Proper treatment of the disorder will depend on whether the abnormality lies within the thyroid gland itself or is the result of a defect in the negative feedback control by the hypothalamus or pituitary.

PharmFACT

The demands on the mother's thyroid gland increase during pregnancy. If women have too little iodine during pregnancy, the damage to the nervous system of the fetus may be irreversible (Harding et al., 2017).

Pathophysiology of Hypothyroid Disorders

67.3 Hypothyroidism, or thyroid deficiency, can occur as a congenital or acquired disorder.

Hypothyroidism may occur as a congenital disorder, or it may be acquired in adulthood. Congenital hypothyroidism is a common, preventable cause of mental retardation. The infant appears normal at birth due to hormones supplied by the mother while in utero. If untreated, congenital hypothyroidism results in a condition known as **cretinism**, marked by profound mental retardation and impaired growth. Almost half of normal brain development occurs during the first 6 months of life, and thyroid hormone is essential for this to occur. If thyroid replacement therapy is begun in the first 6 weeks of life, normal growth and development take place and cretinism can be prevented. In the United States and Canada, screening for hypothyroidism is conducted for most neonates.

Hypothyroidism in older children and adults results in a general slowing of metabolic processes and **myxedema**, a mucous type of edema caused by an accumulation of hydrophilic substances in connective tissues. Primary hypothyroidism, the most common type in children and adults, results from dysfunction of the thyroid gland. Secondary hypothyroidism is due to pathology of the pituitary gland. Tertiary hypothyroidism is a result of a disorder of the hypothalamus. Causes of hypothyroidism include thyroidectomy or ablation of the thyroid gland with radiation, the use of lithium (in the treatment of bipolar disorder), or treatment with antithyroid drugs. Large amounts of iodine or substances that contain iodine, such as kelp tablets, certain cough syrups, the cardiac drug amiodarone, or iodine-containing radiographic contrast media, can block thyroid hormone production and cause goiter and hypothyroidism. Iodine deficiency is rarely a cause of hypothyroidism in the United States due to the widespread use of iodized salt.

The most common cause of hypothyroidism is an autoimmune disorder known as **Hashimoto's thyroiditis**. This disease affects women 5 to 10 times more often than men.

Hypothyroidism affects nearly all major organ systems, with manifestations arising from two factors: a hypometabolic state and myxedematous changes in body tissues. The hypometabolic state is marked by a gradual onset of weakness and fatigue, a tendency to gain weight despite a decreased appetite, and cold intolerance. Hypotension, bradycardia, hypoventilation, and subnormal temperature may occur. In time, the skin becomes rough and dry and may have a yellowish cast; the hair becomes coarse and brittle; and GI motility slows, causing chronic constipation, flatulence, and abdominal distention. Mental dullness, lethargy, slowed reflexes, and memory problems may occur. Because of the importance of thyroid hormone to fetal development, women experiencing hypothyroidism should be treated with thyroid hormone during pregnancy. Women also experience a high incidence of postpartum thyroiditis, which occurs following about 10% of pregnancies.

As fluid accumulates in tissues, the face takes on a puffy look, especially around the eyes; the tongue enlarges; and the voice may be husky. Fluid can accumulate in the pericardial or pleural spaces, causing effusions, cardiac dilation, and bradycardia. **Myxedema coma** or crisis is a life-threatening end-stage condition of hypothyroidism, characterized by coma, hypothermia, cardiovascular collapse, hypoventilation, hyponatremia, hypoglycemia, and

Table 67.2 Signs and Symptoms of Thyroid Emergencies

Thyroid Storm	Myxedema Coma
Tachycardia	Bradycardia
Hyperthermia	Hypothermia
Tachypnea	Hypoventilation
Hypercalcemia	Hyponatremia
Hyperglycemia	Hypoglycemia
Metabolic acidosis	Respiratory and metabolic acidosis
Cardiovascular collapse: cardiogenic shock, hypovolemia, arrhythmias	Cardiovascular collapse: decreased vascular tone
Depressed LOC	Depressed LOC
Emotional lability	Seizures, coma
Psychosis	Hyporeflexia
Tremors, restlessness	–

lactic acidosis. This condition occurs most often in older women. Even with early detection and treatment, the mortality rate is 30% for those who develop myxedema coma. Treatment consists of supportive measures, correction of electrolyte and acid–base imbalances, treatment of hypotension, and immediate thyroid replacement therapy. If hypothermia is present, active rewarming is contraindicated, because this may precipitate vasodilation and lead to cardiovascular collapse. Features of thyroid emergencies are described in Table 67.2.

CONNECTION Checkpoint 67.1

Patients with hypothyroidism tend to have low rates of angina and myocardial infarction. From what you learned in Chapter 35, explain this link. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: Community-Oriented Practice

The Effects of Soy Intake

Over the years, claims about the benefits and risks accruing from the use of soy and soy products have varied widely.

Based on a comprehensive literature review, D'Adamo and Sahin (2014) investigated claims as to the health benefits and risks of soy supplementation. Health benefits of soy that were reviewed included relief of menopausal symptoms and prevention of heart disease, breast cancer, prostate cancer, and osteoporosis. Health risks of soy that were reviewed included increased risk of breast cancer, male hormonal and fertility problems, and effects on thyroid function. This literature review revealed evidence that soy foods and supplements may provide relief from menopausal symptoms and protect against breast cancer and heart disease, but they do not appear to offer protection against osteoporosis. Soy supplementation also appears to affect thyroid function in an inconsistent manner, with both increases and decreases of thyroid activity noted. The evidence on male fertility and reproductive issues was mixed, with some studies demonstrating a harmful impact and others showing no effect.

Because some patients may consume soy as a supplement to or a substitute for animal proteins in their diet, nurses should include a dietary assessment, especially for infants; for adult patients on thyroid hormone replacement therapy, particularly those who are experiencing hypothyroidism after a period of a euthyroid (normal) state; and for postmenopausal women. Currently, the use of soy and soy products warrants caution in infants and postmenopausal women where thyroid function may be disrupted. Nurses should also assess whether vegetarians are following a varied diet to ensure that all essential amino acids are consumed because soy is low in the necessary amino acid methionine.

Pharmacotherapy of Hypothyroid Disorders

67.4 Hypothyroidism is treated by replacement therapy with thyroid hormone.

Hypothyroidism is treated by replacement therapy with T_3 or T_4. The standard replacement regimen consists of levothyroxine (T_4), although combined therapy with levothyroxine plus liothyronine (T_3) is an option. Although T_4 is less biologically active than T_3, it is readily converted to T_3 in peripheral tissues. In most cases, thyroid replacement therapy is lifelong.

In children with cretinism, therapy with levothyroxine should continue for 3 years, after which it should be stopped for 1 month. During this time, thyroid hormone levels are monitored to assess the status of the deficiency and to determine if further treatment is needed.

In adults, serum TSH levels are used to evaluate the progress of therapy. When initiating therapy in older adults, the precaution is to "go low and go slow," because there is a risk for inducing acute coronary syndromes in susceptible individuals. Table 67.3 lists the doses of the drugs used to treat hypothyroidism.

PROTOTYPE DRUG **Levothyroxine (Levothroid, Levoxyl, Synthroid, Unithroid)**

Classification **Therapeutic:** Thyroid hormone
Pharmacologic: Thyroid hormone replacement

Therapeutic Effects and Uses: Levothyroxine is a synthetic form of T_4, with actions identical to endogenous thyroid hormone. It is used for primary or secondary hypothyroidism, congenital hypothyroidism, hypothyroid state resulting from the surgical removal of the thyroid gland, radiation or antithyroid drugs, management of thyroid

Table 67.3 Drugs for Hypothyroidism

Drug Name	Dose for Adults (Maximum Dose Where Indicated)	Adverse Effects
levothyroxine (Levothroid, Levoxyl, Synthroid, Unithroid)	PO: 100–400 mcg/day IV: initial loading dose of 300–500 mcg followed by maintenance doses of 50–100 mcg	*Weight loss, headache, tremors, nervousness, heat intolerance, irritability, sweating, insomnia, menstrual irregularities* Dysrhythmias, hypertension, palpitations, angina
liothyronine (Cytomel, Triostat)	PO: 25–75 mcg/day IV: 25–100 mcg/day	
liotrix (Thyrolar)	PO: 12.5–30 mcg/day	
thyroid, desiccated (Armour thyroid, Thyroid USP)	PO: 60–180 mg/day	

Note: *Italics* indicate common adverse effects. Underline indicates severe adverse effects.

cancer, or treatment of myxedema coma. The drug is given by the oral (PO) route for routine replacement therapy and intravenously (IV) for myxedema coma.

To avoid adverse effects, doses of thyroid hormone are highly individualized for each patient. When given by the PO route, 1 to 3 weeks may be required to obtain full therapeutic benefits. Doses for patients with preexisting cardiac disease are usually increased at 4- to 6-week intervals to avoid the possibility of dysrhythmias or angina attacks.

Mechanism of Action: The actions of levothyroxine are identical to those of endogenous thyroid hormone. The drug increases the metabolic rate, thereby increasing oxygen consumption, respiration, and heart rate; increases the rate of fat, protein, and carbohydrate metabolism; and promotes growth and maturation. Because levothyroxine is converted to T_3, it is not necessary to also give T_3.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Variable; partial absorption from the GI tract (50% to 80%)
Distribution	Gradually released to peripheral tissues; crosses the placenta; secreted in breast milk; more than 99% bound to protein
Primary metabolism	Hepatic
Primary excretion	Kidneys, with some secreted in bile and excreted in feces
Onset of action	PO: Slow; IV: 6–8 h
Duration of action	1–3 weeks; half-life: 6–7 days

Adverse Effects: At therapeutic doses, adverse effects of levothyroxine therapy are rare. At high doses, treatment may cause central nervous system (CNS) excitability such as tremors, headache, nervousness, or insomnia. Cardiovascular adverse effects include palpitations, tachycardia, angina, and cardiac arrest. Other possible adverse events include allergic skin reactions, diarrhea, nausea, and vomiting. Synthroid 100-mcg and 300-mcg tablets contain tartrazine, which may cause an allergic reaction in some patients, especially those sensitive to aspirin. **Black Box Warning:** Use of thyroid hormone for weight loss or the treatment of obesity is contraindicated.

Contraindications/Precautions: The use of levothyroxine is contraindicated if the patient is hypersensitive to the drug, is experiencing thyrotoxicosis, or has severe cardiovascular conditions or acute myocardial infarction (MI). If thyroid hormone is given to patients with adrenal insufficiency, it may cause a serious adrenal crisis; thus, the insufficiency should be corrected prior to administration of levothyroxine. It should be used with caution in patients with cardiac disease, angina pectoris, cardiac dysrhythmias, hypertension, and impaired kidney function, and in older adults. Symptoms of diabetes mellitus may be worsened with administration of thyroid hormone, and doses of antidiabetic drugs may require adjustment.

Drug Interactions: A large number of medications can interact with thyroid hormone and result in either increased or decreased effects. Drugs that decrease the absorption of levothyroxine include cholestyramine, colestipol, calcium- or aluminum-containing antacids, sucralfate, and iron supplements. Several drugs are known to accelerate the metabolism of levothyroxine, including phenytoin, carbamazepine, rifampin, phenobarbital, and sertraline. Levothyroxine increases the effects of warfarin, resulting in an increased risk of bleeding. Digoxin decreases the effectiveness of levothyroxine. Thyroid hormone sensitizes cardiac responsiveness to catecholamines; therefore, administration of epinephrine or norepinephrine must be carefully monitored in these patients to prevent dysrhythmias. **Herbal/Food:** Soybean flour (infant formula), cottonseed meal, walnuts, and dietary fiber may bind and decrease the absorption of levothyroxine sodium from the GI tract. Calcium or iron supplements should be taken at least 4 hours after taking levothyroxine to prevent interference with drug absorption. The patient should also avoid consuming large amounts of foods that can inhibit thyroid secretion, such as strawberries, peaches, pears, cabbage, turnips, spinach, kale, Brussels sprouts, cauliflower, radishes, and peas.

Pregnancy: Category A.

Treatment of Overdose: The treatment of levothyroxine overdose is the same as the treatment of thyroid crisis or thyroid storm, as discussed later in Section 67.6. Treatment is directed at reducing the level of circulating thyroid hormone with antithyroid drugs and decreasing sympathetic stimulation with corticosteroids and beta-adrenergic blockers.

Nursing Responsibilities: Key nursing implications for patients receiving levothyroxine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Thyroid Hormone Replacements.

Drugs Similar to Levothyroxine (Levothroid, Levoxyl, Synthroid, Unithroid)

Other thyroid replacement medications include liothyronine, liotrix, and desiccated thyroid. All thyroid drugs carry a black box warning stating they should not be used for weight loss or to treat obesity.

Liothyronine (Cytomel, Triostat): Approved in 1954, liothyronine is a synthetic form of T_3 used in replacement therapy for hypothyroidism. Its actions, adverse effects, and contraindications are similar to those for endogenous thyroid hormone. It has a shorter onset, half-life, and duration of action than levothyroxine and is more expensive. Liothyronine is readily converted to T_3 in the bloodstream. The injectable form of liothyronine is a preferred drug for the treatment of myxedema coma. It is available in oral and IV formulations. This drug is pregnancy category A.

Liotrix (Thyrolar): Liotrix is a synthetic mixture of T_4 and T_3, in a 4:1 ratio, available in PO form only for the treatment of hypothyroidism. Because levothyroxine is readily converted to T_3, there is no apparent advantage in using liotrix over levothyroxine. Its actions, adverse effects, and contraindications are similar to those for endogenous thyroid hormone. This drug is pregnancy category A.

Thyroid, desiccated (Armour thyroid, Thyroid USP): Desiccated thyroid is an older formulation, approved in 1939, obtained from the dried thyroid glands of pigs. The drug contains T_3 and T_4 in their natural proportions. Desiccated thyroid is less pure and has less reliable content than synthetic formulations and has been replaced by levothyroxine. It is used only for patients who have taken it for years—newly diagnosed cases of hypothyroidism are treated with synthetic thyroid hormone.

CONNECTIONS: Treating the Diverse Patient

Improved Kidney Function from Thyroid Hormone Replacement

Because thyroid hormones affect nearly all body systems, even slight changes in the amount of circulating hormones may have profound effects, especially in the very young and the older adult populations. Recent research suggests that thyroid hormone therapy may help preserve renal function in older patients (Lu, Guo, Liu, & Zhao, 2016). Subclinical hypothyroidism may have significant effects on chronic kidney disease. Several theories exist as to why thyroid replacement improves renal function, including improvement in cardiac status, improvement in dyslipidemias, or the effect on vascular endothelium (Hataya, Igarashi, Yamashita, & Komatsu, 2013; Rhee et al., 2015; Shin et al., 2013). Individualized treatment for subclinical hypothyroidism should be considered in older patients.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Thyroid Hormone Replacements

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, GI, hepatic, and kidney disease; pregnancy; or breastfeeding. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., T_3, T_4, and TSH levels; complete blood count [CBC]; platelets, electrolytes, glucose, and lipid levels).
- Obtain baseline height, weight, and vital signs. Obtain an electrocardiogram (ECG) as needed.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., T_3, T_4, and TSH levels return to normal, associated symptoms ease).
- Continue periodic monitoring of T_3, T_4, and TSH levels and glucose levels.
- Continue monitoring height, weight, and vital signs. Monitor ECG as needed.
- Assess for adverse effects: nausea, vomiting, diarrhea, epigastric distress, skin rash, itching, headache, tachycardia, palpitations, dysrhythmia, sweating, nervousness, paresthesia, tremors, insomnia, heat intolerance, and angina. Hypo- or hypertension, tachycardia, especially associated with dysrhythmia, or angina should be immediately reported to the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Monitor vital signs, appetite, weight, sensitivity to heat or cold, sleep patterns, and ability to perform activities of daily living (ADLs). (As metabolic activity controlled by thyroid hormones stabilizes, the patient should return to normal weight, ADLs, and feelings of wellness.)	• Advise the patient that the drug will help to stabilize thyroid hormone levels quickly, but full effects may take a week or longer to occur. • Instruct the patient to maintain consistent dosing to allow the drug to reach therapeutic levels. • Instruct the patient to weigh self 2 to 3 times per week, record the findings, and bring the record to each clinic visit.
• Avoid iodine-containing foods (e.g., iodized salt, soy sauce, tofu, yogurt, milk, strawberries, eggs) unless approved by the healthcare provider. (Iodine is necessary for the synthesis of thyroid hormone. Increasing or decreasing normal intake may result in adverse drug effects.)	• Provide dietary instruction on foods to avoid. Provide for a dietitian consultation as needed.
• Monitor thyroid function tests. (Results help determine the effectiveness of the drug therapy and the need for dosage changes.)	• Instruct the patient on the need to return periodically for laboratory work.
Minimizing adverse effects: • Monitor for return of original symptoms and report consistent occurrence. (Daily fluctuations in symptoms may occur because hormone replacement therapy does not precisely approximate the body's own levels. Significant increases in original symptoms may signal less-than-optimal therapeutic results. Dramatic "opposite" effect and hypo- or hyperthyroid symptoms may signal drug toxicity.)	• Teach the patient that small daily fluctuations may occur, especially during periods of stress or illness. Any significant or increasing changes in pulse rate, weight, nervousness or fatigue, intolerance to heat or cold, and diarrhea or constipation should be reported to the healthcare provider.
• **Lifespan:** Monitor symptoms in older adults more frequently. (Older patients are more sensitive to thyroid replacement therapy. Minor changes in daily thyroid levels may cause a significant change in symptoms.)	• Teach the patient, family, or caregiver that the lowest dose will be started and gradually increased to find the optimal level. Any significant change in symptoms should be promptly reported to the healthcare provider.
• **Lifespan:** Monitor height, weight, and developmental growth in infants and young children. (Infants and children receiving thyroid replacement therapy should continue to display normal growth and development curves.)	• Teach the parents or caregivers to weigh the child weekly and record. Bring the record to each healthcare visit. • Encourage the parents or caregivers to discuss concerns or any unusual findings that would suggest developmental or growth delays with the healthcare provider if they are noted in the child between healthcare visits.
• Monitor serum glucose levels, especially in patients with diabetes. Patients with diabetes should monitor capillary levels more frequently. (Thyroid replacement therapy may cause changes in glucose levels and an adjustment in antidiabetic medications may be needed.)	• Teach patients with diabetes to monitor capillary glucose levels more frequently during therapy. Report any consistent changes to the healthcare provider.
• Ensure patient safety. Observe for lightheadedness or dizziness. Monitor ambulation until the effects of the drug are known. (Dizziness may be secondary to changes in pulse or blood pressure and should be assessed by the healthcare provider. **Lifespan:** The older adult is especially at risk for falls related to dizziness. Effects of thyroid hormone on bone remodeling may place the patient at risk for fractures.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone if dizziness occurs. When dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Assess the safety of the home environment and discuss needed modifications with the family or caregiver.
• Continue to monitor the effectiveness of all other medications the patient is taking. Teach patients to take thyroid replacement 1 h before or 4 h after foods high in fiber or medications such as cholestyramine, calcium or aluminum antacids, or iron supplements. (Thyroid replacement drugs interact with many drugs and may cause suboptimal or excessive responses. Drugs such as calcium and aluminum antacids decrease absorption of thyroid hormone.)	• Teach the patient to report any unusual symptoms of concern to the healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug in the morning at the same time each day. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Take the drug at the same time each morning to approximate normal body hormone levels. If night shift hours are worked, consult with the healthcare provider about scheduling appropriate time of drug administration.
	  • Avoid foods high in iodine unless approved by the healthcare provider.
	  • To ensure optimal therapeutic response, take the same brand of drug and request the same manufacturer each time the prescription is filled. If the same drug is unavailable, consult with the healthcare provider about dosage or observe for adverse drug effects. Do not switch trade names until the provider has been consulted.

Pathophysiology of Hyperthyroid Disorders

67.5 Hyperthyroidism, or Graves' disease, is an autoimmune disorder accompanied by ophthalmopathy and goiter.

Symptoms of hyperthyroidism have been recorded in medical documents dating back to the 12th century. The most common cause of hyperthyroidism is **Graves' disease**, named after the Irish doctor Robert Graves who described the disorder in 1835. The condition is characterized by the excessive secretion of thyroid hormone.

The two most visible signs of Graves' disease are goiter and **exophthalmos**, an outward bulging of the eyes. Up to one third of those with Graves' disease develop ophthalmopathy, leading to severe eye problems. These include paralysis of the ocular muscles, damage to the optic nerve with some vision loss, and corneal ulceration due to the inability of the eyelids to close. These eye problems are aggravated by smoking, which should be strongly discouraged in patients with Graves' disease. The ophthalmopathy usually stabilizes with treatment but not all eye changes are reversible with therapy. A rare skin disorder, pretibial myxedema, may also occur, with thickening of the skin, plaques, and nodules over the shins and dorsal surface of the feet. Like the ophthalmic changes, these skin changes may persist despite effective treatment of the disease.

Causes of Graves' disease include adenoma and excessive intake of thyroid hormone. The onset is usually between the ages of 20 and 40 years, and it occurs five times more often in women than in men. Graves' disease is an autoimmune disorder in which the thyroid gland is stimulated by **thyroid-stimulating immunoglobulins (TSIs)**. It may occur concurrently with other autoimmune disorders, and there is a familial tendency to the condition.

The manifestations of hyperthyroidism are caused by the hypermetabolic state and the increase in sympathetic nervous system activity. The symptoms include nervousness, irritability, fatigue, insomnia, weight loss despite a large appetite, tachycardia, palpitations, hypertension, shortness of breath, increased sweating, muscle cramps, hyperthermia, and heat intolerance. A fine muscle tremor may occur. Approximately 15% of older adults with new-onset atrial fibrillation, a common cardiac dysrhythmia, have thyrotoxicosis.

Very high levels of circulating thyroid hormone may cause **thyrotoxicosis**. **Thyroid crisis**, or **thyroid storm**, is a rare, life-threatening form of thyrotoxicosis. If untreated, it is associated with mortality rates of 80% to 90%. Even with treatment, mortality from thyroid storm exceeds 20%. It occurs most often in teenage and young adult women with undiagnosed or untreated cases of hyperthyroidism and can be precipitated by the stress of an acute infection, diabetic ketoacidosis, trauma, or manipulation of the thyroid gland during surgery. Manifestations include high fever, cardiovascular effects (tachycardia, heart failure, angina, and MI), and CNS effects (agitation, restlessness, delirium, progressing to coma). It is treated with supportive measures, efforts to reduce body temperature without causing shivering, fluid, glucose and electrolyte replacement, and beta-adrenergic blockers. Aspirin should not be used to lower the body temperature of an individual in thyroid storm because it displaces thyroid hormone from its protein-binding sites in the serum, increasing the level of free, or active, thyroid hormone, which worsens the condition. Antithyroid drugs may be used to decrease thyroid hormone production.

PharmFACT

Although Graves' disease most commonly occurs in adults, it also occurs in children. About 10% of infants born to women with Graves' disease have hyperthyroidism, but most are asymptomatic. Concordance for Graves' disease is 30% to 50% in identical twins (Levitsky, 2016).

Pharmacotherapy of Hyperthyroid Disorders

67.6 Hyperthyroidism is treated with surgery or drugs that reduce the production of thyroid hormone.

Treatment of hyperthyroidism often requires surgical removal of all or part of the thyroid gland. In less serious cases of the disorder, pharmacotherapy can be used to diminish the secretion of thyroid hormone.

One strategy to lower thyroid hormone secretion is to destroy part of the gland (ablation) by administering radioactive iodide (^{131}I). The goal of thyroid ablation is to use the ionizing radiation from the drug to destroy just enough of the thyroid gland to return the patient to a normal thyroid state. This therapy is preferred by many endocrinologists because it results in a permanent, long-term solution to hyperthyroidism. This therapy is contraindicated during pregnancy due to the risk of exposing the fetus to ionizing radiation.

Antithyroid drugs may be administered to manage hyperthyroidism. Propylthiouracil (PTU) and methimazole (Tapazole) prevent the incorporation of iodine into the thyroid hormone molecule and block the conversion of T_4 to T_3 in peripheral tissues. Doses of the antithyroid drugs are listed in Table 67.4.

Treatment of thyroid storm is a medical emergency. Methimazole or propylthiouracil are administered to prevent further synthesis of thyroid hormone. Propylthiouracil also blocks the conversion of T_4 to T_3 in peripheral

Table 67.4 Antithyroid Drugs

Drug Name	Dose for Adults (Maximum Dose Where Indicated)	Adverse Effects
methimazole (Tapazole)	PO: 5–15 mg tid (max: 60 mg/day)	*Nausea, rash, pruritus, urticaria, fever, numbness in fingers, peripheral neuropathy, leukopenia, hypothyroidism* Agranulocytosis, bradycardia, hepatotoxicity
potassium iodide and iodine (Lugol's solution, Thyro-Block)	PO: 125 mg daily	*Diarrhea, nausea, vomiting, stomach pain, fever, weakness, irregular heartbeat, hypothyroidism* Angioneurotic edema, iodine poisoning
propylthiouracil (PTU)	PO: 300–450 mg tid	*Nausea, rash, pruritus, headache, fever, numbness in fingers, diarrhea, myelosuppression, hypothyroidism* Agranulocytosis
radioactive iodide (^{131}I)	PO: 0.8–150 millicurie (a curie is a unit of radioactivity)	*Adverse effects are uncommon* Thyroiditis, hypothyroidism, hypersensitivity

Note: *Italics* indicate common adverse effects. Underline indicates severe adverse effects.

tissues and is preferred for pregnant patients. Potassium iodide solution can be given to immediately block the release of thyroid hormone but should not be given until 1 hour after the administration of antithyroid medications.

Several drugs are used as adjuncts in the therapy of thyroid storm. During hyperthyroid states, beta-adrenergic blocking drugs such as propranolol (Inderal), esmolol (Brevibloc), or metoprolol (Toprol) are given to block the effects of the thyroid hormones on sympathetic receptors in the heart. The actions include a decrease in heart rate and strength of contraction, thereby decreasing myocardial oxygen demands. These effects occur quickly, while the actions of antithyroid drugs take longer to occur. Refer to Chapter 16 for the specific pharmacology of beta-adrenergic blockers.

IV corticosteroids such as hydrocortisone (Solu-Cortef) or dexamethasone (Decadron) may be ordered to treat acute hyperthyroid states. Corticosteroids block the conversion of T_4 to T_3 in peripheral tissues. In addition, severe hyperthyroid states create high levels of stress that deplete adrenal corticosteroids in the body, and administration of replacement doses is necessary. The pharmacology of the corticosteroids is presented in Chapter 68.

CONNECTION Checkpoint 67.2

Patients with Graves' disease have increased hepatic gluconeogenesis, rapid glucose absorption, and increased insulin resistance. From what you learned in Chapter 66, what insulin dosage adjustment is necessary for these patients who also have diabetes mellitus? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Propylthiouracil (PTU)

Classification **Therapeutic:** Antithyroid drug
Pharmacologic: Thyroid hormone inhibitor

Therapeutic Effects and Uses: Approved in 1947, propylthiouracil decreases thyroid hormone levels in hyperthyroid states that are caused by the overproduction of thyroid hormone. It is also used to establish the normal thyroid state prior to surgery or radioactive iodine treatment and for palliative control of toxic nodular goiter. Propylthiouracil is not effective in treating thyroiditis because this condition is due to overrelease, not overproduction, of thyroid hormone.

Mechanism of Action: Propylthiouracil inhibits the first step in the synthesis of thyroid hormone and suppresses the peripheral conversion of T_4 to T_3. It does not affect thyroid hormone that has already been synthesized, so therapeutic response may be delayed by 3 to 12 weeks, until existing supplies of thyroid hormone have been depleted.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Concentrated by the thyroid gland; crosses the placenta; secreted in breast milk; 60–80% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Kidneys
Onset of action	Absorbed within 30 min, but therapeutic effects may take up to 3 weeks
Duration of action	Half-life: 1–2 h; peak: 1–1.5 h

Adverse Effects: Approximately 15% to 20% of patients taking this drug will experience leukopenia, which is normally asymptomatic. Serious hypersensitivity reactions are rare but may include agranulocytosis, aplastic anemia, thrombocytopenia, rash, urticaria, and glomerulonephritis. Arthralgias and joint swelling occur

in 5% of patients. CNS effects include headache, vertigo, neuritis, and paresthesias. Propylthiouracil can also cause hypothyroidism and goiter at high doses. **Black Box Warning:** Severe liver injury and acute hepatic failure have been reported in patients taking propylthiouracil. This drug should be reserved for those unable to tolerate methimazole and in whom radioactive iodine therapy or surgery are not appropriate treatments for hyperthyroidism.

Contraindications/Precautions: The use of propylthiouracil is contraindicated if the patient has a hypersensitivity to the drug. Although contraindicated during pregnancy, the drug occasionally must be administered to women who experience a thyrotoxic crisis during pregnancy, and it is preferred over methimazole because less of the drug crosses the placenta. It should be used with caution during active infection, lactation, and bone marrow depression. Because propylthiouracil can cause liver impairment, caution should be used when treating patients with preexisting hepatic disease.

Drug Interactions: Propylthiouracil increases the actions of anticoagulants, which creates an increased risk of bleeding. Iodine-containing drugs (amiodarone, potassium iodide, sodium iodide, radioactive iodine) and thyroid hormones can inhibit the effectiveness of this drug. Altered serum levels of metoprolol, propranolol, and digoxin can occur as the patient moves from a hyperthyroid to a normal thyroid state. Cross hypersensitivity occurs in about 50% of patients who have experienced a hypersensitivity reaction to methimazole, the other major antithyroid medication. Propylthiouracil should not be used with carbamazepine or clozapine because this may increase the risk of agranulocytosis. **Herbal/Food:** Unknown.

Pregnancy: Category D.

Treatment of Overdose: When propylthiouracil is taken in high doses, it can induce hypothyroidism; the administration of thyroid hormone may be necessary.

Nursing Responsibilities: Key nursing implications for patients receiving propylthiouracil are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antithyroid Drugs.

Drugs Similar to Propylthiouracil (PTU)

Drugs similar to propylthiouracil include Lugol's solution, methimazole, potassium iodide, and radioactive iodide.

Lugol's solution (5% elemental iodine and 10% potassium iodide): This strong iodine solution is given orally to treat hyperthyroidism, as adjunctive therapy 10 to 14 days prior to thyroid surgery, or for the treatment of thyrotoxicosis. It has been used as a topical antiseptic. Although iodine is necessary for the synthesis of thyroid hormone, high levels inhibit both the synthesis and release of thyroid hormone. Chronic use can result in toxicity known as **iodism**, which is characterized by burning in the mouth and throat, a metallic taste, sore teeth and gums, increased salivation and nasal discharge, swollen eyelids, gastric irritation, and diarrhea. The distribution of Lugol's solution is now regulated by the U.S. Drug Enforcement Administration because strong iodine solutions are used in the manufacture of crystal methamphetamine. Potassium iodide is pregnancy category D.

Methimazole (Tapazole): Approved in 1950, methimazole is given by the oral route to correct hyperthyroidism by inhibiting the synthesis of thyroid hormone. Like PTU, it does not affect existing stores of thyroid hormone; thus it may take many weeks before a normal thyroid state is achieved. Its uses, contraindications, and adverse effects are similar to those for PTU, except that methimazole does not induce hypothyroidism or cause serious liver injury. Other important differences are that methimazole does not inhibit conversion of T_4 to T_3; therefore, its effects may take longer to occur. Methimazole has a longer half-life, allowing for once-a-day dosing, while PTU must be taken 3 times a day. Methimazole is usually administered for 12 to 18 months, then tapered or discontinued if TSH levels are normal. This drug is pregnancy category D.

Potassium iodide (Thyro-Block): Potassium iodide is given orally prior to thyroid surgery to reduce the vascularity (risk of bleeding), fragility, and size of the thyroid gland. It may also be used alone for hyperthyroidism or in combination with antithyroid drugs and beta-adrenergic blockers in the treatment of thyroid storm. Like other forms of iodide, it suppresses the synthesis and release of thyroid hormone. It is also used to protect the thyroid gland in instances of radiation exposure secondary to a nuclear incident. It is taken up by the thyroid gland, thereby blocking the uptake of radioactive iodide in the thyroid gland, reducing the risk for developing thyroid cancer. As a protective agent, it must be given immediately prior to, or within 3 hours following, radiation exposure. This drug is pregnancy category D.

Radioactive iodide (^{131}I): Radioactive iodide is an isotope of iodine used for hyperthyroidism. Like all iodine, ^{131}I is taken up by the thyroid gland, where its radioactivity destroys thyroid tissue. The goal is to destroy part of the gland, thereby decreasing the amount of thyroid hormone produced and secreted. In some patients, too much thyroid gland is destroyed and hypothyroidism results, which is then treated with levothyroxine. Approximately two thirds of patients treated with ^{131}I respond to a single treatment, whereas the rest require two or more treatments. Therapeutic effects develop slowly over 2 to 3 months, and the tissue damage is limited to the thyroid

gland with no surrounding structures affected. Although it is contraindicated during pregnancy and breastfeeding, and usually not used in children, ^{131}I has not been known to cause cancer or other serious adverse effects to the thyroid gland or elsewhere in the body. It is used in patients wishing to avoid surgery or those who do not tolerate antithyroid drugs. It is administered PO and is also used to treat thyroid cancer (in high doses) and for the diagnosis of thyroid disorders. This drug is pregnancy category X.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antithyroid Drugs

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, GI, hepatic, or kidney disease; pregnancy; or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., T_3, T_4, and TSH levels, CBC, and glucose).
- Obtain baseline height, weight, and vital signs. Obtain ECG as needed.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., T_3, T_4, and TSH levels return to normal, associated symptoms of hyperthyroidism ease).
- Continue periodic monitoring of T_3, T_4, and TSH levels, CBC, and glucose.
- Continue monitoring height, weight, and vital signs. Monitor ECG as needed.
- Assess for adverse effects: nausea, vomiting, diarrhea, epigastric distress, skin rash, itching, headache, vertigo, and paresthesias.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor vital signs, appetite, weight, sensitivity to heat or cold, sleep patterns, and ability to perform ADLs. (As metabolic activity controlled by thyroid hormones stabilizes, the patient should return to more normal weight, ADLs, and feelings of wellness. Weight and pulse rate are measured to assist in the assessment of the therapeutic response to drug therapy.)	• Advise the patient that the drug will help to stabilize thyroid hormone levels quickly, but other methods (e.g., surgery, radioactive iodine) may be required for long-term management. • Instruct the patient to maintain consistent dosing to allow the drug to reach therapeutic levels. • Instruct the patient to weigh self 2 to 3 times per week, record the findings along with the pulse rate, and bring the record to each healthcare provider visit.
• Avoid iodine-containing foods (e.g., iodized salt, soy sauce, tofu, yogurt, milk, strawberries, eggs) unless approved by the healthcare provider. (Iodine is necessary for the synthesis of thyroid hormone. Increasing or decreasing normal intake may result in adverse drug effects.)	• Provide dietary instruction on which foods to avoid to reduce excessive intake of foods with high iodine content. Provide for dietitian consultation as needed.
• Monitor thyroid function tests. (Results help determine the effectiveness of the drug therapy and need for dosage changes.)	• Instruct the patient on the need to return periodically for laboratory work.
Minimizing adverse effects: • Monitor for the return of original symptoms and report consistent occurrence. (Significant return of hyperthyroid symptoms may indicate that inadequate therapeutic levels are being maintained; symptoms of hypothyroidism may signal drug toxicity.)	• Teach the patient that small daily fluctuations in symptoms may occur, especially during periods of stress or illness. Any significant changes in pulse rate, weight, nervousness, or fatigue, intolerance to heat or cold, and diarrhea or constipation should be reported to the healthcare provider.
• Monitor for signs of infection: fever, rashes, sore throat, malaise, fatigue, or weakness. Monitor CBC and platelet counts. (Antithyroid drugs may cause agranulocytosis.)	• Instruct the patient to report fever, rashes, sore throat, chills, malaise, or weakness to the healthcare provider.
• Continue to monitor the effectiveness of all other medications the patient is taking. (Antithyroid replacement drugs interact with many drugs, particularly those containing iodine such as amiodarone. As a more normal thyroid state is reached, doses of cardiac drugs may need to be adjusted.)	• Review the patient's medication list at each health visit. Instruct the patient to report any unusual symptoms of concern to the healthcare provider.
• **Lifespan:** Monitor symptoms in older adults more frequently. (Older patients are more sensitive to thyroid hormone levels and minor changes in daily thyroid levels may cause a significant change in symptoms.)	• Teach the patient, family, or caregiver that the lowest dose will be started and gradually increased to find the optimal level. Any significant change in symptoms should be promptly reported to the healthcare provider.
• Monitor serum glucose levels, especially in patients with diabetes. Patients with diabetes should monitor capillary glucose levels more frequently. (Antithyroid drugs may cause changes in glucose levels.)	• Teach patients with diabetes to monitor capillary glucose levels more frequently during therapy. Report any consistent changes to the healthcare provider.
• Ensure patient safety. Observe for lightheadedness or dizziness. Monitor ambulation until the effects of the drug are known. (Dizziness may be secondary to changes in pulse or blood pressure or related to adverse drug effects and should be assessed by the healthcare provider. **Lifespan:** The older adult is especially at risk for falls related to dizziness.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone if dizziness occurs. When dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Assess the safety of the home environment and discuss needed modifications with the family or caregiver.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Ensure patient and caregiver safety if radioactive iodine is used. (Even though radioactive iodine provides just low-dose radiation, prolonged contact by care providers or visitors should be avoided.)	• Teach the patient to limit contact with family to 1 h per day per person until the treatment period is over. Young children and pregnant women should avoid contact with the patient. • Advise the patient to increase fluid intake up to 2 L/day as allowed and to void frequently to avoid irradiation to gonads from radioactivity in urine excretion. • Instruct the patient not to expectorate and to cover the mouth when coughing. Any contaminated tissues should be disposed of per the protocol of the agency or healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug in the morning at the same time each day. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Take the drug at the same time each day.
	  • Take the drug 1 h before or 2 h after breakfast.
	  • Avoid foods high in iodine unless approved by the healthcare provider.

Understanding Chapter 67

Key Concepts Summary

67.1 Thyroid hormones contain iodine and stimulate the basal metabolic rate of nearly all tissues.

67.2 An accurate diagnosis of thyroid hormone dysfunction is based on the patient's symptoms and the results of diagnostic tests.

67.3 Hypothyroidism, or thyroid deficiency, can occur as a congenital or acquired disorder.

67.4 Hypothyroidism is treated by replacement therapy with thyroid hormone.

67.5 Hyperthyroidism, or Graves' disease, is an autoimmune disorder accompanied by ophthalmopathy and goiter.

67.6 Hyperthyroidism is treated with surgery or drugs that reduce the production of thyroid hormone.

CASE STUDY: Making the Patient Connection

Remember the patient "Helen Mercado" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Helen is a 38-year-old mother of three young children, who works full time in a department store. She has been feeling extremely tired, has been gaining weight, and says she feels cold all the time. Acting on her feelings that something might be wrong, she goes to her healthcare provider. Her vital signs at that time are as follows: blood pressure, 94/60 mmHg; heart rate, 58 beats/min; temperature, 36.3°C (97.4°F). Her weight has increased 13.6 kg (30 lb) from when she was last seen 6 months ago. She confirms that her appetite has decreased. After completing a physical examination, the healthcare provider orders some laboratory tests including T_3, T_4, and TSH.

Critical Thinking Questions

1. Based on the patient's symptoms, what test results would you anticipate?

2. The healthcare provider orders levothyroxine (Synthroid) 200 mcg PO daily for Helen. What will you teach Helen about this drug and when to take it?
3. Helen asks you if she will need to be on the medication for very long. How will you answer her?
4. What symptoms should Helen report to the provider while she is taking the Synthroid?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

The nurse receives a new patient admission onto a cardiac unit: Carolyn James, a 72-year-old woman, with new-onset atrial fibrillation with rapid ventricular response. The nurse connects the patient to a cardiac monitor and obtains the following vital signs: blood pressure, 168/96 mmHg; respirations, 28 breaths/min; heart rate, 162 beats/min; temperature 38.7°C (101.6°F). The nurse learns from the patient's daughter that Carolyn was recently diagnosed with Graves' disease, but she has not been taking her medications.

1. What diagnostic tests do you expect to see ordered for this patient?
2. What drug therapy do you anticipate for this patient?
3. What long-term therapy do you believe is appropriate for this patient?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient on replacement therapy with levothyroxine (Synthroid) reports feeling nervous and is having occasional palpitations and tremors. The nurse recognizes that these symptoms may indicate what effect is occurring?
    1. The patient is still experiencing hypothyroidism and the dose may need to be increased.
    2. The patient now has normal thyroid function and the levothyroxine (Synthroid) is no longer needed.
    3. The patient has developed diabetes and needs further evaluation.
    4. The patient is experiencing symptoms of hyperthyroidism and the drug dosage may need to be decreased.
2. Which of the following assessment findings would the nurse expect to observe in an adult patient experiencing therapeutic effects from levothyroxine (Synthroid)? (Select all that apply.)
    1. Constipation and weight gain
    2. Decreased blinking and exophthalmos
    3. Decreased reports of fatigue
    4. Decreased blood cholesterol levels
    5. Pulse rate between 60 and 100 beats/minute
3. A patient will be treated with propylthiouracil (PTU) for hyperthyroidism. While the patient is taking this drug, which symptoms will the nurse teach the patient to report to the healthcare provider?
    1. Sore throat, low-grade fever, chills
    2. Increase in appetite and caloric intake
    3. Tinnitus, altered taste, thickened saliva
    4. Insomnia, nightmares, and night sweats
4. Which assessment finding would cause the nurse to withhold a regularly scheduled dose of levothyroxine?
    1. A 1-kg (2-lb) weight gain
    2. A blood pressure reading of 100/70 mmHg
    3. A heart rate of 110 beats/min
    4. A temperature of 37.9°C (100.2°F)
5. A patient is taking a solution of 5% iodine and 10% potassium iodide (Lugol's solution) prior to a thyroidectomy. The patient asks why iodine solution is used since iodine is needed to make thyroid hormone. What is the nurse's best answer?
    1. "The symptoms you were having indicate you were not receiving enough iodine."
    2. "High levels of iodine can temporarily reduce the amount of thyroid hormone your body makes and secretes."
    3. "High levels of iodine are always used prior to thyroidectomy to make up for the loss of iodine when the thyroid is removed."
    4. "The high levels of iodine help prevent diabetes from developing."

6. What should the nurse teach the patient who is newly diagnosed with hypothyroidism and will start taking levothyroxine (Synthroid)?
   1. Take the pill in the afternoon with a high-fiber snack to prevent stomach upset.
   2. Eat plenty of fruits and vegetables such as strawberries, spinach, and kale to replace vital nutrients.
   3. Take the dose in the morning before breakfast, as close to the same time each day as possible.
   4. The drug may be taken every other day if diarrhea occurs.

Chapter 68
Corticosteroids and Drugs Affecting the Adrenal Cortex

Chapter Outline

- Physiology of the Adrenal Gland
- Overview of Corticosteroid Pharmacotherapy
- Adverse Effects of Corticosteroids
- Replacement Therapy with Corticosteroids
  PROTOTYPE *Hydrocortisone (Cortef, Solu-Cortef, Others), p. 1252*
- Corticosteroids for Nonendocrine Conditions
- Mineralocorticoids
  PROTOTYPE *Fludrocortisone, p. 1257*
- Antiadrenal Drugs

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the functions of the three classes of hormones secreted by the adrenal gland.
2. Diagram the negative feedback regulation of corticosteroid secretion.
3. Identify common properties of the corticosteroid medications.
4. Describe the potential adverse effects of long-term corticosteroid therapy.
5. Compare and contrast the pharmacotherapy of acute and chronic adrenocortical insufficiency.
6. Explain how corticosteroids affect the inflammatory and immune responses.
7. Recognize nonendocrine disorders that respond to corticosteroid therapy.
8. Describe indications for pharmacotherapy with mineralocorticoids.
9. Explain the pharmacotherapy of Cushing's syndrome.
10. Describe the nurse's role in the pharmacologic management of adrenal disorders.
11. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
12. Apply the nursing process to the care of patients receiving pharmacotherapy with corticosteroids and mineralocorticoids.

Key Terms

Addison's disease, 1250
adrenal atrophy, 1250
adrenal crisis, 1250
adrenocortical insufficiency, 1250
adrenocorticotropic hormone (ACTH), 1247
Cushing's syndrome, 1258
glucocorticoids, 1246
gonadocorticoids, 1247
hyperaldosteronism, 1257
hypoaldosteronism, 1257
mineralocorticoids, 1246

Though small, the adrenal glands secrete hormones that affect every body tissue. The primary secretions of the adrenal glands, the corticosteroids, are some of the most widely used drugs in medicine. They can be delivered by any route to treat conditions as diverse as dermatitis, lymphoma, ulcerative colitis, allergic rhinitis, and arthritis. This chapter examines the pharmacologic properties of corticosteroids that make them so important to pharmacotherapy.

Physiology of the Adrenal Gland

68.1 The adrenal glands secrete gonadocorticoids, mineralocorticoids, and corticosteroids.

Weighing only two tenths of an ounce, each pyramid-shaped adrenal gland sitting atop each kidney is divided into two major portions: an inner medulla and an outer cortex. The secretions from these two portions have very different functions.

The adrenal medulla secretes 75% to 80% epinephrine, with the remainder of the secretion being norepinephrine. Adrenal release of epinephrine is triggered by activation of the sympathetic division of the autonomic nervous system. Symptoms of the fight-or-flight response resulting from the secretion of these hormones are described in Chapters 12 and 15.

The adrenal cortex secretes three essential classes of steroid hormones: mineralocorticoids, glucocorticoids, and gonadocorticoids. Collectively, the mineralocorticoids and glucocorticoids are called corticosteroids or adrenocortical hormones. Although the terms *corticosteroid* and *glucocorticoid* are sometimes used interchangeably in clinical practice, the term *corticosteroid* technically refers to a hormone or drug that has both glucocorticoid and mineralocorticoid activity. The hormones secreted by the adrenal gland are illustrated in Figure 68.1.

Mineralocorticoids: Aldosterone accounts for more than 95% of the **mineralocorticoids** secreted by the adrenal glands. The primary function of aldosterone is to conserve sodium and water and promote the excretion of potassium by the renal tubule, thus regulating plasma volume. Pharmacotherapy with mineralocorticoids is presented in Section 68.6.

Glucocorticoids: More than 30 different **glucocorticoids** are secreted from the adrenal cortex. Cortisol, also called hydrocortisone, is secreted in the highest amount and is the most important pharmacologically. The liver converts hydrocortisone into cortisone, an active metabolite that is also available as a drug. Corticosterone is an additional steroid secreted by the adrenal cortex.

Glucocorticoids prepare the body for long-term stress and affect the metabolism of nearly every cell. The effects of glucocorticoids are diverse, and include the following:

- Increase the level of blood glucose (hyperglycemic effect) by inhibiting insulin secretion and promoting gluconeogenesis, which is the synthesis of carbohydrates from lipid and protein sources. This decreases glucose utilization by tissues and promotes the storage of glycogen in the liver.
- Increase the breakdown of proteins to amino acids. Amino acids are then converted to glucose and glycogen in the liver, resulting in protein depletion.
- Increase the breakdown of lipids (lipolysis). The fatty acids are then utilized as energy sources.
- Suppress the inflammatory and immune responses.
- Increase the sensitivity of vascular smooth muscle to the actions of norepinephrine and angiotensin II, thus modifying smooth muscle tone.
- Influence the central nervous system (CNS) by affecting mood and maintaining normal nerve excitability.
- Increase the breakdown of bony matrix, resulting in bone demineralization.
- Promote bronchodilation by making bronchial smooth muscle more responsive to sympathetic nervous system activation.
- Stabilize mast cells, inhibiting the release of inflammatory mediators.

As this list confirms, the glucocorticoids are essential hormones for maintaining homeostasis. When given as medications, some of the physiologic actions of glucocorticoids are considered therapeutic effects, while others are adverse effects. Unfortunately, it is impossible to totally separate therapeutic effects from adverse effects when drugs with such widespread actions are used in pharmacotherapy.

The physiologic levels of glucocorticoids vary based on a circadian rhythm. The lowest serum levels occur during

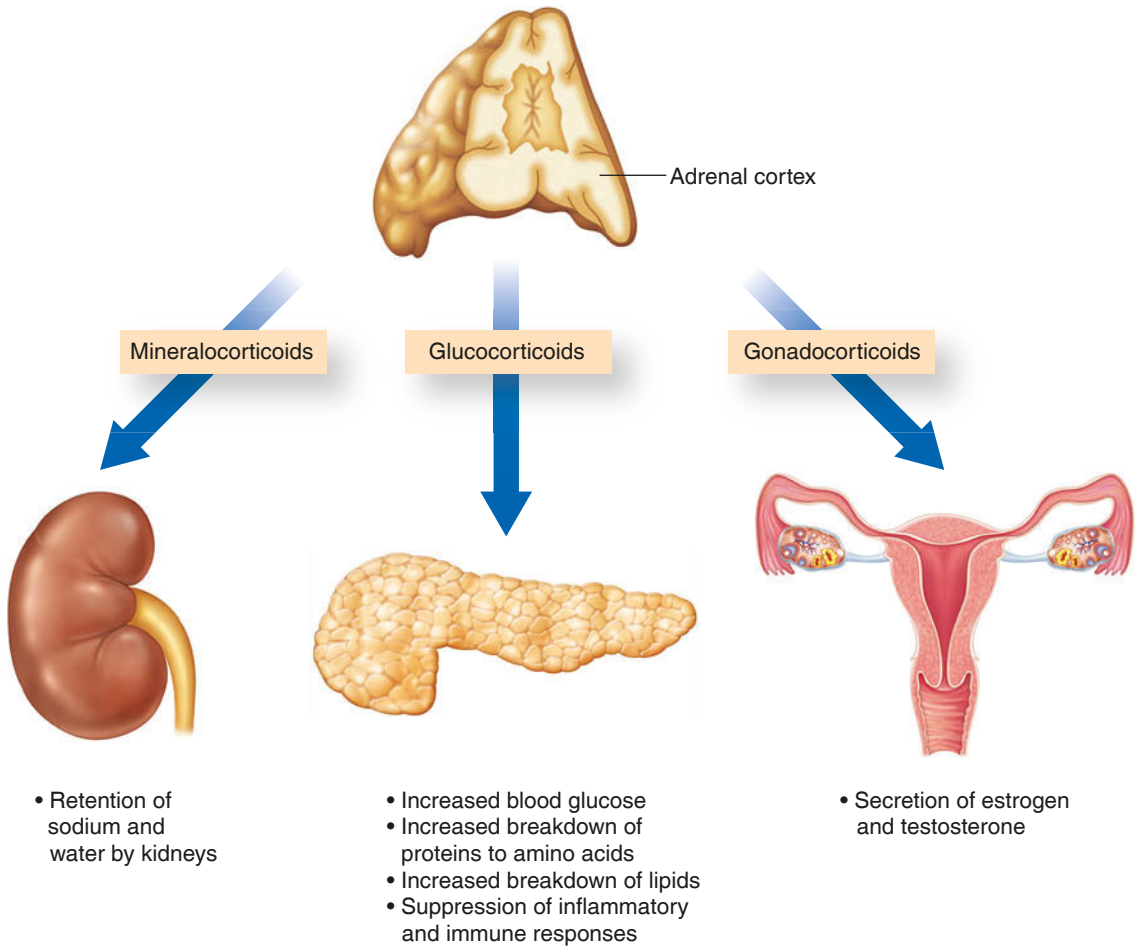

Figure 68.1 Hormonal secretions of the adrenal gland.

early sleep. Secretion rises during the night, with levels peaking at awakening and declining during the day, depending on the needs of the body. Stress can cause a rapid increase in glucocorticoid levels; when faced with internal inflammatory or stressful conditions, the secretion of glucocorticoids can increase to 10 times their baseline level.

Regulation of glucocorticoid levels begins with corticotropin-releasing factor (CRF), secreted by the hypothalamus. CRF travels to the pituitary where it causes the release of **adrenocorticotropic hormone (ACTH)**. ACTH then travels via the blood to reach the adrenal cortex, causing it to release glucocorticoids. When the serum level of cortisol rises, it provides negative feedback to the hypothalamus and pituitary to shut off further release of glucocorticoids. This negative feedback mechanism is illustrated in Figure 68.2.

Gonadocorticoids: The **gonadocorticoids** or sex hormones secreted by the adrenal cortex are mostly androgens, though small amounts of estrogens are also produced. The amounts of adrenal sex hormones are far less than the levels secreted by the testes or ovaries during the reproductive years. Though their amount is small, the adrenal gonadocorticoids contribute to the onset of puberty and are the primary source of endogenous estrogen in postmenopausal women (see Chapter 69). Tumors of the adrenal cortex can cause hypersecretion of gonadocorticoids, resulting in hirsutism and masculinization, signs that are more noticeable in women than men. The physiologic effects of androgens are discussed in Chapter 71.

Overview of Corticosteroid Pharmacotherapy

68.2 Corticosteroids are widely used, and all drugs in the class have similar indications, actions, and adverse effects.

Corticosteroids are some of the most widely prescribed medications because they are useful in treating conditions affecting nearly every body system. Furthermore, some of their indications are for diseases common to all age groups and for diseases that occur frequently in the population. Some are available over the counter (OTC).

Corticosteroids can be classified in many different ways. One method is based on pathophysiology, such as grouping corticosteroids used for the treatment of inflammation, allergies, or neoplasias. Another method is to

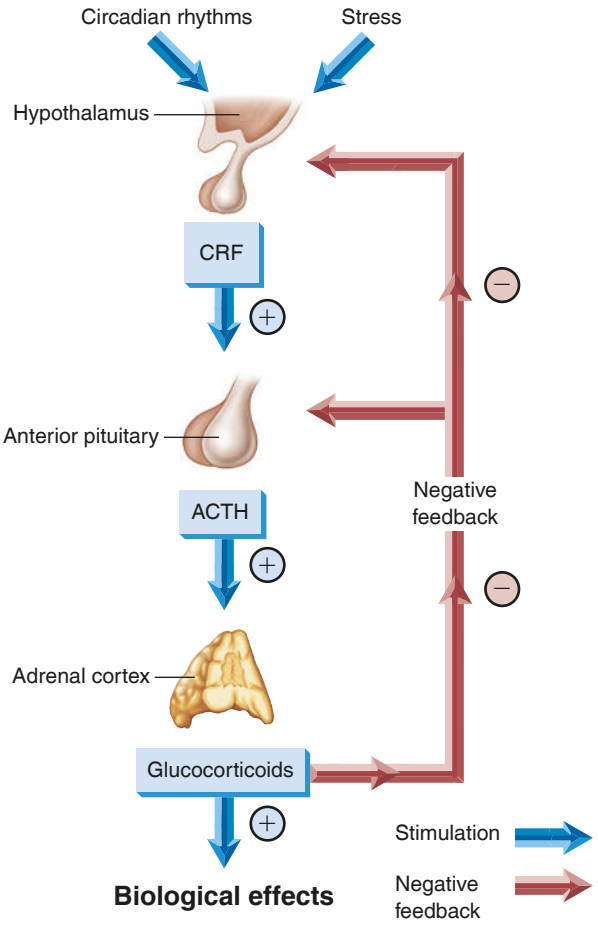

Figure 68.2 Feedback control of the adrenal cortex.

group the drugs by body system, such as corticosteroids used for skin conditions, immune disorders, or lung diseases. A third method is to look at corticosteroid use based on their pharmacologic actions, as listed in Table 68.1. In clinical practice, all methods are used.

Regardless of the method of classification, several general statements can be made about the corticosteroid medications:

- They act by the same mechanism.
- All have the same basic adverse effects, which are dose dependent.
- Indications and adverse effects vary by the dose, length of use, and route of administration.
- They are well absorbed when administered orally or parenterally, and they are widely distributed to all body tissues. Topical administration (intra-articular, inhalation, skin products, and ocular drops) results in systemic absorption, although at a slow rate.
- Most are highly bound to plasma proteins.
- All are metabolized by the liver and excreted by the kidneys.
- All have the potential to cross the placenta (pregnancy category C) and are secreted in breast milk. Use should be avoided during pregnancy and lactation.

Table 68.1 Actions and Indications for Corticosteroids

Pharmacologic Action	Indications
Inhibit cell division	Lymphomas and other neoplasms
Reduce joint inflammation	Rheumatoid arthritis, osteoarthritis, bursitis, tendonitis
Reduce lung inflammation	Asthma, chronic obstructive pulmonary disease (COPD)
Reduce skin inflammation	Dermatitis, psoriasis
Supply exogenous corticosteroids	Replacement therapy
Suppress allergic response	Allergic rhinitis; anaphylaxis
Suppress gastrointestinal (GI) inflammation	Inflammatory bowel disease
Suppress general inflammatory response	Systemic lupus erythematosus
Suppress immune response	Prophylaxis of transplant rejection Autoimmune hemolytic anemia
Suppress ocular inflammation	Conjunctivitis

More than 20 corticosteroids are available as medications, and the choice of a particular drug depends primarily on its pharmacokinetic properties. The duration of action, which is sometimes used to classify these drugs, ranges from short to long acting. Some, such as hydrocortisone, also have mineralocorticoid activity and may cause sodium and fluid retention; others, such as prednisone, have no such effect. Some corticosteroids are available by only one route, such as topical for dermal conditions or intranasal for allergic rhinitis. An overview of the indications for corticosteroid therapy is given in Table 68.1.

Adverse Effects of Corticosteroids

68.3 Long-term therapy with corticosteroids has the potential to cause serious adverse effects in multiple body systems.

Low-dose or brief-duration regimens of corticosteroids produce few clinically significant adverse effects. However, high doses taken for prolonged periods offer a significant risk for serious adverse effects. These adverse effects of corticosteroid therapy are well documented and can impact nearly any body system. The following list includes the most significant adverse events from long-term corticosteroid therapy:

- **Immune response.** Suppression of inflammation and immune responses increases patients' susceptibility to infections. Latent infections, such as herpesvirus or tuberculosis, may be reactivated during corticosteroid therapy. In addition, the anti-inflammatory actions of the corticosteroids may mask the signs of an existing infection.
- **Peptic ulcers.** Prolonged corticosteroid use is associated with the development of peptic ulcers,

CONNECTIONS: Complementary and Alternative Therapies

Fish Oils for Inflammation

Description

Fish oils, also known as marine oils, are lipids found primarily in coldwater fish such as salmon, mackerel, tuna, and herring, as well as in algae oils, green leafy vegetables, beans, and nuts. These oils are rich sources of long-chain polyunsaturated fatty acids of the omega-3 type. The two most studied fatty acids found in fish oils are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

History and Claims

Fish oils are sometimes used for their anti-inflammatory, antithrombotic, antidysrhythmic, and antihyperlipidemic properties.

Standardization

Fish oils are standardized by the amount of omega-3 fatty acids they contain. There is no standard dose; capsules may range from 300 to 2000 mg.

Evidence

Omega-3 fatty acids are known for their triglyceride-lowering activity and their anti-inflammatory actions (National Center for Complementary and Integrative Health, 2017). Several mechanisms are believed to account for the anti-inflammatory activity of EPA and DHA. The two competitively inhibit the conversion of arachidonic acid to the proinflammatory prostaglandins, thus reducing their synthesis.

Many studies have examined a proposed relationship between cognitive ability and high intake of omega-3 fatty acids, and no benefit has been demonstrated in patients with Alzheimer's disease. Randomized clinical trials have not shown statistically significant improvement in cognitive function related to intake of omega-3 fatty acids, although changes in aortic blood pressure were noted (Chew et al., 2015; Pase et al., 2015). Aerobic exercise combined with the use of omega-3 fatty acids demonstrated positive effects that prevented the decline of gray matter, and omega-3s seemed to benefit cognition in those patients who were less active (Köbe et al., 2016; Leckie et al., 2014).

especially when these drugs are combined with nonsteroidal anti-inflammatory drugs (NSAIDs). Both classes of drugs reduce prostaglandin synthesis in the gastric mucosa, which normally provides protection from the high acidity in the stomach. Use of proton pump inhibitors may reduce the incidence of peptic ulcers in patients who are taking corticosteroids (see Chapter 59).

- **Osteoporosis.** Corticosteroids inhibit calcium absorption, suppress bone formation, and accelerate bone resorption—all actions that weaken the bony matrix. Up to 50% of patients on long-term corticosteroid therapy will sustain a fracture due to osteoporosis. Treatment with a bisphosphonate may reduce the incidence of fractures in these patients (see Chapter 72).
- **Behavioral changes.** By an unknown mechanism, corticosteroids can induce psychologic changes. These may be minor, such as nervousness or moodiness, or may involve hallucinations and increased suicidal tendencies.
- **Eye changes.** Cataracts and open-angle glaucoma are potential adverse events of long-term corticosteroid therapy.
- **Metabolic changes.** Corticosteroids have a hyperglycemic action that raises serum glucose and can cause glucose intolerance, especially in patients with diabetes. Mobilization of lipids may cause hyperlipidemia and abnormal fat deposits. Electrolyte changes include hypocalcemia, hypokalemia, and hypernatremia. Fluid retention, weight gain, hypertension (HTN), and edema are other possible effects.
- **Myopathy.** Muscle wasting induced by corticosteroids may cause weakness and fatigue. The myopathy may involve ocular or respiratory muscles.

CONNECTION Checkpoint 68.1

From what you learned in Chapter 41, what drug class includes the preferred drugs for treating mild to moderate inflammation? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Corticosteroids also interact with many drugs. Their hyperglycemic effects may decrease the effectiveness of antidiabetic medications. Combining glucocorticoids with other ulcerogenic drugs such as aspirin and other NSAIDs markedly increases the risk of peptic ulcer disease. Administration with certain diuretics may lead to hypocalcemia and hypokalemia. Vaccines will have a diminished effect if administered during corticosteroid therapy. The nurse should always check for potential drug interactions when a patient is receiving prolonged corticosteroid therapy.

An important goal during long-term corticosteroid therapy is to prevent the development of serious adverse effects. The following strategies are often used to minimize the incidence of serious adverse effects:

- Doses are kept to the lowest amount that will achieve the therapeutic goal. In some cases, concurrent drug therapy with a noncorticosteroid may be implemented to produce additive therapeutic effects, while keeping the corticosteroid dose low. Careful monitoring of the effectiveness of the drug is necessary.

- Corticosteroids are sometimes administered every other day (alternate-day dosing) to minimize adrenal atrophy (see Section 68.4). This prevents constant, negative feedback on the pituitary and forces the patient's adrenal glands to secrete endogenous corticosteroids every other day.
- For acute conditions, patients are administered large doses of corticosteroids for a few days and then the drug dose is gradually decreased until discontinued. This prevents the severe symptoms of adrenal atrophy from developing. For example, methylprednisolone (Medrol Dosepak) consists of twenty-one 4-mg tablets, taken over 6 days. Six tablets are taken on day 1, five on day 2, four on day 3, three on day 4, two on day 5, and one on day 6.
- Whenever possible, corticosteroids should be administered locally by inhalation, intra-articular injections, or topical applications to the skin, eyes, or ears to diminish the extent of systemic effects. Local administration rarely produces systemic adverse effects.

Replacement Therapy with Corticosteroids

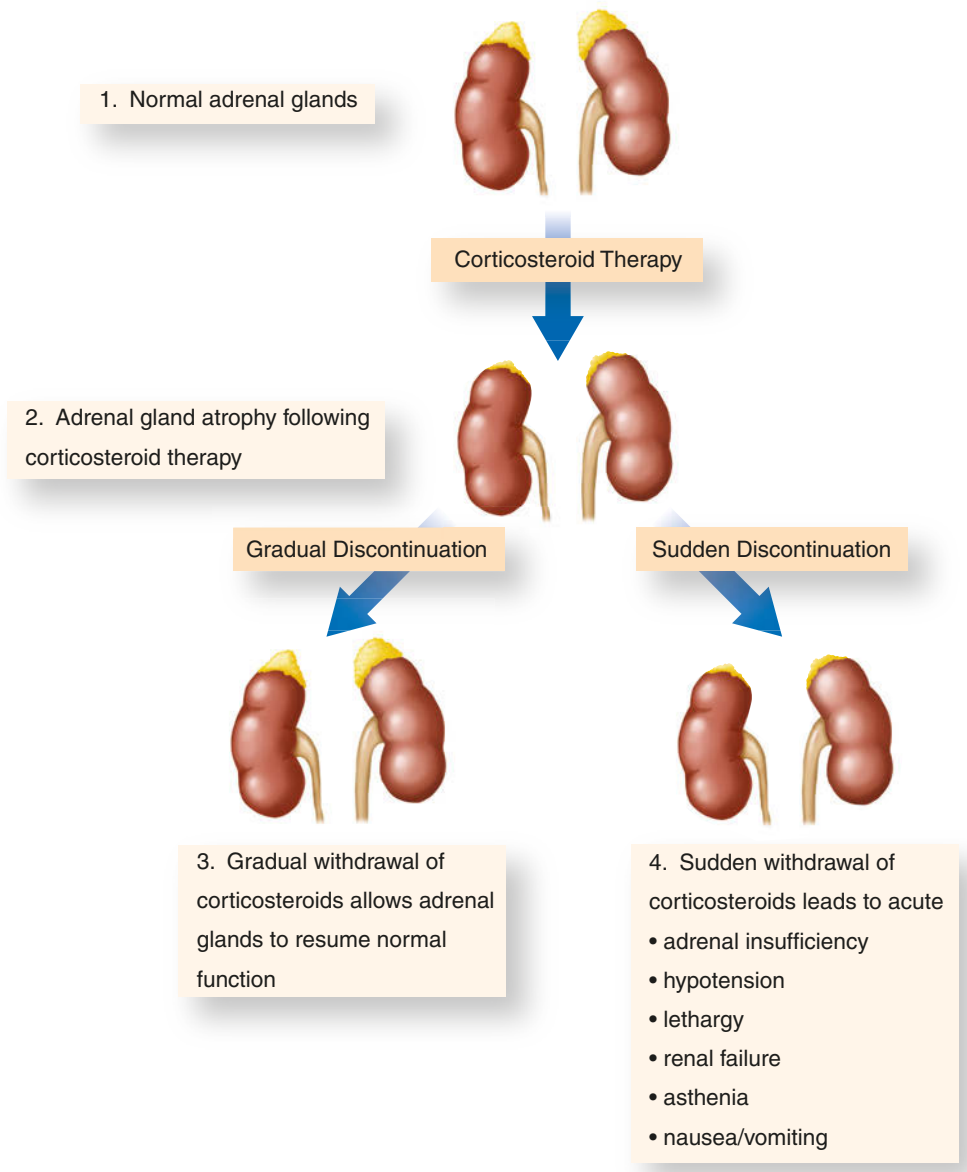
68.4 Adrenocortical insufficiency is treated by administering physiologic levels of corticosteroids.

Lack of adequate secretion by the adrenal cortex, or **adrenocortical insufficiency**, involves a lack of both glucocorticoids and mineralocorticoids. When pathology of the adrenal glands is the cause of the hyposecretion, it is called primary adrenocortical insufficiency, or **Addison's disease**. The most common etiology of primary adrenocortical insufficiency is the autoimmune destruction of both adrenal glands. Hemorrhage, infections, or metastases in the adrenal glands are other potential causes. Addison's disease is rare and includes a deficiency of both glucocorticoids and mineralocorticoids.

PharmFACT

One of the earliest symptoms of Addison's disease is hyperpigmentation of the oral and vaginal mucosas and the sun-exposed areas of the skin. This occurs because high ACTH levels stimulate melanocytes to produce excessive amounts of melanin (Griffing, 2017).

Secondary adrenocortical insufficiency occurs when the adrenal glands are normal, but they are not receiving adequate stimulation due to lack of sufficient ACTH from the pituitary. Low serum levels of both ACTH and cortisol are diagnostic of secondary adrenocortical insufficiency because this indicates that the adrenal gland is not receiving ACTH stimulation. Secondary adrenocortical insufficiency is much more common than primary and can occur when corticosteroids are suddenly withdrawn during pharmacotherapy. Symptoms of primary and secondary adrenocortical insufficiency are the same because both are characterized by inadequate corticosteroid secretion.



The onset of chronic adrenocortical insufficiency is gradual, and it may take several months or even years before an accurate diagnosis is made. Symptoms include hypoglycemia, fatigue, muscle weakness, hypotension, increased skin pigmentation, and GI disturbances such as anorexia, vomiting, and diarrhea. Replacement therapy with corticosteroids is indicated. The goal of replacement therapy is to achieve the same physiologic level of hormones in the blood that would be present if the adrenal glands were functioning properly. Patients requiring replacement therapy usually must take corticosteroids their entire lifetime, and concurrent therapy with a mineralocorticoid such as fludrocortisone is necessary.

Acute adrenocortical insufficiency has a sudden onset and usually occurs when corticosteroids are abruptly withdrawn from a patient who has been on long-term therapy. This is because constant, high amounts of corticosteroid medications provide continuous negative feedback to the hypothalamus and pituitary, shutting down the secretion of ACTH. Without stimulation by ACTH, the adrenal cortex shrinks and stops secreting endogenous corticosteroids, a condition known as **adrenal atrophy**. If the corticosteroid medication is abruptly withdrawn, the shrunken adrenal glands will not be able to secrete sufficient corticosteroids, and symptoms of **adrenal crisis** will appear. Symptoms of this condition include nausea, vomiting, lethargy, confusion, myalgia, arthralgia, fever, asthenia, acute abdominal pain, hypotension, seizures, kidney failure, and coma. Immediate administration of IV hydrocortisone is essential because shock may quickly result if symptoms remain untreated. To prevent adrenal crisis, corticosteroids should be discontinued gradually. The mechanism by which adrenal atrophy is induced by corticosteroid use is illustrated in Pharmacotherapy Illustrated 68.1.

The most frequently prescribed corticosteroids for treating adrenal insufficiency are hydrocortisone, prednisone, and dexamethasone. Doses of these drugs are individualized to the specific amount of replacement therapy needed by the patient, and doses will need to be increased during periods of high stress. Hydrocortisone and dexamethasone can be administered by the intramuscular (IM) or intravenous (IV) routes for acute disease, or orally (PO) for maintenance doses. Prednisone is administered PO. Because dexamethasone and prednisone have little or no mineralocorticoid activity, concurrent fludrocortisone therapy is necessary. Hydrocortisone has some intrinsic mineralocorticoid activity; therefore, concurrent administration

Pharmacotherapy Illustrated 68.1

Corticosteroids and Adrenal Atrophy

of fludrocortisone may not be necessary. Doses for selected corticosteroids are listed in Table 68.2.

Cosyntropin (Cortrosyn) is a drug structurally similar to ACTH that is used as a simple diagnostic test for adrenocortical deficiency. For this test, cosyntropin is injected IV and the plasma levels of cortisol are measured 30 to 60 minutes later. If the adrenal gland responds by secreting corticosteroids after the cosyntropin injection, the pathology lies at the level of the pituitary or hypothalamus (secondary adrenocortical insufficiency). If plasma cortisol levels fail to rise after the injection, the pathology is at the level of the adrenal gland (primary adrenocortical insufficiency).

CONNECTION Checkpoint 68.2

From what you learned in Chapter 43, explain why immunizations are sometimes contraindicated in patients receiving high-dose corticosteroid therapy. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Table 68.2 Selected Corticosteroids

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
betamethasone (Celestone, Diprolene)	PO: 0.6–7.2 mg/day IM: 0.5–9 mg/day	*Mood swings, weight gain, acne, facial flushing, nausea, insomnia, sodium and fluid retention, impaired wound healing, menstrual abnormalities* Peptic ulcer, hypocalcemia, osteoporosis with possible bone fractures, loss of muscle mass, decreased growth in children, possible masking of infections
budesonide (Entocort EC, Pulmicort, Rhinocort)	Intranasal (Rhinocort): 1–2 sprays in each nostril/day (each spray: 32 mcg) PO (Entocort): 9 mg/day	
cortisone	PO: 20–300 mg/day in divided doses	
dexamethasone	PO: 0.25–9 mg/day in divided doses	
hydrocortisone (Cortef, Solu-Cortef, others)	PO: 10–320 mg/day in 3–4 divided doses IV/IM: 15–800 mg/day in 3–4 divided doses (max: 2 g/day)	
methylprednisolone (Depo-Medrol, Medrol, others)	PO: 4–48 mg/day in divided doses	
prednisolone	PO: 5–60 mg 1–4 times/day	
prednisone	PO: 5–60 mg 1–4 times/day	
triamcinolone (Aristospan, Kenalog, others)	PO: 4–48 mg 1–4 times/day	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PROTOTYPE DRUG **Hydrocortisone (Cortef, Solu-Cortef, Others)**

Classification **Therapeutic:** Adrenal hormone
Pharmacologic: Corticosteroid

Therapeutic Effects and Uses: Structurally identical to the natural hormone cortisol, hydrocortisone is a synthetic corticosteroid that is the preferred drug for treating adrenocortical insufficiency. When used for replacement therapy, it is given at physiologic doses. Once proper dosing has been achieved, its therapeutic effects should mimic those of endogenous corticosteroids. Hydrocortisone is also available for the treatment of inflammation, allergic disorders, and many other conditions. Intra-articular injections may be given to decrease severe inflammation in affected joints.

Hydrocortisone is available in six different salts: base, acetate, cypionate, sodium phosphate, sodium succinate, and valerate. Some of the salts, such as hydrocortisone acetate, are designed for topical use, whereas others such as hydrocortisone sodium succinate are for parenteral use only. When administering hydrocortisone, care should be taken to use the correct route for the prescribed formulation of this drug.

Mechanism of Action: The actions of hydrocortisone are complex and the drug is thought to act by multiple mechanisms in different tissues. As a replacement drug, it restores deficient levels of glucocorticoids and, to a lesser extent, mineralocorticoids. As an anti-inflammatory drug, it blocks the actions of various chemical mediators in the inflammatory and allergic responses, including histamine, prostaglandins, and kinins.

Pharmacokinetics:

Route(s)	PO, IV, IM, subcutaneous, rectal, intra-articular, topical
Absorption	Rapid
Distribution	Widely distributed when given PO or parenterally; crosses the placenta; secreted in breast milk; extensively bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	PO: 1–2 h; IM: 20 min
Duration of action	1–1.5 days (PO or IM)

Adverse Effects: When used at low doses for replacement therapy, or by the topical or intranasal routes, adverse effects of hydrocortisone are uncommon. However, signs of Cushing's syndrome can develop with high doses or with prolonged use. Hydrocortisone possesses some mineralocorticoid activity, so sodium and fluid retention may be observed. A wide range of CNS effects have been reported, including insomnia, anxiety, headache, vertigo, confusion, and depression. Cardiovascular effects may include HTN and tachycardia. Long-term therapy may result in peptic ulcer disease, osteoporosis, hyperglycemia, cataracts, HTN, and impaired wound healing.

Contraindications/Precautions: Hydrocortisone is contraindicated in patients who are hypersensitive to the drug or who have known infections, unless the patient is being treated concurrently with anti-infectives. Patients with diabetes, osteoporosis, psychosis, liver disease, or hypothyroidism should be treated with caution. Patients with heart failure (HF) or HTN should be treated with caution due to the possibility of fluid retention with

hydrocortisone. If taken for longer than 2 weeks, hydrocortisone should be discontinued gradually. Caution should be used in treating children because the drug may delay normal growth and development. PO corticosteroids must be used with caution in patients with preexisting GI disease such as peptic ulcers or ulcerative colitis because they may worsen these conditions. Use with potassium-wasting drugs such as thiazide or loop diuretics may increase the risk of hypokalemia. Anticholinesterase drugs may produce severe weakness. Hydrocortisone may cause a decrease in immune response to vaccines and toxoids. Patients on high doses of hydrocortisone should not receive live vaccines due to the possibility of infection. Because hydrocortisone can cause hyperglycemia, doses of insulin and oral hypoglycemic drugs may require adjustment. Vitamin D supplements are recommended to prevent corticosteroid-induced osteoporosis. **Herbal/Food:** Chronic use of aloe, senna, cascara, or buckthorn may cause potassium deficiency.

Pregnancy: Category C.

Treatment of Overdose: Hydrocortisone has no acute toxicity and deaths are rare. No specific therapy is available and patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving hydrocortisone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Systemic Corticosteroids.

Drugs Similar to Hydrocortisone (Cortef, Solu-Cortef, Others)

There are many other corticosteroids, all having the same actions. In addition to hydrocortisone, dexamethasone and prednisone are most frequently used for adrenocortical insufficiency.

Dexamethasone: Dexamethasone is a synthetic corticosteroid that has almost no mineralocorticoid activity. It is 20 to 30 times more potent than hydrocortisone and is available by PO, IV, IM, topical, aerosol, and ophthalmic routes. The parenteral formulations (dexamethasone sodium phosphate) are used for serious disorders such as anaphylaxis, reduction of cerebral edema, or acute adrenocortical insufficiency, or when PO therapy is not possible. Dexamethasone may be injected intra-articularly for the short-term therapy of inflamed joints, or intralesionally into acute inflamed lesions associated with discoid lupus, psoriatic plaques, and granulomatous disorders. It is also indicated for the palliative management of leukemias and lymphomas. Dexamethasone is sometimes found in fixed-dose combinations with antibiotics such as ciprofloxacin to treat otic or ocular infections that have significant inflammation. Systemic forms of the drug are metabolized by the liver to inactive metabolites. Dexamethasone has one of the longest durations of action of any corticosteroid. This drug is pregnancy category C.

Prednisone: Prednisone is rapidly absorbed and is the most frequently prescribed corticosteroid for oral administration. It is about 4 times more potent than hydrocortisone and has a longer duration of action. It has little mineralocorticoid activity. Prednisone is a synthetic corticosteroid whose actions are the result of being metabolized to an active form, which is also available as the drug prednisolone. Although prednisone is available only by the PO route, prednisolone may be administered PO, parenterally, or topically and may be of value in patients with liver impairment because it does not require hepatic activation. Oral solutions (Prelone) and an orally disintegrating tablet (Orapred ODT) are primarily prescribed for treating childhood asthma. When used for inflammation, duration of prednisone therapy is commonly 4 to 10 days. For long-term therapy, alternate-day dosing is used. Prednisone is occasionally used to terminate acute bronchospasm in patients with asthma and as an antineoplastic drug for cancers such as Hodgkin's disease, acute childhood leukemias, and lymphomas. Prednisone has the same adverse effects and contraindications as hydrocortisone. This drug is pregnancy category C.

Corticosteroids for Nonendocrine Conditions

68.5 Corticosteroids are frequently used to suppress the inflammatory and immune responses.

One of the most important physiologic effects of corticosteroids is their natural ability to dampen the immune response and inhibit the synthesis of inflammatory mediators. When used to treat conditions characterized by hyperactive body defenses, the anti-inflammatory effects of the corticosteroids are therapeutic. When the drugs are administered as replacement therapy, however, suppression of the immune response can result in an increased incidence of infections.

Part of the reason for the effectiveness of the corticosteroids in reducing inflammation and the immune response is that they act by multiple mechanisms. These mechanisms include the following:

- Decreased numbers of circulating lymphocytes, eosinophils, monocytes, and basophils
- Inhibited movement of macrophages and leukocytes to areas of inflammation
- Decreased production of inflammatory cytokines, including histamine, bradykinin, interferons, interleukins, and granulocyte-macrophage colony-stimulating factor
- Decreased formation of prostaglandins.

It is important to note that the doses necessary to treat inflammatory and other nonendocrine diseases are much

CONNECTIONS: Lifespan Considerations

Corticosteroid Use by Mothers at Risk for Preterm Labor

Giving corticosteroids to mothers at risk for preterm labor helps to develop the baby's lungs and reduces the chance for serious complications such as infant respiratory distress syndrome if the baby is born preterm. However, the benefit does not last long, approximately 7 days. Due to concerns about effects on birth weight and later childhood disabilities related to repeated corticosteroid use, repeated doses may not be ordered. Crowther, McKinlay, Middleton, and Harding (2015) conducted an analysis of 10 randomized controlled trials found in the Cochrane Pregnancy and Childbirth Group's Trials Register to assess the effect of repeated corticosteroid use prior to preterm labor. Repeated dosages were found to have positive effects in reducing the risk for respiratory distress syndrome in the newborn. Although slight reductions in mean birth weight were noted in these babies, when adjusted for gestational age, these differences were insignificant. And no statistically significant differences in disability outcomes were noted at early childhood follow-up assessments between children whose mothers had received repeated corticosteroids and those who had not received the drug. The authors concluded that the research supports the use of repeated corticosteroids for women at risk for preterm birth to reduce the incidence of respiratory distress and serious health problems in the infant.

Recently, research seems to suggest that optimal timing of drug administration, generally accepted as 7 days before delivery, may be difficult to plan when the outcome of preterm labor is not clear. Rupture of the membranes, cervical dilation over 2 cm, and changes in cervical length have been used to time drug administration (Adams, Kinzler, Chavez, Fazzari, & Vintzileos, 2015; Aghajanian, Nguyen, Greene, & Gregory, 2016). Corticosteroids used in preterm labor may also increase the risk of neonatal death due to infection, especially when healthcare resources are suboptimal, and special care and observation of the newborn are crucial (Althabe et al., 2016).

higher than those used to treat adrenocortical insufficiency. For example, a daily maintenance dose of prednisone for a patient with Addison's disease is 7.5 mg/day. This amount approximates what would normally be secreted by the adrenal glands. Daily doses of prednisone for nonendocrine disorders range from 5 to 30 mg for transplant prophylaxis; 80 mg for chronic lymphocytic leukemia; 40 to 60 mg for Crohn's disease; and 20 to 300 mg for systemic lupus erythematosus. At these high doses, the adverse effects of corticosteroids will quickly manifest and the adrenal gland will begin to atrophy in only 2 to 4 weeks. Interventions should be planned to prevent anticipated adverse effects.

Arthritis: Arthritis is one of the most common diseases affecting older adults. Rheumatoid arthritis (RA) is a chronic autoimmune disease that causes inflammation of joints and is characterized by disfigurement and inflammation of multiple joints. Osteoarthritis is also a progressive joint disease, but it occurs with more advanced age and is characterized by less inflammation than RA. Both types of arthritis are treated with NSAIDs early in the course of the disease. Corticosteroids are administered when inflammation becomes severe, with therapy being limited to 1 to 2 weeks, or until the pain and inflammation subside. If the pain and inflammation are localized to one or two joints, intra-articular injections may be used. Corticosteroids offer only symptomatic treatment and do not alter the course of either type of arthritis. Arthritis pharmacotherapy is presented in Chapter 72.

Inflammatory bowel disease: Inflammatory bowel disease (IBD) is characterized by ulceration in the distal portion of the small intestine (Crohn's disease) or in the large intestine (ulcerative colitis). Various drugs, including the 5-aminosalicylic acid drugs, are used to control inflammation, cramping, and diarrhea. Exacerbations are treated with corticosteroids for brief time periods. Budesonide (Entocort-EC, Uceris) is a corticosteroid that has a delayed release and remains in the intestine to treat the inflammation locally, without causing significant systemic effects. IBD pharmacotherapy is presented in Chapter 60.

Asthma: Asthma is characterized by chronic inflammation that causes bronchoconstriction in the respiratory passages. Inhaled corticosteroids are preferred drugs for the prevention of asthmatic attacks and the management of chronic asthma. The inhaled drugs produce few systemic adverse effects. Oral corticosteroids are used for the short-term management of acute asthma exacerbations. Asthma pharmacotherapy is presented in Chapter 44.

Allergies: Allergic rhinitis is inflammation of the nasal mucosa caused by exposure to allergens. Corticosteroids are applied directly to the nasal mucosa to prevent symptoms of allergic rhinitis. They have largely replaced antihistamines as preferred drugs for this condition. When administered intranasally, the corticosteroids do not exhibit systemic adverse effects. For acute allergies, corticosteroids may be administered parenterally. Because their onset of action is slow, however, they are always administered concurrently with other drugs, such as epinephrine, for this indication. The pharmacotherapy of allergic rhinitis is presented in Chapter 45.

Transplant rejection prophylaxis: Successful tissue transplantation requires the use of immunosuppressant

drugs; otherwise, the patient's immune system would reject the transplant. One or more immunosuppressants are administered at the time of transplantation and are continued for several months following surgery. Corticosteroids are part of most therapeutic regimens to prevent transplant rejection. They may be used for several weeks or maintained for 3 to 6 months following surgery. The prophylaxis of transplant rejection is presented in Chapter 42.

Dermatologic conditions: Topical corticosteroids are the most effective therapy for treating the inflammation and itching of dermatitis. These corticosteroids are specially formulated to penetrate deep into the skin layers. Topical corticosteroids such as betamethasone and hydrocortisone acetate are also the primary, initial treatment for psoriasis. High-potency corticosteroids are used for 1 to 2 weeks, followed by moderate- to low-potency corticosteroids for maintenance therapy. The pharmacotherapy of dermatologic diseases is presented in Chapter 73.

Neoplasms: Corticosteroids such as prednisone and dexamethasone are used as adjuncts in the treatment of certain neoplasms, especially acute childhood leukemias and Hodgkin's disease. They are always used in combination with other antineoplastics. The pharmacotherapy of cancer is presented in Chapter 57.

Edema: Corticosteroids are occasionally used to treat disorders characterized by edema. They have been used for many years to reduce intracranial edema associated with trauma, tumors, and cerebral ischemia. These hormones tend to stabilize capillary membranes. Their effectiveness in treating edema is controversial.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Systemic Corticosteroids

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, respiratory, neurologic, hepatic, or kidney disease; pregnancy; or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], platelets, electrolytes, glucose, lipid profile, hepatic or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., signs and symptoms of inflammation such as redness or swelling are decreased).
- Continue periodic monitoring of CBC, platelets, electrolytes, glucose, lipid profile, hepatic or renal function studies.
- Assess vital signs and weight periodically or if symptoms warrant. Obtain weight daily and report any gain over 1 kg (2 lb) in a 24-h period or more than 2 kg (5 lb) in 1 week. Obtain height and weight of children on long-term corticosteroid therapy.
- Assess for and promptly report adverse effects: nausea, vomiting, symptoms of GI bleeding (dark or tarry stools, hematemesis, coffee-ground emesis, blood in the stool), abdominal pain, dizziness, lightheadedness, confusion, agitation, euphoria or depression, palpitations, tachycardia, HTN, increased respiratory rate and depth, pulmonary congestion, significant weight gain, edema, blurred vision, fever, or infections.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished inflammation, allergic response, and increased feelings of wellness should begin after taking the first dose and continue to improve.)	• Teach the patient to report any return of original symptoms or an increase in inflammation, allergic response, or generalized malaise to the healthcare provider.
Minimizing adverse effects: • Continue to monitor vital signs, especially blood pressure (BP) and pulse. Immediately report tachycardia or BP over 140/90 mmHg, or per parameters as ordered, to the healthcare provider. (Corticosteroids may cause increased BP, HTN, and tachycardia due to increased retention of fluids.)	• Teach the patient how to monitor pulse and BP. Ensure proper use and functioning of any home equipment obtained. Immediately report tachycardia, palpitations, or increased BP to the healthcare provider.
• Continue to monitor periodic laboratory work: CBC, electrolytes, glucose, lipid levels, and hepatic and renal function tests. (Corticosteroids have effects on the CBC and may cause hyperglycemia, hypernatremia, hyperlipidemia, and hypokalemia. Patients with diabetes may require a change in antidiabetic medication if the glucose remains elevated.)	• Instruct the patient on the need to return periodically for laboratory work. • Advise the patient taking corticosteroids long term to carry a wallet identification card and wear medical identification jewelry indicating corticosteroid therapy. • Teach the patient with diabetes to test for blood glucose more frequently, notifying the healthcare provider if a consistent elevation is noted.
• **Lifespan:** Monitor symptoms in older adults more frequently. (Older patients are at increased risk of adverse effects in all body systems due to normal physiologic changes related to aging.)	• Teach the patient, family, or caregiver to follow administration guidelines. Any significant change in symptoms should be promptly reported to the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for and report abdominal pain, black or tarry stools, blood in the stool, hematemesis, coffee-ground emesis, dizziness, lightheadedness, and hypotension, especially if associated with tachycardia. (GI bleeding is an adverse drug effect.)	• Instruct the patient to immediately report any signs or symptoms of GI bleeding. • Teach the patient to take the drug with food or milk to decrease GI irritation. Alcohol use should be eliminated.
• Monitor for signs and symptoms of infection in patients taking corticosteroids. (Corticosteroids suppress the body's normal immune and inflammatory response and may mask the signs and symptoms of infection.)	• Instruct the patient to report any signs or symptoms of infection (e.g., increasing temperature or fever, sore throat, redness or swelling at the site of injury, white patches in the mouth, vesicular rash).
• Monitor for osteoporosis (e.g., bone density testing) periodically in patients on long-term corticosteroids. Encourage adequate calcium intake, weight-bearing exercise, and avoidance of carbonated sodas. (Corticosteroids affect bone metabolism and may cause osteoporosis and fractures. Weight-bearing exercise stresses bone and encourages normal bone remodeling. Excessive or long-term consumption of carbonated sodas has been linked to an increased risk of osteoporosis.)	• Teach the patient to maintain adequate calcium in the diet, avoid carbonated sodas, and do weight-bearing exercises at least 3–4 times per week. • Teach postmenopausal women and patients on prolonged corticosteroid therapy to consult with their provider about the need for vitamin D or additional drug therapy (e.g., bisphosphonates) for osteoporosis prevention.
• Monitor for unusual changes in mood or affect. (Corticosteroids may cause increased or decreased mood, euphoria, depression, or severe mental instability.)	• Teach the patient, family, or caregiver to promptly report excessive mood swings or unusual changes in mood.
• Weigh the patient daily and report a gain of 1 kg (2 lb) or more in a 24-h period, or more than 2 kg (5 lb) per week, or increasing peripheral edema. Measure intake and output in the hospitalized patient. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Patients will experience some fluid retention but should report weight gain, as above, or edema to the healthcare provider.)	• Instruct the patient to weigh self daily, ideally at the same time of day. The patient should report weight gain of more than 1 kg (2 lb) in a 24-h period, or more than 2 kg (5 lb) per week, or increasing peripheral edema to the healthcare provider.
• **Lifespan:** Monitor height and weight in children. (Children receiving long-term corticosteroid therapy should continue to display normal growth and development curves.)	• Teach the parents or caregivers to weigh the child periodically at home and record. Bring the record to each healthcare visit. • Encourage the parents or caregivers to discuss concerns or any unusual findings that would suggest developmental or growth delays with the healthcare provider if they are noted in the child between healthcare visits.
• Monitor vision periodically in patients taking corticosteroids. (Corticosteroids may cause increased intraocular pressure and an increased risk for glaucoma, and may cause cataracts.)	• Teach the patient to have eye examinations twice yearly or more frequently as instructed by the healthcare provider. Immediately report any eye pain, rainbow halos around lights, diminished vision, blurring, and inability to focus.
• Do not stop the drug abruptly. Drug dosages must be tapered off if used for longer than 1–2 wk. (Adrenal insufficiency and crisis may occur with profound hypotension, tachycardia, and other adverse effects if the drug is stopped abruptly.)	• Teach patients to not stop corticosteroids abruptly and to notify the healthcare provider if unable to take medication for more than 1 day due to illness.
• Patients taking corticosteroids as replacement therapy for adrenal insufficiency should obtain and carry PO and injectable medication forms, especially when traveling. (In an emergency, replacement medication may not be readily available and the patient may be unable to take an oral dose. Having doses readily available ensures that the drug can be taken or given if another replacement is not available.)	• Instruct patients on replacement therapy to obtain and carry replacement doses in both PO and parenteral forms for emergency use.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., with food or milk, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching. Household measuring devices such as teaspoons differ significantly in size and amount and should not be used for pediatric or liquid doses.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs, including:
	  • Take the drug in the morning at the same time each day.
	  • Take the drug with food, milk, or a meal to prevent GI upset.
	  • Do not use household measuring spoons to measure liquid or pediatric doses. Use the measuring device included with the drug or obtain a dose syringe or other device from a pharmacy or the healthcare provider.

Mineralocorticoids

68.6 Patients with adrenal insufficiency often require replacement therapy with mineralocorticoids.

Aldosterone is the primary hormone regulating sodium and potassium balance in the body. Regulation of aldosterone secretion is through activation of the renin-angiotensin-aldosterone system. When plasma volume falls, the kidney secretes renin, which results in the production of angiotensin II. Angiotensin II then promotes aldosterone secretion, which in turn acts on the renal tubules to promote sodium and water retention and increased excretion of potassium.

Lack of adequate aldosterone secretion, or **hypoaldosteronism**, may be caused by a number of disorders. The three broad categories of hypoaldosteronism are as follows:

- **Decreased stimulation of the adrenal cortex.** Beta blockers, NSAIDs, and calcium channel blockers may reduce renin serum levels and suppress the stimulation of aldosterone secretion. Angiotensin-converting enzyme (ACE) inhibitors block the formation of angiotensin II, which is the normal signal for aldosterone secretion.
- **Hyposecretion of aldosterone.** Low aldosterone secretion may result from primary adrenal insufficiency (Addison's disease), which is usually a deficiency in the secretion of both glucocorticoids and mineralocorticoids. Heparin can also suppress aldosterone synthesis and secretion.
- **Aldosterone resistance.** The renal tubules may become resistant to the actions of aldosterone. Aldosterone resistance occurs during diseases of the renal tubules and may also result from therapy with spironolactone (Aldactone) or progestins.

Whenever possible, the cause of hypoaldosteronism is identified and treated. In some cases, replacement therapy with fludrocortisone is necessary.

Excessive secretion of aldosterone, or **hyperaldosteronism**, is usually caused by a benign tumor of the adrenal gland. Also known as Conn's syndrome, symptoms include HTN caused by fluid retention and muscle weakness due to hypokalemia. Surgical excision of the adrenal tumor is the preferred treatment for most patients; however, pharmacotherapy with spironolactone (Aldactone) may benefit patients whose surgical risk is high. Spironolactone is a potassium-sparing diuretic that blocks the actions of aldosterone in the renal tubule. Spironolactone is featured as a drug prototype in Chapter 32.

CONNECTION Checkpoint 68.3

From what you learned in Chapter 31, name the two drugs classified as aldosterone antagonists and give their indications. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Fludrocortisone**

Classification **Therapeutic:** Drug for hypoaldosteronism
Pharmacologic: Mineralocorticoid

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1954, fludrocortisone is an oral corticosteroid that possesses a high degree of mineralocorticoid activity that mimics aldosterone. Although it has some glucocorticoid activity, this action is minimal at therapeutic doses. It is approved for the treatment of Addison's disease and for salt-losing forms of adrenogenital syndrome, a life-threatening congenital disorder that occurs during the first few weeks of life. It has been used off-label to treat neurogenic orthostatic hypotension.

Mechanism of Action: Fludrocortisone has the same pharmacologic actions as aldosterone. It acts on the distal renal tubule to promote sodium and water reabsorption and increased urinary potassium excretion.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Distributed to most tissues; crosses the placenta; secreted in breast milk; highly bound to plasma protein
Primary metabolism	Hepatic to inactive metabolites
Primary excretion	Renal
Onset of action	Peak plasma level: 1.5 h
Duration of action	Half-life: 3.5 h

Adverse Effects: Most adverse effects of fludrocortisone are the result of excessive mineralocorticoid activity: sodium and fluid retention, edema, cardiomegaly, HTN, and HF. Excessive urinary loss of potassium may result in symptoms of hypokalemia: nausea, vomiting, prolongation of the QT interval, muscle cramps, and fatigue.

Contraindications/Precautions: Fludrocortisone must be used with caution if the patient has any disorders in which fluid accumulation could be hazardous, such as HF, HTN, chronic kidney disease (CKD), or hepatic impairment. Because the drug has glucocorticoid properties that

could lead to immunosuppression, it should not be administered to patients with a known systemic fungal infection.

Drug Interactions: If used with drugs that cause potassium loss, fludrocortisone use will result in additive hypokalemia. Potassium-wasting drugs include thiazide and loop diuretics and amphotericin B. Fludrocortisone should be used with caution in patients taking digoxin due to the potential for hypokalemia-induced digoxin toxicity. Concurrent use with androgens may cause additive sodium retention and edema. Fludrocortisone may affect glycemic control in patients with diabetes; doses of antidiabetic drugs may need to be increased. **Herbal/Food:** Sodium intake should be monitored because high levels may lead to sodium retention.

Pregnancy: Category C.

Treatment of Overdose: Overdosage results in HTN, edema, and hypokalemia. Treatment is symptomatic. Potassium supplements may be beneficial.

Nursing Responsibilities: Key nursing implications for patients receiving fludrocortisone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Systemic Corticosteroids.

Drugs Similar to Fludrocortisone

Fludrocortisone is the only drug in its class.

Antiadrenal Drugs

68.7 Antiadrenal drugs may be administered to lower serum corticosteroid levels in patients with Cushing's syndrome.

Cushing's syndrome occurs when high levels of corticosteroids are present in the body over a prolonged time period. Although hypersecretion of these hormones can occur due to pituitary or adrenal tumors, the most common cause of Cushing's syndrome is long-term therapy with high doses of systemic corticosteroids. Signs and symptoms include adrenal atrophy, osteoporosis, HTN, increased risk of infections, delayed wound healing, acne, peptic ulcers, general obesity, and a redistribution of fat around the face (moon face), shoulders, and neck (buffalo hump). Mood and personality changes are common, and the patient may become psychologically dependent on the drug. Some corticosteroids, including hydrocortisone, also have mineralocorticoid activity and can cause retention of sodium and water. Because of their anti-inflammatory and immunosuppressant properties, corticosteroids may mask signs of infection. It is important to note that corticosteroids do not have anti-infective properties. Even though the patient may not exhibit signs and symptoms of infections, the microorganisms continue duplicating and spreading. This could result in a delay in the initiation of antibiotic therapy.

PharmFACT

Cushing's syndrome caused by adrenal or pituitary tumors is quite rare, has a peak incidence between the ages of 25 and 40 years, and afflicts 5 times as many women as men (Nguyen, 2017).

Because Cushing's syndrome has a high mortality rate, medical intervention is necessary. The primary therapeutic goal is to identify and treat the cause of the excess corticosteroids. If the patient is receiving high doses of a corticosteroid medication, gradual discontinuation of the drug is usually sufficient to reverse the syndrome. When the cause of the hypersecretion is an adrenal tumor or an ectopic tumor secreting ACTH, surgical removal is indicated.

When removal of the tumor is not possible, a secondary option is to administer medications to reduce the excess cortisol secretion. The antifungal drug ketoconazole has been the traditional drug for long-term therapy of Cushing's syndrome. Used off-label for this indication, ketoconazole rapidly blocks the synthesis of glucocorticoids, lowering serum levels. Unfortunately, the falling glucocorticoid level signals the pituitary to release more ACTH. Eventually, the very high levels of ACTH may overcome ketoconazole's inhibition of glucocorticoid synthesis. Although effective, ketoconazole carries a black box warning that it should be used only for fungal infections that have not responded to other medications due to the potential for serious hepatotoxicity.

A newer approach is the drug pasireotide (Signifor), which was approved in 2012 to treat Cushing's syndrome in patients for whom pituitary surgery is not an option. Pasireotide is closely related to somatostatin (growth hormone–inhibiting hormone). Binding of pasireotide to somatostatin receptors causes inhibition of ACTH secretion by the pituitary and subsequently corticosteroid secretion from the adrenals. Given by the subcutaneous route, several weeks or months of therapy may be needed for optimal suppression of corticosteroid secretion. The drug is pregnancy category C.

Mitotane (Lysodren) is an antineoplastic drug that is specific for cells of the adrenal cortex. It is approved to treat inoperable tumors of the adrenal gland. Although not specifically approved for Cushing's syndrome, it will reduce symptoms of this disorder if they are caused by an adrenal cancer. Gastrointestinal symptoms such as anorexia, nausea, and vomiting will occur in 80% of patients. CNS adverse effects, including depression, lethargy, and dizziness, occur in 40% of patients. The drug is pregnancy category C.

Understanding Chapter 68

Key Concepts Summary

68.1 The adrenal glands secrete gonadocorticoids, mineralocorticoids, and corticosteroids.

68.2 Corticosteroids are widely used, and all drugs in the class have similar indications, actions, and adverse effects.

68.3 Long-term therapy with corticosteroids has the potential to cause serious adverse effects in multiple body systems.

68.4 Adrenocortical insufficiency is treated by administering physiologic levels of corticosteroids.

68.5 Corticosteroids are frequently used to suppress the inflammatory and immune responses.

68.6 Patients with adrenal insufficiency often require replacement therapy with mineralocorticoids.

68.7 Antiadrenal drugs may be administered to lower serum corticosteroid levels in patients with Cushing's syndrome.

CASE STUDY: Making the Patient Connection

Remember the patient "Charlie Harness" from the beginning of the chapter? Now read the remainder of the story. Based on the information presented within this chapter, answer the critical thinking questions that follow.

Charlie Harness is a 36-year-old man who, while clearing out weeds and brush in his yard, pulled up a patch of poison ivy. He was not concerned about the incident because he had never reacted to poison ivy in the past. Later that afternoon, he experienced intense itching, first on his hands and arms, which then spread to his chest, shoulder, and back. A macular rash appeared on his arms and small blisters erupted on his hands. He is seen in the local urgent care clinic by the nurse practitioner, who diagnosed the rash as allergic dermatitis caused by poison ivy and prescribed prednisone 60 mg/day for 4 days, then tapering by 10 mg every 2 days for a 14-day treatment regimen.

Critical Thinking Questions

1. Why has Charlie reacted to the poison ivy now when he has had no reaction to previous exposures?
2. Why would the nurse practitioner use a 14-day prednisone taper and not a Medrol Dosepak for Charlie?
3. What would you teach Charlie about not abruptly discontinuing this medication before completing the entire taper? Why?
4. Charlie asks you if there are any additional precautions that he should take related to his exposure. How would you respond?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Monica Hamric, a 53-year-old woman, is referred to the endocrinologist for evaluation after being seen by the advanced practice nurse. She has a history of systemic lupus erythematosus, managed with corticosteroids, and has begun to experience weight gain, facial hirsutism with thinning of the hair on her head, spontaneous bruising, muscle weakness, and a recent diagnosis of diabetes. She has been taking prednisone (Deltasone) for the past 3 months. The physical examination reveals that Monica has developed a "buffalo hump" on her shoulder and red striae on her abdominal and underarm areas. Her blood pressure is also elevated, measuring 162/100 mmHg. The healthcare provider has diagnosed Monica with Cushing's syndrome related to her prednisone use. Monica will be withdrawn from the prednisone and started on immunosuppressant therapy. Because she has taken the prednisone for some time, how do you anticipate the drug will be stopped and why?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient has been given a few prescriptions for acute bronchitis. One of the prescriptions is for methylprednisolone (Medrol Dosepak). The nurse will teach the patient to report which adverse effects to the healthcare provider? (Select all that apply.)
   1. Edema
   2. Tinnitus
   3. Eye pain or vision changes
   4. Dizziness upon standing
   5. Abdominal pain

2. A patient has been taking a thiazide diuretic for treatment of hypertension and has been prescribed hydrocortisone (Cortef) for a significant allergic reaction to shellfish. Which symptom should be immediately reported to the provider?
   1. Irregular heart rate and rhythm
   2. Delayed wound healing
   3. Weight gain of 2 to 3 pounds in 1 week
   4. Elevated serum lipid levels

3. An older adult patient with chronic bronchitis has been receiving low-dose therapy with dexamethasone for several months to reduce the inflammation occurring secondary to the bronchitis. What teaching should this patient receive to reduce the risk of osteoporosis related to dexamethasone use? (Select all that apply.)
   1. Perform weight-bearing exercises at least 3 to 4 times weekly.
   2. Increase dietary intake of calcium and vitamin D–rich foods.
   3. Remain sedentary except during periods of exercise.
   4. Increase fluid intake, including carbonated sodas, but avoid alcohol.
   5. Request a prescription for a bisphosphonate drug from the provider.

4. A patient with adrenocortical insufficiency has started therapy with fludrocortisone. What important intervention related to this drug therapy should the nurse teach the patient?
   1. "Report any abdominal pain or changes in your stool color."
   2. "Return monthly for laboratory work to assess blood lipid levels."
   3. "Report any unusual changes in your mood."
   4. "Weigh yourself daily, ideally at the same time each day."

5. A patient who has been taking dexamethasone for rheumatoid arthritis was unable to take the drug for several days due to an intestinal virus. The patient seeks treatment in the emergency department for complaints of severe nausea, vomiting, lethargy, fever, and hypotension. What drug does the nurse anticipate will be given to this patient?
   1. Fludrocortisone
   2. Ketoconazole (Nizoral)
   3. Hydrocortisone (Solu-Cortef)
   4. Mitotane (Lysodren)

6. A patient with chronic adrenal insufficiency taking hydrocortisone (Cortef) and fludrocortisone is planning a family vacation. What essential teaching does this patient need prior to taking this trip?
   1. "Take your blood pressure once or twice while you're gone."
   2. "Avoid crowded indoor areas to avoid infections."
   3. "Have your vision checked before you leave."
   4. "Carry an oral and injectable form of both drugs with you on your trip."

Chapter 69
Estrogens, Progestins, and Drugs Modifying Uterine Function

Chapter Outline

- Hormonal Regulation of Female Reproductive Function
- Estrogens

  PROTOTYPE *Conjugated Estrogens (Cenestin, Enjuvia, Premarin), p. 1265*
- Progestins

  PROTOTYPE *Medroxyprogesterone (Depo-Provera, Depo-SubQ-Provera, Provera), p. 1269*
- Hormone Replacement Therapy
- Uterine Stimulants: Oxytocics

  Ergot Alkaloids

  Prostaglandins

  PROTOTYPE *Oxytocin (Pitocin), p. 1274*
- Uterine Relaxants: Tocolytics
- Pharmacotherapy of Female Infertility and Female Sexual Desire Disorder

  PROTOTYPE *Clomiphene (Clomid, Serophene), p. 1281*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the roles of the hypothalamus, pituitary, and ovaries in maintaining female reproductive function.
2. Identify indications for estrogen pharmacotherapy.
3. Identify indications for progestin pharmacotherapy.
4. Compare and contrast the advantages and disadvantages of hormone replacement therapy during menopause.
5. Explain the use of uterine stimulants to promote labor and delivery.
6. Discuss the use of uterine relaxants in suppressing preterm labor.
7. Explain how drug therapy may be used to treat female infertility.
8. Describe the nurse's role in the pharmacologic management of disorders and conditions of the female reproductive system.
9. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
10. Apply the nursing process to the care of patients receiving pharmacotherapy for disorders and conditions of the female reproductive system.

tocolytics, 1277

The steroid hormones estrogen and progesterone are responsible for the growth, development, and reproductive health of females throughout the lifespan. Deficiencies or excesses of these hormones can result in profound changes that extend beyond the reproductive system. These hormones impact virtually every body system including effects on coagulation, blood vessels, bone, muscles, overall body metabolism, and behavior. Stimulating hormones from the pituitary also affect reproductive function, including fertility, labor, delivery, and the production and ejection of breast milk. This chapter examines hormones and drugs used to treat conditions associated with the female reproductive system.

Hormonal Regulation of Female Reproductive Function

69.1 Regulation of the female reproductive system is achieved by hormones from the hypothalamus, pituitary gland, and ovary.

The two primary hormones of the female reproductive system are estrogen and progesterone. During a woman's childbearing years, nearly all estrogen and progesterone is secreted by the ovaries. Small amounts of estrogen are secreted by nonreproductive organs, including the adrenal glands, liver, kidney, skeletal muscle, and adipose tissue. In postmenopausal women, nearly all estrogen and progesterone is secreted by these nonreproductive tissues. In men, estrogen and progesterone are also secreted in small amounts by the testes.

Unlike men, who secrete steady and continuous levels of testosterone throughout adult life, secretion of the female sex hormones is variable and complex. Knowledge of these complexities is essential to understanding the pharmacotherapy of the female reproductive system. Although this section reviews physiology that is relevant to drug therapy, the student should refer to an anatomy and physiology textbook for more detailed information.

Secretion of female reproductive hormones varies on a 28-day menstrual cycle. The menstrual cycle is described by changes that occur in the ovaries (ovarian cycle) and in the lining of the uterus (uterine cycle). Both cycles are controlled by hormones from the hypothalamus and pituitary. The first day of menstruation is considered day 1 of the cycle. The hormonal changes that occur during the ovarian and uterine cycles are illustrated in Figure 69.1.

The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which travels a short distance to the pituitary to stimulate the secretion of the gonadotropins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Both of these anterior pituitary hormones act on the ovary and promote the development of immature ovarian follicles. Under the influence of FSH and LH, several ovarian follicles begin the maturation process each month during the reproductive lifespan. As ovarian follicles mature, they secrete increasing amounts of estrogen. On approximately day 14 of the ovarian cycle, a surge of LH (and to a lesser extent FSH) secretion causes one follicle to expel its oocyte (egg), a process called **ovulation**. The LH surge is an absolute requirement for ovulation and, thus, conception. The oocyte begins its journey through the uterine tube and eventually reaches the uterus.

The ruptured follicle, minus the oocyte, remains in the ovary and is transformed into the **corpus luteum**, an endocrine tissue that secretes steadily increasing amounts of progesterone for the next 12 days. Progesterone thickens the uterine mucosa, readying this organ for implantation and potential pregnancy.

High progesterone and estrogen levels in the final third of the uterine cycle provide negative feedback to shut off GnRH, FSH, and LH secretion, as illustrated in Figure 69.2. Without stimulation from FSH and LH, estrogen and progesterone levels fall sharply, the endometrium is shed, and menstrual bleeding begins a new monthly cycle.

Estrogens

69.2 Estrogens are administered as replacement therapy, to prevent conception, and for certain neoplasms.

Estrogen is a general term for three different steroid hormones: estradiol, estrone, and estriol. Estradiol is present in

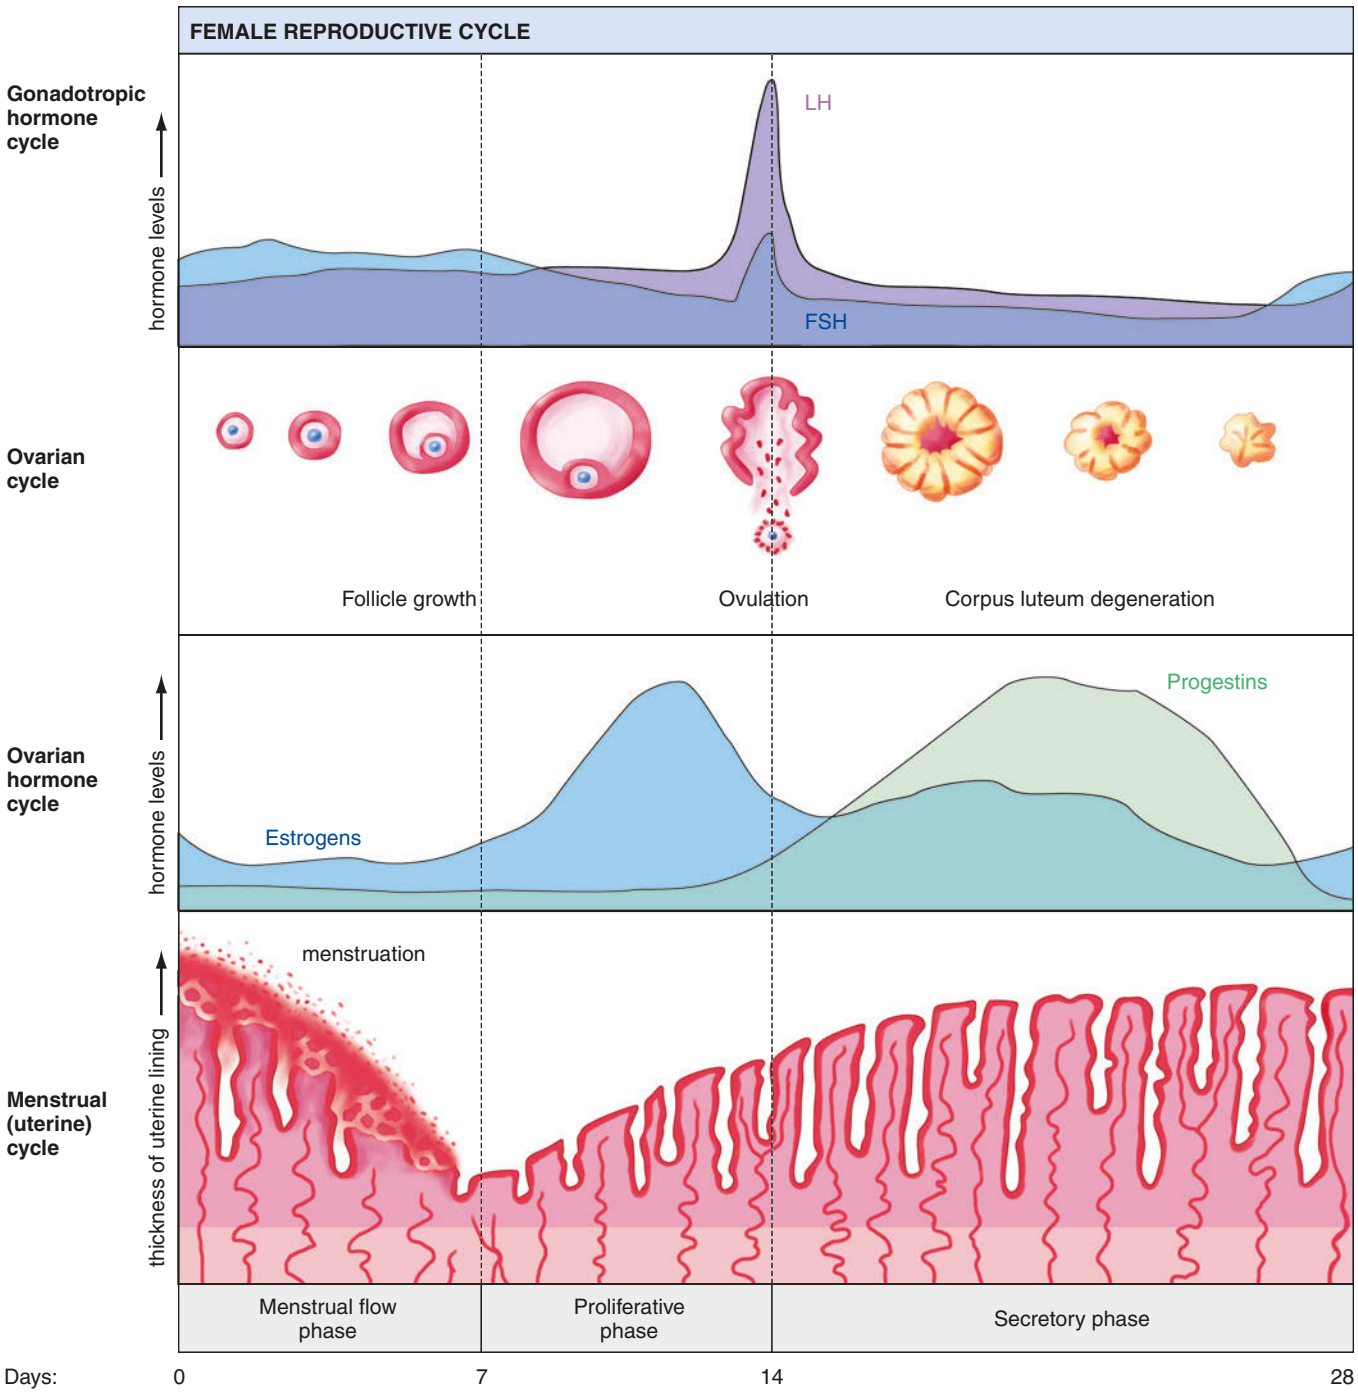

Figure 69.1 Hormonal changes during the ovarian and uterine cycles.

the body in the largest amount. Estrogens are responsible for the maturation of the reproductive organs and for the appearance of the secondary sex characteristics of the female during puberty. When women enter menopause around ages 50 to 55, the secretion of estrogen by the ovaries diminishes and eventually stops.

Apart from its reproductive functions, estrogen also affects the heart, liver, blood vessels, and bones. Estrogen decreases the levels of low-density lipoprotein (LDL) and increases the amount of high-density lipoprotein (HDL) in the blood. These effects are cardioprotective and help lower the risk of myocardial infarction (MI) in premenopausal women. By blocking resorption of the bony matrix, estrogen causes bones to grow longer and stronger in younger women. As estrogen levels decrease in postmenopausal women, the risk of osteoporosis and bone fractures dramatically increases.

Estrogens are used as contraception and to treat menopausal symptoms, female hypogonadism, and primary ovarian failure. When used as replacement therapy following surgical removal of the ovaries, estrogen is usually combined with a progestin. The purpose of the progestin is to counteract some of the adverse effects of estrogen on the

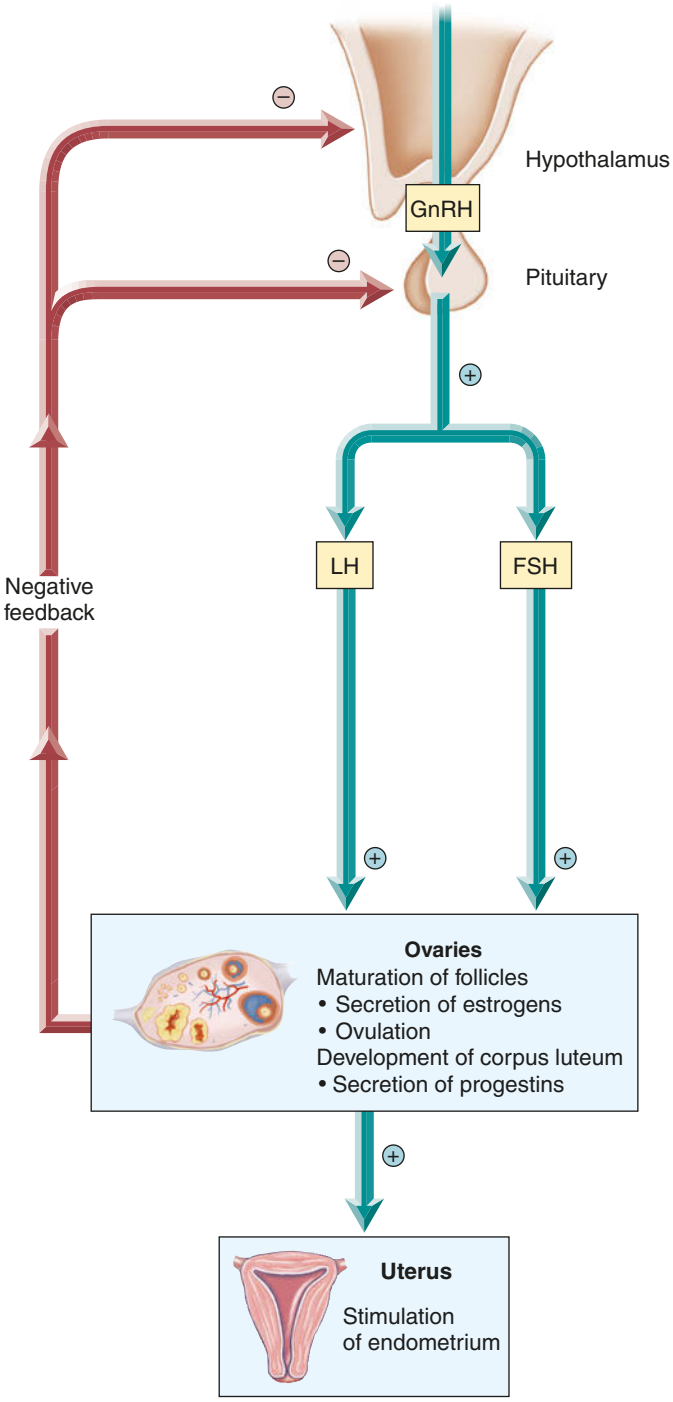

Figure 69.2 Negative feedback control of the female reproductive hormones.

uterus. Estrogen drugs are listed in Table 69.1. The contraceptive uses of estrogen are presented in Chapter 70.

High doses of estrogens are sometimes used to treat advanced prostate and breast cancer. Prostate cancer is usually dependent on androgens for growth, and administration of estrogens will suppress androgen secretion. In the treatment of cancer, estrogen is nearly always used in combination with other antineoplastics.

PROTOTYPE DRUG **Conjugated Estrogens (Cenestin, Enjuvia, Premarin)**

Classification **Therapeutic:** Hormone
Pharmacologic: Estrogen

Therapeutic Effects and Uses: Conjugated estrogen, equine (Premarin) was approved by the U.S. Food and Drug Administration (FDA) in 1938 and contains a mixture of different natural estrogens, traditionally obtained from pregnant mares' urine. Conjugated estrogen A (Cenestin) and conjugated estrogen B (Enjuvia) contain a mixture of 9 to 10 different synthetic plant estrogens.

The primary indication for conjugated estrogens has been to treat moderate to severe vasomotor symptoms of menopause, such as hot flashes and night sweats, caused by diminished estrogen secretion by the ovaries. Topical preparations may be used to treat symptoms associated with menopause such as vulvar or vaginal atrophy and dyspareunia (pain during intercourse). Replacement therapies include treatment of female hypogonadism and use following oophorectomy. Premarin is approved for the palliative treatment of prostate cancer and certain types of breast cancer. Conjugated estrogens have been used in the past for osteoporosis prophylaxis in postmenopausal women, but safer therapies have replaced these drugs for this indication.

Conjugated estrogens are usually administered by the oral (PO) route. For dysfunctional uterine bleeding, they may be administered by the intramuscular (IM) or intravenous (IV) routes.

Mechanism of Action: Conjugated estrogens bind to intracellular estrogen receptors that stimulate deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) to synthesize proteins responsible for the biologic effects of estrogens.

Pharmacokinetics:

Route(s)	PO, IM, IV, intravaginal
Absorption	Rapid absorption from the gastrointestinal (GI) tract, readily absorbed through the skin and mucous membranes, slow absorption through IM injections
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; bound primarily to albumin
Primary metabolism	Hepatic metabolism by CYP3A4 to estrone, estradiol, and estriol
Primary excretion	Renal
Onset of action	PO: 30–60 min; IM: 15–30 min
Duration of action	Half-life: 4–18 h

Adverse Effects: The most frequently reported adverse effects of conjugated estrogens include headache,

Table 69.1 Selected Estrogens and Progestins

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Estrogens		
estradiol (Alora, Climara, Divigel, Elestrin, Estrace, Estraderm, others)	PO (Estrace): 0.5–2 mg daily Transdermal patch: 1 patch (0.025–0.1 mg/day) once weekly (Climara) or twice weekly (Alora, Estraderm, Minivelle) Topical gel (Divigel, Elestrin): 0.25–1.0 g/day applied to skin of upper thigh or arm Vaginal cream (Estrace): 1 g 1–3 times/wk maintenance dose Vaginal ring (Estring, Femring): 1 ring every 90 days	*Breakthrough bleeding, spotting, breast tenderness, libido changes* Hypertension (HTN), gallbladder disease, MI, deep vein thrombosis, increased endometrial cancer risk, hypercalcemia, dementia, fetal toxicity (PO and parenteral forms)
estradiol valerate (Delestrogen)	IM: 10–20 mg q4wk	
estrogen, conjugated (Cenestin, Enjuvia, Premarin)	PO: 0.3–1.25 mg daily for 21 days each month	
estropipate (Ogen)	PO: 0.75–6 mg daily for 21 days each month Vaginal cream (Ogen): 2–4 g/day	
Progestins		
medroxyprogesterone (Depo-Provera, Depo-SubQ-Provera, Provera)	PO (Provera): 5–10 mg daily on days 1–12 of menstrual cycle IM (Depo-Provera): 400–1000 mg/wk Subcutaneous (Depo-SubQ-Provera): 104 mg every 3 months. Give first dose during the first 5 days of the menstrual period	*Breakthrough bleeding, spotting, breast tenderness, weight gain* Amenorrhea, dysmenorrhea, depression, thromboembolic disorders, fetal toxicity (PO and parenteral forms)
progesterone (Crinone, Endometrin, Prochieve, Prometrium)	IM (amenorrhea or uterine bleeding): 5–10 mg/day Vaginal (assisted reproductive technology): 90-mg gel once daily or 100-mg tablets bid–tid	
Estrogen–Progestin Combinations		
conjugated estrogens with medroxyprogesterone (Premphase, Prempro)	PO (Premphase): Estrogen 0.625 mg/daily on days 1–28; add 5 mg medroxyprogesterone daily on days 15–28 PO (Prempro): Estrogen 0.3 mg and medroxyprogesterone 1.5 mg daily Vaginal cream: Insert 0.5–2 g daily for 3–6 months	*Breakthrough bleeding, spotting, breast tenderness, weight gain* Amenorrhea, dysmenorrhea, depression, thromboembolic disorders, HTN
estradiol with norgestimate	PO: 1 mg estradiol for 3 days, followed by 1 mg estradiol combined with 0.09 mg norgestimate for 3 days	
ethinyl estradiol with norethindrone acetate (Activella)	PO: 0.5–0.1 mg of estradiol and 0.5–1 mg norethindrone Transdermal patch: 1 patch, twice weekly	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

infections, abdominal cramps and bloating, breast tenderness, and vaginal bleeding. Other less common adverse effects may include thromboembolic events, fluid retention, edema, acute pancreatitis, appetite changes, skin eruptions, mental depression, decreased or increased libido, fatigue, nervousness, and weight gain. The risks of adverse effects increase in patients over age 35. Effects are dose dependent. **Black Box Warnings:** Estrogens have been associated with a higher risk of endometrial cancer in postmenopausal women (see Section 69.4). Using conjugated estrogens with medroxyprogesterone increases the risk of breast cancer. Estrogens when used alone increase the risk of stroke, deep vein thrombosis (DVT), MI, and pulmonary emboli. They may increase the risk for dementia.

Contraindications/Precautions: Estrogens should be avoided in patients who have a history of breast cancer, cervical cancer, endometrial cancer or hyperplasia, prostate cancer, and hepatic diseases or cancer. Additionally, because estrogens have been associated with thromboembolic disorders, hypercalcemia, and lupus, they should not be prescribed without a thorough investigation of these conditions. Estrogens should be used with caution in patients with lipid disorders because they may increase HDL cholesterol and triglycerides. They are contraindicated in patients with undiagnosed abnormal vaginal bleeding. Because estrogens are classified as category X, pregnancy and lactation are contraindications for this drug.

Drug Interactions: Estrogen is metabolized by CYP450 enzymes and may interact with other drugs metabolized in the liver. The following drugs will decrease the effects of conjugated estrogens: corticosteroids, erythromycin, heparin, rifampin, tetracycline, and warfarin. Use with azole antifungals, diltiazem, or statins may increase the effects of conjugated estrogens. **Herbal/Food:** St. John's wort, red clover, and black cohosh have weak estrogenic effects and may interfere with estrogen therapy. Effects of estrogen may be enhanced if combined with ginseng. Estrogen may decrease the absorption of folic acid. If allergic to soy products, patients should not take Cenestin because it contains soy estrogens.

Pregnancy: Category X.

Treatment of Overdose: Overdose will cause nausea, vomiting, and breakthrough bleeding, which are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving conjugated estrogens are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Estrogen.

Drugs Similar to Conjugated Estrogens (Cenestin, Enjuvia, Premarin)

Other estrogens are listed in Table 69.1. These drugs have the same actions, adverse effects, and contraindications as those of conjugated estrogens.

CONNECTION Checkpoint 69.1

The majority of drugs in this chapter are pregnancy category X. From what you learned in Chapter 2, what is the difference between a category D drug and a category X drug? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Progestins

69.3 Progestins are administered to treat dysfunctional uterine bleeding, to prevent conception, and for certain neoplasms.

Progestins are synthetic hormones that have actions identical to natural, endogenous progesterone. In combination with estrogen, progesterone promotes breast development and regulates the monthly changes of the uterine cycle. Under the influence of estrogen and progesterone, the uterine endometrium becomes more vascular and thickens in preparation for receiving a fertilized egg. If implantation does not occur, levels of progesterone fall dramatically and menses begins. If pregnancy does occur, the ovary will continue to secrete progesterone, maintaining a healthy endometrium until the placenta develops sufficiently to begin producing the hormone.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Estrogen

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, peripheral vascular, thyroid, hepatic, or kidney disease; migraine headaches; diabetes; pregnancy; or breastfeeding. Note personal or family history of thromboembolic disorders (e.g., MI, stroke, peripheral vascular disease) and of reproductive cancers (e.g., breast, uterine, or ovarian cancer).
- Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], platelets, electrolytes, glucose, lipid, and thyroid function levels), Pap test, human papilloma virus (HPV) screening, and pregnancy test.
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., symptoms of menopause or ease of dysfunctional uterine bleeding).
- Continue periodic monitoring of CBC, platelets, and thyroid function studies.
- Monitor vital signs and weight at each healthcare visit.
- Assess for adverse effects: nausea, vomiting, headache, weight gain, breast tenderness, skin rash, acne, fluid retention, changes in mood, and midcycle breakthrough bleeding. Immediately report tachycardia, palpitations, HTN, especially associated with angina, severe headache, cramping in calves, chest pain, or dyspnea.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (Maintaining consistent daily doses for treatment of menopausal symptoms or dysfunctional uterine bleeding will ensure that hormone levels stay stable and symptoms ease.)	• Instruct the patient to take the drug at the same time daily to help with remembering to take the pill. Do not omit, increase, or decrease doses without consulting the healthcare provider. Omitting doses increases the chance of breakthrough bleeding.

Minimizing adverse effects:
• Monitor for symptoms of cardiopulmonary, cerebrovascular, and peripheral vascular thromboembolism. Monitor blood pressure at each clinical visit. (Thromboembolic events are a possible adverse effect of estrogen drugs. The risk increases with age over 35, in women with a previous history of cardiovascular disease, and in women who smoke. Monitor for symptoms of peripheral thrombophlebitis, pulmonary embolism, MI, stroke, or other complications related to blood clots.)
	• Instruct the patient to immediately report:
	  • Dyspnea, chest pain, or blood in sputum (possible pulmonary embolism)
	  • Heaviness, chest pain, or overwhelming feeling of fatigue and weakness accompanied by nausea and diaphoresis (possible MI)
	  • Sudden, severe headache, especially if associated with a preheadache aura, dizziness, difficulty with speech, numbness in arm or leg, and difficulty with vision (possible stroke)
	  • Warmth, redness, swelling, or tenderness in calf or pain on walking (possible thrombophlebitis).
	• Teach the patient to monitor blood pressure periodically and report any blood pressure above 140/90 mmHg or per parameters set by the healthcare provider.

• Encourage smoking cessation and provide information about smoking cessation programs. (Smoking greatly increases the risk of adverse effects of hormone therapy.)	• Advise the patient of the risk of smoking while using estrogens and discuss smoking cessation programs, providing referrals to appropriate support groups and literature on smoking cessation programs.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor Pap tests, HPV screening, and breast examinations as ordered. (Pap tests and breast examinations, including mammography as appropriate, will monitor for the development of breast tumors or of cervical cancer.)	• Teach the patient how to perform breast self-examinations, noting that monthly examinations may not be recommended by the healthcare provider except for women at high risk for breast cancer. For women over age 40, advise the patient on the need for follow-up mammography per healthcare provider recommendations. • Advise the patient on the need for routine age-appropriate gynecologic examinations to ensure continued health. Frequency may be decreased after age 65 after consultation with the healthcare provider.
• Monitor for the occurrence of any breakthrough bleeding. Report any continuous, unusual, or heavy bleeding. (Small amounts of spotting may occur, especially with low-dose hormone therapy, at midcycle. Any continuous, unusual, or heavy bleeding may indicate adverse effects or disease and should be reported because an increased risk of endometrial cancer has been noted with estrogen use.)	• Teach the patient that slight spotting may occur midcycle while on estrogens but to report any unusual changes in the amount or if the bleeding continues.
• Monitor hepatic function tests and symptoms of liver dysfunction, lipid profile studies, and thyroid levels periodically. (Estrogens are associated with increased risk of gallbladder disease and a rare risk of hepatotoxicity. **Diverse Patients:** Because estrogens metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Instruct the patient to return periodically for laboratory tests. • Teach the patient to report any symptoms of abdominal or right upper quadrant discomfort or pain, yellowing of the skin or sclera, fatigue, anorexia, darkened urine, or clay-colored stools immediately.
• Monitor concurrent drug therapy and any new prescriptions received. (Many drugs decrease or alter the effectiveness of estrogens including drugs in the penicillin, barbiturate, antiseizure, antidepressant, and benzodiazepine classifications. Check for drug interactions that may affect hormone effectiveness before any new prescription is started.)	• Teach the patient to advise all healthcare providers of the use of estrogens before beginning any new prescription.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient in proper self-administration of the drug, e.g., consistently at the same time each day to help remember the dose, followed by teach-back. (Utilizing time during nurse administration of these drugs helps reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Oral drugs should be taken at the same time each day to help remember the dose. Follow instructions if a dose is missed.
	  • Transdermal patches (e.g., Climara) are changed weekly or every other week per the healthcare provider's directions.
	  • Apply topical gels or creams only to the area to be treated. Do not wear tampons after intravaginal application.

Whereas the function of estrogen is to cause proliferation of the endometrium, progesterone limits and stabilizes endometrial growth. Progestins are preferred drugs for treating many uterine abnormalities. They are also a component of HRT and are used as contraceptives (see Chapter 70).

The primary noncontraception indication for progestins is **dysfunctional uterine bleeding**, a condition in which hemorrhage occurs on a noncyclic basis or in abnormal amounts. Dysfunctional uterine bleeding is common in adolescents and menopausal women and is often associated with anovulatory menstrual cycles. **Anovulatory cycles** are those that occur without ovulation. Dysfunctional uterine bleeding is the health problem most frequently reported by women and a common reason for a hysterectomy.

PharmFACT

Dysfunctional uterine bleeding most commonly occurs at the extreme ages of the reproductive years. The most severe cases occur in adolescents during the first 2 years after the onset of menstruation. Abnormal bleeding also occurs in 50% of perimenopausal women (Estephan, 2016).

Ninety percent of dysfunctional uterine bleeding cases result from anovulation. Possible causes of uterine bleeding include early abortion, pelvic neoplasms, thyroid disorders, pregnancy, and infection. Types of dysfunctional uterine bleeding include the following:

- **Amenorrhea.** Absence of menstruation
- **Endometriosis.** Abnormal location of endometrial tissues

- **Oligomenorrhea.** Infrequent menstruation
- **Menorrhagia.** Prolonged or excessive menstruation occurring at regular intervals
- **Breakthrough (intermenstrual) bleeding.** Hemorrhage between regular menstrual periods
- **Premenstrual syndrome (PMS).** Symptoms developed during the luteal phase
- **Postmenopausal bleeding.** Hemorrhage following menopause
- **Endometrial carcinoma.** Cancer of the endometrium.

Dysfunctional uterine bleeding is often due to a hormonal imbalance between estrogen and progesterone. Although estrogen increases the thickness of the endometrium, bleeding occurs sporadically unless it is balanced by adequate progesterone secretion. Administration of a progestin in a regimen starting 5 days after the onset of menses and continuing for the next 20 days can sometimes help to reestablish a normal, monthly cyclic pattern. Oral contraceptives may also be prescribed for this disorder.

In patients experiencing heavy bleeding, high doses of conjugated estrogens may be administered for 3 weeks prior to adding medroxyprogesterone for the last 10 days of therapy. Treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) helps to ease painful menstrual flow. If aggressive hormonal therapy fails to stop the heavy bleeding, dilation and curettage (D&C) may be necessary.

Progestins are occasionally prescribed for the treatment of metastatic endometrial carcinoma. In these cases, they are used for palliation, in combination with other antineoplastics. Selected progestins and their dosages are shown in Table 69.1.

PROTOTYPE DRUG	**Medroxyprogesterone (Depo-Provera, Depo-SubQ-Provera, Provera)**

Classification **Therapeutic:** Hormone, drug for dysfunctional uterine bleeding
Pharmacologic: Progestin

Therapeutic Effects and Uses: Approved in 1959, medroxyprogesterone is a synthetic progestin with a prolonged duration of action. Like progesterone, the primary target tissue for medroxyprogesterone is the uterine endometrium. It antagonizes the effects of estrogen on the uterus, thus restoring normal hormonal balance. It also inhibits the midcycle LH surge, which prevents ovulation, and causes a thick cervical mucus plug that is resistant to the passage of sperm.

Medroxyprogesterone is given PO (Provera) to treat dysfunctional uterine bleeding or secondary amenorrhea. It is administered IM (Depo-SubQ-Provera) at high doses for the palliative treatment of inoperable metastatic endometrial or renal cell carcinoma. At low doses, the drug is given by the subcutaneous route (Depo-Provera) as a contraceptive. The use of medroxyprogesterone in contraception is presented in Chapter 70. The drug has been used off-label to treat symptoms of menopause.

Mechanism of Action: This drug is a synthetic derivative of progesterone with prolonged, variable duration of action and androgenic and antiestrogenic activity. The drug inhibits GnRH, thus preventing the LH surge and ovulation.

Pharmacokinetics:

Route(s)	PO, IM, subcutaneous, IV
Absorption	Readily absorbed from the GI tract or IM
Distribution	Crosses the placenta; secreted in breast milk; 90% bound to protein
Primary metabolism	Hepatic
Primary excretion	Feces
Onset of action	PO: 30–60 min; IM: 15–30 min
Duration of action	Half-life: 30 days (PO); 50 days (IM)

Adverse Effects: The most common adverse effects of medroxyprogesterone are breast tenderness, breakthrough bleeding, and other menstrual irregularities. Weight gain, depression, hypertension (HTN), nausea, vomiting, fluid retention, and vaginal candidiasis may also occur. **Black Box Warning:** Progestins combined with conjugated estrogens may increase the risk of stroke, DVT, MI, pulmonary emboli, and invasive breast cancer. Women age 65 or older have an increased risk of dementia when treated with progestins. Women receiving injectable medroxyprogesterone are at significant risk for loss of bone mineral density.

Contraindications/Precautions: Patients with a history of thromboembolic disorders, or who are pregnant, should not take progestins. Doses should be reduced in patients with hepatic impairment. Patients with preexisting breast, uterine, or vaginal cancer should not receive medroxyprogesterone unless it is for palliation of advanced cancer. The drug should be used cautiously in patients with a history of psychic depression, and the drug should be discontinued at the first sign of recurring depression. The drug is absolutely contraindicated in patients with known or suspected pregnancy (category X) or in those with undiagnosed vaginal bleeding.

Drug Interactions: Serum levels of medroxyprogesterone are decreased by barbiturates, carbamazepine, rifabutin, rifampin, and topiramate. Azole antifungals, carbamazepine, nicardipine, and protease inhibitors such as ritonavir will increase the effects of medroxyprogesterone. **Herbal/Food:** St. John's wort may cause intermenstrual bleeding and loss of efficacy. Grapefruit may increase the effects of medroxyprogesterone.

Pregnancy: Category X.

Treatment of Overdose: Overdose is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving medroxyprogesterone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Progestin.

Drugs Similar to Medroxyprogesterone (Depo-Provera, Depo-SubQ-Provera, Provera)

Progestins used as contraceptives include desogestrel, dienogest, levonorgestrel, norethindrone, and norgestrel. These are presented in Chapter 70. Another progestin is progesterone.

Progesterone (Crinone, Endometrin, Prochieve, Prometrium): Approved in 1978, progesterone is available in a variety of formulations. As a vaginal suppository (Endometrin) or vaginal gel (Crinone, Prochieve), progesterone is used to treat infertile women with progesterone deficiency as part of an assisted reproductive technology system. The vaginal formulations may also be used as progesterone supplements to support embryo implantation and early pregnancy. When used intravaginally, the drug may be absorbed and cause systemic adverse effects such as breast tenderness, bloating, drowsiness, headaches, irritability, and mood swings.

Oral capsules (Prometrium) are approved to treat secondary amenorrhea and may be used off-label to ease symptoms of PMS. Prometrium is also indicated for the prevention of endometrial hyperplasia in postmenopausal women who are receiving conjugated estrogens.

Progesterone IM injections are indicated for amenorrhea and to stop abnormal uterine bleeding. Adverse effects and contraindications are the same as those for medroxyprogesterone. The PO and IM progesterone formulations carry the same black box warnings as medroxyprogesterone and are pregnancy category X. The vaginal gel is category B.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Progestin

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, peripheral vascular, thyroid, hepatic, or kidney disease; migraine headaches; diabetes; pregnancy; or breastfeeding. Note personal or family history of thromboembolic disorders (e.g., MI, stroke, peripheral vascular disease) and of reproductive cancers (e.g., breast, uterine, or ovarian cancer).
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., CBC, platelets, electrolytes, glucose, lipid, and thyroid function levels), Pap test, HPV screening, pregnancy test.
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., symptoms of menopause or ease of dysfunctional uterine bleeding).
- Continue periodic monitoring of CBC, platelets, and thyroid function studies.
- Monitor vital signs and weight at each healthcare visit.
- Assess for adverse effects: nausea, vomiting, headache, weight gain, breast tenderness, skin rash, acne, fluid retention, changes in mood, midcycle breakthrough bleeding. Immediately report tachycardia, palpitations, HTN, especially associated with angina, severe headache, cramping in calves, chest pain, or dyspnea.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (Maintaining consistent daily doses for treatment of menopausal symptoms or dysfunctional uterine bleeding will ensure that hormone levels stay stable and symptoms ease.)	• Instruct the patient to take the drug at the same time daily to help with remembering to take the pill. Do not omit doses or increase or decrease dose without consulting the healthcare provider. Omitting doses increases the risk of breakthrough bleeding.

Minimizing adverse effects:
• Monitor for symptoms of cardiopulmonary, cerebrovascular, and peripheral vascular thromboembolism. Monitor blood pressure at each clinical visit. (Thromboembolic events are a possible adverse effect of progestin drugs. The risk increases with age over 35, in women with a previous history of cardiovascular disease, and in women who smoke. Monitor for symptoms of peripheral thrombophlebitis, pulmonary embolism, MI, stroke, or other complications related to blood clots.)
	• Instruct the patient to immediately report:
	  • Dyspnea, chest pain, or blood in sputum (possible pulmonary embolism)
	  • Heaviness, chest pain, or an overwhelming feeling of fatigue and weakness accompanied by nausea and diaphoresis (possible MI)
	  • Sudden, severe headache, especially if associated with a preheadache aura, dizziness, difficulty with speech, numbness in arm or leg, difficulty with vision (possible stroke)
	  • Warmth, redness, swelling, or tenderness in calf or pain on walking (possible thrombophlebitis).
	• Teach the patient to monitor blood pressure periodically and report any blood pressure above 140/90 mmHg or per parameters set by the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Encourage smoking cessation and provide information about smoking cessation programs. (Smoking greatly increases the risk of adverse effects of hormone therapy.)	• Advise the patient of the risk of smoking while using progestins and discuss smoking cessation programs, providing referral to appropriate support groups and literature on smoking cessation programs.
• Assess for the presence of bone or musculoskeletal pain on each healthcare visit, especially in patients taking injectable progestins. (Progestins are associated with an increased risk of loss of bone density. Bone density monitoring, e.g., DEXA scan, may be ordered periodically. Immediately report any sudden, severe pain or difficulty with ambulation or movement.)	• Instruct the patient to immediately report any sudden and severe pain, or continuous moderate pain, in joints or muscles, loss of motion, or difficulty with ambulation or movement to the healthcare provider.
• **Lifespan:** Monitor mental status in patients age 65 or older or patients with a history of depression or psychiatric illness. (Progestins are associated with increased risk of dementia in women age 65 or older.)	• Instruct the patient, family, or caregiver to promptly report any changes in behavior, depression, or mental status to the healthcare provider.
• Monitor concurrent drug therapy and any new prescriptions received. (Many drugs decrease or alter the effectiveness of progestins including drugs in the penicillin, barbiturate, antiseizure, antidepressant, and benzodiazepine classifications. Check for drug interactions that may affect hormone effectiveness before any new prescription is started.)	• Teach the patient to advise all healthcare providers of the use of progestins before beginning any new prescription.
• Monitor Pap tests, HPV screening, and breast examinations as ordered. (Pap tests and breast examinations, including mammography as appropriate, will monitor for the development of breast tumors or of cervical cancer.)	• Teach the patient how to perform breast self-examinations, noting that monthly examinations may not be recommended by the healthcare provider except for women at high risk for breast cancer. For women over age 40, advise the patient on the need for follow-up mammography per healthcare provider recommendations. • Advise the patient on the need for annual gynecologic examinations to ensure continued health. Frequency may be decreased after age 65 after consultation with the healthcare provider.
• Monitor for the occurrence of any breakthrough bleeding. Report any continuous, unusual, or heavy bleeding. (Small amounts of spotting may occur, especially with low-dose hormone therapy, at midcycle. Any continuous, unusual, or heavy bleeding may indicate adverse effects or disease and should be reported.)	• Teach the patient that slight spotting may occur midcycle while on progestin but to report any unusual changes in the amount or if the bleeding continues.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient or caregiver in proper self-administration of the drug, e.g., consistently at the same time each day to help remember the dose, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Oral drugs should be taken at the same time each day to help remember the dose. Follow instructions if dose is missed.
	  • Take the drug with food or milk to decrease the possibility of nausea.

Hormone Replacement Therapy

69.4 Hormone replacement therapy provides relief from menopause symptoms but may have serious long-term negative effects.

Menopause is characterized by a progressive decrease in estrogen secretion by the ovaries resulting in the permanent cessation of menses. The **climacteric** is the period of endocrine, somatic, and psychologic changes that occur during the transition to menopause. There are over 30 million menopausal women in North America and each decade millions more reach the climacteric. Menopause is neither a disease nor a disorder, but is a natural consequence of aging that is often accompanied by unpleasant symptoms that include hot flashes, night sweats, irregular menstrual cycles, vaginal dryness, and bone mass loss.

PharmFACT

Women who enter menopause at an early age (40–45 years) are at increased risk for developing future heart failure. Smoking can increase this risk, even for women who enter menopause from ages 46 to 49 (Rahman, Åkesson, & Wolk, 2015).

During the past 40 years, healthcare providers have commonly prescribed **hormone replacement therapy (HRT)** during menopause. HRT supplies physiologic doses of estrogen, sometimes combined with a progestin, to treat unpleasant symptoms of menopause and to

Table 69.2 Potential Consequences of Estrogen Loss Related to Menopause

Stage	Symptoms and Conditions
Early menopause	Headaches Hot flashes Insomnia Irregular menstrual cycles Mood disturbances, depression, irritability
Midmenopause	Sexual disinterest Skin atrophy Stress urinary incontinence Vaginal atrophy, increased infections, painful intercourse
Postmenopause	Alzheimer's-like dementia Cardiovascular disease Colon cancer Osteoporosis

prevent the long-term consequences of estrogen loss listed in Table 69.2.

Beginning in the mid-1960s, large numbers of perimenopausal and menopausal women received conjugated estrogen (Premarin). Premarin was widely prescribed, despite a lack of research on its effectiveness and long-term effects. The drug's popularity extended several more decades, making Premarin one of the most frequently prescribed medications in the United States. In addition, a significant number of women were prescribed conjugated estrogens combined with medroxyprogesterone (Prempro).

In the mid-1970s, however, studies showed that women who had used estrogen (without progestin) for 7 years or longer were more likely to develop uterine (endometrial) cancer. Progestins were then added to the HRT regimen to lower the risk of endometrial cancer.

Two large, randomized, double-blind, placebo-controlled studies have challenged the safety of using HRT during menopause. The Women's Health Initiative (WHI) and the Heart and Estrogen/Progestin Replacement Study (HERS) helped disprove some of the benefits of HRT for postmenopausal women. More than 26,000 women were enrolled in these studies, which were discontinued early when it became clear that the potential benefits of long-term HRT were not being realized. The results of the study depended on whether the HRT consisted of estrogen alone or an estrogen–progestin combination. Researchers reached the following conclusions:

- Women taking estrogen–progestin combination HRT experienced a statistically significant increased risk of MI, stroke, breast cancer, dementia, and venous thromboembolism. The risks were higher in women older than age 60; women ages 50 to 59 actually experienced a slight decrease in adverse cardiovascular events.
- Women taking estrogen–progestin combination HRT experienced a decreased risk of hip fractures and colorectal cancer.
- Women taking estrogen alone experienced an increased risk of stroke and other thromboembolic disorders.
- Women taking estrogen alone did not experience an increased risk of breast cancer or MI.

The adverse effects documented in the WHI study and others were significant enough to suggest that the potential benefits of long-term HRT may not outweigh the risks for many women.

To be clear, HRT does offer relief from the immediate, distressing vasomotor menopausal symptoms, prevents osteoporosis-related fractures, and may offer some degree of protection from colorectal cancer. These are certainly significant and important benefits from HRT. The risks of HRT include increased incidence of MI, thromboembolic events, breast cancer (estrogen–progestin combinations), ovarian cancer (estrogen alone), and possibly dementia, urinary incontinence, and gallbladder disease. Until research provides more definitive answers, the choice of HRT to treat menopausal symptoms remains a highly individualized one, between the patient and her healthcare provider.

In recent years, several drugs have been marketed to treat symptoms of menopause while lowering the potential adverse effects of estrogen–progestin combinations. Duavee is a combination drug that contains conjugated estrogens with bazedoxifene, which belongs to a class of drugs called selective estrogen receptor modifiers (SERMs). Duavee offers the advantages of preventing intense hot flashes (the estrogen component) while reducing the risk of osteoporosis-related fractures that are common in postmenopausal women (the SERM component). Approved in 2013, Duavee was the first HRT to include a SERM instead of a progestin. This drug carries the same black box warning as that for conjugated estrogens regarding an increased risk of endometrial cancer and DVT. Duavee is given by the oral route and is pregnancy category X.

Another SERM, ospemifene (Osphena), was approved in 2013 to treat dyspareunia, a type of acute pain in postmenopausal women that may occur during intercourse. Ospemifene acts as an estrogen agonist on the vagina, increasing the thickness of the vaginal epithelium. This drug carries the same black box warning as conjugated estrogens regarding an increased risk of endometrial cancer and DVT. Ospemifene is given by the oral route and is pregnancy category X.

In 2016 the FDA approved an additional drug for treating dyspareunia caused by postmenopausal vulvar or vaginal atrophy. Prasterone (Intrarosa) is administered as a once-daily vaginal insert. This drug consists of dehydroepiandrosterone (DHEA), a natural hormone secreted primarily by the adrenal gland. Metabolically, DHEA is converted into androgens and estrogens. It is interesting to note that DHEA is a widely used dietary supplement that is claimed to produce a wide variety of positive effects,

including increased muscle strength, memory, and bone density. Most of these claims have little scientific basis. Although DHEA tablets are available OTC in the United States, its use is banned by world sports organizations.

Uterine Stimulants: Oxytocics

69.5 Oxytocics are drugs used to stimulate the uterus and promote labor and delivery.

Oxytocics are drugs that stimulate uterine contractions and promote the induction of labor. The most widely used oxytocic is the natural hormone oxytocin, which is secreted by the posterior pituitary gland. The target organs for oxytocin are the uterus and the breast. Increasing amounts of oxytocin are secreted as the uterus is distended by the growing fetus. As pregnancy progresses, the number of oxytocin receptors in the uterus increases, making it even more sensitive to the effects of the hormone. As blood levels of oxytocin rise, uterine smooth muscle is stimulated to contract, thus promoting labor and the delivery of the baby and the placenta.

Oxytocin and other uterine stimulants are indicated only when there are demonstrated risks to the mother or fetus in continuing the pregnancy. Parenteral oxytocin (Pitocin) may be given to induce labor. Doses in an IV infusion are increased gradually, every 15 to 60 minutes, until a normal labor pattern is established. After delivery, IV oxytocin is administered to control postpartum uterine bleeding by temporarily restricting blood flow to this organ. Doses of these drugs are listed in Table 69.3.

In postpartum women, oxytocin is released in response to suckling, whereby it promotes the ejection (letdown) of milk from the mammary glands. Oxytocin does not increase the volume of milk production; this function is provided by the pituitary hormone prolactin, which increases the synthesis of milk. Although rare, deficiencies of prolactin can result in insufficient milk to conduct breastfeeding. The actions of oxytocin during breastfeeding are illustrated in Figure 69.3.

Ergot alkaloids are obtained from a fungus that grows on rye plants. These drugs are used as alternatives to oxytocin to control postpartum hemorrhage. The primary drug in this class, methylergonovine (Methergine), is effective at promoting uterine contractions but is rarely prescribed due to the risk of serious HTN. Ergot alkaloids are also second-line drugs in the pharmacotherapy of migraines.

Table 69.3 Uterine Stimulants and Relaxants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Stimulants (Oxytocics)		
oxytocin (Pitocin)	To control postpartum bleeding: 10–40 units per infusion pump in 1000 mL of IV fluid at a rate to prevent uterine atony To induce labor: IV: 0.5–2 milliunits/min, gradually increasing the dose no greater than 1–2 milliunits/min at 30- to 60-min intervals until contraction pattern is established	*Nausea, vomiting, maternal dysrhythmias* Fetal bradycardia, uterine rupture, fetal intracranial hemorrhage, water intoxication, fetal brain hemorrhage
Ergot Alkaloid		
methylergonovine (Methergine)	PO: 0.2–0.4 mg bid–qid	*Nausea, vomiting, uterine cramping* Shock, severe HTN, severe dysrhythmias
Prostaglandins		
carboprost (Hemabate)	IM (initial): 250 mcg (1 mL) repeated at 1.5- to 3.5-h intervals if indicated by uterine response	*Nausea, vomiting, cramping, diarrhea, fever* Uterine laceration, rupture, or hemorrhage
dinoprostone (Cervidil, Prepidil, Prostin E_2)	Intravaginal insert (Cervidil): 10 mg (1 insert) Intravaginal gel (Prepidil): 0.5 mg Intravaginal suppository: 20 mg (1 suppository)	
Relaxants (Tocolytics)		
magnesium sulfate	IV: 1–4 g in 5% dextrose by slow infusion (initial max dose: 10–14 g/day, then no more than 30–40 g/day at a max rate of 1–2 g/h)	*Flushing, sweating, muscle weakness* Complete heart block, circulatory collapse, respiratory paralysis
nifedipine (Adalat, Procardia)	PO: Initial dose of 20 mg, followed by 20 mg after 30 min. If contractions persist, therapy can be continued with 20 mg q3–8h for 48–72 h with a maximum dose of 160 mg/day After 72 h, if maintenance is still required, long-acting nifedipine 30–60 mg daily can be used	*Flushing, sweating, muscle weakness* Complete heart block, circulatory collapse, respiratory paralysis
terbutaline (Brethine)	IV: 2.5–10 mcg/min; increase every 10–20 min; duration of infusion: 12 h (max: 17.5–30 mcg/min) PO (maintenance dose): 2.5–10 mg q4–6h as long as necessary to delay preterm labor	*Nervousness, tremor, drowsiness* Bronchoconstrictions, dysrhythmias, altered maternal and fetal heart rates

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

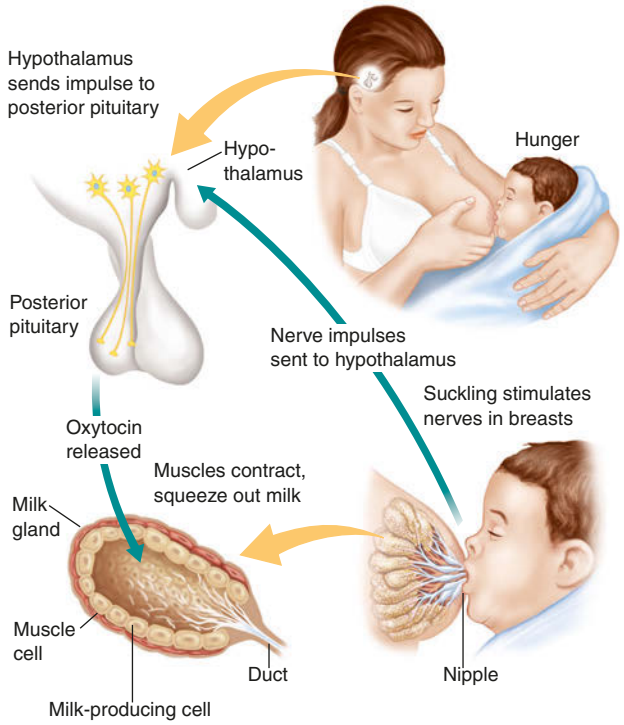

Figure 69.3 Oxytocin and breastfeeding.

Several prostaglandins are also used as uterine stimulants. Unlike most hormones that travel through the blood to affect distant tissues, prostaglandins act directly at the site where they are secreted. In the uterus, prostaglandins cause intense smooth muscle contractions. Carboprost (Hemabate) may be used to control postpartum hemorrhage. Dinoprostone (Cervidil, Prepidil, Prostin E_2) is used intravaginally to promote cervical ripening, a softening and dilation of the cervix that must occur prior to vaginal delivery. Misoprostol (Cytotec) is another prostaglandin that has been used off-label to promote cervical ripening. When used in high doses, the prostaglandins can induce pharmacologic abortion (see Chapter 70).

CONNECTIONS: Patient Safety

Incomplete Medication Order

It has been a very busy morning on the obstetrics unit with multiple patient discharges and several new admissions. One patient is a 35-year-old woman with preeclampsia who is admitted for labor induction with an order that reads "Begin oxytocin infusion at 2 milliunits/min and increase by 2 milliunits/min every 30 min." The nurse places a call to the obstetrician to clarify this. What is missing from this order?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

PROTOTYPE DRUG Oxytocin (Pitocin)

Classification **Therapeutic:** Drug to induce labor, uterine stimulant
Pharmacologic: Hormone, oxytocic

Therapeutic Effects and Uses: Oxytocin (Pitocin), identical to the natural hormone secreted by the posterior pituitary gland, is the preferred drug for inducing labor. Given by IV infusion antepartum, oxytocin induces labor almost immediately by increasing the frequency and force of contractions of uterine smooth muscle. It is administered during the final stages of labor, after the cervix is dilated, membranes have ruptured, and presentation of the fetus has occurred. It is also used to induce labor in cases of maternal diabetes, preeclampsia, eclampsia, and erythroblastosis fetalis. It should not be used for elective induction of labor, due to potential adverse effects to the mother or baby.

Oxytocin is also approved to reduce postpartum hemorrhage following expulsion of the placenta and to aid in returning normal muscular tone to the uterus. This drug is approved at higher doses for the adjunct management of incomplete or inevitable abortion. Intranasal forms once used to promote milk letdown are no longer available in the United States.

Mechanism of Action: Oxytocin increases the intensity and frequency of uterine smooth muscle contractions. When stimulated by sucking, oxytocin causes smooth muscle in alveolar ducts to contract, thus ejecting milk from the breast.

Pharmacokinetics:

Route(s)	IV or IM
Absorption	Destroyed in the GI tract
Distribution	Widely distributed in extracellular fluid; small amounts may cross the placenta; secreted in breast milk
Primary metabolism	Rapidly destroyed in the kidney and the liver
Primary excretion	Small amounts via the kidney
Onset of action	IV: immediate; IM: 3–5 min
Duration of action	Half-life: 3–5 min

Adverse Effects: The most common adverse effects of oxytocin are rapid, painful uterine contractions and fetal tachycardia. Uterine rupture or fetal trauma from too-rapid expulsion through the pelvis, seizure, and coma are regarded as the most serious adverse effects. The risk of uterine rupture is increased in women who have delivered five or more children. When given IV, vital signs of the fetus and mother must be monitored continuously to prevent fetal complications, such as dysrhythmias or intracranial hemorrhage. **Black Box Warning:** Oxytocin is not

indicated for the elective induction of labor. Elective induction is the initiation of labor in a pregnant patient who has no medical indications for induction.

Contraindications/Precautions: Oxytocin has an antidiuretic effect and care must be taken to avoid water intoxication. Oxytocin is contraindicated when there is evidence of fetal distress, placenta previa, uterine prolapse, active herpes infection, abnormal fetal position, and cervical cancer. Breastfeeding should be delayed for at least 24 hours after the drug is discontinued.

Drug Interactions: Vasoconstrictors used concurrently with oxytocin may cause severe HTN. Oxytocin may cause adverse cardiovascular effects when administered with fibrinolysin, warfarin, and cyclopropane anesthesia. **Herbal/Food:** Ephedra used with oxytocin may lead to HTN.

Pregnancy: Category X.

Treatment of Overdose: Overdose will cause severe cramping and possible damage to the uterus. Discontinuation of the infusion will result in a rapid resolution of symptoms due to the short half-life of the drug.

Nursing Responsibilities: Key nursing implications for patients receiving oxytocin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Oxytocin (Pitocin).

Drugs Similar to Oxytocin (Pitocin)

Uterine stimulants also include prostaglandins (carboprost and dinoprostone) and the ergot alkaloid methylergonovine.

Carboprost (Hemabate): Carboprost, equivalent to endogenous prostaglandin F_2 alpha, is approved for controlling postpartum bleeding that has not responded to oxytocin and for inducing pharmacologic abortion between weeks 13 and 20 of gestation. For postpartum bleeding, it is administered by the IM route every 15 to 90 minutes until hemorrhage is controlled. Nausea, vomiting, diarrhea, and fever are common adverse effects. This drug is pregnancy category C.

Dinoprostone (Cervidil, Prepidil, Prostin E_2): Dinoprostone, or prostaglandin E_2, is approved to prepare the cervix for labor or to abort a fetus that has died. To promote cervical ripening, it is administered intravaginally. The gel form of the drug is placed into the cervical canal using prefilled syringes and doses may be repeated every 6 hours, as needed. The vaginal insert releases the drug slowly, over 12 hours. The insert may be quickly and easily removed once labor begins. Both the gel and the insert may stimulate the uterus to begin contracting. Like carboprost, GI effects and fever are very common adverse effects. This drug is pregnancy category C.

Methylergonovine (Methergine): Ergonovine is an older drug, approved in 1946. It may be administered by the PO,

CONNECTIONS: Complementary and Alternative Therapies

Soy as a Phytoestrogen

Description

Soy, or soybean, is a nutritional food that is a major source of protein for many cultures, especially those in China and Japan. In the United States, soy has become increasingly popular and is one of the top 10 most utilized supplements. In addition to its nutritional value, soy contains estrogen-like (phytoestrogen) substances known as isoflavones. Soy milk is made by grinding soybeans into a fine powder, which is then mixed with water. Other products include soy sauce, soy flour, tofu, nutritional snack bars, and soy protein drinks.

History and Claims

Soy has been used as a nutritional source for thousands of years. Claims for soy's benefits include anticancer effects, treatment of osteoarthritis, cholesterol-lowering effects, and reduction of menopausal symptoms. Soy isoflavones have been identified as dietary components that have an important role in reducing the incidence of breast and prostate cancers.

Standardization

Standardization of soy is either to the amount of bean extract or to the amount of isoflavones in the product. The standard dose has not been established.

Evidence

Soy is one of the most studied dietary supplements. For many years soy was believed to provide superlative health benefits, including lowering of LDL cholesterol. Both the FDA and the American Heart Association (AHA) recognized the use of soy products as providing beneficial results in coronary heart disease in the 1990s. Eating soy protein as a replacement for meat and meat products may reduce the risk of heart disease and improve heart health. It has also been shown to reduce hot flashes in menopause, although large-scale studies are inconclusive. Soy isoflavones have antioxidant properties and appear to inhibit angiogenesis and metastasis. Some studies have found a small reduction in prostate cancer and breast cancer risk for those who are taking soy isoflavones (Chen et al., 2014; Mahmoud, Yang, & Bosland, 2014). Soy isoflavones may also be a promising supplement for cancer chemoprevention or treatment, but more research is needed to draw definitive conclusions in these areas.

IM, or IV routes to control postpartum hemorrhage and restore uterine tone. The IV route is used only in emergency situations because it may produce serious HTN or stroke in the mother. Uterine contractions begin in 3 to 5 minutes after an IM dose. Cramping and GI-related adverse effects are common with this drug. The drug is contraindicated during pregnancy because it can cause immediate uterine contractions that could injure the fetus. This drug is pregnancy category C.

CONNECTION Checkpoint 69.2

Calcium channel blockers, including nifedipine, are widely used to treat cardiovascular disorders. From what you learned in Chapter 30, what effects would you expect nifedipine to have on vascular smooth muscle, myocardial oxygen demand, and myocardial conduction? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Oxytocin (Pitocin)

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including current length of pregnancy duration; presence of preeclampsia or eclampsia; recent labor; type of delivery; history of labors or cesarean births; cardiovascular, neurologic, hepatic, or kidney disease; diabetes; or breastfeeding.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., CBC, platelets, coagulation studies, electrolytes, glucose, magnesium level, and hepatic and kidney function studies).
- Obtain baseline height, weight, and vital signs.
- Obtain fetal heart rate, intrauterine positioning.
- Check for presence of cervical dilation and effacement. Monitor quality and duration of any existing contractions. Monitor fetal response to contractions, noting any sign of fetal distress.
- Check for postpartum bleeding and note the number of pads saturated.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., strong, regular contractions supportive of labor, control of postpartum bleeding).
- Continuously monitor timing, quality, and duration of contractions. Immediately report sustained uterine contractions to the healthcare provider.
- Continuously monitor fetal heart rate and response to contractions. Immediately report signs of fetal distress to the healthcare provider.
- Continue periodic monitoring of CBC, platelets, electrolytes, glucose, and magnesium levels.
- Monitor vital signs frequently and immediately report any blood pressure above 140/90 mmHg or less than 90/60 mmHg, especially if accompanied by tachycardia, or per set parameters to the healthcare provider.
- Continue to monitor postpartum bleeding and pad count. Notify the healthcare provider if more than two full-size pads are saturated in a 2-h time period.
- Assess for adverse effects: nausea, vomiting, or headache. Immediately report tachycardia, palpitations, HTN, especially associated with angina, severe headache, or dyspnea. Immediately report any severe abdominal pain, sustained uterine contraction, diminished urine output, dizziness, drowsiness, confusion, changes in level of consciousness, or seizures.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. IV oxytocin must be given via infusion pump to allow for precise dosing. (Infusion pumps allow for rapid dosage adjustments to maintain uterine contractions supportive of labor until cervical dilation has reached approximately 5–6 cm.)	• Teach the patient about the rationale for all IV and monitoring equipment and the need for frequent monitoring to allay anxiety. • Teach the patient that labor contractions will gradually increase and that the drug will be decreased or stopped once contractions reach an optimal level. • Encourage laboring patients to use pain control measures (e.g., therapeutic breathing) or pain control drugs as needed and as ordered.
Minimizing adverse effects: • Monitor timing, quality, and duration of contractions continuously. Immediately report any sustained uterine contractions to the healthcare provider. Stop the drug infusion, infuse normal saline or solution as ordered, and place the patient on her side until follow-up orders are obtained if sustained contractions continue. (Oxytocin may cause sustained uterine muscle contractions with potential uterine rupture. Uterine contractions must be monitored and any continuous, sustained contractions reported immediately.)	• Teach the patient that labor contractions will increase in strength and duration and will be monitored. Instruct the patient to immediately report any sustained contraction or severe abdominal pain.
• Continuously monitor the fetal heart rate and response to contractions. Immediately report any signs of fetal distress to the healthcare provider. (Uterine contractions can affect the amount of blood flow through the placenta with diminished oxygenation to the fetus. Changes in fetal heart rate may signal fetal distress, and the patient should be placed on her side, oxygen administered unless otherwise ordered, the infusion stopped, and the healthcare provider notified.)	• Teach the patient that the fetal heart rate will also be monitored along with uterine contractions. Explain the purpose of all monitoring equipment to allay anxiety.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor vital signs and urine output frequently, and immediately report any blood pressure above 140/90 mmHg or less than 90/60 mmHg, especially if accompanied by tachycardia or diminished urine output, to the healthcare provider. (Oxytocin has vasoconstrictive and water-retention properties. Blood pressure and heart rate may increase and water intoxication is a possible adverse effect. Blood pressure or pulse rate exceeding parameters, increasing disorientation or confusion, and diminished urine output may signify adverse drug effects or possible complications.)	• Instruct the patient to immediately report any headache, dizziness, disorientation or confusion, palpitations, chest pressure, or pain.
• Monitor fundal firmness and location, postpartum bleeding, and pad count. Notify the healthcare provider if more than two full-size pads are saturated in a 2-h time period. (Oxytocin may be given to control postpartum bleeding. Lochia that increases, or if two or more pads are saturated over a 2-h period, should be immediately reported to the healthcare provider.)	• Instruct the patient to report any sudden increase in lochia, dizziness, lightheadedness, or if more than two pads are saturated after 2 h.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, monitoring needs, what adverse effects to observe for, and when to report them.

Uterine Relaxants: Tocolytics

69.6 Uterine relaxants are used to suppress preterm labor.

Preterm labor, the initiation of labor prior to week 37 of gestation, is a major cause of neonatal mortality. The most common cause is premature rupturing of membranes or infections of the chorion or uterus. If the organ systems of the fetus are determined to be immature, attempts may be made to delay labor because preterm infants have a high morbidity and mortality rate. Suppressing labor allows additional time for the fetal organs to develop and may permit the pregnancy to reach normal term. Bedrest is mandatory and corticosteroids may be administered to accelerate fetal lung maturity and reduce the incidence of neonatal respiratory distress syndrome. Antibiotics such as ampicillin or erythromycin are indicated if the preterm labor is due to a uterine or chorionic infection. Preterm labor can be stopped and delivery delayed in about 50% of women, if the membranes have not yet ruptured. The success rate is only 25% in patients with membrane rupture.

Tocolytics are uterine relaxants prescribed to suppress preterm labor contractions. Typically, the mother is given a monitor with a sensor that records uterine contractions and this information is used to determine the doses and timing of tocolytic medications. Tocolytics can generally delay labor by only 24 to 72 hours, but this is often enough time for the fetus to develop normal lung function. The benefits of these drugs must be carefully weighed against their potential adverse effects, which include tachycardia in both the mother and the fetus. There is no clear evidence that tocolytics reduce perinatal or neonatal mortality.

Only a few drugs are available as tocolytics, and none can be realistically considered a prototype. For over 30 years, magnesium sulfate was the preferred drug for delaying preterm labor, but some evidence suggests that it may be ineffective and that it poses undue risks to the fetus and mother. The only drug that is FDA approved for this indication is ritodrine (Yutopar), but it is no longer available in the United States. Calcium channel blockers and beta-adrenergic agonists appear to be effective and are used off-label for this indication. Doses for these drugs are listed in Table 69.3.

Magnesium sulfate: A traditional preferred tocolytic, magnesium sulfate is administered by continuous IV infusion via a controlled pump device until preterm contractions diminish, usually in about 30 minutes. It is used off-label for this indication. During therapy, careful monitoring of deep tendon reflexes, blood pressure, respirations, urinary output, and serum magnesium concentrations are necessary. Early signs of magnesium overdose include flushing of the skin, sedation, confusion, intense thirst, and muscle weakness. Extreme levels cause neuromuscular blockade with resultant respiratory paralysis, heart block, and circulatory collapse. In 2013, the FDA changed the pregnancy rating for this drug from A to D and warned that use for more than 5 to 7 days in pregnant women may result in fetal harm. This drug is featured as a prototype

electrolyte in Chapter 33 for the treatment of magnesium deficiency.

Nifedipine (Adalat, Procardia): Nifedipine is a calcium channel blocker widely prescribed for the treatment of HTN and angina. The drug has been used off-label as a tocolytic as an option to magnesium sulfate. Nifedipine is given either by the PO or sublingual route. A typical regimen includes a loading dose followed by additional PO doses every 15 to 20 minutes until contractions diminish. Nifedipine appears to be as effective as magnesium sulfate and the beta-adrenergic agonists but exhibits fewer adverse effects. Adverse effects include acute pulmonary edema, dysrhythmias, and hypotension. A prototype feature for nifedipine is presented in Chapter 30. This drug is pregnancy category C.

Terbutaline (Brethine): Terbutaline is a beta$_2$-adrenergic agonist that is FDA approved to treat acute bronchospasm due to asthma. It has been used off-label to suppress preterm contractions due to its ability to relax smooth muscle. It is given by the subcutaneous route either by injection every 20 minutes or by using a continuous infusion device. It may also be administered orally. The FDA has issued a black box warning that administration of terbutaline for more than 48 to 72 hours during pregnancy can result in serious adverse reactions, including death of the fetus. The mother may experience increased heart rate, dysrhythmias, myocardial ischemia, transient hyperglycemia, hypokalemia, and pulmonary edema. The fetus may experience increased heart rate and neonatal hypoglycemia. This drug is pregnancy category C.

Pharmacotherapy of Female Infertility and Female Sexual Desire Disorder

69.7 Female infertility may be treated with drugs that promote oocyte maturation and ovulation.

Infertility is defined as the inability to become pregnant after at least 1 year of frequent, unprotected intercourse. Infertility is a common disorder: 25% of couples experience difficulty in conceiving children at some point during their reproductive lifetimes. It is estimated that female reproductive tract conditions contribute to approximately 60% of the infertility disorders. Drugs used to treat female infertility are listed in Table 69.4. Treatment of male infertility is presented in Chapter 71.

The three primary causes of female infertility are pelvic infections, physical obstruction of the uterine tubes,

Table 69.4 Drugs for Female Infertility

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
bromocriptine (Parlodel)	PO: 1.25–2.5 mg/daily (max: 2.5 mg bid–tid)	*Nausea, vomiting, cramping, constipation, drowsiness, headache, orthostatic hypotension, anorexia* GI bleeding, psychosis, seizures, syncope
clomiphene (Clomid, Serophene)	PO first course: 50 mg/day for 5 days; start on fifth day of cycle following start of spontaneous or induced bleeding (with progestin) Second course if ovulation: Repeat first course until conception or for 3 cycles Second course if no ovulation: 100 mg/day for 5 days as above (max: 100 mg/day)	*Weight gain, symptoms of PMS, hot flashes, dermatitis* Blurred vision, ovarian hyperstimulation, cataracts, thrombosis of temporal arteries
danazol	PO: 200–400 mg bid for 3–6 months; may extend to 9 months	*Hirsutism, alopecia, voice deepening, weight gain, vaginal dryness, reduction in breast size, edema, emotional lability, hot flashes* Thromboembolic events, hepatotoxicity, intracranial HTN, fetal toxicity
FSH- and LH-Enhancing Drugs		
chorionic gonadotropin-HCG (Novarel, Ovidrel, Pregnyl)	IM: 5000–10,000 units 1 day following last dose of menotropins	Women: *Pelvic pain, depression, fatigue* Ovarian hyperstimulation syndrome Men: *Gynecomastia, acne* Aggressive behavior, depression
follitropin alfa (Gonal-F)	Subcutaneous: 75 international units/day initially, then increased by 37.5 international units at the end of 14 days. Further 37.5-unit dose increases may be made every 7 days (max: 300 international units/day)	*Headache, nausea, abdominal pain, diarrhea, increased infections* Ovarian hyperstimulation syndrome, thromboembolic disorders
follitropin beta (Follistim AQ)	Subcutaneous: 50–75 international units/day initially, then increased by 25–50 international units at the end of 14 days (max: 300 international units/day)	

Table 69.4 Drugs for Female Infertility (*continued*)

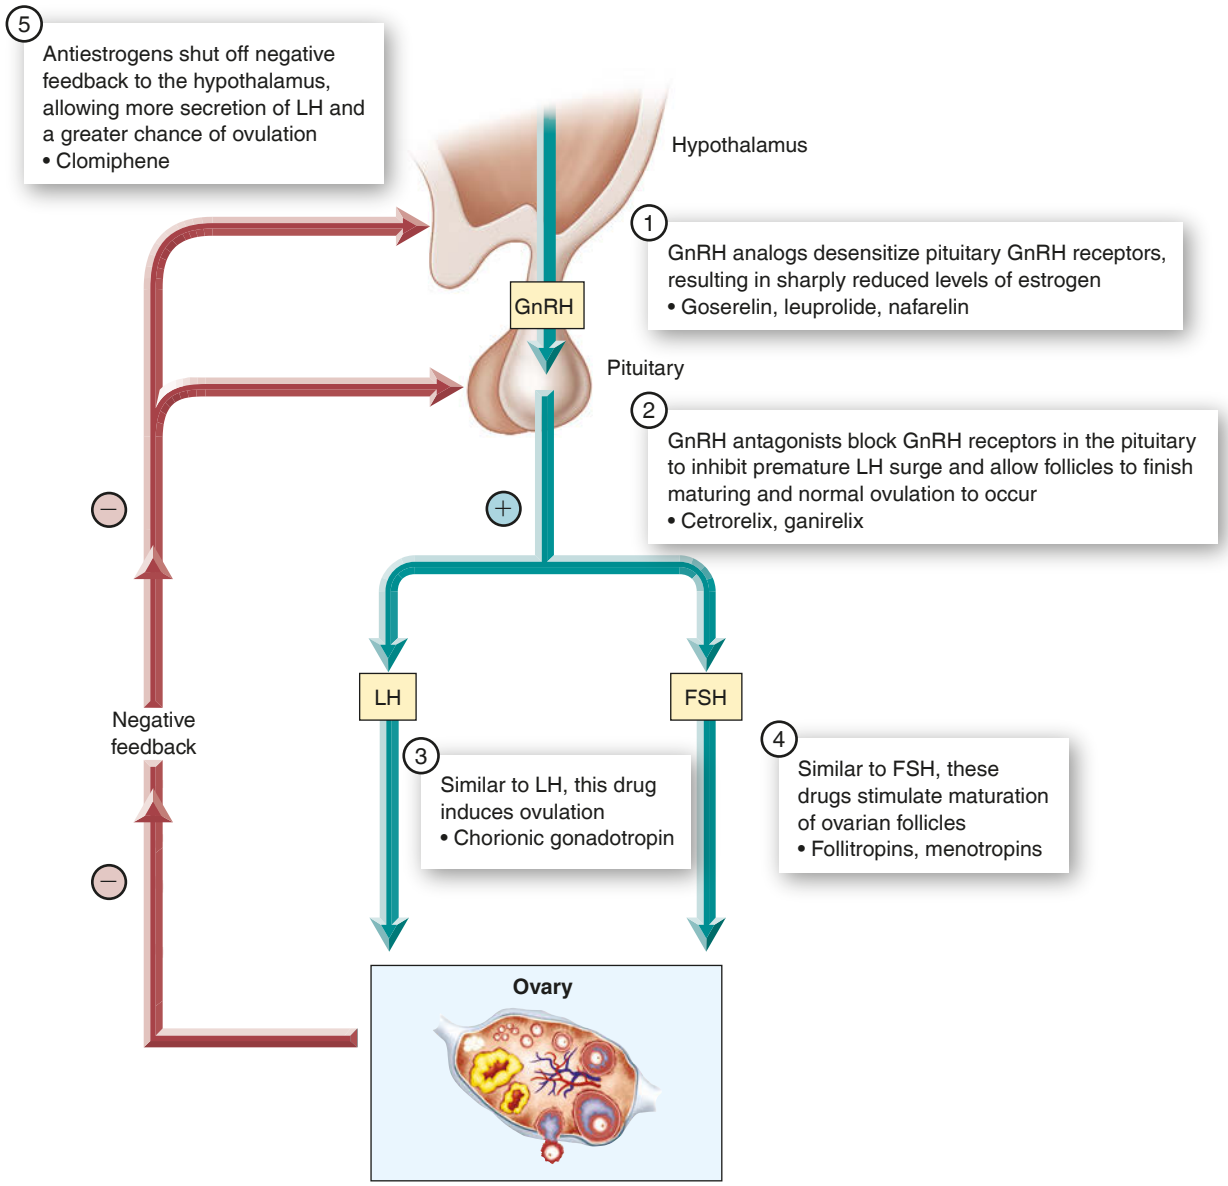
Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
menotropins (Menopur, Repronex)	Subcutaneous: 225 international units initially with 125 international unit dosage increases not more often than every 2 days	*Abdominal cramps, fullness, or pain, injection-site reaction, nausea* Ovarian hyperstimulation syndrome, thromboembolic disorders, respiratory disorders
urofollitropin (Bravelle)	For ovulatory women: subcutaneous: 150 international units once daily until sufficient follicular development is attained For anovulatory women: subcutaneous: 75 international units once daily. The dose should not be increased more than twice in any cycle or by more than 75 international units per adjustment	*Headache, nausea, abdominal pain, diarrhea, increased infections* Ovarian hyperstimulation syndrome, thromboembolic disorders
GnRH Antagonists		
cetrorelix (Cetrotide)	Subcutaneous: 0.25 mg/day during the early to midfollicular phase of the cycle following the initiation of FSH	*Hot flashes, headache, menstrual irregularities* Fetal death, ovarian hyperstimulation syndrome
ganirelix	Subcutaneous: 250 mcg once daily during the early to midfollicular phase of the cycle following the initiation of FSH	
GnRH Analogs/Agonists		
goserelin (Zoladex)	Subcutaneous implant for endometriosis: 3.6 mg every 28 days Subcutaneous implant for advanced carcinoma: 10.8 mg every 3 months	Women: *Headache, depression, sweating, acne, vaginitis, vaginal dryness, menstrual irregularities, bone density loss, emotional lability* Tumor flare (goserelin, leuprolide) Men: *Erectile dysfunction, lethargy, gynecomastia* Heart failure All patients: *Pain at injection site, hot flashes, loss of libido* Bone density loss, fractures
leuprolide (Eligard, Lupron, Viadur)	IM for endometriosis: 3.75 mg every month or 11.25 mg every 3 months Subcutaneous for infertility: 0.5–1 mg/day. By day 3 of the menstrual cycle, the dosage is typically decreased by 50%	
nafarelin (Synarel)	Intranasal: 2 inhalations/day (200 mcg/inhalation), one in each nostril; begin between days 2 and 4 of menstrual cycle (may increase to 800 mcg/day as 2 inhalations)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

and lack of ovulation. Extensive testing is often necessary to determine the exact cause, and it is not uncommon to find multiple etiologies for the infertility.

For women whose infertility is due to inadequate ovulation, pharmacotherapy may be of value. **Ovulatory dysfunction** is defined as the presence of abnormal, irregular, or absent ovulation. Signs and symptoms of ovulatory dysfunction include irregular or absent menses, excessive abdominal bloating, and mood lability. Confirmation of the disorder is made by measuring hormone levels.

Ovulatory dysfunction may occur at the level of the hypothalamus, pituitary, or ovary, and pharmacotherapy is targeted to the specific cause of the dysfunction. The most common etiology of ovulatory dysfunction is **polycystic ovary syndrome**, a condition in which the ovaries are filled with follicular cysts and the patient has elevated levels of androgens and estrogen. Hirsutism is commonly observed in these women due to the excessive androgen levels. Another cause of ovulatory dysfunction is hyperprolactinemia, excessive levels of the hormone prolactin, which is most frequently caused by a tumor of the pituitary gland.



Many women with ovulatory dysfunction can be successfully treated with drug therapy; restoring regular, monthly ovulation is an essential goal of fertility management. Ovulation induction protocols are sometimes divided into the following three medication groups, which are shown in Pharmacotherapy Illustrated 69.1:

- Drugs used to promote maturation of ovarian follicles
- Drugs used to trigger ovulation at the end of follicular maturation
- Drugs that promote ovulation to occur on a regular, monthly basis, at the midpoint of the menstrual cycle.

Promotion of follicle maturation: Ovulation cannot occur unless the ovarian follicles receive a hormonal signal to mature each month. This signal is normally supplied by LH and FSH during the first few weeks of the menstrual cycle. Clomiphene (Clomid, Serophene) is the traditional preferred drug for treating female infertility because it stimulates the release of LH, resulting in the maturation of more ovarian follicles than would normally occur. The rise in LH level induced by clomiphene is sufficient to induce ovulation in about 80% of treated patients. The use of clomiphene assumes that the pituitary gland is able to respond by secreting LH, and that the ovaries are responsive to LH. If either of these assumptions is false, other treatment options must be considered.

Pharmacotherapy Illustrated 69.1

Mechanisms of Action of Drugs Used to Treat Female Infertility

If the infertility is a result of endocrine disruption at the pituitary level, therapy with human menopausal gonadotropin (HMG) or GnRH may be indicated. These therapies are generally indicated only after clomiphene has failed to induce ovulation. Also known as menotropins (Menopur, Repronex), HMG acts on the ovaries to increase follicle maturation and results in a 25% incidence of multiple pregnancies. Successful therapy with HMG assumes that the ovaries are responsive to LH and FSH. Newer formulations use recombinant DNA technology to synthesize gonadotropins containing nearly pure FSH, rather than extracting the FSH-LH mixture from urine.

Promotion of ovulation: Unless maturing follicles receive the final "burst" of LH, ovulation will not occur. HMG is similar in structure to natural LH and produces the same effect: ovulation.

Restoration of a normal monthly pattern of ovulation: The success of conception will be improved if a regular, monthly pattern of ovulation is established. Premature ovulation, the expulsion of the oocyte from the ovary before it has fully matured, is prevented by the use of two antagonists of GnRH: ganirelix and cetrorelix (Cetrotide).

Stimulation of the ovary by certain fertility drugs causes the ovaries to enlarge. Mild enlargement may cause pelvic pain but is generally benign and disappears when therapy is discontinued. One serious complication of certain fertility drugs is **ovarian hyperstimulation syndrome (OHS)**. The onset of OHS is characterized by rapid, massive enlargement of the ovaries accompanied by nausea, vomiting, rapid weight gain, ascites, respiratory difficulties, increased risk of thromboembolism, and progressive kidney impairment. Progressive symptoms call for discontinuation of drug therapy, fluid restriction, bedrest, and symptomatic treatment of nausea, vomiting, and pain. Although OHS can be fatal, most cases resolve in 1 to 2 weeks.

Endometriosis, a cause of infertility, is characterized by the presence of endometrial tissue that has implanted outside the uterus in locations such as the surface of pelvic organs or the ovaries. Approximately 25% to 50% of infertile women have endometriosis. Being responsive to hormonal stimuli, this abnormal tissue can cause pain, dysfunctional uterine bleeding, and dysmenorrhea. The pain, discomfort, and infertility brought on by endometriosis may be treated by danazol, nafarelin, and leuprolide. These drugs suppress the production of estrogen and progesterone, resulting in a decrease in growth potential of endometrial tissues. Surgical removal, ablation, or laser vaporization of the abnormal endometrial lesions may be necessary. Women who have completed their childbearing or who are postmenopausal may consider a hysterectomy with oophorectomy.

Leuprolide (Lupron) and nafarelin (Synarel) are GnRH agonists that produce an initial release of LH and FSH, followed by suppression due to the negative feedback effect on the pituitary. Many women experience relief from the symptoms of endometriosis after 3 to 6 months of leuprolide therapy, and the benefits may extend well beyond the treatment period. As an alternative choice, danazol is an anabolic steroid that suppresses FSH production, which in turn shuts down both ectopic and normal endometrial activity. While leuprolide is given only by the parenteral route, danazol is given orally. Estrogen–progestin oral contraceptives are also useful in treating endometriosis.

PharmFACT

The most important preventable causes of infertility are chlamydia and gonorrhea infections. These infections can cause pelvic inflammatory disease, which can lead to infertility and ectopic pregnancies (Centers for Disease Control and Prevention, 2016).

PROTOTYPE DRUG Clomiphene (Clomid, Serophene)

Classification **Therapeutic:** Infertility drug
Pharmacologic: Ovarian stimulant

Therapeutic Effects and Uses: Approved in 1967, clomiphene is a first-line drug for female infertility caused by ovulatory dysfunction. It acts by inducing ovulation in anovulatory women. The pregnancy rate of patients taking clomiphene is high, and twins occur in about 3% to 5% of treated patients. Therapy is usually begun with a low dose for 5 days following menses because this is the time of greatest follicle maturation. If ovulation does not occur, the dose is increased. If ovulation still is not induced, HCG is added to the regimen. If pregnancy has not occurred following six cycles of successful ovulation, the drug is usually discontinued and other means of restoring fertility are explored. The use of clomiphene does not permanently restore normal follicle maturation. Its effects diminish once the drug is discontinued.

Clomiphene is used off-label to treat low sperm counts (oligospermia) in men. Just as in women, the drug increases the secretion of LH. In men, LH stimulates the testes to produce testosterone and additional sperm.

Mechanism of Action: Clomiphene is a SERM that has both estrogen agonist and antagonist effects, depending on the tissue. In the pituitary and hypothalamus, clomiphene acts as an "antiestrogen," shutting off LH secretion, which is required for ovulation. Clomiphene competes for estrogen receptors in the hypothalamus by sending a message that estrogen levels are low; in response, LH is secreted, leading to ovarian stimulation.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed
Distribution	Crosses the placenta; unknown if secreted in breast milk; 90% bound to protein
Primary metabolism	Hepatic
Primary excretion	Feces; small amounts in urine
Onset of action	30–60 min
Duration of action	Half-life: 5–7 days; peak effects: 4–10 days

Adverse Effects: Few serious adverse effects occur during clomiphene therapy. The most common are weight gain, symptoms of PMS, hot flashes, allergic dermatitis, and urticaria. The most serious adverse effects are blurred vision, ovarian hyperstimulation, cataracts and other visual impairments, and thrombosis of temporal arteries. The drug may cause ovarian enlargement with subsequent pelvic pain in about 14% of women taking the drug.

Contraindications/Precautions: Clomiphene should be avoided in patients with lactation, gynecomastia, fibrocystic breast disease, liver disease, ovarian cysts not due to polycystic ovary syndrome, and hepatic,

thyroid, or adrenal dysfunction. The drug is contraindicated in patients with dysfunctional uterine bleeding until the cause can be determined. Pregnant patients must not take this drug.

Drug Interactions: Androgens will reduce the success of clomiphene therapy. **Herbal/Food:** Black cohosh and chasteberry have estrogen effects that may reduce the effectiveness of clomiphene.

Pregnancy: Category X.

Treatment of Overdose: Symptoms of overdose include nausea or vomiting, visual blurring, hot flashes, and pelvic pain. The patient is treated symptomatically.

Nursing Responsibilities:

- Prior to beginning therapy, obtain a pregnancy test to confirm that the patient is not pregnant. This is a category X drug that could cause fetal abnormalities.
- Assess for abnormal vaginal bleeding. If present, ensure that neoplastic lesions are not present prior to initiating therapy.
- Prior to initiating therapy, exclude other causes of infertility, such as thyroid disorders, adrenal disorders, hyperprolactinemia, and male factor infertility.
- Monitor laboratory results for increased levels of FSH and LH, and pregnancy.
- Counsel patients regarding the timing of drug therapy and intercourse to achieve pregnancy.
- Monitor for signs of ovarian hyperstimulation syndrome such as rapid weight gain, increased abdominal girth, nausea, vomiting, dyspnea, and chest pain. Report symptoms immediately to the prescriber.

Patient and Family Education:

- Record basal temperature at the same time each day on a graph to determine if ovulation has occurred. Ovulation occurs on days 4 through 10 in women who respond to treatment. There is an increased possibility of a multiple pregnancy.
- Take the medication at the same time each day to maintain consistent drug levels.
- Discontinue the drug and notify the healthcare provider if pelvic pain or abdominal distention occurs. This may indicate ovarian enlargement or presence of a ruptured ovarian cyst.
- Immediately report blurred vision, spots or flashes in the eyes, severe hot flashes, uterine bleeding, headache, and nausea to the healthcare provider.
- Report signs of jaundice such as yellowing of the skin or eyes, light-colored stool, and fever.
- Immediately notify the healthcare provider of any known or suspected pregnancy.

Drugs Similar to Clomiphene (Clomid, Serophene)

Other drugs for female infertility include bromocriptine, cetrorelix, chorionic gonadotropin-HCG, danazol, follitropins, ganirelix, goserelin, leuprolide, menotropins, and nafarelin.

Bromocriptine (Parlodel): Approved in 1978, bromocriptine is chemically related to the ergot alkaloids and is indicated for a large number of diverse conditions. The drug is a dopamine agonist, activating dopaminergic receptors in the hypothalamus. For infertility, its primary use is to treat prolactin-secreting tumors of the pituitary, which often cause amenorrhea and female infertility. Normal menses are usually restored after 6 to 8 weeks of therapy. This reduces elevated serum prolactin levels and restores ovulation and ovarian function in amenorrheic women. It is used as a short-term treatment for amenorrhea in the absence of pituitary tumors. It is also approved to treat acromegaly and Parkinson's disease and to improve glycemic control in patients with type 2 diabetes. Off-label indications include mastalgia associated with PMS, alcoholism, cocaine withdrawal, and neuroleptic malignant syndrome. Bromocriptine causes frequent adverse effects that include nausea, vomiting, cramping, constipation, drowsiness, headache, orthostatic hypotension, and anorexia. This drug is pregnancy category C.

Cetrorelix (Cetrotide): Approved in 2000, cetrorelix is a GnRH antagonist given by the subcutaneous route that blocks GnRH receptors in the pituitary. Women undergoing ovarian stimulation with FSH or menotropins therapy experience a sharp rise in estrogen levels due to the maturing follicles, which can trigger an early surge of LH and premature ovulation. Cetrorelix inhibits this premature LH surge in women who are undergoing controlled ovarian stimulation for assisted reproduction, thus allowing follicles to finish maturing and normal ovulation to occur. The only indication for cetrorelix is infertility. Adverse effects are minor and include hot flashes and headache. It is contraindicated for use in primary ovarian failure, chronic kidney disease (CKD), and pregnancy. This drug is pregnancy category X.

Chorionic gonadotropin-HCG (Novarel, Ovidrel, Pregnyl): This drug has two forms. HCG is secreted by the placenta and obtained and purified from the urine of pregnant women. Choriogonadotropin alfa (r-HCG, Ovidrel) is a recombinant form with actions identical to those of HCG. The chorionic gonadotropin drugs have the same actions as LH and can mimic the LH surge that normally causes ovulation. As part of an assisted reproductive program, chorionic gonadotropin is administered at midcycle, after clomiphene or FSH has been used to mature sufficient numbers of ovarian follicles. A single IM dose is sufficient to induce ovulation. The drug has few adverse effects when administered as a single dose in women. This drug is pregnancy category X.

In males, HCG is approved to treat prepubertal cryptorchidism, hypogonadism, and oligospermia. Therapy in males may continue for several months and gynecomastia, acne, and behavioral changes may occur.

Danazol: Danazol is a PO drug used to treat endometriosis. Approved in 1976, the drug exerts antiestrogenic and weak androgenic properties, which cause ectopic endometrial tissue to atrophy. After 6 weeks of therapy, danazol causes anovulation and amenorrhea, which are its therapeutic effects. When the drug is discontinued, normal ovulation and menstrual cycles return in about 2 to 3 months. Danazol is also approved to treat fibrocystic breast disease and for the prophylaxis of hereditary angioedema. The drug has androgenic actions that may cause permanent masculinization effects such as hirsutism, alopecia, voice deepening, and weight gain. Women may experience effects of estrogen deficiency such as vaginal dryness, reduction in breast size, emotional lability, and hot flashes. Serious adverse effects include thromboembolism, hepatic adenoma, and intracranial HTN. This drug is pregnancy category X.

Follitropins: The follitropins are three different drugs with the same actions. All are versions of human FSH. Urofollitropin (Bravelle) is FSH purified from the urine of postmenopausal women. Follitropin alfa (Gonal-F) and follitropin beta (Follistim AQ) are FSH obtained through recombinant DNA technology. All three FSH products are given by the parenteral route. The function of FSH (and the follitropins) is to stimulate the maturation of ovarian follicles. The drugs are given early in the menstrual cycle, followed by a dose of chorionic gonadotropin, which provides the boost for ovulation. Multiple births, including triplets, quadruplets, and quintuplets, are common during therapy with follitropins. In men, follitropins are used to stimulate spermatogenesis in patients with hypogonadism and oligospermia. Minor adverse effects include headache, nausea, abdominal pain, diarrhea, and increased infections. The most serious potential adverse effects are OHS, thromboembolism, acute respiratory distress syndrome, and exacerbation of asthma. The follitropins are pregnancy category X.

Ganirelix: Like cetrorelix, ganirelix is a GnRH antagonist given by the subcutaneous route that blocks GnRH receptors in the pituitary. Approved in 1999, its only indication is for female infertility. Ganirelix inhibits the premature LH surge in patients undergoing controlled ovarian stimulation for assisted reproduction. Adverse effects are minor and include hot flashes, menstrual irregularities, and headache. It is contraindicated for use in primary ovarian failure, CKD, and pregnancy. This drug is pregnancy category X.

Goserelin (Zoladex): Goserelin is a GnRH hormone agonist. It has the same physiologic actions as endogenous GnRH; however, the way it is administered causes the opposite effect. Natural GnRH is released by the hypothalamus in an "on–off" pulsatile manner, which stimulates the release of LH and FSH (and eventually estrogen). Like GnRH, goserelin first stimulates LH and FSH secretion. With continuous administration, however, the pituitary receptors become insensitive to the effects of GnRH and the gland stops releasing LH and FSH. Without FSH or LH, the levels of estrogen in women and testosterone in men fall dramatically. This hypoestrogenic state relieves the symptoms of endometriosis. It is also approved for palliative treatment of estrogen-dependent breast cancer and for advanced prostate cancer. Goserelin is available subcutaneously as a once-monthly implant (for men or women) and a 3-month implant for men with prostate cancer. Women may experience hypoestrogenic effects such as vaginal dryness, depression, menstrual irregularities, bone density loss, emotional lability, and hot flashes. Men may experience erectile dysfunction, gynecomastia, and loss of libido. Pain at the injection site is common. This drug is pregnancy category X.

Leuprolide (Eligard, Lupron, Viadur): Like goserelin, leuprolide is a GnRH agonist. The two drugs act by the same mechanism: desensitizing pituitary GnRH receptors, resulting in sharply reduced levels of estrogen and testosterone. For relief of endometriosis symptoms, a depot IM injection is given once monthly or once every 3 months, depending on the dose. Treatment of endometriosis is limited to 6 months. Like goserelin, it is also approved for the palliative treatment of advanced prostate cancer and used off-label for breast cancer. Leuprolide is an orphan drug for treating precocious (early) puberty in children less than 9 years old. The drug was once widely used to treat infertility by inhibiting premature LH surges but the GnRH antagonists are now used for this indication. The adverse effects are the same as those for goserelin. This drug is pregnancy category X.

Menotropins (Menopur, Repronex): Approved in 1975, menotropins is sometimes referred to as HMG. Menotropins is a product containing a combination of FSH and LH purified from the urine of postmenopausal women. The FSH activity of menotropins is significantly higher than its LH activity. Like the follitropins, menotropins is given by the parenteral route during the first half of the menstrual cycle to promote follicle maturation. At the end of therapy, HCG is often administered to supply the LH surge necessary for ovulation. Menotropins therapy is associated with a 20% to 35% possibility of multiple births. In men, menotropins is FDA approved to stimulate spermatogenesis in patients with hypogonadism and oligospermia. In men, gynecomastia, acne, and behavioral changes may occur. In women, the drug often causes ovarian enlargement and OHS is possible. Serious pulmonary conditions such as acute respiratory distress syndrome and exacerbation of asthma have been reported. This drug is pregnancy category X.

Nafarelin (Synarel): Like goserelin and leuprolide, nafarelin is a GnRH agonist. The three drugs act by the same mechanism: desensitizing pituitary GnRH receptors, resulting in sharply reduced levels of estrogen and testosterone. Unlike the other GnRH analogs, nafarelin is applied topically to the nasal mucosa, where the drug is rapidly absorbed. When used to treat endometriosis, the typical dose is one spray in each nostril daily. It is also approved to treat precocious puberty and used off-label for hirsutism. Nafarelin may be used off-label to prevent premature LH surges in women with infertility; however, ganirelix and cetrorelix are more frequently prescribed for this indication. Adverse effects are the same as those of the other GnRH agonists goserelin and leuprolide. This drug was approved in 1990 and is pregnancy category X.

69.8 Low sexual desire in women may be treated with pharmacotherapy.

Hypoactive sexual desire disorder (HSDD), also called female sexual interest arousal disorder, is a condition marked by a persistent lack of interest in sexual activity over a prolonged period. To be diagnosed with HSDD, the patient must be experiencing marked distress or interpersonal difficulty that negatively impacts her quality of life.

In 2015 the FDA approved the first drug for female HSDD. Flibanserin (Addyi) is approved to treat HSDD in premenopausal women who previously had no problems with sexual desire. The drug carries a black box warning that it can cause severe hypotension and syncope if taken concurrently with alcohol or moderate or strong inhibitors of CYP3A4, such as azole antifungals, ritonavir, telaprevir, or verapamil. Because of the potential for serious hypotension, the FDA requires prescribers to complete special training. In addition, pharmacies must be certified to dispense the medication, and patients must sign an agreement that they understand the adverse effects. Common adverse effects include dizziness, sleepiness, nausea, fatigue, and dry mouth. The mechanism by which flibanserin increases sexual desire is not known.

Understanding Chapter 69

Key Concepts Summary

69.1 Regulation of the female reproductive system is achieved by hormones from the hypothalamus, pituitary gland, and ovary.

69.2 Estrogens are administered as replacement therapy, to prevent conception, and for certain neoplasms.

69.3 Progestins are administered to treat dysfunctional uterine bleeding, to prevent conception, and for certain neoplasms.

69.4 Hormone replacement therapy provides relief from menopause symptoms but may have serious long-term negative effects.

69.5 Oxytocics are drugs used to stimulate the uterus and promote labor and delivery.

69.6 Uterine relaxants are used to suppress preterm labor.

69.7 Female infertility may be treated with drugs that promote oocyte maturation and ovulation.

69.8 Low sexual desire in women may be treated with pharmacotherapy.

CASE STUDY: Making the Patient Connection

Remember the patient "Maureen John" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow the case study.

Maureen John is 46 years old and exhibiting signs of menopause. She reports a change in her menstrual cycle regularity. For the past year, her periods have occurred between 6 and 8 weeks apart and have lasted only 2 to 3 days. Previously, she experienced her periods approximately every 28 days and they lasted from 4 to 5 days. She reports to the nurse that she is now feeling easily fatigued, has more mood swings, occasional headaches, hot flashes, insomnia, bouts of depression, and irritability. She is also concerned about her loss of libido. She admits to smoking half a pack of cigarettes a day and drinking several cups of coffee

during work hours. She has a family history of HTN, cardiac disease, and diabetes, but she has never been diagnosed with any of those disorders.

A complete history and physical examination, along with a vaginal examination and a Pap smear were performed.

Critical Thinking Questions

1. Do you think that Maureen is a candidate for hormone replacement therapy? Why or why not?
2. Create a list of some treatment options for Maureen.
3. Maureen asks about the precautions related to suggested treatment options. How would you respond?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Prithi Kaur, a 23-year-old woman, and her 25-year-old husband attend the infertility clinic for evaluation. Efforts at becoming pregnant naturally for the past 2 years have failed. They inform the nurse that the husband has a 3-year-old son from an earlier relationship. The wife has never conceived. Both denied any sexually transmitted infections. The patient is started on clomiphene (Clomid) 50 mg for 5 days.

1. Prithi asks you, the nurse, "What are some causes of infertility?" How would you respond?
2. What instructions would you give to the patient regarding the administration of this drug?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A 52-year-old patient experiencing symptoms of menopause is interested in taking hormone replacement therapy (HRT) with conjugated estrogen (Premarin). Which conditions may be a contraindication for HRT for this patient? (Select all that apply.)
   1. History of type 2 diabetes mellitus
   2. History of deep vein thrombosis
   3. History of breast cancer with "lumpectomy" treatment
   4. History of hyperlipidemia, controlled by drug therapy
   5. History of two cesarean births
2. The nurse is evaluating the effect of an oxytocin infusion in a laboring woman. Which of the following indicates that the drug is exerting therapeutic effects?
   1. Hemorrhage is controlled.
   2. Contractions are sustained at 60 seconds long.
   3. Contractions are occurring every 4 minutes and lasting 20 seconds.
   4. Milk letdown has begun in preparation for breastfeeding.
3. Which instruction about clomiphene (Clomid) will the nurse provide to a woman with infertility?
   1. "The drug will be taken for a year and then reevaluated for an increased dose."
   2. "The drug will be continued for the first 3 months of pregnancy to guard against miscarriage."
   3. "You may stay on this indefinitely until pregnancy occurs. There are few adverse effects."
   4. "If pregnancy does not occur within six cycles, other options for treatment will be explored."
4. A 48-year-old patient has received a prescription for medroxyprogesterone (Provera) for treatment of dysfunctional uterine bleeding. Because of related adverse effects, the nurse will teach the patient to monitor and report which symptoms?
   1. Insomnia or difficulty falling asleep
   2. Excessive mouth, eye, or vaginal dryness
   3. Joint pain or pain on ambulation
   4. Breakthrough spotting between menstrual periods
5. The patient informs the healthcare provider that she has been trying to become pregnant for more than 2 years and has not used any form of contraception. The healthcare provider prescribes clomiphene (Clomid) 50 mg/day for 5 days. The nurse should instruct the patient to begin taking the drug on the:
   1. First day of the menstrual cycle.
   2. Fifth day of the menstrual cycle.
   3. Fifth day after ovulation.
   4. Last day of the menstrual cycle.

6. A patient in preterm labor is receiving magnesium sulfate by IV infusion. Which early sign of magnesium toxicity would prompt the nurse to stop the infusion and notify the provider?
   1. Hyperactive patellar reflexes
   2. Chest congestion and coughing
   3. Seizure activity
   4. Sedation and intense thirst

Patient "Lila Bastian," 19 years old

Chapter 70
Drugs for Modifying Conception

Chapter Outline

- Options and Choices for Birth Control
- Combination Oral Contraceptives

  Estrogen–Progestin Combinations

  PROTOTYPE *Estradiol and Norethindrone (Ortho-Novum, Others), p. 1292*
- Adverse Effects of Combination Oral Contraceptives
- Progestin-Only Oral Contraceptives
- Long-Acting Reversible Contraceptives
- Spermicides

  PROTOTYPE *Nonoxynol-9, p. 1298*
- Emergency Contraception
- Drugs for Pharmacologic Abortion

  PROTOTYPE *Mifepristone (Mifeprex), p. 1302*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the choices available for birth control.
2. Delineate advantages and disadvantages of the different contraceptive options.
3. Explain the mechanisms by which estrogens and progestins prevent conception.
4. Compare the safety and effectiveness of different birth control methods.
5. Compare and contrast the options available for long-term contraception.
6. Explain the use of drugs for emergency contraception and for terminating pregnancy.
7. Describe the nurse's role in the pharmacologic management of patients who are taking oral contraceptives.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to the care of patients receiving pharmacotherapy for contraception.

Key Terms

abortifacients, 1301
chloasma, 1294
contraception, 1288
ectopic pregnancy, 1292
emergency contraception (EC), 1300
long-acting reversible contraceptives (LARCs), 1295
progesterone, 1289
spermicides, 1298

About 60 to 70 million women in the United States are of childbearing age (15–44 years). Of these women about 62% practice **contraception**, the use of devices, drugs, or surgery to prevent pregnancy (Daniels, Daugherty, Jones, & Mosher, 2015). This chapter discusses the female sex hormones that are used to modify conception, describes other widely used methods of contraception, and identifies the nursing connections to patient and family education.

Options and Choices for Birth Control

70.1 Selection of a contraceptive is based on effectiveness, safety, and personal choice.

The decision to engage in sexual activity is one of the most important decisions in life; the choice affects not just the partners, but may impact generations to follow. A couple engaging in intercourse on a regular basis without contraceptive protection has a 90% probability of conceiving a child over the course of a year. Thus, the voluntary choice to use contraceptive measures is a critical decision faced by most women in the childbearing years.

Prior to the 1960s, the three primary methods of avoiding pregnancy were total abstinence, abstinence during periods of greatest fertility (rhythm or calendar method), and withdrawal prior to ejaculation (coitus interruptus). The discovery of oral contraceptives and the development of long-acting reversible contraceptives (LARCs) have given couples more effective choices for birth control. For women unable to take medication for contraception, intrauterine devices are safe and effective alternatives. Many contraceptive options are now available, each having specific advantages and disadvantages. The primary options, their effectiveness, and advantages and disadvantages are listed in Table 70.1.

Women make personal birth control decisions based on several factors. The effectiveness for preventing pregnancy and the safety of the medication or device are the highest priorities. Other factors, however, may be of personal concern. Women who engage in intercourse frequently or who are likely to forget to take their medication may prefer the convenience of the LARCs. For patients who have a history of thromboembolic disorders, barrier protection or the use of progestin-only types of contraceptives are safer options. Factors that influence their decisions include the following:

- Effectiveness of the chosen method
- Adverse effects and safety
- Age
- Frequency of intercourse
- Ease of use and the ability to adhere to the required regimen
- Preexisting medical conditions
- Cultural or religious beliefs.

Women seeking to prevent conception need to discuss the available options with their healthcare provider. Final decisions on choosing a contraceptive should be made voluntarily with full knowledge of its advantages and disadvantages, effectiveness, adverse effects, contraindications, and potential long-term risks. When the desire to have children in the future no longer exists, sterilization of either the male or female partner is the most common and effective option for birth control. Whatever the choice of birth control, personal motivation must be taken into consideration because it is important that the woman be consistent in using the chosen method if pregnancy is to be prevented.

Contraceptives act in different regions of the female reproductive tract. The student should refer to Pharmacotherapy Illustrated 70.1 often while reading this chapter to obtain an overall perspective on the sites and mechanisms of contraceptive action.

Combination Oral Contraceptives

70.2 The most effective oral contraceptives include combinations of low-dose estrogens and progestins.

The physiology and pharmacologic indications for the female sex hormones estrogen and progesterone are presented in Chapter 69. Because estrogen and progesterone are the two classes of drugs used most frequently for contraception, the student should review that chapter before proceeding.

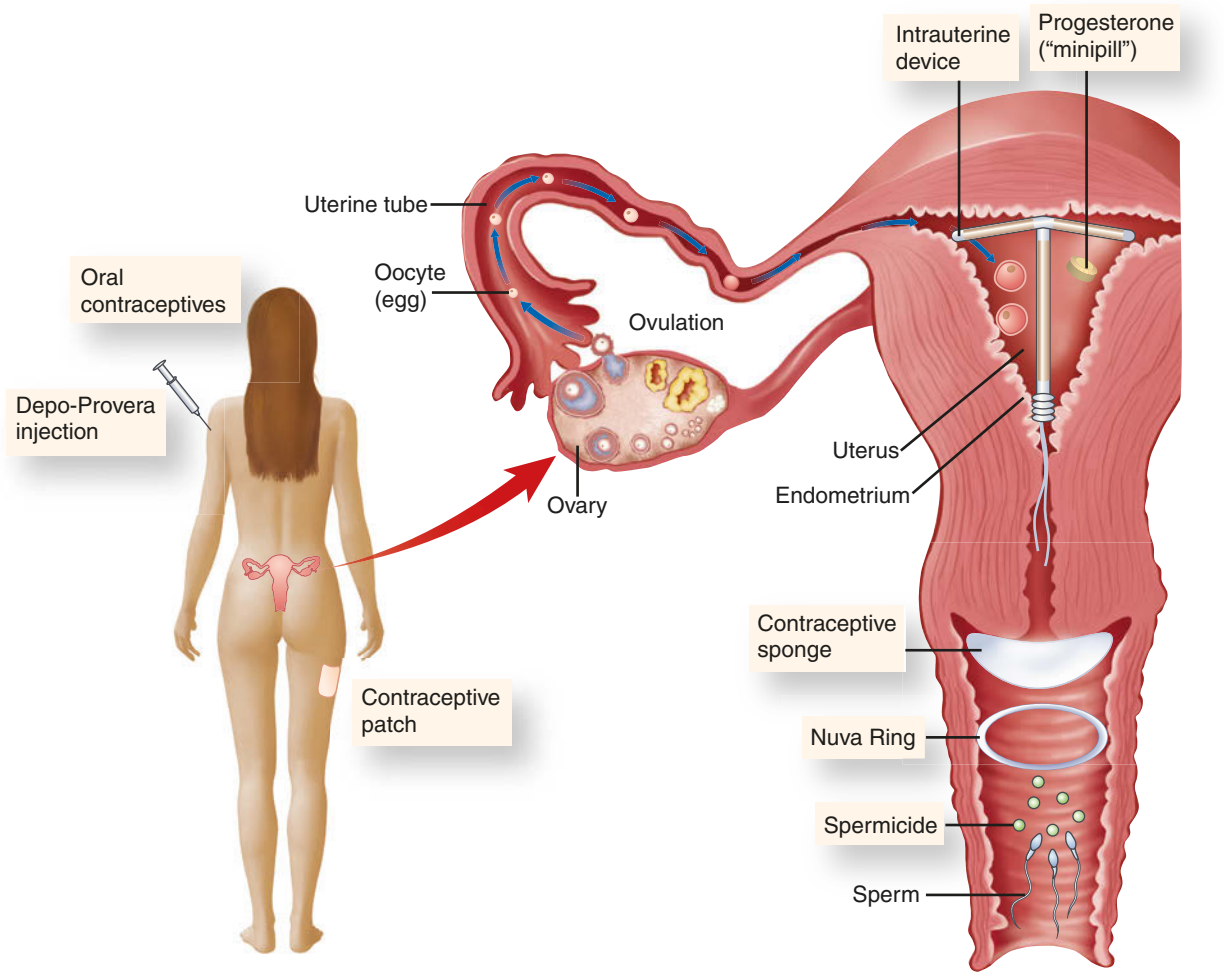
The most widespread pharmacologic use of estrogen and progesterone is to prevent pregnancy. *Estrogen* is a general term that refers to several female sex hormones. The

Table 70.1 Effectiveness of Conception Modifiers

Type	Description	PREGNANCY RATE (%/YEAR)* With Perfect Use	PREGNANCY RATE (%/YEAR)* With Typical Use	Selected Advantages	Selected Disadvantages
Hormonal Methods					
Combination oral contraceptives (OCs)	Daily tablets	0.3%	9%	Very effective, decreased risk of ovarian and endometrial cancer	Fluid retention, venous thromboembolism, amenorrhea, nausea, vomiting, irregular bleeding, headache; must be taken daily
Progestin-only OCs	Daily tablets	0.5%	9%	No estrogen adverse effects; may be used in women with history of thromboembolic disease	Less effective than combination OCs; frequent spotting, amenorrhea, ectopic pregnancy
Progestin injections	Every 3 months	0.2%	6%	Do not have to take daily pills; long-term protection	Amenorrhea, irregular bleeding, headache, loss of bone density, may delay return of fertility when discontinued
Transdermal patches	Weekly patch	0.3%	9%	Do not have to take daily pills; easy to apply	Similar to OCs; higher risk of thromboembolic disease compared to OCs, irritation at application site
Subdermal progestin implants	Every 3 years	0.05%	1%	Do not have to take daily pills; long-term protection	Amenorrhea, irregular bleeding, headache
Barrier and Miscellaneous Methods					
Condoms (male), diaphragms	Coitus based	2–6%	12–18%	Inexpensive; some protection against sexually transmitted infections, no hormonal adverse effects; few significant adverse effects	Less convenient than hormonal methods
Spermicides	Coitus based	18%	28%	Inexpensive, no hormonal adverse effects	Ineffective if used without barrier protection; inconvenient; vaginal irritation
Contraceptive sponge	Coitus based	9–20%	12–24%	Inexpensive; no hormonal adverse effects; protection lasts 24 h	Allergic reactions, vaginal dryness or irritation; less convenient
Intrauterine devices/systems	Mirena, Skyla, Copper T380A; every few years	0.2–0.6%	0.2–0.8%	Effective, long-term contraception; decreased menstrual flow and cramping; inexpensive; no hormonal adverse effects (Copper T380A), quick return of fertility	Irregular bleeding, pelvic pain, spontaneous expulsion, uterine perforation
Withdrawal method	Coitus based	4%	22%	Free; no adverse effects	Requires cooperation of partner, inconvenient and ineffective
Biologic	Calendar/ rhythm	3–5%	24%	Free; no adverse effects	Requires cooperation of partner, inconvenient and ineffective

*Pregnancy rates from using the various methods listed vary considerably in the scientific literature.

ones used in oral contraceptives are the synthetic estrogens ethinyl estradiol and ethinyl valerate. All estrogens have the same pharmacologic actions.



Progestin is a general term that refers to synthetic hormones that have actions identical to progesterone. Although **progesterone** is the natural progestin secreted by the corpus luteum, it is rarely used for contraception. Instead, synthetic progestins including norethindrone, norgestrel, desogestrel, dienogest, and levonorgestrel are used. The synthetic progestins have a longer half-life than progesterone, which allows for the convenience of once-daily dosing. All progestins have the same pharmacologic activity.

The first oral contraceptive (OC) was approved by the U.S. Food and Drug Administration (FDA) in 1960, and it was quickly recognized as a landmark discovery in reproductive medicine. The majority of oral contraceptives, known as "the pill," contain combinations of estrogen and progestin. Medications containing estrogen or progestin for the purpose of preventing pregnancy are sometimes called hormonal contraceptives. Approximately 30% of the women who choose contraceptive methods select OCs. These inexpensive, readily available drugs are 90% effective at preventing pregnancy when taken daily. They are excellent methods of contraception for women who are healthy and have no contraindications. One advantage of OCs is that they can be discontinued at any time without long-lasting adverse effects. In addition, one of the OCs, Natazia, has an additional indication: heavy menstrual bleeding.

A large number of combination OC preparations are available, differing in dose and by type of estrogen and

Pharmacotherapy Illustrated 70.1

Mechanisms of Action of Contraceptives

progestin, as listed in Table 70.2. Selection of a specific drug is individualized for each patient and determined by which product gives the best contraceptive protection with the fewest adverse effects. Treatment is generally initiated with the lowest dose that effectively provides contraceptive protection. Daily doses of estrogen in OCs have declined from 150 mcg 50 years ago to about 20 mcg in newer formulations. This reduction has resulted in a significant decrease in estrogen-related adverse effects.

Typically, administration of an OC begins on day 5 of the menstrual cycle and continues for 21 days. During the other 7 days of the month, the patient takes a placebo. Although the placebo serves no pharmacologic purpose, it does encourage the patient to take the pills on a daily basis. Some of these placebos contain iron, which replaces iron lost due to menstrual bleeding.

A common problem with OCs, and likely the most frequent reason for treatment failure (pregnancy), is forgetting to take the medication daily. If one dose is missed, taking two pills the following day usually provides for continuous contraception. If two consecutive doses are missed, two tablets should be taken on both the day the missed doses are remembered and the following day. The regular schedule should then be continued, but a second method of contraception should be used for at least 7 days after restarting the pills. If 3 or more consecutive days are missed, the patient should implement other contraceptive precautions until the regimen can be restarted in the next monthly cycle. Figure 70.1 shows a typical monthly OC packet with the 28 pills.

Estrogen–progestin combination OCs act by preventing ovulation. They accomplish this by providing negative feedback to the pituitary, which suppresses the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) near the midpoint of the menstrual cycle. Without the influence of LH and FSH, the ovarian follicles cannot mature and ovulation is prevented. The estrogen–progestin

Trivora-28	ethinyl estradiol, 30 mcg	levonorgestrel, 0.05 mg
	ethinyl estradiol, 40 mcg	levonorgestrel, 0.075 mg
	ethinyl estradiol, 30 mcg	levonorgestrel, 1.25 mg
Four-phasic		
Natazia	ethinyl valerate, 3 mg	—
	ethinyl valerate, 2 mg	dienogest, 2 mg
	ethinyl valerate, 2 mg	dienogest, 2 mg
	ethinyl valerate, 1 mg	—
Progestin Only		
Micronor	None	norethindrone, 0.35 mg
Nor-QD	None	norethindrone, 0.35 mg
Emergency Contraceptive		
Plan B and Plan B One Step	None	levonorgestrel, 1.5 mg

combination drugs also make the uterine endometrium less favorable to receiving an embryo, thus reducing the likelihood of implantation. In addition, the hormones promote the formation of a thick cervical mucus that slows sperm transport and inhibits the process that allows sperm to penetrate the ovum. The student should refer to Figure 69.2 in Chapter 69 for a review of the negative feedback control of female reproductive hormones.

PharmFACT

From 2011 to 2015, 56% of sexually active female teens (ages 15–19) used oral contraceptives to prevent pregnancy. The use of emergency contraception in this group increased from 14% in 2006–2010 to 23% in 2011–2015 (Abma & Martinez, 2017).

The four types of estrogen–progestin OC formulations are monophasic, biphasic, triphasic, and a four-phase version. The monophasic OC delivers a constant dose of estrogen and progestin throughout the 21-day treatment cycle. In biphasic drugs, the amount of estrogen in each pill remains constant, but the amount of progestin is increased toward the end of the treatment cycle to better nourish the uterine lining. In triphasic formulations, the amounts of both estrogen and progestin vary in three distinct phases during the treatment cycle. In 2010 the first four-phase OC, called Natazia, was introduced. Natazia contains a synthetic estrogen called estradiol valerate and a progestin called dienogest; this is the first time this specific combination has been used. The manufacturer claims that this four-phase combination more closely resembles the natural monthly hormonal variation. Natazia was also the first OC approved to treat heavy menstrual bleeding.

Figure 70.1 An oral contraceptive showing the daily doses and the different formulation taken in the last 7 days of the 28-day cycle. Courtesy of Fuse/Corbis/Getty Images.

When discontinuing OCs it may take several months for ovulation to return to normal and for monthly menstrual periods to become regular. Some women can conceive in the first month, whereas others experience a delay for up to a year before fertility is restored. The length of contraceptive use does not appear to affect fertility. The incidence of miscarriage is not increased in women who conceive after having taken OCs.

CONNECTION Checkpoint 70.1

Certain drugs that are used to treat infertility block the negative feedback cycle by occupying the estrogen receptors in the hypothalamus. From what you learned in Chapter 69, name the class of drugs that can do this and explain how they are used to increase fertility. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Although the main purpose for taking combination OCs is to prevent pregnancy, there are several other benefits. Women who are taking OCs report less painful menstruation and may have reduced incidences of the following disorders: **ectopic pregnancy**, which is the development of the fetus elsewhere rather than in the uterus; pelvic inflammatory disease (PID); ovarian and endometrial cancer; colorectal cancer; iron deficiency anemia; and benign breast diseases. Women on OCs also experience a better regulated menstrual flow and fewer outbreaks of acne.

Seasonale is an "extended regimen" OC that consists of tablets containing levonorgestrel and ethinyl estradiol that are taken for 84 consecutive days, followed by seven placebo tablets (without hormones). This allows for continuous contraceptive protection while extending the time between menses; only four periods are experienced per year. Seasonique is similar, but instead of inert tablets for 7 days, the patient takes low-dose estrogen tablets. A lower dose formulation of Seasonique, called LoSeasonique, is also available.

PROTOTYPE DRUG: Estradiol and Norethindrone (Ortho-Novum, Others)

Classification **Therapeutic:** Combination oral contraceptive
Pharmacologic: Estrogen–progestin

Therapeutic Effects and Uses: The primary use of Ortho-Novum is to prevent pregnancy, for which it is about 90% effective. Ortho-Novum is available in monophasic, biphasic, and triphasic formulations. Off-label indications for the drug include acne vulgaris (in females who have achieved menarche), endometriosis, hypermenorrhea, dysfunctional uterine bleeding, and hirsutism related to hyposecretion of estrogen or oversecretion of androgens. Noncontraceptive benefits of Ortho-Novum include improvement in menstrual cycle regularity and decreased incidence of dysmenorrhea.

Mechanism of Action: Ortho-Novum decreases the potential for conception by inhibiting ovulation. When the right combination of estrogens and progestins is present in the bloodstream, the release of FSH and LH is inhibited, thus preventing ovulation.

Pharmacokinetics:

Route(s)	Oral (PO)
Absorption	83% (norethindrone) and 47–73% (ethinyl estradiol)
Distribution	Widely distributed; secreted in breast milk
Primary metabolism	Hepatic and GI mucosa; extensively metabolized
Primary excretion	Renal and feces
Onset of action	30–60 min
Duration of action	Half-life: 3–27 h

Adverse Effects: The most common adverse effects of Ortho-Novum are nausea, breast tenderness, weight gain, and breakthrough bleeding. Less common serious adverse effects include edema, unexplained loss of vision, diplopia, intolerance to contact lenses, gallbladder disease, nausea, abdominal cramps, changes in urinary function, dysmenorrhea, breast fullness, fatigue, skin rash, acne, headache,

vaginal candidiasis, photosensitivity, and changes in urinary patterns. Cardiovascular adverse effects, the most serious of all, may include hypertension (HTN) and thromboembolic disorders. The estrogen component of the pill can lead to venous and arterial thrombosis, which results in pulmonary, myocardial, and thrombotic strokes.

Other conditions that are associated with OCs are abnormal uterine bleeding; benign hepatic adenoma; multiple births; elevated plasma glucose; retinal disorder; and melanoderma, a patchy or generalized skin discoloration caused by increased production of melanin. These conditions, though rare, have been reported, and tend to disappear immediately after discontinuing the use of OCs. **Black Box Warning:** Cigarette smoking increases the risk of serious cardiovascular adverse effects in women taking hormonal contraceptives containing estrogen. This risk increases markedly with age (over age 35) and with heavy smoking (more than 15 cigarettes per day).

Contraindications/Precautions: There are many contraindications and precautions regarding the use of OCs. The risk of cancer following long-term OC use has been extensively studied. Because some studies have shown a small increase in the incidence of breast cancer, OCs are contraindicated in patients with known or suspected breast cancer. The incidences of endometrial and ovarian cancers, however, are significantly reduced after long-term OC administration. It is likely that the relationship between the long-term use of these drugs and cancer will continue to be a controversial and frequently researched topic. Obesity is a risk factor for treatment failure and for increased possibilities of thromboembolic events. OCs may significantly worsen symptoms of lupus. Mood disorders, including depression, may be worsened in patients taking OCs. All combination OCs are pregnancy category X and are contraindicated in pregnancy.

Drug Interactions: A number of anticonvulsants (phenobarbital, phenytoin, and carbamazepine) and antibiotics (tetracyclines, rifampin, and ampicillin) can reduce the effectiveness of OCs, thus increasing a woman's risk of pregnancy. Women who are taking these drugs should be advised to use additional means of birth control or to have their OC dosages revised. Because OCs can reduce the effectiveness of warfarin, heparin, insulin, and certain oral antidiabetic drugs, dosage adjustment may be necessary. Protease inhibitors (indicated for human immunodeficiency virus infection) are contraindicated because they may result in contraceptive failure. Patients who are taking theophylline for asthma or imipramine as an antidepressant in conjunction with OCs should be evaluated often because these drugs may accumulate to toxic levels in these individuals. **Herbal/Food:** OCs have been shown to cause breakthrough bleeding when used concurrently with St. John's wort.

CONNECTIONS: Community-Oriented Practice

Macular Edema in Women on Oral Contraceptives

A higher risk of thromboembolic conditions is associated with OC use. Women are advised to immediately report any signs or symptoms such as calf redness and swelling, chest pain, dyspnea, or severe headache to their provider. Macular edema, secondary to retinal vascular occlusion, is also possible. If untreated, it may lead to progressive vision loss and blindness (Yeh et al., 2015). Because vision loss from macular edema may be insidious or sudden, with or without pain, *any* decrease in visual acuity while a woman is on OCs should be evaluated by an ophthalmologist and retinal vascular occlusion ruled out as a causative factor.

Pregnancy: Category X.

Treatment of Overdose: There is no specific treatment for overdose. The patient is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving conjugated estrogens are included in the Nursing Practice Application for Patients Receiving Hormonal Contraceptives.

Drugs Similar to Estradiol and Norethindrone (Ortho-Novum, Others)

Dozens of different estrogen–progestin combinations are available as OCs. All have the same types of adverse effects. Those with higher doses may be expected to produce more adverse effects.

Adverse Effects of Combination Oral Contraceptives

70.3 The adverse effects of combined oral contraceptives are uncommon but may be serious in some women.

The adverse effects of combination OCs have been extensively studied, and various risk factors have been identified. These are summarized in Table 70.3. For the large majority of patients, OCs are safe and serious adverse effects are uncommon. A few of the adverse effects, however, may be serious. Because OCs are so widely prescribed, nurses should become familiar with the adverse effects and incorporate them into the teaching component of the treatment plan.

Much of the early research on OCs was performed on women who were taking high doses of estrogens and progestins. Most, and perhaps all, of the serious adverse effects

Table 70.3 Adverse Effects Associated with Combination Oral Contraceptives

Adverse Effect	Prevention
Breast milk reduction	Some studies suggest that OCs may reduce the quantity of breast milk. They should not be taken until 6 weeks postpartum.
Cancer	Women who test positive for the HPV have an increased risk of cervical cancer. These patients should have regular checkups. Because estrogens promote the growth of certain types of breast cancer, patients with a history of this cancer should not take OCs.
Glucose elevation	OCs may cause slight increases in blood glucose. Patients with diabetes should monitor their serum glucose carefully during OC therapy.
Hypertension	Risk is increased with age, dose, and length of therapy. Blood pressure should be monitored periodically and antihypertensives prescribed as needed.
Increased appetite, weight gain, fatigue, depression, acne, hirsutism	These are common effects that are often caused by high amounts of progestin. The dose of progestin may need to be lowered.
Lupus exacerbation	Symptoms of systemic lupus erythematosus may worsen in some patients. A progestin-only OC may be an option for these patients.
Menstrual irregularities	Amenorrhea or hypermenorrhea is often caused by low amounts of progestin. The dose of progestin may need to be increased. Breakthrough bleeding and spotting are common with the low-dose OCs. The patient may need a higher dose product.
Migraines	Estrogen may decrease or increase the incidence of migraines. Because migraines are a risk factor for stroke, patients with migraines should seek advice from their healthcare provider.
Nausea, edema, breast tenderness	These are common effects that are often caused by high amounts of estrogen. The dose of estrogen may need to be lowered.
Teratogenicity	Estrogens are pregnancy category X. Patients should be advised to discontinue OCs if pregnancy is confirmed.
Thromboembolic disorders	Estrogens promote blood clotting. OCs should not be prescribed for patients with a history of thromboembolic disorders, strokes, or coronary artery disease or for those who are heavy smokers.

of OCs are dose dependent. The newer low-dose formulations result in far less risk than the original OCs.

The Centers for Disease Control and Prevention and the World Health Organization have developed a comprehensive list of preexisting medical conditions as absolute contraindications for the use of estrogen–progestin contraceptives (Curtis et al., 2016). These include current breast cancer, severe hepatic disease, major surgery with prolonged immobilization, migraines (with aura), impaired cardiac function, complicated valvular heart disease, HTN (systolic ≥ 160 mmHg or diastolic ≥ 100 mmHg), smoking (age ≥ 35, ≥15 cigarettes/day), history of stroke, systemic lupus erythematosus (positive or unknown antiphospholipid antibodies), and high risk for thromboembolic disorders. Relative contraindications exist when there are preexisting disorders such as depression, migraines (without aura), epilepsy, epilepsy therapy (with certain anticonvulsants), and controlled HTN. The nurse should discuss nonhormonal contraceptive choices for women who have serious medical conditions for which OCs are contraindicated.

CONNECTION Checkpoint 70.2

Thromboembolic events are a serious concern for many patients who are taking OCs. From what you learned in Chapter 38, identify the classes of drugs that may be used to reduce the risk of thromboembolic events in high-risk patients. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

About 5% of women who are taking OCs will develop HTN because the drugs elevate angiotensin and aldosterone levels. Angiotensin is a vasopressor substance produced by the kidney, and aldosterone is a hormone secreted by the adrenal cortex of the kidney (see Chapter 31). The action of both substances can result in HTN. The mean elevation from high doses of OCs is about 3 to 6 mmHg systolic and 2 to 5 mmHg diastolic. Low-dose formulations do not pose a major risk for HTN.

OCs can mimic certain symptoms of pregnancy, including breast tenderness, nausea, bloating, and **chloasma**, which is a darkened pigmentation found on the forehead, temples, cheeks, and upper lips. If a woman suspects pregnancy while taking an OC, the drug should be discontinued immediately because estrogen and progestin can cause fetal harm.

Because estrogen and progesterone can stimulate the growth of some types of cancers, the incidence of cancer in women taking OCs has been studied for several decades in large numbers of women. Some studies have demonstrated that long-term use may pose a slightly higher risk of breast cancer, whereas others have shown no relationship. Cervical cancer is also slightly increased, and this has been closely associated with human papillomavirus (HPV) infections. The risk of liver cancer may be increased. However, OCs appear to have protective effects for ovarian and endometrial cancers that continue for many years after the drugs are discontinued. A protective effect has also been observed for colorectal cancer. Conclusions of these studies

are that women who have a personal or very close family history of breast cancer should explore nonhormonal means of contraception. All women who are taking OCs should be instructed to perform breast self-examinations, as recommended by their healthcare provider, and be aware of the importance of routine scheduling of mammograms as appropriate for their age range.

Other conditions associated with OCs are abnormal uterine bleeding, benign hepatic adenoma, multiple births, retinal disorders, and melanoderma. These conditions, though rare, have been reported and they normally resolve after discontinuing the use of OCs. OCs may accelerate the formation of gallstones in patients who have preexisting gallbladder disease. The drugs may increase glucose levels and suppress insulin responsiveness, although this can be prevented by adjustments in the insulin dose of patients with diabetes.

Although not an adverse effect, healthcare providers and their patients should be aware that some studies have indicated that the combined hormonal patch and oral levonorgestrel emergency contraception may have lower rates of effectiveness in women who are obese (Simmons & Edelman, 2016). The correlation between effectiveness and weight (or BMI) is an ongoing area of research.

When discussing the risks and benefits of hormonal contraception with patients, the nurse should place the drug in context with the health risks associated with pregnancy and delivery. Many patients do not understand that pregnancy itself may cause many challenging health conditions for the mother. Pregnancy-related mortality in the United States averages 16 deaths per 100,000 live births, with non-Hispanic black women having the highest incidence of death (Creanga et al., 2015). Maternal morbidity includes conditions such as hemorrhages, preeclampsia or eclampsia, obstetric trauma, infections, gestational diabetes, and HTN. Placed in the proper context, the risks of pregnancy for most patients (those without absolute contraindications for OC use) are likely as great, or greater, than hormonal contraception.

Progestin-Only Oral Contraceptives

70.4 Oral contraceptives that contain only progestin are often used when estrogen is contraindicated.

Although most OCs use a combination of estrogen and progestin, a few products contain only progestin. The progestin-only OCs, sometimes called minipills, are less effective at preventing ovulation. They prevent pregnancy primarily by causing a thick, viscous cervical mucus at the entrance to the uterus that discourages sperm penetration. They also tend to inhibit implantation of a fertilized egg.

Progestin-only oral contraceptives are taken daily throughout the month without the use of placebo tablets. Minipills are somewhat less effective than estrogen–progestin combinations, having a failure rate of 1% to 4%. Their use also results in a higher incidence of irregular menstrual cycles, including amenorrhea, prolonged bleeding, or breakthrough spotting. Menstrual irregularity is the most frequently reported adverse effect. The risk of ectopic pregnancy is higher with progestin-only products. Progestin-only PO drugs are generally reserved for patients who are at high risk for estrogen-related adverse effects or who are lactating. Unlike estrogens, progestins are not associated with a higher risk of thromboembolic events, and they do not have any effect on breast cancer. The progestin-only products are pregnancy category X.

Products that contain norethindrone only include Aygestin, Camila, Errin, Jolivette, Nora-BE, and Ortho Micronor. In addition to contraception, norethindrone therapy is approved to treat amenorrhea, dysfunctional uterine bleeding, and endometriosis. The doses used for contraception are only 0.35 mg/day, whereas those for uterine conditions are 2.5 to 10 mg/day. Detailed information on the contraindications, drug interactions, and adverse effects of progestins are included in Chapter 69, along with a prototype feature for medroxyprogesterone (Depo-Provera, Depot-SubQ-Provera, Provera).

Long-Acting Reversible Contraceptives

70.5 Long-acting contraceptives and novel delivery methods offer women additional birth control choices.

Delivery methods have been developed that are able to provide long-acting reversible contraception for periods lasting from weeks to years. The **long-acting reversible contraceptives (LARCs)** and novel delivery systems were developed to offer ease of use and improve adherence. They vary in efficacy, reversibility, and discreteness of use.

Transdermal patch: Transdermal hormonal contraception is a safe, effective, and easy-to-use birth control method. Approved in 2001, Ortho-Evra is a topical patch worn on the skin of the buttock, arms, or trunk that contains ethinyl estradiol and norelgestromin. The patch slowly releases the hormones, which penetrate the skin and are distributed throughout the body. The patch is changed every 7 days for the first 3 weeks, followed by a patch-free week 4 (days 22–28). The patch may be worn during bathing, exercise, and other daily activities. Should the patch fall off, which occurs in about 5% of the applications, it should be replaced as soon as possible. The serum estrogen levels of patients who use the patch are 60%

CONNECTIONS: Preparing for Advanced Practice

Contraceptive Choices

Case

Lauren, a 33-year-old mother of four, is married and is looking for a reliable method of birth control. When asked about her plans for more children, she states that she is not interested in having another child right now but may want another child in the future. She insists on a contraceptive method other than condoms because her husband doesn't like using them. She was taking "the pill" for a while, but had a difficult time remembering to take a pill every day and she would miss several days at a time. You conduct some basic screening and obtain the following information: blood pressure, 126/82 mmHg; pulse, 62 beats/min; and respiratory rate, 16 breaths/min; she does not smoke or drink and denies drug use. Her body mass index (BMI) is 22 (normal weight). You determine she is a candidate for a transdermal patch and after discussion about potential risks and adverse effects, she is started on Ortho-Evra and is taught how to use it. Is this an appropriate birth control option for Lauren?

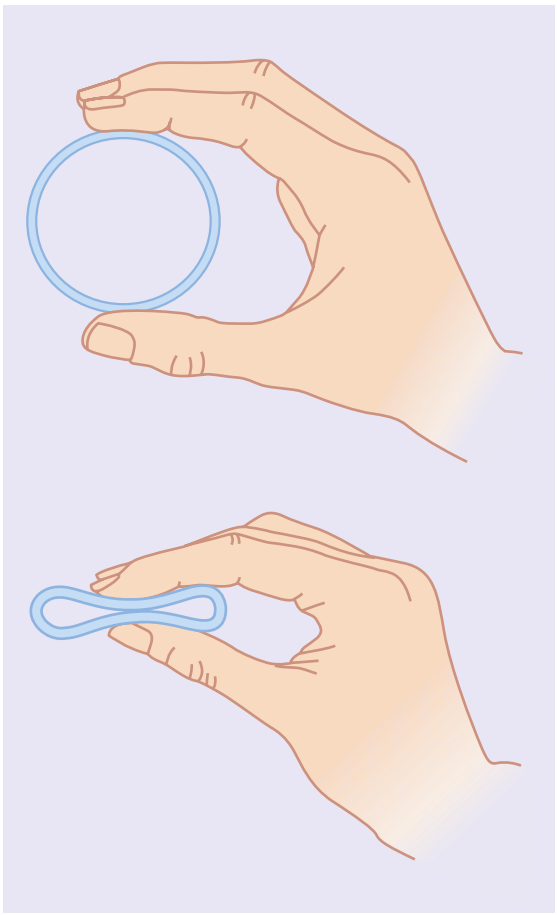
Discussion

Deciding on the right method of birth control is very personal and is a common reason women seek gynecologic care. Using the birth control patch is safe, simple, and convenient. Lauren's ability to become pregnant will return quickly when use of the patch is stopped, and because the patch works like the pill, it increases adherence for women who are concerned about forgetting to take a pill every day.

Lauren's BMI was within normal range. However, if it were above the normal range or she weighed over 90 kg (198 lb), the transdermal patch would not be a good option. Research shows that the transdermal patch is less effective in women who are obese.

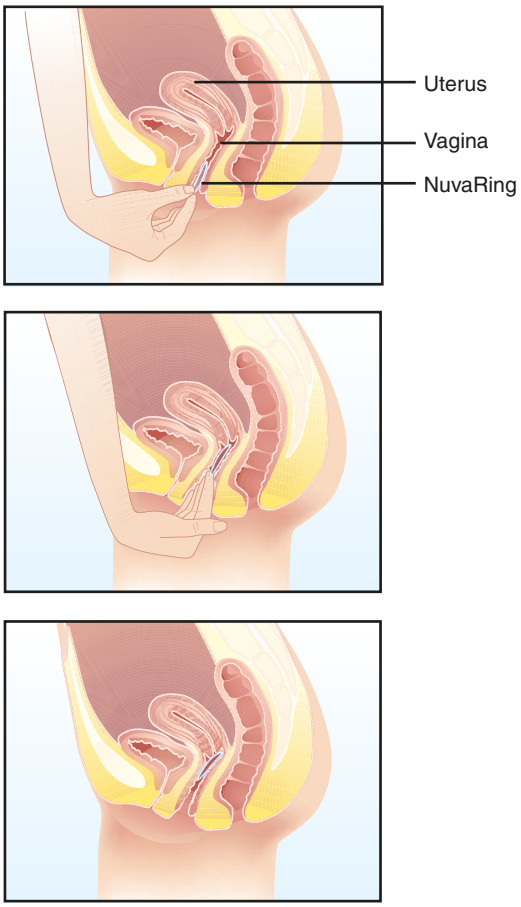
Healthcare providers should offer patients an additional prescription for the contraceptive patch in case of detachment. The drug is mixed with the adhesive and, therefore, patches that do not stick must be replaced to maintain therapeutic levels of hormone.

higher compared to those of patients who take combination OCs. Used patches still contain significant hormone levels and must be discarded in a waste container away from children and pets. They should not be flushed down the toilet because residual estrogen can pollute wastewater, lakes, and streams.



Adverse effects and contraindications are the same as those for OCs. Some research suggests that patients using the patch have an increased risk of venous thromboembolism (VTE) compared to women taking OCs. In response to this research, the FDA created a black box warning for Ortho-Evra that women with a history of blood clots should discuss other means of contraception with their healthcare provider.

Vaginal ring: The NuvaRing, illustrated in Figure 70.2, is a flexible, soft vaginal ring impregnated with a low-dose, sustained release, combined hormonal contraceptive. It is approximately 5 to 7.5 cm (2–3 in.) in diameter and contains ethinyl estradiol and etonogestrel. The ring is inserted into the vagina once a month to provide 3 weeks of contraceptive protection. The ring slowly releases the hormones, which are absorbed across the vaginal mucosa into the blood and distributed throughout the body. The contraceptive action is systemic in nature and not localized to the vagina. The ring is removed at the end of week 3, and a new ring is inserted a week later. If forgotten and left in place for more than 3 weeks, contraceptive action may be lost.



The main adverse effects of the NuvaRing are similar to those of combination OCs. Women sometimes discontinue using the vaginal delivery method due to discomfort of the device during intercourse. Women who are experiencing uterine prolapse must monitor the ring frequently because it may fall out. Adverse effects include nausea, bloating, headaches, breast tenderness, and breakthrough bleeding. If the ring is expelled from the vagina, it may be rinsed with water and replaced. Local effects may include vaginal irritation, sensation of a foreign body, and vaginitis. The NuvaRing should be discarded in a waste container away from children and not flushed down the toilet.

Depot injection methods: Intramuscular (IM) medroxyprogesterone acetate (Depo-Provera) was approved for contraceptive use in the United States in 2004. A single deep IM injection provides 3 months of contraceptive protection. The same drug may be injected subcutaneously (Depo-SubQ-Provera) with the same duration of action and effectiveness. Medroxyprogesterone suppresses ovulation, inhibits sperm from reaching the egg by thickening the cervical mucus, and prevents a fertilized egg from implanting in the uterus. Neither depot delivery method contains estrogen. The drug is usually given on days 1 through 5 of the menstrual cycle. The depot injection methods are very effective at preventing pregnancy.

Once injected the actions of the drug cannot be reversed and fertility may not be restored for up to 12 months after discontinuation. The most common adverse effects are menstrual disturbances, headache, acne, injection-site reactions, weight gain, and decreased libido. This drug carries a black box warning that long-term use causes significant loss of bone mineral density. This drug is pregnancy category X. Medroxyprogesterone is also approved to treat inoperable endometrial and renal cell carcinomas and menstrual disturbances. A prototype feature for medroxyprogesterone may be found in Chapter 69.

(a)

(b)

Figure 70.2 Vaginal medication administration: (a) The NuvaRing® contraceptive; (b) proper insertion of the NuvaRing.

Subdermal implant: Although several contraceptive subdermal implants have been approved since 1996, only Nexplanon is available. Formerly called Implanon, the implant consists of a single plastic tube about the size of a matchstick, containing 68 mg of the progestin etonogestrel. Inserted on the inner side of the upper arm, the device releases the progestin slowly, for up to 3 years. Although the device can be readily removed, some women may experience pain, inflammation, or hematoma at the removal site. Other adverse effects are the same as those of other progestins.

Intrauterine devices: Intrauterine devices (IUDs) are LARCs designed in a T shape that are safe, inexpensive, and reliable methods of contraception. They are placed by the healthcare provider and offer a major advantage for women who are likely to forget a daily pill or who prefer greater ease of use. Unlike OCs, these devices have no effect on ovulation. The IUD is not felt by the woman or her partner during intercourse and it can be removed at any time. Fertility returns quickly after removal of the device.

Liletta, Mirena, Kyleena, and Skyla are called hormonal IUDs because they contain levonorgestrel that is released very slowly to prevent conception for 3 to 6 years, depending on the product. Contraception results from a thickening of the endometrium and increased cervical mucus that slows down sperm motility. The most common adverse effects include uterine and vaginal bleeding, dysmenorrhea, intermenstrual bleeding and spotting, abdominal and pelvic pain, and ovarian cysts.

The oldest product, ParaGard, is a plastic device that is partially covered with copper. It is believed that the copper triggers a spermicidal-like reaction in the body that slows sperm motility and prevents the sperm from reaching the ovum. If fertilization does occur, implantation is not likely to happen because the copper causes endometrial changes to make the lining less favorable. It can be left in place for up to 10 years, and the main adverse effects are bleeding between menses, dysmenorrhea, and expulsion of the device. ParaGard is an effective, nonhormonal option for patients who have contraindications to using estrogen or progesterone.

PharmFACT

The use of long-acting reversible contraception has increased markedly in recent years. From 2002 to 2013, the use of intrauterine devices increased 83% and the use of subdermal hormonal implants tripled (Branum & Jones, 2015).

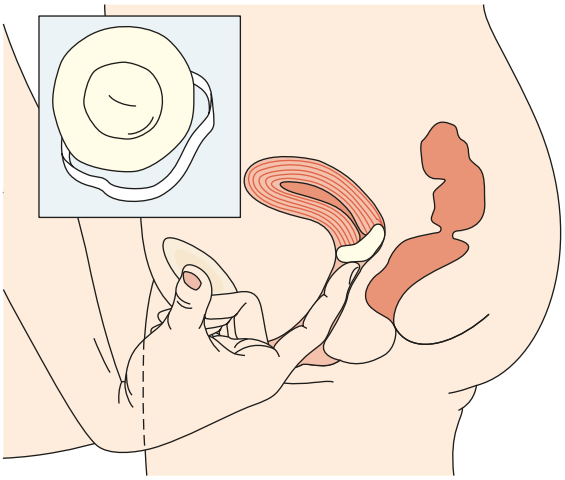


Figure 70.3 The contraceptive sponge is moistened well with water and inserted into the vagina with the concave portion positioned over the cervix.

Spermicides

70.6 Spermicides are safe but should be combined with barrier protection for maximum effectiveness.

Spermicides are drugs that kill sperm. They come in a variety of creams, foams, jellies, and suppositories that immobilize or destroy sperm when inserted into the vagina prior to intercourse. Spermicides are available over the counter (OTC).

To be effective, spermicides must be applied high into the vagina, as close to the cervix as possible, approximately 20 minutes before intercourse. Most spermicides have a duration of action of only 1 hour and must be reapplied if coitus extends beyond this time.

The contraceptive sponge, which is illustrated in Figure 70.3, is soft and absorbent and contains nonoxynol-9. The sponge is moistened with water to activate the spermicides and inserted into the vagina to cover the cervix. The sponge releases the drug slowly and may provide up to 24 hours of contraceptive protection. It is left in place for 6 hours after intercourse but must be removed by 30 hours after insertion. The sponge delivery system has the same effectiveness as spermicidal gels, creams, and suppositories. Adverse effects include local irritation and vaginal dryness.

Patients should be informed that spermicides have low levels of effectiveness when used alone and should therefore be used in conjunction with barrier methods such as condoms and diaphragms. Nonoxynol-9 does not offer any protection against chlamydia, gonorrhea, or the human immunodeficiency virus (HIV). In fact, frequent use of spermicides disrupts the vaginal epithelium and may actually increase the risk of HIV transmission from an infected partner. Patients must be instructed to take added precautions to prevent such transmissions.

PROTOTYPE DRUG Nonoxynol-9

Classification **Therapeutic:** Intravaginal contraceptive
Pharmacologic: Spermicide

Therapeutic Effects and Uses: Originally approved in 1963, nonoxynol-9 is a topical contraceptive that acts by inhibiting the ability of sperm to reach the ovum. Most products have a duration of spermicidal action of 60 minutes; the contraceptive sponge provides 24 hours of protection.

Pharmacokinetics: Nonoxynol-9 disrupts the cell membrane of sperm, causing it to lose motility and function. The carrier (foam, sponge, cream, etc.) may also act as a physical barrier to sperm motility.

Route(s)	Apply or insert vaginally
Absorption	Minimal absorption
Distribution	Acts locally, killing the sperm on contact
Primary metabolism	Not metabolized
Primary excretion	Small amounts by the kidneys and in feces
Onset of action	Immediate for creams, foams, gels, and sponge; 5–15 min for suppositories
Duration of action	Up to 24 h after intercourse (sponge)

Adverse Effects: Adverse effects are uncommon. Vaginal irritation and dryness, increase in vaginal infections, toxic shock syndrome, and irritation of the genitalia of the sexual partner have been reported.

Contraindications/Precautions: Women with cystocele, prolapsed uterus, sensitivity or allergy to nonoxynol-9, vaginitis, or toxic shock syndrome, or those who are pregnant, postabortion, or postpregnancy should avoid this drug.

Drug Interactions: Intravaginal azole antifungals may inactivate the spermicides.

Pregnancy: Category C.

Treatment of Overdose: Overdose is not likely.

Nursing Responsibilities:

- Monitor for signs of vaginal infection or irritation.

Patient and Family Education:

- Be aware that spermicides should be used in conjunction with barrier methods such as condoms or diaphragms.
- Be aware that this drug does not protect against the transmission of HIV or sexually transmitted infections.
- Discontinue nonoxynol-9 if pregnancy is suspected.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Hormonal Contraceptives

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, peripheral vascular, migraines, thyroid, hepatic, or kidney disease; diabetes; pregnancy; or breastfeeding. Note personal or family history of thromboembolic disorders (e.g., MI, stroke, peripheral vascular disease) and of reproductive cancers (e.g., breast, uterine, or ovarian cancer).
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], platelets, electrolytes, glucose, lipid, and thyroid function levels), Pap test, HPV screening, and pregnancy test.
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects dependent on the reason the drug is given (e.g., pregnancy prevention).
- Continue periodic monitoring of CBC, platelets, thyroid function, and glucose.
- Monitor vital signs and weight at each healthcare visit.
- Assess for adverse effects: nausea, vomiting, headache, weight gain, breast tenderness, skin rash, acne, fluid retention, changes in mood, or midcycle breakthrough bleeding. Immediately report tachycardia, palpitations, HTN, severe headache, cramping in calves, chest pain, or dyspnea.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (OCs are nearly 100% effective when taken as required. Skipping doses increases the risk of pregnancy. Transdermal patches, depot injections, or IUDs may be desirable for women who experience difficulty adhering to OCs or for those who choose not to take daily medication.)	• Instruct the patient to take the pill at the same time daily to help with remembering to take it. Do not omit, increase, or decrease doses without consulting the healthcare provider. Omitting or decreasing doses increases the chance of pregnancy; increasing doses may increase the risk of adverse effects. • Encourage women to discuss LARCs with their healthcare provider as appropriate.

Minimizing adverse effects:
• Monitor for symptoms of cardiopulmonary, cerebrovascular, and peripheral vascular thromboembolism. Monitor blood pressure at each clinical visit. (Thromboembolic events are a possible adverse effect of OC drugs. The risk increases in women with a previous history of cardiovascular disease, women classified as obese, and in women who smoke. Monitor for symptoms of peripheral thrombophlebitis, pulmonary embolism, MI, stroke, or other complications related to blood clots.)
	• Instruct the patient to immediately report:
	  • Dyspnea, chest pain, or blood in sputum (possible pulmonary embolism)
	  • Heaviness, chest pain, or overwhelming feeling of fatigue and weakness accompanied by nausea and diaphoresis (possible MI)
	  • Sudden, severe headache, especially if associated with a prehead-ache aura, dizziness, difficulty with speech, numbness in an arm or leg, or difficulty with vision (possible stroke)
	  • Eye problems such as blurred vision or loss of vision (possible stroke, retinal hemorrhage or thrombus)
	  • Warmth, redness, swelling, or tenderness in calf, or pain on walking (possible thrombophlebitis).
	  • Teac**h** the patient to monitor blood pressure periodically and report any blood pressure above 140/90 mmHg or per parameters as ordered by the healthcare provider.

• Encourage smoking cessation and provide information about smoking cessation programs. (Smoking greatly increases the risk of experiencing the adverse effects of hormone therapy.)	• Advise the patient of the risk of smoking while using OCs; discuss and provide literature on smoking cessation programs, providing referral to appropriate support groups.
• Monitor Pap tests, HPV screening, and breast examinations as ordered. (Pap tests and breast examinations, including mammography as appropriate, will monitor for the development of breast tumors or cervical cancer.)	• Teach the patient how to perform breast self-examinations, but monthly examinations may not be recommended by the healthcare provider except for women at high risk for breast cancer. For women over age 40, advise the patient on the need for follow-up mammography as per the healthcare provider recommendations. • Advise the patient on the need for regularly scheduled gynecologic examinations to ensure continued health.
• Monitor the occurrence of any breakthrough bleeding. Report any continuous, unusual, or heavy bleeding. (Spotting may occur, especially with low-dose hormone therapy, at midcycle. Any continuous, unusual, or heavy bleeding may indicate adverse effects, pregnancy loss, or disease and should be reported.)	• Teach the patient that spotting may occur midcycle while on OCs but to report any unusual changes in the amount or if the bleeding continues.
• Monitor hepatic function tests and symptoms of liver dysfunction, lipid profile studies, and thyroid levels periodically. (OCs are associated with an increased risk of gallbladder disease and a rare risk of hepatotoxicity.)	• Instruct the patient to return periodically for laboratory tests. • Teach the patient to report any symptoms of abdominal or right upper quadrant discomfort or pain, yellowing of the skin or sclera, fatigue, anorexia, darkened urine, or clay-colored stools. Report any severe abdominal pain immediately.
• Monitor concurrent drug therapy and any new prescriptions received. (Many drugs decrease or alter the effectiveness of OCs including drugs in the penicillin, tetracycline, barbiturate, antiseizure, antidepressant, and benzodiazepine classifications.)	• Teach the patient to advise all healthcare providers of the use of OCs before beginning any new prescription.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient in proper self-administration of the drug, e.g., consistently at the same time each day to help with remembering to take the dose, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the pill at the same time daily to help with remembering to take it. If a dose is missed, take the drug as follows:
	  • *For estrogen–progestin combination OCs:* If a dose is missed, take it as soon as it is remembered, and take the next pill at its normally scheduled time. If two consecutive doses are missed, take 2 tablets on both the day the missed doses are remembered and on the following day. Follow the remaining schedule of pills, but a second method of contraception (e.g., a barrier method) should be used for at least 7 days after restarting the pills. If 3 or more consecutive days are missed, use another form of contraception until the pills can be restarted in the next monthly cycle.
	  • *For progestin-only OCs:* If a dose is missed, take the pill as soon as remembered, but use an additional form of contraception until the next cycle of pills is started.
	  • *Transdermal patches (e.g., Ortho-Evra) and vaginal rings (e.g., NuvaRing):* Patches and rings are changed weekly for 3 weeks, followed by 1 week of being patch- or ring-free. If the patch falls off or the ring falls out, it should be replaced with a new patch or ring. Safely discard used patches or rings in the trash.

- Carefully follow the instructions on the label for applying the drug, or use as directed by the healthcare provider. If excessive burning, stinging, or irritation occurs, try a product with a lower strength of nonoxynol-9.
- If using a diaphragm, place 1 to 3 tsp of the spermicide in the dome prior to insertion.
- Leave the spermicide and diaphragm in place 6 hours after intercourse.
- Use the spermicide before the first and every subsequent act of intercourse.
- Report burning; inflammation; intense vaginal and vulvar itching; cheesy, curd-like discharge; painful intercourse; and dysuria to the healthcare provider.

Drugs Similar to Nonoxynol-9

There are no drugs that are similar to nonoxynol-9.

Emergency Contraception

70.7 Emergency contraception provides a reproductive option for women who have unprotected sex or contraceptive failure.

Emergency contraception (EC) is the prevention of implantation following unprotected intercourse or contraceptive failure. Statistics suggest that almost half the pregnancies in the United States are unplanned and some of these occur due to the inconsistent use or failure of contraceptive devices. EC, commonly referred to as the "morning after pill," offers a means of protecting against unwanted pregnancies.

The treatment goal for these patients is to provide effective and immediate contraception. EC must be taken as soon as possible after intercourse. When used accordingly, these drugs act by preventing ovulation; they do not cause abortion. If implantation of an embryo has already occurred, the drugs used for EC will have no effect on the established pregnancy. Two different medications are approved for EC: Plan B and ulipristal (Ella). Table 70.4 lists drugs, routes, and dosages for EC. These drugs are not intended to replace regular methods of contraception.

Plan B is approved for OTC purchase without age restriction. Plan B has largely been replaced by Plan B One Step, which offers the convenience of a single 1.5-mg dose.

The active drug in Plan B is levonorgestrel, which is the same progestin used for contraception in some IUDs (see Section 70.5). There is, however, a large difference in doses. Whereas the long-acting Mirena releases 20 mcg/day of levonorgestrel over a 5-year period, Plan B delivers a total of 1500 mcg of levonorgestrel in a single day. The drug is most effective when taken either within 72 hours (Plan B) or 120 hours (Plan B One Step) after unprotected intercourse.

Plan B is not 100% effective. The normal rate of pregnancy from a single unprotected sex act is 8%; Plan B is estimated to lower this risk to 1% to 2%. Serious adverse

Table 70.4 Drugs for Emergency Contraception and Pharmacologic Abortion

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Drugs for Emergency Contraception		
levonorgestrel (Plan B, Plan B One Step)	PO (Plan B): 1 tablet within 72 h of intercourse followed by 1 tablet 12 h later (0.75 mg in each pill) PO (Plan B One Step): 1 tablet (1.5 mg) within 120 h of intercourse	*Nausea, heavy menstrual bleeding, lower abdominal pain, headache, fatigue, and dizziness* Serious adverse effects are rare when only 1 or 2 doses are administered
ulipristal (Ella)	PO: 1 tablet (30 mg) within 5 days of unprotected intercourse or contraceptive failure	*Headache, abdominal pain, nausea, dysmenorrhea, fatigue, dizziness* Serious adverse effects are rare when only 1 dose is administered
Drugs for Pharmacologic Abortion		
carboprost (Hemabate)	IM (initial): 250 mcg (1 mL) repeated at 0.5- to 3.5-h intervals if indicated by uterine response. Dosage may be increased to 500 mcg (2 mL) if uterine contractility is inadequate after several doses of 250 mcg (1 mL), not to exceed a total dose of 12 mg or continuous administration for 1 month	*Nausea, vomiting, cramping, diarrhea, fever* Uterine laceration, rupture, or hemorrhage
dinoprostone (Cervidil, Prepidil, Prostin E_2)	Intravaginal: Insert 20-mg suppository high in the vagina; repeat q2–5h until abortion occurs or membranes rupture (max: total dose 240 mg)	*Nausea, vomiting, cramping, diarrhea, fever* Uterine laceration, rupture, or hemorrhage
methotrexate with misoprostol	IM methotrexate (50 mg/m^2) followed 5 days later by intravaginal 800 mcg of misoprostol	*Nausea, vomiting, diarrhea* Abdominal pain, headache, uterine hemorrhage, respiratory arrest
mifepristone (Mifeprex) with misoprostol	PO: 200 mg of mifepristone on first day, followed 24–48 h later with 800 mcg of misoprostol	*Nausea, vomiting, diarrhea* Abdominal pain, headache, uterine hemorrhage

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

effects with Plan B are uncommon. Nausea and vomiting are the most common adverse effects, and abdominal pain, fatigue, headache, irregular (increased or decreased) menstrual bleeding, and dizziness are reported by a number of patients. Fertility returns quickly after taking Plan B; therefore, the patient should be encouraged to implement routine contraception measures as soon as possible.

In 2010, ulipristal (Ella) was approved as a single-dose product for EC. This drug is a mixed progesterone agonist–antagonist that acts by preventing ovulation. Unlike Plan B, which is available OTC, ulipristal requires a prescription. One advantage of ulipristal is that it retains its effectiveness for 5 days following unprotected sex.

Drugs for Pharmacologic Abortion

70.8 Abortifacients are drugs that are used to terminate pregnancy.

A woman who is in early pregnancy may decide that she is no longer able to carry the child to term. In some pregnancies, major abnormalities may be identified in the fetus that would prevent it from reaching term. The nurse should use his or her knowledge of the stages of fetal growth and development to counsel the patient regarding the risks and benefits of available options. The nurse must, however, be aware of applicable state laws and regulations that restrict certain treatments.

One option for the patient may be a medical abortion. Pharmacologic (medical) abortion is the removal of an embryo by the use of drugs after implantation has occurred. Drugs used to induce abortion are called **abortifacients**.

Once the ovum has been fertilized, several drugs are available to terminate the pregnancy, as listed in Table 70.4. A single dose of mifepristone (Mifeprex) followed 24 to 48 hours later by a single dose of misoprostol is a frequently used regimen. Although the mifepristone–misoprostol combination should never be used as a substitute for an effective means of contraception, these drugs do offer women a safer alternative than surgical abortion. The actions of the two drugs are as follows:

- Mifepristone acts by blocking progesterone receptors, resulting in softening and dilation of the cervix and degeneration of the uterine endometrium. If given within 3 days of intercourse, mifepristone alone is almost 100% effective at preventing pregnancy. Given up to 9 weeks after conception, mifepristone aborts the implanted embryo.
- Misoprostol is a prostaglandin that induces strong uterine contractions, thus increasing the effectiveness of the pharmacologic abortion.

Pharmacologic abortion must be conducted under the close supervision of a healthcare provider. The patient is often required to sign consent forms after it has been determined that the pregnancy is under 49 days. The patient

receives an assessment by the healthcare provider 2 days after dosing. If abortion has not occurred, additional misoprostol may be administered and the patient returns to the healthcare provider in 14 days to confirm that abortion is complete. Occasionally pharmacologic abortion does not occur and the patient is referred for surgical abortion. The primary adverse effect of mifepristone–misoprostol is cramping that occurs soon after taking misoprostol. Nausea is common. The most serious adverse effect is prolonged bleeding, which may continue for 1 to 2 weeks after dosing.

Methotrexate, an antineoplastic drug, is sometimes combined with intravaginal misoprostol. Methotrexate 50 mg/m^2 is given IM, followed in 5 days by 800 mcg of intravaginal misoprostol. If abortion does not occur within 24 hours, the misoprostol is repeated. The treatment is 96% effective at causing abortion. Most patients experience adverse effects such as nausea, vomiting, diarrhea, headache, dizziness, abdominal cramping, and hot flashes.

Prostaglandins may also be used to induce abortion. Prostaglandins are natural hormones that produce a diverse number of local actions in virtually every body system. In the uterus, the normal function of prostaglandins is to cause contraction of smooth muscle. They serve a valuable function in inducing contractions at the beginning of labor and in promoting cervical ripening.

The three approved prostaglandins include dinoprostone (Cervidil, Prepidil, Prostin E_2), carboprost (Hemabate), and misoprostol. All three may be used to induce uterine contractions that can expel an implanted embryo and result in abortion up to the second trimester. Dinoprostone is used early in pregnancy and comes in preparations of vaginal suppositories (Prostin E), vaginal inserts (Cervidil), and gel, which are inserted high into the vaginal canal. Carboprost is administered by deep IM injection and misoprostol by tablet. When used for abortion, misoprostol is administered with either mifepristone or methotrexate. Nausea, vomiting, and diarrhea are common adverse effects of prostaglandins and uterine cramping is expected. Drug-induced fever occurs in the majority of patients and may last up to 6 hours. Because rare instances of uterine laceration and rupture have been reported, the patient is monitored closely for uterine activity, excessive pain, and vaginal bleeding. Indications for the prostaglandins are given in Table 70.5.

PROTOTYPE DRUG Mifepristone (Mifeprex)

Classification **Therapeutic:** Drug for abortion
Pharmacologic: Abortifacient, progesterone antagonist

Therapeutic Effects and Uses: Approved in 2000, mifepristone was originally indicated for terminating pregnancies of less than 49 days gestation, but this was expanded to 70 days in 2016. Due to the controversial nature of this drug, distribution is restricted and tightly controlled. It is not available in pharmacies and is sold directly to approved, registered prescribers. Surgical intervention must be readily available in case of incomplete abortion, severe bleeding, or other serious complications. As revised by the FDA in 2016, pharmacotherapy with mifepristone requires one 200-mg tablet of mifepristone followed 24 to 48 hours later by 800 mcg of misoprostol taken by the buccal route. Patients must return to their healthcare provider between 7 and 14 days to assess whether pregnancy termination has occurred.

Mifepristone may be used off-label as a means of EC. Given as a single 600-mg dose, it has the same effectiveness and safety profile as Plan B. Other off-label indications include breast cancer, endometriosis, uterine leiomyomata, Cushing's syndrome, and termination of ectopic pregnancy (in combination with methotrexate).

Mechanism of Action: Mifepristone is a strong antagonist of progesterone and corticosteroids. This drug blocks the supportive effects of progesterone on the uterine lining. If given within 72 hours of intercourse, a fertilized ovum will not be able to implant in the uterus. During early pregnancy, mifepristone acts by increasing the synthesis of prostaglandins and sensitizing the uterus

Table 70.5 Indications for Prostaglandins

	INDICATIONS				
Drug	Abortifacient	Control of Postpartum Bleeding	Cervical Ripening Induction	Labor Induction	Other
carboprost (Hemabate) prostaglandin F_2	A	A	O	O	Hemorrhagic cystitis (O); hydatidiform mole (O)
dinoprostone (Cervidil, Prepidil, Prostin E_2) prostaglandin E_2	A	—	A	—	Hydatidiform mole (A)
misoprostol prostaglandin E_1	O	O	O	O	Nonsteroidal anti-inflammatory drug–induced ulcer prophylaxis (A); kidney transplant rejection prophylaxis (O)

Note: A = FDA-approved indication; O = off-label indication.

to the effects of prostaglandins. When misoprostol (a prostaglandin) is given 24 to 48 hours after mifepristone, the prostaglandin increases uterine contractions, which aids in expelling the embryo from the uterus.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Crosses the placenta; it is unknown if secreted in breast milk; 98% bound to plasma protein
Primary metabolism	Hepatic (CYP3A4)
Primary excretion	Mostly feces, small amounts in urine
Onset of action	Rapid
Duration of action	Half-life: 18 h

Adverse Effects: Nearly all patients who take the mifepristone–misoprostol combination experience adverse effects. The most frequent adverse effects of mifepristone are headache, dizziness, nausea, vomiting, fatigue, and abdominal pain or cramping. Vaginal bleeding and spotting will occur for about 16 days. **Black Box Warning:** Serious and sometimes fatal infections and prolonged heavy bleeding have occurred. Excessive or prolonged bleeding may be a sign of incomplete abortion and prompt medical intervention is required. Rare cases of septic shock have been reported.

Contraindications/Precautions: Because mifepristone is a corticosteroid antagonist, its use in patients who are taking long-term corticosteroid therapy or who have chronic adrenal failure is contraindicated. The mifepristone–misoprostol combination is contraindicated in patients with ectopic pregnancy because the therapy will be ineffective. Those on anticoagulant therapy or who otherwise have an increased risk for bleeding should not receive mifepristone. Patients with an IUD in place should have the device removed before mifepristone is administered. The drug is contraindicated for use in patients who are unable to understand the implications of abortion or who may not comply with the established regimen. Safety in patients under age 18 has not been established. When administered for nonabortion indications, this drug is contraindicated in pregnancy (category X).

Drug Interactions: Because mifepristone is taken in only one or two doses, serious drug interactions are unlikely. This drug does, however, have an extended half-life that may cause interactions after it is discontinued. Mifepristone is metabolized by hepatic CYP450 enzymes and may interact with drugs that induce or inhibit this enzyme system. For example, phenytoin, phenobarbital, and carbamazepine induce CYP3A4, increasing the metabolism of mifepristone and lowering its serum levels. **Herbal/Food:** St. John's wort and grapefruit juice may decrease serum levels of mifepristone.

Pregnancy: Category X.

Treatment of Overdose: Overdose has rarely occurred with mifepristone. Treatment is supportive.

Nursing Responsibilities:

- Conduct a comprehensive health assessment, including the patient's ability to understand the consequences of drug therapy and her ability to comply with the regimen.
- Confirm a positive pregnancy test and that the length of gestation is less than 9 weeks.
- Ensure that the proper emergency medical support is available in case of partial abortion or excessive bleeding.
- Assess the patient's medical history for the presence of an IUD, use of anticoagulants, presence of bleeding disorders, or corticosteroid therapy.
- Instruct the patient on the expected adverse effects, especially cramping, and that vaginal bleeding may continue for several weeks to a month.
- Instruct the patient on steps to take in case of emergency, including the phone number and address of the nearest emergency center.

Lifespan and Diversity Considerations:

- Because mifepristone is metabolized through the CYP450 metabolic pathways, monitor ethnically diverse populations more frequently to ensure optimal therapeutic effects and minimize adverse effects.

Patient and Family Education:

- Follow the therapeutic regimen exactly as prescribed by the healthcare provider.
- Attend all follow-up appointments because these are essential for safe and effective drug therapy.
- Immediately report heavy vaginal bleeding (use of more than two thick sanitary pads per hour for 2 consecutive hours), persistent vomiting, severe abdominal cramps, fever of 38°C (100.4°F) or higher, or weakness to the healthcare provider.
- Do not take any other prescription or nonprescription drugs, dietary supplements, or herbal products without approval of the healthcare provider.
- Resume or initiate birth control immediately after the treatment ends or as directed by the healthcare provider.

Drugs Similar to Mifepristone (Mifeprex)

There are no drugs that are similar to mifepristone.

Understanding Chapter 70

Key Concepts Summary

70.1 Selection of a contraceptive is based on effectiveness, safety, and personal choice.

70.2 The most effective oral contraceptives include combinations of low-dose estrogens and progestins.

70.3 The adverse effects of combination oral contraceptives are uncommon but may be serious in some women.

70.4 Oral contraceptives that contain only progestin are often used when estrogen is contraindicated.

70.5 Long-acting contraceptives and novel delivery methods offer women additional birth control choices.

70.6 Spermicides are safe but should be combined with barrier protection for maximum effectiveness.

70.7 Emergency contraception provides a reproductive option for women who have unprotected sex or contraceptive failure.

70.8 Abortifacients are drugs that are used to terminate pregnancy.

CASE STUDY: Making the Patient Connection

Remember the patient "Lila Bastian" from the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Lila, a 19-year-old college student, comes to the clinic for renewal of her prescription for OC pills. She finished her last pack of pills (Ortho-Novum) 10 days ago. She has been unable to get to the clinic to have her prescription renewed before today. She remembers having unprotected intercourse 2 days ago, and now she is concerned that she will become pregnant. Lila asks the nurse, "How can you help me?"

A complete history and physical examination finds Lila in very good health. Her vital signs are temperature, 36.7°C (98°F); pulse, 68 beats/min; respiratory rate, 18 breaths/min; and blood pressure, 118/71 mmHg. Her weight is 62.6 kg (138 lb) and her height is 1.7 m (5 ft 7 in.). Her skin is dry and warm to the touch, mucous membranes are pink and moist, and there are no outward signs of distress. Her abdomen is soft and not tender, and there are no signs of bloating or distention. She has no vaginal bleeding at this time. Lila emphasizes that she only had sex once, 2 days ago. A urine pregnancy test is negative. Lila is prescribed the emergency contraceptive Plan B.

Critical Thinking Questions

1. Lila asks you, the nurse, if it is too late to prevent pregnancy. How would you respond to her question?
2. How does Plan B work to prevent pregnancy? What is another emergency contraceptive option that Lila could use?
3. What instructions would you give Lila regarding pregnancy and Plan B for emergency contraception?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Gina Martin, age 22, has been taking combination OCs for the past 2 years. Her healthcare provider orders antibiotics for a recurrent throat infection. As she is leaving the clinic, she asks you, the nurse, if she should temporarily discontinue her OC.

1. Explain the relationship between antibiotics and OCs.
2. What advice would you give Gina with regard to continuing the OC?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Estradiol–norethindrone (Ortho-Novum) is prescribed for each of the following patients. Which patients would the nurse consider at highest risk for an adverse response to this therapy? (Select all that apply.)
    1. A 38-year-old with a body mass index classified as overweight
    2. A 16-year-old athlete with asthma
    3. A 22-year-old who smokes two packs of cigarettes per day
    4. An 18-year-old with a history of chronic clinical depression
    5. A 42-year-old who has delivered four healthy children

2. The patient who is taking estradiol and drospirenone (Yasmin) informs the nurse that she forgot to take her pills for the past 2 days. Which response by the nurse would be best when addressing this concern?
    1. "Take two pills today and tomorrow then resume your normal dosage."
    2. "Take one pill now and resume your normal dosage time tomorrow."
    3. "Skip another day and then resume the normal medication schedule."
    4. "Stop taking the pills and have a pregnancy test performed as soon as possible."

3. The patient is interested in taking levonorgestrel–estradiol (Seasonique) and asks how to take it. Which would be the correct response provided by the nurse?
    1. "Seasonique is taken one pill per day for 3 weeks, then 1 week of 'dummy pills' with inert ingredients."
    2. "Seasonique is taken year-round without a break and without a period."
    3. "Seasonique is taken for 2 months then off for 1 month using regular oral contraceptives."
    4. "Seasonique is taken for 84 days followed by 7 days of a lower dose that comes with the pack."

4. The nurse is teaching the patient who has received a prescription for mifepristone (Mifeprex) and misoprostol to terminate a pregnancy. When should the patient be instructed to take the misoprostol?
    1. Take it after taking one additional dose of mifepristone (Mifeprex).
    2. Take it 1 week after taking the mifepristone (Mifeprex).
    3. Take it 24 to 48 hours after taking mifepristone.
    4. Take it only if she is still bleeding in 3 days.

5. The nurse is providing health education about contraceptive methods to a group of young adults. Which of the following statements is correct about the use of spermicides?
    1. They are extremely effective in preventing pregnancy.
    2. They have relatively low levels of effectiveness when used alone.
    3. They are the main causes of HIV and pelvic inflammatory disease.
    4. They can prevent ectopic pregnancy.

6. Rank the following contraceptive methods in order of effectiveness from most to least effective:
    1. Depo-Provera
    2. Spermicides
    3. Calendar rhythm
    4. Oral contraceptives
    5. Transdermal (Ortho-Evra)

Chapter 71
Drugs for Disorders and Conditions of the Male Reproductive System

Chapter Outline

- Regulation of Male Reproductive Function
- Pharmacotherapy with Androgens
  PROTOTYPE *Testosterone, p. 1311*
- Anabolic Steroids
- Etiology of Male Sexual Dysfunction
- Pharmacotherapy of Male Infertility
- Pharmacotherapy of Erectile Dysfunction
  PROTOTYPE *Sildenafil (Viagra), p. 1317*
- Pathophysiology of Benign Prostatic Hyperplasia
- Pharmacotherapy of Benign Prostatic Hyperplasia
  Alpha$_1$-Adrenergic Antagonists
  5-Alpha Reductase Inhibitors
  PROTOTYPE *Finasteride (Proscar), p. 1322*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the physiologic effects of androgens.
2. Describe the roles of the hypothalamus, pituitary, and testes in regulating male reproductive function.
3. Explain the role of androgens in the treatment of male hypogonadism, delayed puberty, and breast cancer.
4. Describe the potential consequences associated with the use of anabolic steroids to enhance athletic performance.
5. Identify the types and causes of male sexual dysfunction disorders.
6. Explain the role of drugs in the management of male infertility.
7. Describe the etiology, pathogenesis, and pharmacotherapy of erectile dysfunction.
8. Describe the pathogenesis and pharmacotherapy of benign prostatic hyperplasia.
9. Compare and contrast the nonpharmacologic and pharmacologic management of disorders and conditions of the male reproductive system.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Apply the nursing process to the care of patients receiving pharmacotherapy for disorders and conditions of the male reproductive system.

hypogonadism, 1309
impotence, 1316
interstitial endocrine (Leydig) cells, 1308
libido, 1309
oligospermia, 1315
virilization, 1308

As in women, reproductive function in men is regulated by a small number of hormones from the hypothalamus, pituitary, and gonads. Because hormonal secretion in men is relatively constant throughout the adult lifespan, the pharmacologic treatment of reproductive disorders in men is less complex and more limited than in women. This chapter examines the drugs used to treat the disorders and conditions of the male reproductive system.

Regulation of Male Reproductive Function

71.1 Male reproductive function is controlled through the secretion of androgens.

Male reproduction function is controlled by **androgens**, which are hormones secreted by **interstitial endocrine (Leydig) cells** in the testes. Testosterone, the primary androgen, is responsible for maturation of the male reproductive system and the secondary sex characteristics of men. Other important androgens include androstenedione and dehydroepiandrosterone (DHEA). Androgens are sometimes referred to as anabolic steroids.

Androgens are responsible for the development of the male urogenital system in the fetus. After birth the interstitial endocrine cells are quiet until activated by the gonadotropins, which are hormones secreted by the pituitary gland. The resulting increased production of testosterone by the testes begins the cascade of changes that accompany the onset of puberty in the male adolescent. The increased testosterone levels are responsible for the process of **virilization**, or the development of the male sexual characteristics. During the next several years, the testes, scrotum, and penis enlarge until they reach adult proportions. Pubic and axillary hair grows and other body hair becomes more adult-like in nature. The production of sperm that are capable of fertilizing an ovum begins in the seminiferous tubules of the testes. The cartilage of the larynx grows, causing the deeper toned male voice. Sebaceous gland activity is stimulated, resulting in an increase in the level of acne. The final change is the growth of facial hair.

Testosterone also has profound metabolic effects in nonreproductive tissues. Of particular importance is its ability to build skeletal muscle mass and to stimulate bone growth, which contributes to the differences in muscle strength and body composition between men and women. Testosterone promotes the synthesis of erythropoietin, resulting in an increased production of red blood cells (RBCs) and accounting for the higher hemoglobin and hematocrit levels found in males.

Androgen secretion is regulated by the same pituitary hormones that control reproductive function in women. Although the name follicle-stimulating hormone (FSH) applies to its target in the female ovary, this same hormone influences testosterone secretion in men. Luteinizing hormone (LH), more accurately called interstitial cell–stimulating hormone (ICSH) in the male reproductive system, regulates the production of testosterone by the interstitial endocrine cells of the testes. Unlike the 28-day cyclic secretion of estrogen and progesterone in women, testosterone secretion is relatively constant in adult men. Beginning in puberty, testosterone production increases rapidly and continues to maintain a high level of production until later adulthood, after which it slowly declines. Normal plasma concentrations of testosterone are 250 to 1000 mg/dL. If the level of testosterone in the blood rises above normal, negative feedback to the pituitary shuts off the secretion of LH and FSH. The relationship among the hypothalamus, pituitary, and the male reproductive hormones is illustrated in Figure 71.1.

Precursor molecules of testosterone, androstenedione and DHEA, are secreted in small amounts by the adrenal glands. Their production in the adrenal gland is controlled by the secretion of adrenocorticotropic hormone (ACTH). These weaker androgens are converted to testosterone once they reach peripheral tissues. Adrenal androgens have a role in the growth of pubic hair and are thought to influence the skeletal growth spurt in adolescents. In adult men, the adrenal androgens have minimal effects due to the comparatively larger amount of testosterone secreted by the testes.

Pharmacotherapy with Androgens

71.2 Androgens are used to treat hypogonadism and delayed puberty in males, and breast cancer in females.

Androgens are used to treat testosterone deficiency in men, delayed puberty, oligospermia, hypogonadism,

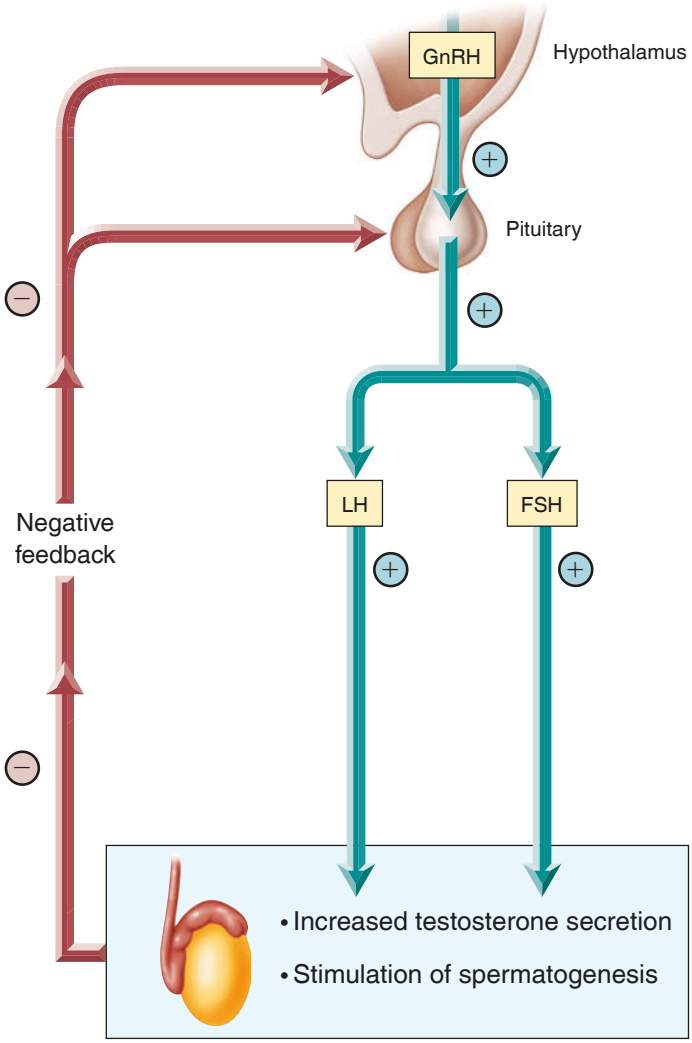

Figure 71.1 Hormonal control of the male reproductive hormones.

anemia, muscle-wasting disorders, and certain cancers. These hormones are listed in Table 71.1.

Lack of sufficient testosterone secretion by the testes can result in male **hypogonadism**. Hypogonadism may be congenital or acquired later in life. When the condition is caused by a testicular disorder, it is called primary hypogonadism. Examples of disease states that may cause primary testicular failure include mumps, testicular trauma or inflammation, and certain autoimmune disorders.

A deficiency in FSH and LH secretion by the pituitary will result in a lack of stimulus to the testes to produce androgens. Lack of FSH and LH secretion may have a number of causes, including Cushing's syndrome, thyroid disorders, estrogen-secreting tumors, and therapy with gonadotropin-releasing hormone (GnRH) agonists such as leuprolide (Lupron). Hypogonadism that is caused by defects in the pituitary or hypothalamus is known as secondary hypogonadism.

Insufficient testosterone secretion may delay the onset of puberty. If total lack of testosterone secretion occurs, puberty will not occur. In adult men, symptoms of hypogonadism include diminished secondary sex characteristics such as sparse axillary, facial, and pubic hair; increased subcutaneous fat; reduced muscle mass; and smaller testes. The lack of testosterone can lead to erectile dysfunction (ED); low sperm counts (oligospermia); a decrease in the amount of ejaculate; and decreased **libido**, or a lack of interest in sexual intercourse. Nonspecific complaints may include behavioral and mood changes such as irritability, fatigue, depression, and a general loss of motivation.

Hypogonadism is confirmed by obtaining serum testosterone levels. Assessment of LH and FSH levels, as well

Table 71.1 Selected Androgens and Anabolic Steroids

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
fluoxymesterone	PO: 5–20 mg/day	*Acne, gynecomastia, hirsutism and male sex characteristics (in women), sodium and water retention, emotional lability, amenorrhea, decreased libido, hypercholesterolemia* Anaphylaxis, testicular atrophy, and oligospermia at high doses; priapism, peliosis hepatis, benign intracranial hypertension (HTN), thromboembolism
methyltestosterone (Android, Methitest, Testred)	PO: 10–50 mg/day Buccal: 5–25 mg/day	
nandrolone	IM: 50–200 mg/wk	
oxandrolone (Oxandrin)	PO: 2.5–20 mg/day divided bid–qid for 2–4 wk	
oxymetholone (Anadrol-50)	PO: 1–5 mg/kg/day	
testosterone (buccal patch: Striant) (transdermal patch: Androderm) (topical gels: AndroGel, Fortesta, Testim, Vogelxo) (implantable pellets: Testopel) (nasal spray: Natesto)	Buccal: 30 mg q12h Transdermal: Apply one to two 2.5-mg patches daily (max: 5 mg/day) Gel: Apply 5–50 g daily, depending on product Pellets: 150–450 mg every 6 months (each pellet is 75 mg) Nasal spray: 1 spray in each nostril tid	
testosterone cypionate (Depo-Testosterone)	IM: 50–400 mg q2–4wk	
testosterone enanthate (Delatestryl)	IM: 50–400 mg q2–4wk	
testosterone undecanoate (Aveed)	IM: 750 mg initially, followed by the same dose at 4 wk and q10wk thereafter	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

as prolactin, estradiol, and thyroid hormone levels, may be useful in determining causation. Low serum levels of testosterone concurrent with normal or elevated levels of FSH and LH suggest that the testes are unresponsive to hormonal activation; thus the patient has primary hypogonadism. If testosterone, FSH, and LH levels are all low, this would indicate secondary hypogonadism.

Pharmacotherapy of hypogonadism includes replacement therapy with testosterone or other androgens. For boys experiencing delayed puberty, puberty is generally induced when the boy reaches 15 to 17 years of age using a long-acting testosterone preparation. A 6-month period of androgen therapy is given, followed by 6 months without the drug. If further therapy is needed, then testosterone cypionate (Depo-Testosterone) may be administered every 2 to 4 weeks. Therapy may be continued for up to 4 years. Once appropriate physiologic hormonal levels have been attained, the normal progression of pubertal changes typically occurs.

In the adult patient a variety of testosterone replacement preparations are available. The patient should experience improved libido, increased amount of ejaculate, and correction of ED within days or weeks of initiating therapy. Male sex characteristics become better defined, depression resolves, and muscle strength rapidly improves. Therapy with androgens is targeted to return serum testosterone to normal physiologic levels. Above-normal levels serve no therapeutic purpose and increase the risk of adverse effects.

Nonreproductive uses: Because androgens have widespread physiologic effects, they have been used to treat certain nonreproductive disorders. Testosterone promotes the synthesis of erythropoietin, which is essential for RBC production, and the drug may be used to correct anemia unresponsive to other treatments. These indications include aplastic anemia and anemias associated with chronic kidney disease and chemotherapy. Taking advantage of the anabolic effects of testosterone on bone and skeletal muscle, the drug is sometimes given to debilitated patients who have muscle-wasting disease, such as that seen in patients with acquired immunodeficiency syndrome (AIDS).

High doses of androgens are occasionally used for the palliative management of certain types of breast cancer in combination with other antineoplastics. The high doses required for breast cancer treatment will cause virilization in women. Androgen therapy is contraindicated in males with breast cancer because it promotes the growth of the cancer. Similarly, because the growth of most prostate carcinomas is testosterone dependent, androgens should not be prescribed for older men unless the possibility of prostate cancer has been ruled out. Patients with prostate carcinoma are sometimes given a GnRH agonist such as leuprolide (Lupron) to reduce circulating testosterone levels.

Testosterone formulations: Testosterone is available in a wide variety of formulations. All are equally effective and the choice is based on healthcare provider experience, ease of use, and the personal preference of the patient. Common to all dosage forms is the need for regular follow-up healthcare visits to ensure that the serum testosterone level is maintained within the designated range.

Intramuscular (IM) testosterone: Testosterone cypionate (Depo-Testosterone), testosterone undecanoate (Aveed), and testosterone enanthate (Delatestryl) are IM forms of testosterone. These drugs are slowly absorbed, metabolized to free testosterone, and result in blood levels that will vary widely after administration. This variation in serum levels may cause patients to experience fluctuations in their libido and energy and experience mood swings. Patients tend to report soreness at the site of injection. IM injections are given deep in the gluteal muscle every 2 to 4 weeks.

Implantable testosterone pellets: Testopel is a long-acting form of testosterone that is implanted subcutaneously, usually on the anterior abdominal wall. One to six pellets are implanted depending on the dose required. Testosterone levels are obtained regularly during therapy and the number of pellets adjusted accordingly. To induce puberty, low doses are usually used for 4 to 6 months. For adult replacement therapy higher doses are administered, with the effectiveness of the pellets lasting 3 to 4 months.

Transdermal testosterone patch: The Androderm patch is applied to the upper arm, thigh, back, or abdomen, rotating application sites. The patch is not to be applied to the scrotum or to damaged skin. A rash at the site of the application tends to be the only adverse effect noted. The patches are applied in the evening and changed daily. Because the used patches contain some testosterone, they should be disposed of safely, away from children and pets.

Transdermal testosterone gel: AndroGel, Fortesta, Testim, and Vogelxo are testosterone gels that are indicated for the treatment of hypogonadism. The drug is applied once daily in the morning to clean and dry skin of the upper arms, shoulders, or abdomen (not the genitals). Showering or swimming should be avoided for several hours after application to avoid washing off the drug. The alcohol-based gels dry quickly: The testosterone is absorbed in the skin in about 30 minutes and released slowly to the blood. Many patients prefer the gels because they cause less local irritation, do not fall off like the patches, and deliver a more consistent level of testosterone. A disadvantage is that the gel can be transferred to another individual by skin-to-skin contact, causing virilization of female contacts and potential fetal harm. Testosterone levels should be measured

after a few weeks of therapy and at regular intervals thereafter to ensure that physiologic levels have been achieved.

Approved in 2014 by the U.S. Food and Drug Administration (FDA), Natesto delivers testosterone gel via intranasal spray. Absorption is rapid across the nasal mucosa, but the drug needs to be applied three times daily. The most common side effects are nasal related and include nasopharyngitis, rhinorrhea, and epistaxis.

Testosterone buccal tablets: Striant is a form of testosterone that produces a continuous supply of testosterone in the blood. Patients are instructed to place a tablet in the gum area just above the incisor, holding it in place for 30 seconds. Usual doses are one tablet every 12 hours, alternating sides of the cheek. Patients may eat, drink, and chew gum with the buccal tablet in place. This route exhibits only minor adverse effects such as local irritation to the area, bad taste, and altered taste perceptions.

PROTOTYPE DRUG Testosterone

Classification **Therapeutic:** Male sex hormone
Pharmacologic: Androgen, anabolic steroid, antineoplastic

Therapeutic Effects and Uses: The primary therapeutic use of testosterone is to treat delayed puberty and hypogonadism in boys by promoting virilization, including maturation of the sexual organs, growth of facial hair, and a deepening of the voice. In adult men testosterone administration will increase libido and restore masculine characteristics that may be deficient. Testosterone is approved to treat ED when the cause is associated with low androgen levels. The drug is also approved for the palliative treatment of inoperable breast cancer in women. Off-label indications for testosterone include treatment of postpubertal cryptorchidism, microphallus, anemia in patients with chronic kidney disease (CKD), female-to-male gender change, and AIDS-associated wasting syndrome.

Testosterone base is administered by the IM route, although other salts are available for the transdermal, implantable pellets, and buccal routes. Testosterone was classified as a Schedule III controlled substance in 1991 because it was being widely abused by weight lifters and other athletes.

Mechanism of Action: Testosterone binds to specific receptors located in the cell cytoplasm. The hormone-receptor complex then migrates to the nucleus where it acts on the deoxyribonucleic acid (DNA) to promote the synthesis of specific messenger ribonucleic acid (mRNA) molecules. These form templates for the production of specific proteins that mediate testosterone effects.

Pharmacokinetics:

Route(s)	Buccal, transdermal, IM, implantable pellets
Absorption	Cypionate and enanthate are slowly absorbed from IM sites
Distribution	98% bound to sex hormone–binding globulin; unknown if secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	90% renal, 6% feces
Onset of action	Steady-state levels are reached in 3–4 weeks
Duration of action	2–4 weeks cypionate and enanthate; half-life: 10–100 min

Adverse Effects: Androgens may cause either decreased or increased libido. Salt and water are often retained, causing edema, and a diuretic may be indicated. Liver damage and hepatic cancer are potentially serious adverse effects and are of special concern when high doses are taken for prolonged periods. Acne and skin irritation are common during therapy. High doses may suppress spermatogenesis, reduce ejaculatory volume, and cause oligospermia. **Black Box Warning:** Virilization in children and women may occur following secondary exposure. Children and women should avoid touching the application sites in men using testosterone gel. Signs of virilization in women include suppression of ovulation, lactation, or menstruation; hoarseness or deepening of their voice, which is often irreversible; hirsutism; oily skin; clitoral enlargement; regression of breasts; and male-pattern baldness.

Contraindications/Precautions: Testosterone is contraindicated in men with known or suspected breast or prostatic carcinomas because it can promote the growth of these tumors. It is contraindicated in women who are or may become pregnant (category X). The drug may worsen prostatic hyperplasia. Testosterone should be used with caution in patients with CKD or hepatic impairment. Caution must be used if testosterone is administered to patients with diabetes mellitus, history of myocardial infarction (MI), coronary artery disease (CAD), benign prostatic hyperplasia (BPH), and acute intermittent porphyria and in geriatric patients. Monitoring of serum cholesterol and serum electrolytes, as well as liver function tests, is needed throughout therapy because testosterone may increase these values.

Drug Interactions: Testosterone may potentiate the effects of oral (PO) anticoagulants and increase the risk of severe bleeding. Concurrent use of testosterone with corticosteroids may cause additive edema, which can be a serious concern for those with heart failure. Hepatotoxic

drugs should be avoided because their use with testosterone can cause additive liver damage. The 5-alpha reductase drugs (finasteride) used to treat prostatic hyperplasia are antiandrogenic and their use with testosterone will inhibit the therapeutic effects of both drugs. **Herbal/Food:** Insulin requirements may decrease, and the risk of hepatotoxicity may increase when used with echinacea. Evaluation of calcium levels is necessary because hypercalcemia may result.

Pregnancy: Category X.

Treatment of Overdose: There is no specific treatment for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving testosterone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Androgens.

Drugs Similar to Testosterone

Other androgens include fluoxymesterone, methyltestosterone, and oxandrolone. All are pregnancy category X.

Fluoxymesterone: Approved in 1983, fluoxymesterone is a PO androgen that is indicated for male hypogonadism and the palliative therapy of inoperable breast cancer in women. This drug has the same adverse effects, contraindications, and actions as those of testosterone. Like other androgens, hepatitis and hepatic neoplasms may occur with long-term use. Fluoxymesterone should be used with caution in patients with preexisting cardiac or CKD because the edema caused by the drug can worsen these disorders. Older men have an increased risk for prostate cancer when taking androgens.

Methyltestosterone (Android, Methitest, Testred): Methyltestosterone is available as PO tablets, capsules, or buccal tablets. It is indicated for male hypogonadism, delayed male puberty, and inoperable breast cancer in women. This drug has the same adverse effects, contraindications, and actions as those of testosterone. Caution must be used during long-term use because of the potential for hepatotoxicity and for the development of prostate cancer in older men.

Oxandrolone (Oxandrin): Originally approved in 1964, oxandrolone is an anabolic steroid with actions and adverse effects that are the same as testosterone. It is approved to promote weight gain in patients who are severely ill, to decrease bone pain that accompanies osteoporosis, and to offset protein catabolism associated with prolonged administration of corticosteroids.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Androgens

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, peripheral vascular, thyroid, hepatic, or kidney disease; diabetes; prostatic hyperplasia; or breast cancer.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, lipid levels).
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., hormone levels normalize, normal signs of masculinization are present).
- Continue periodic monitoring of CBC, electrolytes, glucose, lipid levels, hepatic and kidney function laboratory values.
- Monitor vital signs, height, and weight at each healthcare visit.
- Assess for adverse effects: nausea, vomiting, headache, weight gain, fluid retention, edema, increased blood pressure (BP), changes in mood, irritability, or agitation. Immediately report tachycardia, palpitations, HTN, especially associated with angina or dyspnea, or abdominal pain, especially right upper quadrant and associated with yellowed skin or sclera, darkened urine, or clay-colored stools.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (Appropriate administration, especially of gels or transdermal forms, will optimize drug absorption and therapeutic effects.)	• Teach the patient the appropriate administration techniques.
Minimizing adverse effects: • Monitor BP at each clinical visit. Check weight and for the presence of edema. (Androgens cause sodium and water retention with resulting increases in weight, BP, and possible edema. Immediately report any BP over 140/90 mmHg, peripheral edema, or weight gain.)	• Teach the patient to monitor BP on a weekly basis. Report any BP over 140/90 mmHg, or as directed, to the healthcare provider. Report any weight gain of 1 kg (2 lb) in 24 h or 2 kg (5 lb) in 1 wk to the healthcare provider. Report any peripheral edema. Ensure proper functioning of any equipment used at home.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor electrolytes, lipid levels, and hepatic function laboratory values periodically. (Androgens may cause increases in cholesterol and calcium levels. Hepatotoxicity and hepatic neoplasms are rare but potential adverse effects. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hepatotoxicity.)	• Instruct the patient to return periodically for laboratory tests. • Teach the patient to immediately report any symptoms of abdominal or right upper quadrant discomfort or pain, yellowing of the skin or sclera, fatigue, anorexia, darkened urine, clay-colored stools, weakness, lethargy, nausea, or vomiting.
• Monitor blood glucose levels in patients with diabetes more frequently. Report consistent elevations to the healthcare provider. (Androgens may affect carbohydrate metabolism, leading to increased glucose levels.)	• Teach men with diabetes to monitor capillary blood sugar more frequently while on the drug and to report consistent elevations to the healthcare provider.
• Monitor height and growth in children and adolescents. (Androgen administration may result in premature closure of epiphyseal bone endings and loss of normal growth patterns.)	• Teach the patient, family, or caregiver to measure height once per month or as directed. Return for clinical assessments as needed, approximately every 6 months, to monitor bone growth.
• Monitor drug use in adolescent patients. (Abuse of androgens and anabolic steroids may occur, along with resulting adverse effects.)	• Teach the adolescent patient, family, or caregiver to maintain daily dosing as instructed and not to increase the dosage unless instructed to do so by the healthcare provider. The drug should never be shared with others.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient or caregiver in proper self-administration of the drug, e.g., consistently at the same time each day to help with remembering to take the dose, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • *Oral drugs* should be taken at the same time each day to help with remembering the dose.
	  • *Transdermal patches* (e.g., Testoderm, Androderm) should be applied to the upper arm, thigh, back, or abdomen. Change the patch and rotate sites daily, and report any skin irritation. Discard used patches safely in the trash. Do not apply the patch to the scrotal area or on broken or irritated skin.
	  • *Buccal tablets* (e.g., Striant) should be placed between the cheek and upper gum near the incisor and held in place for 30 seconds. Eating, drinking, and chewing gum may continue while the tablet is in place. Rotate from side to side, avoiding areas of irritation.
	  • *Gels and creams* (e.g., AndroGel and Testim) should be applied to the upper arms, shoulders, or abdomen. Do not apply to the scrotal area or to broken or irritated skin. Swimming and showering should be avoided for several hours following administration. Do not allow women or children to come in contact with the drug or application sites, because the drug may rub off and cause adverse effects.
	  • *Transdermal pellets* (e.g., Testopel) are implanted in the abdominal wall every 3–6 months.
	  • *Injections* should be given into deep gluteal muscle. If the patient is to administer his own injections, teach the appropriate technique, followed by teach-back until the patient is comfortable and demonstrates proper technique.

Anabolic Steroids

71.3 Often abused by athletes, anabolic steroids can cause serious adverse effects.

Testosterone has both androgenic and anabolic effects. Its androgenic effects are responsible for creating and maintaining the male sexual characteristics. The hormone's **anabolic effects** relate to its ability to accelerate the growth of RBCs, muscle, bone, and neural tissues.

Anabolic steroids also include testosterone-like substances that were originally developed to produce the anabolic effects of androgens while minimizing the androgenic effects. They are often taken inappropriately by athletes who hope to build muscle mass and strength, thereby obtaining a competitive edge. The use of anabolic steroids to improve athletic performance is illegal and all major athletic organizations prohibit the use of anabolic steroids by their participants. Many adolescents take these drugs to enhance their appearance, rather than to compete in athletics.

Interestingly, despite their regulation, some formulations of anabolic steroids can be purchased over the counter (OTC) or online. They are promoted as natural steroid alternatives for building muscle mass. FDA-approved

anabolic steroids, including all testosterone products, oxandrolone, oxymetholone, and nandrolone, are classified as Schedule III drugs under the Anabolic Steroid Control Acts of 1990 and 2004 because of their abuse potential. The anabolic steroids are listed in Table 71.1

PharmFACT

In 2013, approximately 3% of 12th-grade boys and about 1% of 12th-grade girls reported having taken anabolic steroids at some time in their life. This is about 50% fewer than reported in 2002 (LaBotz & Griesemer, 2016).

When taken in large doses for prolonged periods, anabolic steroids can produce significant adverse effects, some of which may persist for months after discontinuation of the drugs. When given in higher doses, androgen suppresses the release of LH and FSH, resulting in oligospermia, testicular atrophy, and impotence in men. In female athletes menstrual irregularities are likely with an obvious increase in masculine appearance, such as hair growth and reduction in breast size. When administered to children and teens, androgens can promote premature epiphyseal plate closure, thereby reducing adult height. Anabolic steroids are hepatotoxic, and permanent liver damage or hepatic carcinoma may result with prolonged use. Accompanying salt and water retention can result in hypertension (HTN). These drugs tend to raise low-density lipoprotein (LDL) and lower high-density lipoprotein (HDL) cholesterol levels, possibly accelerating atherosclerosis. Acne is common. Behavioral changes include an increase in aggressive behavior and psychologic dependence. Another unusual adverse effect is peliosis hepatis, which is a condition in which liver, and sometimes splenic, tissue is replaced with blood-filled cysts. These cysts are sometimes asymptomatic and may not be recognized until life-threatening hepatic failure or intra-abdominal hemorrhage occurs. Anabolic steroids are pregnancy category X medications and their use is contraindicated during pregnancy.

In 2016, the FDA added new warning labels to all testosterone products and other prescription anabolic steroids. The new label is intended to alert prescribers to the abuse and dependence potential of these products and to the serious adverse effects that can result from abuse. It also advises healthcare providers of the importance of measuring serum testosterone when abuse is suspected.

CONNECTION Checkpoint 71.1

Anabolic steroids are often taken illegally by "stacking" or "pyramiding." From what you learned in Chapter 27, define the use of these terms in the abuse of these drugs. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Etiology of Male Sexual Dysfunction

71.4 Male sexual dysfunction may have both medical and psychologic etiologies.

Approximately 50% of men will experience some form of sexual dysfunction during their adult life. The primary types of male dysfunction disorders may be classified as follows:

- Diminished libido: lack of interest in sexual activity
- Erectile dysfunction (ED): inability to obtain or maintain an erection
- Ejaculation disorder: premature, delayed, or retrograde ejaculation
- Infertility: inability to conceive a child.

Certain causes of male sexual dysfunction are treatable, either medically or surgically, or can be improved to the degree that a couple can achieve successful conception or maintain a satisfactory sexual lifestyle. For example, therapy with testosterone can rapidly increase libido in patients who have insufficient serum testosterone levels or hypogonadism. Many men with ED can now be successfully treated with medications.

A large number of drugs can cause or worsen male sexual dysfunction, as listed in Table 71.2. In most cases, the dysfunction is dose related and is much less evident when a single drug is taken at low doses. However, taking multiple drugs that have the potential to cause sexual adverse effects may result in additive sexual dysfunction. The two most common drug classes that cause sexual dysfunction are antihypertensives and antidepressants. Because sexual adverse effects are a potential cause of nonadherence, nurses should ask specific questions regarding changes in sexual function when their patients are taking these drugs.

Many comorbid medical conditions are associated with sexual dysfunction. Conditions that result in general debility, such as pain, muscle weakness, shortness of breath, or stroke, may cause dysfunction. Diabetes and HTN are the two chronic medical conditions most frequently associated with male sexual dysfunction. Patients who present with psychologic conditions such as anxiety and depression have a high incidence of sexual dysfunction. Other factors associated with ED include obesity and cigarette smoking. Combining multiple risk factors, for example, a man who has diabetes, is obese, takes antihypertensive drugs, and smokes, will result in a high risk for sexual dysfunction.

Nurses play a key role in treating male sexual dysfunction by obtaining a thorough medical history and by recognizing factors that contribute to the disorder. Should patients experience unacceptable sexual adverse effects from their medications, alternative drugs can usually be

Table 71.2 Selected Drugs That May Cause or Worsen Male Sexual Dysfunction

Drug/Drug Class	Sexual Adverse Effect(s)
Antihypertensives	
alpha$_1$-adrenergic antagonists (e.g., alfuzosin, tamsulosin)	Retrograde ejaculation, priapism
angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril)	ED
beta-adrenergic antagonists (e.g., propranolol)	Diminished libido, ED
methyldopa	Diminished libido, ED
spironolactone	Diminished libido, ED, gynecomastia
thiazide diuretics	ED
Nervous System Drugs	
carbamazepine	ED
haloperidol	Inhibited ejaculation, priapism
lithium carbonate	ED
phenothiazines (e.g., chlorpromazine)	Diminished libido, ED, inhibited ejaculation, priapism
selective serotonin reuptake inhibitors (e.g., fluoxetine)	Anorgasmy, inhibited ejaculation, diminished libido
trazodone	Priapism
tricyclic antidepressants (e.g., imipramine)	Diminished libido, ED, inhibited ejaculation
Other Drugs	
alcohol	ED
anabolic steroids	Infertility
antineoplastics (e.g., cyclophosphamide)	Infertility
cimetidine	Diminished libido, ED, gynecomastia
digoxin	ED
finasteride	Diminished libido, ED, gynecomastia
methotrexate	Infertility

substituted. Encouraging patients to receive treatment for anxiety, depression, and other comorbid conditions sometimes helps improve the sexual dysfunction. All men at risk for ED should be encouraged to maintain optimal weight, stop smoking, and limit their alcohol use.

Pharmacotherapy of Male Infertility

71.5 Male infertility is treated with endocrine drugs that boost sperm production.

Infertility affects approximately 6.1 million people in the United States, or roughly 10% of the reproductive age population. It is estimated that 30% to 40% of infertility among couples is due to difficulties with the male reproductive system.

Like female infertility, male infertility may have a number of complex causes. The most common congenital cause is Klinefelter's syndrome, which is the presence of an extra X chromosome. Acquired infertility may result from testicular trauma; pituitary or hypothalamus disorders; and infections such as mumps, chronic tuberculosis, and sexually transmitted infections. Infertility may occur with or without signs of hypogonadism. Rarely, life-threatening conditions such as testicular cancer and pituitary tumors may be the cause. In addition, the lack of ability to conceive may be caused by factors such as ED or ejaculation disorders. Identifying the etiology of infertility is important because not all causes can be successfully treated with pharmacotherapy.

The most obvious etiology of male infertility is lack of sufficient sperm production. **Oligospermia** is the presence of less than 20 million sperm per milliliter of ejaculate. **Azoospermia**, which occurs in 15% of men with infertility, is the complete absence of sperm in ejaculate. Azoospermia can be caused by severely reduced or absent sperm production, or it may indicate an obstruction of the vas deferens or ejaculatory duct that can be corrected surgically. Drug therapy with calcium channel blockers, colchicine, spironolactone, and cimetidine can lower sperm production.

Depending on the cause of the condition, one goal of pharmacotherapy for male infertility may be to increase sperm production. If the cause of the infertility is decreased testosterone secretion due to hypogonadism, administration of this hormone can increase sperm production and cure the condition.

Another method of increasing sperm production is to stimulate the testes with pituitary hormones. Pharmacotherapy often begins with IM injections of human chorionic gonadotropin (HCG) 3 times per week over 1 year. Although HCG is secreted by the placenta, its effects in men are identical to those of LH: increased testosterone secretion and spermatogenesis. Sperm counts are conducted periodically to assess therapeutic progress. If HCG is unsuccessful, therapy with menotropins (Menopur, Repronex) or newer recombinant forms of FSH may be attempted. Menotropins consists of a mixture of purified FSH and LH, which increases testosterone and sperm production.

Once testosterone levels rise, either through the administration of testosterone or HCG, the natural feedback mechanism of the body will signal the pituitary to shut down testosterone secretion in the testes. To boost testosterone levels, antiestrogen drugs such as tamoxifen (Nolvadex) and clomiphene (Clomid) have been used to block the negative feedback of adrenal estrogen to the pituitary and hypothalamus, thus increasing the levels of FSH and LH. Unfortunately, these drugs produce only a small increase in sperm count and can produce such adverse effects as gynecomastia, decreased libido, and weight gain. Clomiphene is presented as a prototype drug for female infertility in Chapter 69.

Other pharmacologic approaches to treating male infertility have been attempted. If retrograde ejaculation has been identified as a probable cause, sympathomimetics may be used to convert to normal, antegrade ejaculation. Various nutritional supplements, such as zinc to improve sperm production, L-carnitine to improve sperm motility and sperm count, and vitamins C and E as antioxidants to reduce reactive intermediates, have been tested. Unfortunately these and other therapies have not conclusively been shown to have any positive effect on male infertility.

Drug therapy of male infertility is not as successful as pharmacotherapy in women because only about 5% of infertile men have an endocrine etiology for their disorder. Many years of therapy may be required. Because of the expense of pharmacotherapy, the large number of injections needed, and the relative lack of success, other means of conception for the infertile man should be explored. A wide range of assistive reproduction procedures, including *in vitro* fertilization or intrauterine insemination, may be pursued.

CONNECTION Checkpoint 71.2

Clomiphene is used for both male and female infertility. From what you learned in Chapter 69, how does this drug act to improve female fertility? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Erectile Dysfunction

71.6 Erectile dysfunction is a common disorder that may be successfully treated with inhibitors of the enzyme phosphodiesterase-5.

Erectile dysfunction (ED) is defined as the consistent inability to either attain an erection or to sustain an erection long enough to achieve satisfactory sexual intercourse. **Impotence**, a term often used interchangeably with ED, is the total inability to achieve an erection, an inconsistent ability to achieve an erection, or the ability to have only brief erections. An estimated 15 to 30 million men in the United States have ED. The incidence of ED increases with age, although it may occur in men of any age.

Penile erection is a complex event that has psychologic, neuromuscular, and vascular components. Sexual arousal results in the release of neurotransmitters, primarily nitric oxide and epinephrine, from the hypothalamus. This stimulation along the autonomic nerves results in the release of an enzyme that makes cyclic guanosine monophosphate (cGMP). cGMP causes dilation of the arterioles leading to the major erectile tissues of the penis, called the **corpora cavernosa**. Rigidity of the penis results when the increased local blood flow and pressure fill the vascular spaces within the corpora. This engorgement causes occlusion of the veins that drain blood from the corpora, allowing the penis to remain rigid long enough for successful coitus. When stimulation ends or after ejaculation, cGMP is removed by the enzyme phosphodiesterase-5 (PDE-5). At this point, the pressure in the penis decreases, the veins dilate, blood leaves the corpora, and the penis quickly loses its rigidity. The anatomy of the penis is illustrated in Figure 71.2.

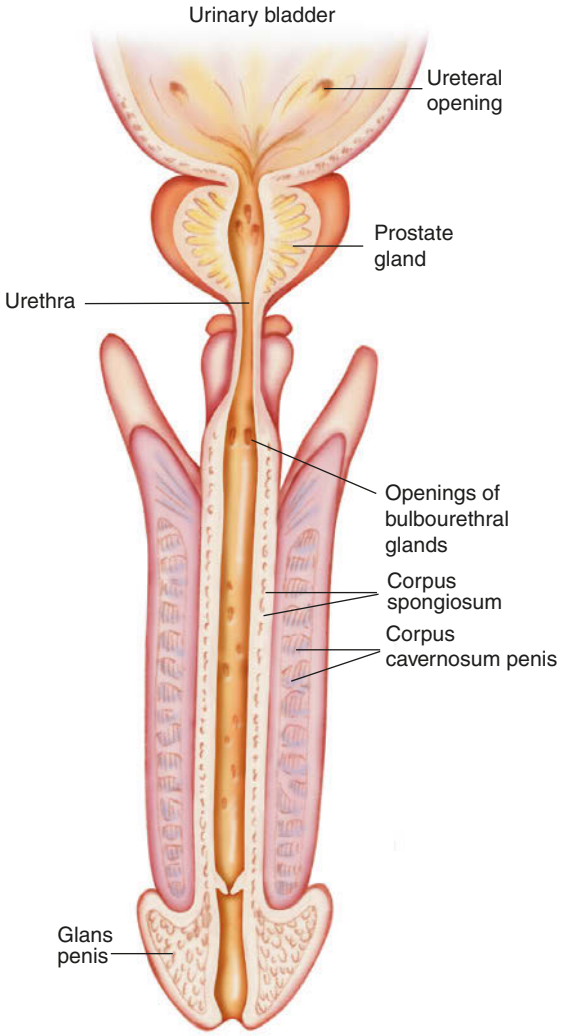

Figure 71.2 Anatomy of the penis.

Organic causes of ED may include damage to the nerves serving the penis or a decrease in blood flow through the blood vessels involved in the erection reflex. Many chronic illnesses have the potential to damage the arteries, smooth muscle, and fibrous tissues of the penis, most notably atherosclerosis, diabetes, stroke, kidney disease, and HTN. Psychogenic causes may include depression, fatigue, stress, or fear of sexual failure. In some men, a number of common drugs cause impotence as an adverse effect, including thiazide diuretics, phenothiazines, selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), propranolol (Inderal), and diazepam (Valium). Another potential cause of ED is hypogonadism,

Table 71.3 Drugs for Erectile Dysfunction

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
avanafil (Stendra)	PO: 100 mg approximately 30 min before intercourse (max: 200 mg once/day)	*Nasal congestion, headache, facial flushing, dizziness, vision abnormalities, myalgia* Hypotension when taken with nitrates, priapism, hearing loss, nonarteritic anterior ischemic optic neuropathy
sildenafil (Viagra)	PO: 25–50 mg approximately 30–60 min before intercourse (max: 100 mg once/day)	
tadalafil (Cialis)	PO: 10 mg approximately 30 min before intercourse (max: 20 mg/day); once-daily dosing: 2.5–5 mg daily	
vardenafil (Levitra, Staxyn ODT)	PO: 10 mg approximately 1 h before intercourse (max: 20 mg once/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

which can cause an inability to develop an erection, owing to the loss of libido. Nerve innervation and blood flow to the penis may be damaged by surgery, particularly during procedures involving the prostate gland.

A thorough health history of male patients should include questions regarding sexual function. Laboratory tests to check for possible metabolic or hormonal causes of ED include serum testosterone, prostate-specific antigen (PSA), blood chemistries, and prolactin and thyroxin levels. A nocturnal penile tumescence and rigidity (NPTR) test may be ordered. This test monitors the number of erections during sleep and is used to differentiate between the psychologic and physiologic causes of ED. A penile blood flow test is also used to determine whether there is sufficient arterial and venous flow through the penis. Patients who have diminished or abnormal blood flow may find that the drugs used to treat ED are not effective. These patients may have more success with penile implants.

The treatment of ED is becoming more prevalent as the population ages because more men are becoming affected by the disorder. If hormones are the cause of the dysfunction, treatment is aimed at correcting the abnormality. In some, testosterone replacement therapy by IM injection or transdermal patches may assist with ED, particularly if associated with hypogonadism or low libido. If the cause is found to be psychologic, treatment will usually consist of a combination of psychotherapy and pharmacotherapy.

The approval of sildenafil (Viagra), the first PDE-5 inhibitor, revolutionized the treatment of ED. Three other PDE-5 inhibitors have since been approved by the FDA: avanafil (Stendra), vardenafil (Levitra, Staxyn), and tadalafil (Cialis). Drugs for ED are listed in Table 71.3.

The PDE-5 inhibitors do not cause an erection. They merely enhance the erection resulting from physical contact or other sexual stimuli by maintaining relaxation of the smooth muscle in the penis and increasing blood flow. These drugs are not as effective in promoting erections in men who do not have ED. Despite considerable research interest, PDE-5 inhibitors have no effects on female sexual function. These drugs are not approved for use by women.

The PDE-5 inhibitors are equally effective at promoting erections in 60% to 80% of male patients, and the adverse effects are similar. The most common adverse effects are nasal congestion, headache, facial flushing, and dizziness. These drugs produce a 5- to 10-mm fall in blood pressure, but this drop is usually not clinically important. In patients who are taking nitrates or multiple antihypertensive medications, however, this blood pressure change may produce symptoms of hypotension. Therefore, PDE-5 inhibitors are contraindicated in patients who are taking organic nitrates in any form. Organic nitrates include nitroglycerin and isosorbide mononitrate.

Alprostadil (Caverject, Edex, Muse) is an alternative for men who have contraindications to the use of PDE-5 inhibitors. Caverject and Edex formulations are self-injected directly into the corpora cavernosa just prior to intercourse. Muse is a pellet containing the drug that is inserted by an applicator into the urethra just prior to intercourse. Alprostadil by either method should not be used more than 3 times per week and not more than once in 24 hours. Penile pain, burning sensations, and priapism are common adverse effects and, more rarely, penile fibrosis. The effectiveness of alprostadil is less than that of the PDE-5 inhibitors or intracavernosal injections, and the strength of the erection can be improved by using a constriction ring.

PROTOTYPE DRUG Sildenafil (Viagra)

Classification **Therapeutic:** Drug for treating impotence
Pharmacologic: Phosphodiesterase-5 inhibitor

Therapeutic Effects and Uses: Approved in 1998, sildenafil is a PO drug and was the first PDE-5 inhibitor approved for ED. The onset of action is relatively rapid (less than 1 hour), and its effects last up to 4 hours.

In 2005, sildenafil (Revatio) was approved for the treatment of pulmonary arterial HTN. For this indication, blocking PDE-5 in pulmonary vascular smooth muscle causes vasodilation and reduction in arterial HTN. The drug improves exercise capacity in these patients. The dosing for Revatio is 5 to 20 mg three times daily. Off-label indications include prevention of pulmonary HTN induced by altitude sickness and treatment of Raynaud's phenomena resistant to vasodilator therapy.

Mechanism of Action: Sildenafil inhibits PDE-5 and increases and preserves cGMP levels in the penis. This relaxes smooth muscle in the corpus cavernosa, allowing increased blood flow into the penis and allowing a harder and longer lasting erection in about 70% of men taking the drug.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapid; bioavailability: 40%
Distribution	96% protein bound
Primary metabolism	Hepatic (CYP3A4 and 2C9)
Primary excretion	80% feces, 12% renal
Onset of action	20–60 min
Duration of action	24 h; half-life: 4 h

Adverse Effects: Sildenafil is well tolerated and adverse effects are usually transient and mild. Common adverse effects include headache, dizziness, flushing, rash, and nasal congestion. The most serious adverse effect, hypotension, occurs in patients who are concurrently taking organic nitrates for angina and can result in MI and sudden cardiac death. Sildenafil can produce blurred vision, increased sensitivity to light, or changes in color perception in 10% of patients using it. Priapism, a sustained erection lasting longer than 6 hours, has been reported with sildenafil use and may lead to permanent damage of penile tissue.

Contraindications/Precautions: Sildenafil is contraindicated in patients who are taking nitrates and in those with hypersensitivity to this drug. It is contraindicated in patients with severe cardiovascular disease, recent MI, stroke, heart failure, or dysrhythmias, and in the presence of anatomic deformities of the penis. This drug should be used with caution in patients with CKD or hepatic impairment. Patients with preexisting visual disturbances should not use sildenafil.

Drug Interactions: Cimetidine, erythromycin, and ketoconazole will increase serum levels of sildenafil and necessitate lower drug doses. Concurrent use with nitrates is contraindicated and will result in hypotension and possibly death. Protease inhibitors (ritonavir, amprenavir, others) will cause increased sildenafil levels, which may lead to toxicity. Rifampin may decrease sildenafil levels, leading to decreased effectiveness. Concurrent use of sildenafil with drugs that lower blood pressure, including alpha$_1$-adrenergic antagonists, should be avoided due to the potential for additive hypotension. **Herbal/Food:** Administration of sildenafil with high-fat meals should be avoided because absorption is decreased. Grapefruit juice increases the plasma concentrations of sildenafil and may cause adverse effects.

Pregnancy: Category B (not approved for women).

Treatment of Overdose: There is no specific treatment for overdose.

Nursing Responsibilities:

- Obtain a complete physical examination, including a history of sexual dysfunction; cardiovascular or peripheral vascular disease; thyroid, hepatic, or kidney disease; diabetes; or prostatic hyperplasia.
- Obtain a complete drug history including prescription, OTC, and recreational or illicit drug use.
- Obtain baseline vital signs and notify the healthcare provider of blood pressure below 90/60 mmHg.
- Notify the prescriber if the patient takes a drug for angina or HTN such as nitroglycerin because these drugs may cause a sudden, unsafe drop in blood pressure.
- Monitor liver function tests. Patients with cirrhosis or severe decreased liver function may start with lower doses to prevent hepatotoxicity.
- Monitor for visual adverse effects such as blurred vision, the inability to differentiate between green and blue, perception of a blue tinge to objects, or photophobia. Observe safety precautions until it is known whether sensory-perceptual alterations occur to prevent falls and other injuries.
- Monitor for presence of headache, dizziness, flushing, rash, and nasal congestion.

Lifespan and Diversity Considerations:

- Monitor hepatic and renal function laboratory values and cardiac status more frequently in the older adult because normal physiologic changes related to aging may increase the risk of adverse effects.

Patient and Family Education:

- Keep all laboratory visits to evaluate liver function.
- Take this drug 30 to 60 minutes before anticipated sexual activity. Do not take more than one dose in a 24-hour period.
- Alert all healthcare providers to the use of sildenafil before starting any new medication.
- Avoid high-fat meals before taking this drug because it may cause a delay in drug action.
- Immediately report any chest pain, unrelieved visual changes, eye pain, lights or flashes in the eyes, or an erection that lasts longer than 4 hours or is painful to the healthcare provider.

Drugs Similar to Sildenafil (Viagra)

The other PDE-5 inhibitors are avanafil, tadalafil, and vardenafil.

Avanafil (Stendra): The newest ED drug, avanafil, was approved in 2012 and acts by the same mechanism as the other three PDE-5 inhibitors. It acts in 15 to 30 minutes, which is the fastest of the drugs in this class. It has a

duration of about 6 hours, which is short compared to 36 hours for tadalafil. Avanafil may be taken twice daily. This drug's absorption is not affected by food. The adverse effects and contraindications are the same as those of other drugs in this class. This drug is pregnancy category C (not approved for women).

Tadalafil (Cialis): Initially approved in 2003, tadalafil acts by the same mechanism as sildenafil, which is relaxation of penile arterial and trabecular smooth muscle. This drug's absorption is not affected by food. It acts within about 60 minutes and has a longer duration of action than sildenafil: up to 36 hours. The longer duration allows for more spontaneity of sexual activity. Contraindications include patients who take nitrates, and dosing can be prescribed every 72 hours. Tadalafil produces less blood pressure decrease than the other drugs in this class, making it safer for patients with heart failure or a history of MI. It also results in a lower incidence of visual disturbances. Other adverse effects are similar to those of sildenafil. A daily dosing of 2.5-mg tadalafil for erectile dysfunction was approved in 2008. This drug is pregnancy category B (not approved for women).

Like sildenafil, tadalafil (Adcirca) is also approved to treat pulmonary arterial HTN. The dose for this indication is higher, at 40 mg/day. In 2011, tadalafil (Cialis) was approved for the symptomatic treatment of BPH. Although its exact mechanism is still being investigated, tadalafil is believed to reduce BPH symptoms by relaxing urinary smooth muscles and increasing blood perfusion and oxygenation of the bladder and prostatic tissue.

Vardenafil (Levitra, Staxyn ODT): Like other drugs in this class, vardenafil allows for relaxation of arterial and trabecular smooth muscle in the penis. Approved in 2003, vardenafil acts within 30 to 60 minutes and its effects continue for 4 to 5 hours. In 2010, an orally disintegrating tablet (ODT) form of this drug (Staxyn) was approved. Headache, flushing, rhinitis, and dyspepsia are the common adverse effects. Vardenafil may prolong the QT interval and is to be used with caution in patients who are taking nitrates. Administration with high-fat meals should be avoided because absorption is decreased. This drug is pregnancy category B (not approved for women).

CONNECTIONS: Patient Safety

Increased Plasma Drug Concentrations

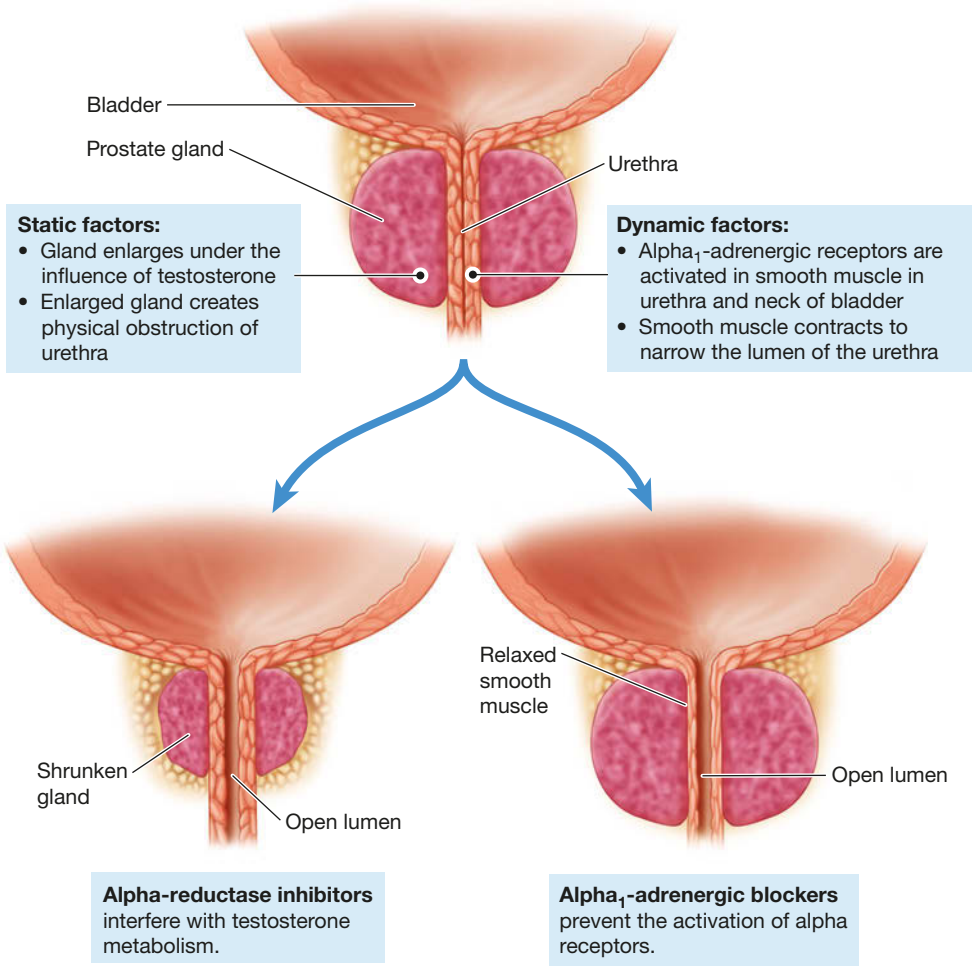
A 53-year-old man is prescribed sildenafil (Viagra) for treatment of erectile dysfunction. His medical history reveals no cardiovascular disease and no other medication use, and his blood pressure is within normal range. Later that evening, he is admitted to the emergency department with reports of chest pain and dizziness and has a blood pressure of 80/48 mmHg. The triage nurse notes in the electronic health record that the patient took two acetaminophen (Tylenol) tablets 4 hours before taking the sildenafil. A dietary history reveals that he follows a gluten-free diet and drinks three glasses of grapefruit juice daily. What is a potential cause of this patient's symptoms, and what should the nurse teach this patient?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Pathophysiology of Benign Prostatic Hyperplasia

71.7 Benign prostatic hyperplasia is an enlargement of the prostate that occurs in older men.

The prostate is a gland the size of a walnut that surrounds the male urethra. Its primary function is to contribute fluids to the ejaculate. The prostate contains two major types of tissues:



- **Epithelial tissue.** This is the glandular portion of the prostate that secretes fluids for the ejaculate. The growth of prostatic epithelial tissue is controlled by the presence of androgens. Testosterone is converted to its active metabolite, dihydrotestosterone (DHT), in the epithelial cells of the prostate by the enzyme 5-alpha reductase.
- **Stomal tissue.** This is smooth muscle tissue, which is controlled by alpha$_1$-adrenergic receptors. When activated, these receptors cause the smooth muscle to contract around the urethra.

Benign prostatic hyperplasia (BPH), an abnormal enlargement of the prostate, is the most common benign neoplasm in older men. The exact cause of BPH is unknown. It is present in 70% of men by age 60 and 90% by age 80. Other than age, the risk factors for BPH include a family history of the disorder, smoking, heavy alcohol consumption, HTN, diabetes, a diet high in meats and fats, and African American ancestry. BPH is not considered to be a precursor to prostate carcinoma, though it is well known that many men with BPH eventually experience prostate cancer.

The characteristic feature of BPH is an enlargement of the prostate gland that decreases the outflow of urine by obstructing the urethra, causing difficult urination. The pathogenesis of BPH involves two components: static and dynamic. The static factors are caused by the physical enlargement of the prostate gland due to the overgrowth of the epithelial cells. The gland can double or triple in size with aging, creating a blockage of urine outflow at the neck of the bladder. The dynamic factors are due to excessive numbers of alpha$_1$-adrenergic receptors located in stromal tissue in the neck of the urinary bladder and in the prostate

Pharmacotherapy Illustrated 71.1

Mechanism of Action of Antiprostatic Drugs

gland. When activated, these receptors compress the urethra and provide resistance to urine outflow from the bladder. The two mechanisms of disease, static and dynamic, have led to two different classes of drugs for treating the symptoms of BPH. These mechanisms are shown in Pharmacotherapy Illustrated 71.1.

Certain frequently used medications may worsen symptoms of BPH. Alpha$_1$-adrenergic drugs, which include decongestants such as pseudoephedrine and phenylephrine, activate alpha$_1$-adrenergic receptors in the bladder neck, restricting urine flow. Drugs with anticholinergic effects such as antihistamines, TCAs, or phenothiazines may worsen the associated urinary retention. Testosterone and other anabolic steroids may increase prostate enlargement, which contributes to the physical obstruction of the urethra. Drugs that worsen symptoms of BPH should be avoided in older men.

There is no clear correlation between the symptoms experienced by patients and the size of the prostate. Some men may have minimal enlargement and experience moderate symptoms, whereas others may have extremely enlarged glands and be asymptomatic. This is because the smooth muscle in the urinary bladder has the ability to compensate for the obstruction by contracting with greater force to eject the urine stream. Over time, the bladder is no longer able to compensate and symptoms of BPH manifest, such as increased urinary frequency (usually with small amounts of urine), increased urgency to urinate, postvoid leakage, excessive nighttime urination (nocturia), decreased force of the urine stream, and a sensation that the bladder did not completely empty.

Some patients do not seek medical attention until complications caused by the long-standing obstruction at the neck of the urinary bladder arise. Serious complications include recurrent urinary infections, incontinence, gross hematuria, bladder stones, and CKD.

Pharmacotherapy of Benign Prostatic Hyperplasia

71.8 In its early stages, benign prostatic hyperplasia may be treated successfully with drug therapy.

The goal of treatment for patients with BPH focuses on minimizing the urinary obstruction and preventing complications. Drug therapy can only treat symptoms; it cannot reverse or cure BPH. Patients who are asymptomatic or who present with mild symptoms generally do not receive pharmacotherapy. Not all BPH is progressive, and many patients never experience moderate or advanced symptoms. Patient education such as avoiding caffeine or alcohol intake, eliminating drugs that worsen BPH, and restricting fluids close to bedtime may be sufficient to achieve symptomatic improvement. Morning diuretic therapy may be used to reduce nighttime diuresis. The patient is reevaluated at 6- to 12-month intervals to assess for worsening symptoms.

When symptoms of BPH worsen, pharmacotherapy is indicated. Only a few drugs are available for the pharmacotherapy of BPH, and these are listed in Table 71.4. Drugs that are used to treat BPH have limited effectiveness and have value only in treating mild to moderate disease as an alternative to surgery. Because pharmacotherapy does not cure the disease, these medications must be taken for the remainder of the patient's life or until surgery is indicated. If the drugs are discontinued, the prostate returns back to its enlarged state and symptoms of BPH return. In advanced cases, transurethral resection of the prostate or a laser prostatectomy is needed to restore the patency of the urethra.

The major drug classes for treating BPH are the alpha$_1$-adrenergic antagonists and the 5-alpha reductase inhibitors. Research has shown that combination therapy with an alpha$_1$ antagonist and a 5-alpha reductase inhibitor is more effective than therapy with either drug alone. This is the preferred treatment for patients with moderate symptoms of BPH. More recently, tadalafil (Cialis), a PDE-5 inhibitor, joined the list of approved drugs for BPH.

The alpha$_1$-adrenergic antagonists act on the stromal tissue of the prostate to relax smooth muscle in the prostate gland, bladder neck, and urethra, thus easing the urinary obstruction. Doxazosin (Cardura) and terazosin (Hytrin) are of particular value to patients who have both HTN and BPH; these two disorders occur concurrently in about 25% of men older than 60. Three alpha$_1$ antagonists, silodosin (Rapaflo), tamsulosin (Flomax), and alfuzosin (Uroxatral), are selective for the prostate and have no effect on blood pressure at normal doses. Drugs in this class improve urine flow and reduce other symptoms of BPH after 1 to 2 weeks of therapy. Common adverse effects include headache, fatigue, and dizziness. Doxazosin and terazosin are not associated with an increased risk of sexual dysfunction, but ejaculatory disorders have been reported with silodosin, tamsulosin, and alfuzosin. Reflex tachycardia due to stimulation of baroreceptors is common with alpha$_1$ antagonists. Additional information on the alpha$_1$ antagonists is presented in Chapter 16.

Some patients are unable to tolerate the cardiovascular adverse effects of the alpha$_1$-adrenergic antagonists. For these patients, the 5-alpha reductase inhibitors are used as monotherapy. These drugs act by blocking 5-alpha reductase, the enzyme responsible for converting testosterone to DHT, which is its active metabolite. Without DHT the hormonal signal for prostatic epithelial tissue

Table 71.4 Drugs for Benign Prostatic Hyperplasia

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Alpha$_1$-Adrenergic Antagonists		
alfuzosin (Uroxatral)	PO: 10 mg/day (max: 10 mg/day)	*Orthostatic hypotension, headache, dizziness, decreased libido, decreased ejaculate volume* First-dose phenomenon (severe hypotension and syncope), tachycardia
doxazosin (Cardura)	PO: 1–8 mg/day (max: 8 mg/day)	
doxazosin XL (Cardura XL)	Extended release: 4–8 mg/day (max: 8 mg/day)	
silodosin (Rapaflo)	PO: 8 mg once daily with a meal	
tamsulosin (Flomax)	PO: 0.4 mg 30 min after a meal (max: 0.8 mg/day)	
terazosin (Hytrin)	PO: Start with 1 mg at bedtime, then 1–5 mg/day (max: 20 mg/day)	
5-Alpha Reductase Inhibitors		
dutasteride (Avodart)	PO: 0.5 mg/day	*Sexual dysfunction, decreased libido, decreased ejaculate volume, gynecomastia* Possible increased risk for prostate cancer
finasteride (Proscar)	PO: 5 mg/day (max: 5 mg/day)	
Phosphodiesterase-5 Inhibitors		
tadalafil (Cialis)	PO: 5 mg once daily	See Table 71.3

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTIONS: Complementary and Alternative Therapies

Saw Palmetto

Description

Saw palmetto (*Serenoa repens*) is a dwarf palm tree that grows in the coastal regions of the southern United States. The berries of the saw palmetto are used in supplements. More than 2 million men in the United States use saw palmetto each year in the hopes that it will treat their symptoms of BPH.

History and Claims

Like finasteride, saw palmetto is thought to help stop a cascade of prostate-damaging enzymes that may create BPH. In theory, it occupies binding sites on the prostate that are typically occupied by DHT, an enzyme that may trigger BPH, inhibiting growth of the prostate gland.

Standardization

Saw palmetto is available in capsule, tablet, and liquid dosage forms. PO saw palmetto products should be standardized to contain 80% or more of the active ingredients, which are fatty acids.

Evidence

Although several clinical studies have suggested that saw palmetto may be beneficial in treating BPH symptoms, there has been no conclusive evidence to demonstrate that it is as effective as finasteride in treating mild to moderate BPH (National Center for Complementary and Integrative Health, 2016). Although considered a safe supplement, saw palmetto may cause damage to the liver and pancreas, and it is vital that the nurse obtain a thorough health and supplement use history and advise the patient of its potential adverse effects.

growth is eliminated, thus causing the enlarged prostate to shrink in size. The most commonly prescribed drug in this class is finasteride (Proscar), which is featured below as a prototype for BPH. These drugs may take several months to shrink the size of the prostate; thus, they are not appropriate for severe disease. The 5-alpha reductase inhibitors produce few adverse effects, although they can cause sexual dysfunction and gynecomastia in some patients. Because they are pregnancy category X, patients who are taking these drugs should not donate blood because of the possibility that the donated blood would be given to a pregnant woman.

CONNECTION Checkpoint 71.3

Alpha$_1$-adrenergic antagonists are very susceptible to causing the first-dose phenomenon. From what you learned in Chapter 16, define this phenomenon and describe what should be done to minimize its effects. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Finasteride (Proscar)**

Classification **Therapeutic:** Drug for BPH
Pharmacologic: Antiandrogen, 5-alpha reductase inhibitor

Therapeutic Effects and Uses: Approved in 1992, finasteride is a PO drug that inhibits the metabolism of testosterone. The drug is sometimes called an antiandrogen. Finasteride shrinks enlarged prostates, helping to restore urinary function. It is most effective in patients with larger prostates. It is sometimes prescribed in combination with doxazosin to reduce the risk of symptomatic progression of BPH. This drug is also marketed as Propecia, which is prescribed to promote hair regrowth in patients with male-pattern baldness. Doses of finasteride are five times higher when prescribed for BPH than when prescribed for baldness.

Off-label indications for finasteride take advantage of its antiandrogen effects. It may be used to treat mild to moderate hirsutism in females. Although some clinical trials suggested the drug exerted a protective effect against prostate cancer, the drug insert from the manufacturer clearly states it is not to be prescribed for this purpose.

Mechanism of Action: Finasteride acts by inhibiting 5-alpha reductase, which is the enzyme responsible for converting testosterone to one of its metabolites, 5-alpha dihydrotestosterone. This active metabolite causes proliferation of prostate cells and promotes enlargement of the gland. Finasteride promotes regression of prostate epithelial tissue and decreases mechanical obstruction of the urethra.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Crosses the blood–brain barrier; found in semen; 90% bound to plasma protein
Primary metabolism	Hepatic (CYP3A4)
Primary excretion	39% renal, 57% feces
Onset of action	Maximum effects take 3–6 months
Duration of action	2 weeks

Adverse Effects: Finasteride is well tolerated and adverse effects are generally mild and transient. Finasteride causes various types of sexual dysfunction in up to 16% of patients, including gynecomastia, impotence,

diminished libido, and ejaculatory disorders such as decreased volume of ejaculate. The drug reduces sperm production and may impair fertility. The actual incidence of drug-induced sexual dysfunction is difficult to estimate because a large percentage of older men develop these symptoms as a consequence of aging or comorbid conditions. Other minor adverse effects include headache, nausea, rash, dizziness, and asthenia. Men over age 55 may have a slightly increased risk of developing high-grade prostate cancer.

Contraindications/Precautions: Contraindications to finasteride include hypersensitivity to the drug, pregnancy (category X), lactation, or use in women and children. The pregnant nurse or pharmacist should avoid handling crushed medication because it may be absorbed through the skin and cause harm to a male fetus. Caution must be used when administering the drug to patients with CKD or hepatic impairment.

Drug Interactions: Use with anticholinergics may decrease the effects of finasteride. Use of finasteride with testosterone will result in a reduction in the effects of both drugs. **Herbal/Food:** Saw palmetto may potentiate the effects of finasteride.

Pregnancy: Category X.

Treatment of Overdose: There is no specific treatment for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving finasteride are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Benign Prostatic Hyperplasia.

Drugs Similar to Finasteride (Proscar)

The only other 5-alpha reductase inhibitor is dutasteride.

Dutasteride (Avodart): Approved in 2001, dutasteride is a PO drug approved only for the treatment of BPH. Compared to finasteride, dutasteride causes a greater inhibition of 5-alpha reductase and thus is able to more effectively lower DHT levels. Dutasteride has a half-life of 5 weeks and it remains in the body for several months after the drug is stopped. Like finasteride, sexual adverse effects such as reduced ejaculate volume, diminished libido, and ED occur in some patients. Other warnings, contraindications, and actions are the same as those of finasteride. Jalyn is a fixed-dose combination drug that contains dutasteride with tamsulosin. Dutasteride is pregnancy category X.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Benign Prostatic Hyperplasia

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, peripheral vascular, thyroid, hepatic, or kidney disease; diabetes; prostatic hyperplasia (PSA); or prostatic cancer.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., CBC, hepatic and renal function tests).
- Obtain baseline vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., urinary stream increases, lessened urinary retention).
- Continue periodic monitoring of CBC, hepatic and renal function laboratory values, and PSA levels.
- Monitor vital signs at each healthcare visit.
- Assess for adverse effects: nausea, headache, rash, dizziness, or sexual dysfunction.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (Full therapeutic effects from 5-alpha reductase inhibitors may take 3–6 months to be achieved.)	• Teach the patient to continue taking the medication consistently during the early months of therapy and that the drug may take several months to achieve its full effects.
Minimizing adverse effects: • Continue to monitor hepatic function laboratory values periodically. (Hepatotoxicity is a potential adverse effect. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hepatotoxicity. **Diverse Patients:** Because finasteride metabolizes through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Teach the patient to immediately report any increasing symptoms of urinary retention or slowing of the urinary stream. A prostate examination may be indicated. • Teach the patient to immediately report any symptoms of abdominal or right upper quadrant discomfort or pain, yellowing of the skin or sclera, fatigue, anorexia, darkened urine, clay-colored stools, weakness, lethargy, nausea, or vomiting.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor BP at each clinical visit. Check weight and for presence of edema. (Alpha$_1$-adrenergic antagonists may trigger sodium and water retention with resulting increases in weight, BP, and possible edema. Immediately report any BP over 140/90 mmHg, peripheral edema, or weight gain.)	• Teach the patient taking alpha$_1$-adrenergic antagonists to monitor BP on a weekly basis. Report any BP over 140/90 mmHg, or as directed, to the healthcare provider. Report any weight gain of 1 kg (2 lb) in 24 h or 2 kg (5 lb) in 1 wk to the healthcare provider. Report any peripheral edema. Ensure proper functioning of any equipment used at home.
• Monitor urine output and symptoms of dysuria such as hesitancy or nocturia. (5-alpha reductase inhibitors may cause urinary frequency, nocturia, or hesitancy.)	• Have the patient promptly report urinary hesitancy, frequency, or an increase in nocturia.
• Give the first dose of any alpha$_1$-adrenergic antagonist at bedtime. (A first-dose response may result in a greater initial drop in BP than subsequent doses. This may also occur if the dose is increased. **Lifespan:** Be cautious with the older adult who has a greater risk for falls.)	• Instruct the patient to take the first dose of medication at bedtime, immediately before going to bed, and to avoid driving for 12–24 h after the first dose, or when the dosage is increased, until the effects are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Do not abruptly stop alpha$_1$-adrenergic antagonists used for BPH. (Rebound HTN and tachycardia may occur.)	• Teach the patient not to stop the medication abruptly and to call the healthcare provider for instructions if unable to take the medication for more than 2 days due to illness.
• Protect against unintentional exposure to 5-alpha reductase inhibitors by women of childbearing age and children, including through handling of crushed or broken drugs. (The drug has teratogenic effects and handling by women of childbearing age should be avoided. Men should wear condoms during sexual activity and should not donate blood while taking the drug and up to 1 month after stopping the drug.)	• Teach the patient to keep the drug in a secure location to guard against unintentional exposure to women of childbearing age or children. • Teach the patient to use condoms consistently for sexual activity to avoid exposing women of childbearing age to semen, which may also contain the drug. • Instruct the patient not to donate blood during the time the drug is taken and up to 1 month after the drug is stopped.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, the appropriate dose and scheduling, what adverse effects to observe for, and when to report them.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient or caregiver in proper self-administration of the drug, e.g., consistently over several months of therapy, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss the appropriate dosing and administration needs.

Understanding Chapter 71

Key Concepts Summary

71.1 Male reproductive function is controlled through the secretion of androgens.

71.2 Androgens are used to treat hypogonadism and delayed puberty in males, and breast cancer in females.

71.3 Often abused by athletes, anabolic steroids can cause serious adverse effects.

71.4 Male sexual dysfunction may have both medical and psychologic etiologies.

71.5 Male infertility is treated with endocrine drugs that boost sperm production.

71.6 Erectile dysfunction is a common disorder that may be successfully treated with inhibitors of the enzyme phosphodiesterase-5.

71.7 Benign prostatic hyperplasia is an enlargement of the prostate that occurs in older men.

71.8 In its early stages, benign prostatic hyperplasia may be treated successfully with drug therapy.

CASE STUDY: Making the Patient Connection

Remember the patient "Mike Mayhew" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

One year after his divorce, Mike, a 34-year-old man, began dating and soon met Dana. The couple found that they had a lot in common and enjoyed each other's company. As the relationship grew, the couple became more intimate and sexually involved. However, the emotional scars from his previous marriage were painful and deeply affected him.

After the divorce, Mike was depressed and had low self-esteem. The condition required short-term hospitalization, and he now follows up on an outpatient basis with a psychiatrist. He has been taking antidepressants and was recently prescribed tadalafil (Cialis) for a diagnosis of ED. Mike also has a past history of HTN and is taking nifedipine (Procardia).

Critical Thinking Questions

1. What factors in Mike's life and health history do you think are contributing to the diagnosis of ED?
2. If you were the nurse, what patient education instructions would you provide to Mike regarding administration of tadalafil (Cialis) along with nifedipine (Procardia)?
3. After considering both options, Mike would rather be prescribed sildenafil (Viagra) instead of tadalafil (Cialis). What should the healthcare provider discuss with Mike about this request?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Morrie Jones, a 72-year-old man, has been having difficulty with urinary frequency and excessive nighttime urination. He scheduled an appointment with his healthcare provider and is diagnosed with BPH. He is prescribed finasteride (Proscar) and needs to see his healthcare provider again in 6 months.

1. How would you explain the purpose of finasteride (Proscar) in treating BPH?
2. What education would you provide Mr. Jones that he may find helpful in dealing with BPH?
3. What additional health history and physical assessment findings would be considered in diagnosing this condition?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. An adult patient has been receiving testosterone (Testoderm) for the treatment of primary hypogonadism. Which laboratory test would the nurse monitor to determine that this drug therapy is effective?
   1. Red blood cell count
   2. Sperm count
   3. FSH
   4. LH

2. The patient with erectile dysfunction is being evaluated for pharmacotherapy. Which question should the nurse ask prior to initiating therapy with sildenafil (Viagra)?
   1. "Are you currently taking medications for angina?"
   2. "Do you have a history of diabetes?"
   3. "Have you ever had an allergic reaction to penicillin products?"
   4. "Have you ever been treated for gastric ulcers?"

3. The nurse is teaching a patient who has received a prescription testosterone gel (AndroGel) for treatment of symptoms related to low androgen levels. What instructions should the nurse give the patient? (Select all that apply.)
   1. "Apply the gel to the scrotal and perineal area daily."
   2. "Avoid exposing women to the gel or to areas of skin where gel has been applied."
   3. "Report any weight gain over 2 kilograms (5 pounds) in 1 week's time."
   4. "Avoid showering or swimming for at least 12 to 14 hours after applying the gel."
   5. "Maintain a low-fat diet and return periodically for blood lipid laboratory studies."

4. The nurse is counseling a patient about the goal of therapy with sildenafil (Viagra). What will the nurse teach the patient about the drug's effects?
   1. It should always result in a penile erection within 10 minutes.
   2. It is not effective if sexual dysfunction is psychologic in nature.
   3. It will result in less intense feelings with prolonged use.
   4. It may heighten sexual response in female partners.

5. The nurse is teaching the patient about the use of finasteride (Proscar). What patient teaching related to this medication is needed? (Select all that apply.)
   1. Finasteride promotes shrinkage of an enlarged prostate and helps restore urinary function.
   2. The drug should not be handled by women who may be pregnant.
   3. Finasteride affects both near and far vision in older adult men.
   4. Six to 12 months may be required before the benefits of finasteride are achieved.
   5. The drug may cause significant dizziness, which can be avoided by making position changes slowly.

6. A patient who has taken finasteride (Proscar) for the past 8 months reports a sudden increase in urinary hesitancy, urinary retention, and slowing of the urinary stream. What will the nurse teach this patient to do?
   1. Continue to take the drug to achieve full effects.
   2. Decrease the intake of coffee, tea, and alcohol.
   3. Discuss the use of a low-dose diuretic with the healthcare provider.
   4. Return to the healthcare provider for a prostate exam.

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the role of calcium in maintaining homeostasis in the nervous, muscular, skeletal, and cardiovascular systems.
2. Identify the recommended dietary allowance and the normal serum levels of calcium.
3. Explain the roles of parathyroid hormone, calcitonin, and vitamin D in maintaining calcium balance.
4. Explain the etiology, pathogenesis, and pharmacotherapy for hypocalcemia, hypercalcemia, osteomalacia, osteoporosis, rickets, osteoarthritis, rheumatoid arthritis, and gout.
5. Describe the nurse's role in the pharmacologic management of bone and joint disorders.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to the care of patients receiving pharmacotherapy for bone and joint disorders.

Key Terms

acute gouty arthritis, 1355

rheumatoid arthritis (RA), 1348
selective estrogen receptor modulators (SERMs), 1343
uricosurics, 1357
xanthine oxidase, 1357

Disorders associated with bones and joints can lead to immobility and affect a patient's ability to fulfill activities of daily living (ADLs). In addition, the skeletal system serves as the primary repository for calcium, which is one of the body's most important minerals.

This chapter focuses on the pharmacotherapy of important skeletal and joint disorders such as osteomalacia, osteoporosis, arthritis, and gout. The importance of calcium balance and the action of vitamin D are stressed because they are critical to the proper structure and function of bones.

Role of Calcium in Body Homeostasis

72.1 Adequate levels of calcium in the body are necessary to transmit nerve impulses, to prevent muscle spasms, and for proper bone health.

Calcium balance is critical to the proper functioning of the nervous, muscular, skeletal, and cardiovascular systems. In the nervous system calcium ions influence the release of neurotransmitters and the excitability of all neurons. Contraction is dependent on calcium ion movement in skeletal, smooth, and cardiac muscle cells. Calcium is important for the normal functioning of other body processes such as blood coagulation by converting prothrombin into thrombin and in activating enzymes that catalyze many essential chemical reactions.

Calcium is the major cation for the structure of the bones and teeth. Total body content of calcium is about 1200 g or approximately 2% of the total body weight. More than 99% of that calcium is in the skeletal system and is bound as a hard matrix known as hydroxyapatite crystals. Only about 1% of the calcium in bone is rapidly exchangeable with blood calcium; the remaining calcium is more stable and slowly exchanged.

Much of the calcium found outside of bone circulates in the blood. Calcium exists in plasma in three forms: ionized, bound, and complexed. About 50% of the serum calcium is in an active, ionized form that participates in intracellular functions, including neuromuscular activity and blood coagulation. This is the only physiologically and clinically significant form of calcium. An adequate amount of free or ionized calcium is required for normal body functions. Most of the remaining 50% of calcium in plasma is bound to plasma proteins, primarily albumin, and other substances and is unavailable for general use by the body.

To maintain homeostasis, the body must obtain sufficient amounts of calcium through proper nutrition and dietary supplements. Unfortunately, only 30% to 50% of dietary calcium is absorbed from the small intestine. The amount absorbed, however, is dynamic and changes with body conditions. Absorption is increased by moderate amounts of fat or high protein intake, high gastric acidity, and when certain hormones are secreted in response to low blood calcium. Decreased absorption occurs with vitamin D deficiency, high-fat diet, decreased gastric acidity, certain hormones secreted in response to high blood calcium, and conditions that increase gastrointestinal (GI) motility such as diarrhea. Dietary calcium that remains unabsorbed is excreted in feces. Calcium can also be lost through the nails, hair, sweat, and other body fluids. In lactating women, large amounts are lost through breast milk.

The recommended dietary allowance (RDA) of calcium for healthy adults is 1000 to 1200 mg/day. Higher amounts are needed by pregnant and lactating women, growing children, and postmenopausal women, as given in Table 72.1. The best dietary sources of calcium are dairy products. The calcium found in milk is the most readily available form because milk contains sufficient amounts of vitamin D, which is necessary for calcium absorption. Other rich sources of calcium include seafood, such as salmon, oysters, and clams, and green leafy vegetables, such as kale, broccoli, spinach, and mustard greens. If the body does not obtain enough dietary calcium, it will remove calcium from the bones, resulting in bones that become soft and weakened and that eventually develop osteoporosis. The importance of meeting the daily RDA for calcium is vital to both women and men. Although not as

Table 72.1 Recommended Dietary Allowances for Calcium

Age/Condition	U.S. RDA (mg)
0–6 months	200
7–12 months	260
1–3 years	700
4–8 years	1000
9–18 years	1300
19–50 years	1000
51–70 years	1000 (men) 1200 (women)
71+	1200
Pregnant and lactating women (14–18 years)	1300
Pregnant and lactating women (19–50 years)	1000

prevalent, men may develop bone conditions such as osteoporosis, and adequate calcium intake should be added to their list of preventive healthcare interventions.

The normal serum calcium range varies widely and is dependent on gender, age, and season. A normal reference range may be considered 8.5 to 10.5 mg/dL. Serum calcium concentrations that exceed 11.5 mg/dL result in symptoms of hypercalcemia, which causes a decrease in sodium permeability across cell membranes. This is a dangerous state because nerve conduction depends on the proper influx of sodium into cells. When calcium levels in the bloodstream are below 8.0 mg/dL, a state of hypocalcemia develops and the cell membranes become hyperexcitable. If this situation becomes severe, convulsions or muscle spasms may result.

PharmFACT

In the United States, 2 million osteoporotic fractures occur each year. It is estimated that almost 10 million individuals have osteoporosis. (Bethel, 2017).

Regulation of Calcium Balance

72.2 Calcium balance is regulated by parathyroid hormone, calcitonin, and vitamin D.

Calcium balance is controlled by parathyroid hormone, calcitonin, and vitamin D. Acting together, these three substances regulate the rate of absorption of calcium from the small intestine, the excretion of calcium from the kidney, and the movement of calcium into and out of bone. Calcium balance is illustrated in Figure 72.1.

Parathyroid hormone: Parathyroid hormone (PTH) is secreted from the parathyroid gland, as illustrated in Figure 72.1. The parathyroid glands contain calcium receptors that are able to sense very small changes in serum calcium concentration. When the serum levels of ionized calcium decrease, the parathyroid glands secrete PTH. PTH directly increases calcium reabsorption in the renal tubule and releases calcium from bone (resorption). PTH indirectly increases serum calcium by promoting the formation of activated vitamin D, which then increases calcium absorption from the GI tract. The overall effect of these physiologic changes is to rapidly (within minutes) increase serum calcium, returning it to normal levels.

The parathyroid glands are regulated by a typical negative feedback loop. An increase in the ionized serum calcium is recognized by calcium receptors in the parathyroid gland, which suppress PTH secretion. A second piece of the negative feedback loop is that activated vitamin D also shuts down PTH secretion. Without PTH present, the absorption of calcium from the GI tract is diminished, the reabsorption in the kidney tubule decreases, and calcium remains deposited in bone.

The exchange of calcium between the serum and bones is influenced by PTH and calcitonin. PTH stimulates bone cells called osteoclasts. These cells accelerate the process of **bone resorption**, or demineralization, which breaks down bone into its mineral components. Once bone is broken down (resorbed), calcium becomes available to be transported and used elsewhere in the body. The opposite of this process is **bone deposition**, or bone building, which is accomplished by cells called osteoblasts. This process, which removes calcium from the blood to be placed in bone, is stimulated by the hormone calcitonin. It is important to note that maintaining normal serum calcium levels takes precedence over the calcium requirements of the bone. If serum calcium levels are low, bone resorption will occur even if it compromises the structural integrity of the bone matrix.

Calcitonin: When serum calcium levels become elevated, the hormone **calcitonin** is released by the thyroid gland. Calcitonin acts in opposition to PTH and vitamin D to decrease the plasma levels of calcium by inhibiting the resorption of calcium from bone and increasing the excretion of calcium by the kidney, thus decreasing the concentration of serum calcium. It is important to note that calcitonin does not affect the rates of calcium absorption from the small intestine. Calcitonin is available as a medication for the treatment of osteoporosis.

Vitamin D: Vitamin D and calcium metabolism are intimately related: Absorption of calcium is increased in the presence of vitamin D, and absorption is inhibited by vitamin D deficiency. Thus, calcium disorders are often associated with vitamin D disorders.

Vitamin D is unique among vitamins because it is the only vitamin that the body is able to synthesize from precursor molecules. Several steps, however, are required

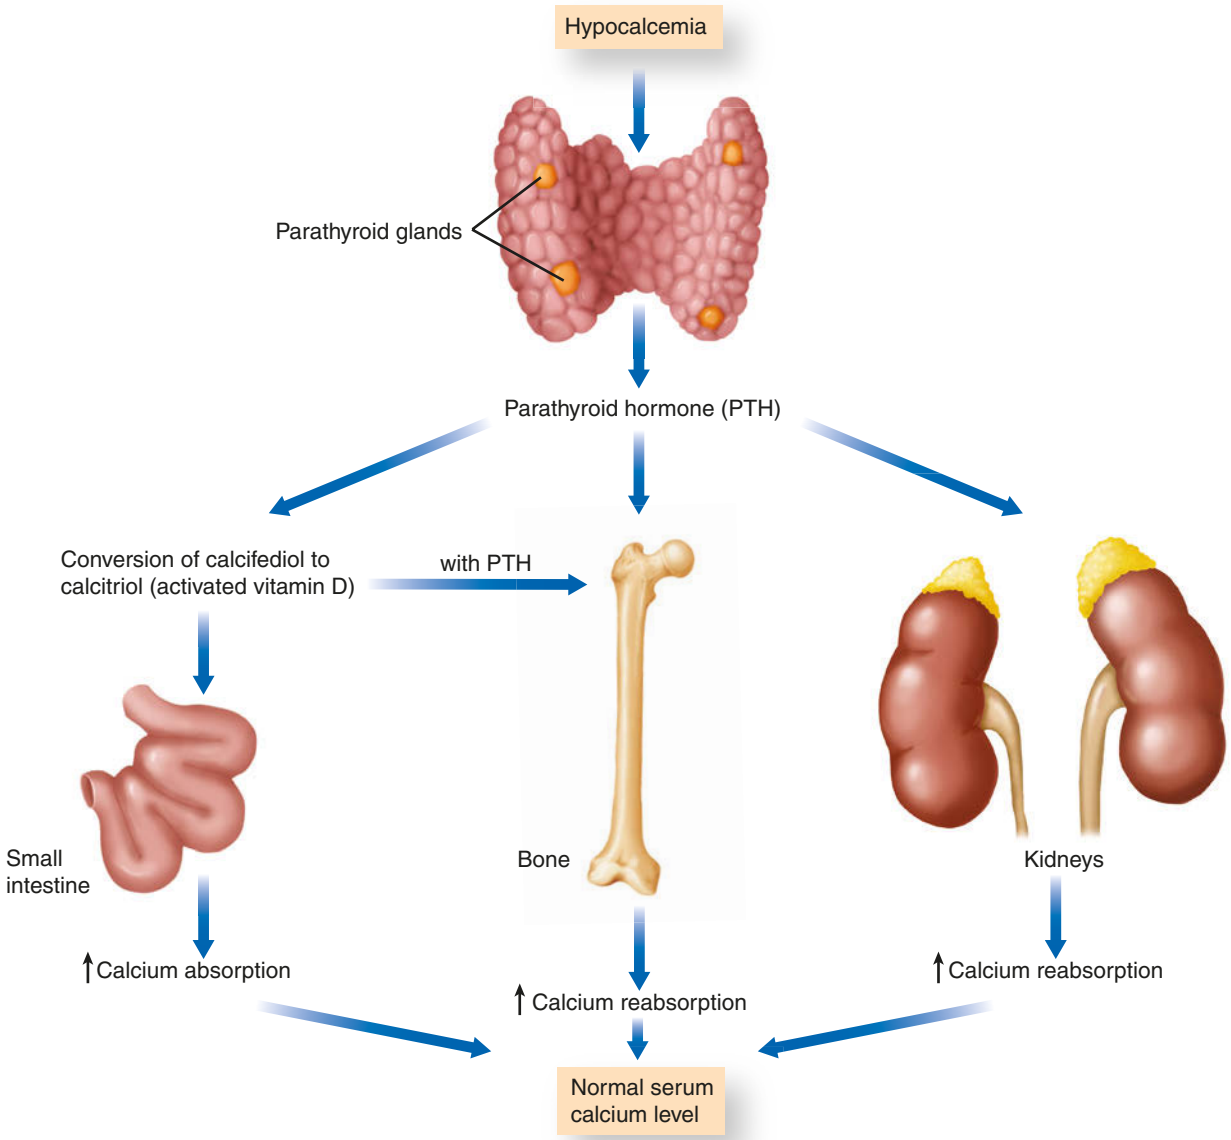

Figure 72.1 Calcium balance.

before vitamin D can act on target tissues, as illustrated in Figure 72.2. In the skin, **cholecalciferol**, the inactive form of vitamin D, is synthesized from cholesterol. Exposure of the skin to sunlight or ultraviolet light increases the level of cholecalciferol in the blood. Cholecalciferol can also be obtained from dietary products such as milk or other foods fortified with vitamin D.

Following its absorption from dietary sources or formation in the skin, cholecalciferol is converted to an intermediate vitamin form called calcifediol. Kidney enzymes metabolize calcifediol to **calcitriol**, the active form of vitamin D. PTH stimulates the formation of calcitriol at the level of the kidneys. Patients with extensive kidney disease are unable to adequately synthesize calcitriol and thus frequently experience calcium and vitamin D abnormalities. The primary function of calcitriol is to increase calcium absorption from the GI tract. Dietary calcium is absorbed more efficiently in the presence of active vitamin D and PTH, resulting in higher serum levels of calcium, which is then transported to bone, muscle, and other tissues.

CONNECTION Checkpoint 72.1

Inhibition of calcium transport into cells can have important physiologic effects. From what you learned in Chapter 30, what are the primary indications for pharmacotherapy with calcium channel blockers? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

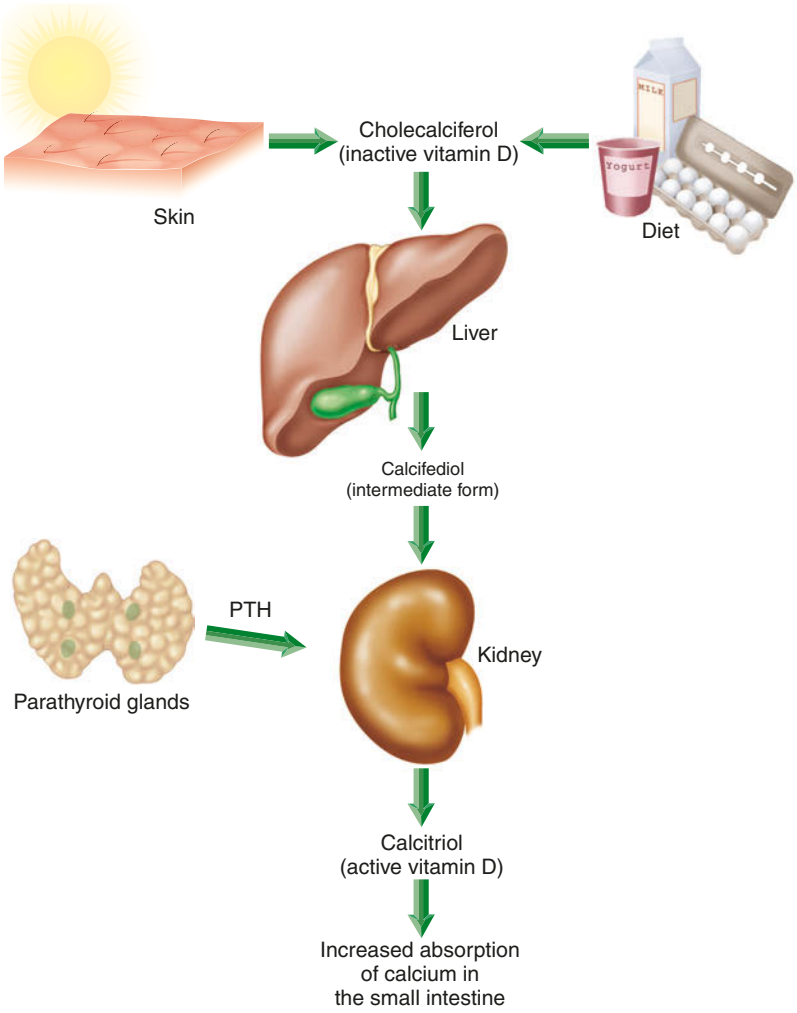

Figure 72.2 Pathway for vitamin D activation.

Pharmacotherapy of Calcium Imbalances

72.3 Hypocalcemia and hypercalcemia are treated with nutritional adjustments or with pharmacotherapy.

Calcium imbalances occur frequently. When minor, dietary means may be used to correct the imbalance; however, serious imbalances require pharmacotherapy.

Treatment of Hypocalcemia

Hypocalcemia is not a disease but is a sign of underlying pathology; thus, diagnosis of the cause of hypocalcemia is essential. Many factors can cause hypocalcemia. Lack of sufficient dietary calcium or vitamin D intake is a common cause and one that can be easily reversed by nutritional adjustments. If hypocalcemia occurs despite normal dietary intake, GI causes must be examined, such as excessive vomiting or the presence of malabsorption disorders. Damage to renal tubular cells may cause excessive loss of calcium in the urine. Most patients with chronic kidney disease (CKD) will require calcium and vitamin D therapy to prevent hypocalcemia.

Another etiology for hypocalcemia is hypoparathyroidism leading to decreased secretion of PTH, as occurs when the thyroid and parathyroid glands are diseased or surgically removed. A rare cause of hypocalcemia is pseudohypoparathyroidism, which is an uncommon group of genetic disorders where the target organs for PTH (bone and kidneys) become resistant to the hormone. Recombinant PTH (Natpara) is available as an adjunct to calcium and vitamin D therapy in controlling hypoglycemia in patients with hypoparathyroidism.

Drug therapy is occasionally a cause of hypocalcemia. Blood transfusions and certain anticonvulsants such as phenytoin and phenobarbital can lower serum calcium levels. In addition, overtreatment with drugs that are used to lower serum calcium can result in overshooting normal levels. Some of these include furosemide, phosphate therapy, or bisphosphonates. Of special concern is long-term therapy with corticosteroids, which is a very common cause of hypocalcemia and osteoporosis. To help prevent corticosteroid-induced osteoporosis, patients should receive daily supplements of calcium and vitamin D.

Hypocalcemia is frequently asymptomatic. Signs and symptoms of hypocalcemia are those of nerve and muscle excitability. The symptoms include confusion, paresthesias around the mouth and in the digits, carpopedal spasms, and hyperreflexia. Muscle twitching, tremors, or cramping may be evident. Two clinical signs are Chvostek's sign and Trousseau's sign. Chvostek's sign is elicited by tapping on the facial nerve just below the temple. A positive sign is a twitch of the nose or lip. Trousseau's sign is the contraction of the hand and fingers when the arterial blood flow in the arm is occluded for 5 minutes.

Intestinal cramping and hyperactive bowel sounds may be present because the low calcium levels affect the smooth muscle of the GI tract. Severe symptoms include convulsions, laryngeal spasms, and tetany. Tetany is a continuous muscle spasm that can interfere with breathing and even cause death. The characteristic electrocardiogram (ECG) change is a prolonged QT interval, indicating prolonged ventricular depolarization with characteristically weak cardiac muscle contractions.

Unless the hypocalcemia is especially severe or life threatening, adjustments in diet may be attempted prior to initiating therapy with calcium supplements. Increasing the consumption of calcium-rich foods, especially dairy

products, fortified orange juice, cereals, and green leafy vegetables, is often sufficient to restore calcium balance.

PROTOTYPE DRUG Calcium Salts

Classification **Therapeutic:** Calcium supplement
Pharmacologic: Drugs for hypocalcemia

Therapeutic Effects and Uses: Calcium salts are available in a wide variety of products and formulations. Calcium has two major forms: complexed and elemental. Most calcium supplements are in the form of complexed calcium. These products are often compared on the basis of their ability to release elemental calcium into the bloodstream. The greater the ability of complexed calcium to release elemental calcium, the more potent the supplement. Table 72.2 lists the doses for selected calcium supplements.

For mild, chronic hypocalcemia, effective and inexpensive calcium supplements are readily available over the counter (OTC) in a variety of formulations. Calcium carbonate and calcium citrate are two common salts for routine supplementation. Many calcium supplements also contain vitamin D.

The administration of intravenous (IV) calcium salts may be necessary for severe cases of hypocalcemia or if the patient is in tetany. Repeated infusions are sometimes required to return the serum calcium level to normal. Constant monitoring of serum calcium is required during IV administration to prevent hypercalcemia.

In addition to preventing or treating hypocalcemia, calcium salts are administered for many other conditions, including osteoporosis, Paget's disease, osteomalacia, chronic hypoparathyroidism, rickets, pregnancy, lactation, and rapid childhood growth. Calcium carbonate is a common antacid used to treat heartburn. It may also be used to bind excessive dietary phosphate in patients with hyperphosphatemia caused by end-stage renal failure.

IV calcium gluconate can protect the heart against the hyperexcitability of excessive potassium (hyperkalemia) and help to maintain cardiorespiratory function during magnesium sulfate toxicity (hypermagnesemia) situations. IV calcium salts have been administered during cardiac arrest due to their ability to increase cardiac muscle tone and the force of systolic contraction (positive inotropic effect). However, the use of calcium salts in cardiac resuscitation has declined and is limited to patients with cardiac disease who have hypocalcemia because calcium salts may cause dysrhythmias at high doses.

Mechanism of Action: Calcium salts restore the normal serum levels of calcium, which promotes deposition of the mineral in bone. This helps to restore bone strength and prevent fractures. Calcium also restores normal neuromuscular function and muscular contraction.

Pharmacokinetics: The pharmacokinetics of calcium salts varies by the route of administration and the specific formulation. They are widely distributed and excreted primarily in the feces, with about 20% in the urine. The duration of action of calcium salts is generally only a few hours.

Adverse Effects: Oral (PO) calcium products are safe and produce few adverse effects when used as directed. The most common adverse effect of calcium supplements is hypercalcemia, which is caused by taking too much of this supplement. This can be especially serious in the IV formulations. Symptoms of hypercalcemia include drowsiness, lethargy, weakness, headache, anorexia, constipation, increased gastric acid secretion, nausea, vomiting, a tingling sensation, increased urination, and thirst. IV administration of calcium may cause pain and burning at the IV site, severe venous thrombosis, necrosis, sloughing of the skin (with extravasation), hypotension, sensations of heat waves (peripheral vasodilation), fainting, bradycardia, cardiac dysrhythmias, and cardiac arrest. Large doses of

Table 72.2 Selected Calcium Salts

Drug	Calcium Content	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Calcium Supplements (All doses are in terms of elemental calcium.)			*Constipation, nausea, vomiting, metallic taste* Hypercalcemia (drowsiness, lethargy, headache, anorexia, nausea, vomiting, increased urination, and thirst), dysrhythmias, cardiac arrest, confusion, delirium, stupor, coma
calcium acetate (PhosLo)	25%	PO: 2–4 tablets with each meal (each tablet contains 169 mg elemental calcium)	
calcium carbonate (Rolaids, Os-Cal, Tums, others)	40%	PO: 1–2 g bid–tid	
calcium chloride	27 mg Ca/mL	IV: 0.5–4 g by slow infusion (1 mL/min)	
calcium citrate (Citracal)	21%	PO: 1–2 g bid–tid	
calcium gluconate (Kalcinate)	9% (PO); 9 mg Ca/mL (IV)	PO: 0.5–2 g bid–tid IV: 0.5–4 g by slow infusion (1 g/h)	
calcium lactate (Cal-Lac)	13%	PO: 325–650 mg bid–tid before meals	
calcium phosphate tribasic (Posture)	39%	PO: 1–2 g bid–tid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

supplemental calcium may lead to the formation of symptomatic kidney stones.

Contraindications/Precautions: Calcium salts are contraindicated in patients with ventricular fibrillation, metastatic bone disease, renal calculi, hypercalcemia, predisposition to hypercalcemia, hyperparathyroidism, certain malignancies, and digoxin toxicity. Calcium salts should not be injected into the myocardium or administered by the subcutaneous or intramuscular (IM) route. Caution must be used with patients who have renal or cardiac insufficiency, dysrhythmias, dehydration, diarrhea, hyperphosphatemia, sarcoidosis, or history of kidney stones. Immobilized patients are at high risk for the development of hypercalcemia.

Drug Interactions: Concurrent use with digoxin increases the risk of dysrhythmias and enhances the inotropic effects of digoxin. Magnesium may compete for GI absorption. Calcium decreases the absorption of tetracyclines and fluoroquinolones, such as ciprofloxacin. Their use may antagonize the effects of verapamil and possibly other calcium channel blockers. **Herbal/Food:** Zinc-rich foods such as shellfish, dried beans, sesame seeds, pumpkin seeds, and many meats may decrease the absorption of calcium. Alcohol, caffeine, and carbonated beverages affect the absorption of calcium. Oxalic acid in spinach, rhubarb, Swiss chard, and beets can suppress calcium absorption. Phytic acid, which is present in bran and whole-grain cereals, depresses calcium absorption.

Pregnancy: Category B or C.

Treatment of Overdose: Measures may be taken to treat cardiac abnormalities caused by the hypercalcemia that results from overdose.

Nursing Responsibilities: Key nursing implications for patients receiving calcium supplementation are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Osteoporosis.

Drugs Similar to Calcium Salts

A large number of calcium salts are available. A summary of their indications is shown in Table 72.3.

Treatment of Hypercalcemia

In patients with CKD, the kidneys are unable to control mineral metabolism. As a consequence, the parathyroid glands secrete large amounts of parathyroid hormone, which can cause serious hypercalcemia. This disorder is called secondary hyperparathyroidism (secondary HPT) because the condition is not a disease of the parathyroid gland itself but is a consequence of CKD.

The two drugs for treating secondary HPT, cinacalcet (Sensipar) and etelcalcetide (Parsabiv), are called calcimimetics because they mimic the effects of calcium in tissues. The drugs act on the calcium sensors in the parathyroid, in effect tricking the gland into thinking the body has plenty of calcium. The gland thus reduces its secretion of parathyroid hormone.

Cinacalcet was approved by the U.S. Food and Drug Administration (FDA) in 2004. Given PO, the dose is slowly

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Osteoporosis

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including musculoskeletal, GI, cardiovascular, neurologic, endocrine, hepatic, or kidney disease. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations, alcohol use, or smoking. Be alert to possible drug interactions.
- Obtain a history of any current symptoms and their effect on ADLs. Assess muscle strength and gait and note any pain or discomfort on movement or at rest. Obtain bone density studies if ordered.
- Obtain a dietary history, noting adequacy of essential vitamins, minerals, and nutrients obtained through food sources, particularly calcium, vitamin D, and magnesium. Note amount of soda or other nondairy fluid intake daily.
- Note sunscreen use and amount of sun exposure.
- Obtain baseline height, weight, and vital signs.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, calcium, phosphorus, and magnesium levels, hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., calcium, phosphate, and magnesium levels are within normal limits, bone density studies show improvement).
- Continue monitoring laboratory values as appropriate, especially calcium, phosphorus, and magnesium.
- Assess for and promptly report adverse effects: nausea, vomiting, abdominal pain, esophageal irritation, constipation, diarrhea, or symptoms of electrolyte imbalances. Severe GI irritation or pain should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Review the dietary history with the patient and discuss food source options for correcting any deficiencies, particularly calcium and vitamin D. Encourage the patient to adopt a healthy lifestyle of increased activity or exercise, adequate sun exposure, limited or eliminated caffeine, soda, and alcohol consumption. (Adequate amounts of calcium, vitamin D, and magnesium are needed for bone health. Any deficiencies should be corrected before bisphosphonates are started. Adequate sun exposure, approximately 15–20 min/day without sunscreen, may assist in vitamin D formation. Excessive soda, caffeine, or other nondairy intake may increase the risk of osteoporosis due to lessened calcium consumption and decreased calcium absorption from caffeine effects.)	• Encourage adequate amounts of calcium, vitamin D, and magnesium from food sources. Provide educational pamphlets or web-based references to reputable sources as needed (e.g., NIH Office of Dietary Supplements). Provide dietitian referral as needed. • Encourage limited amounts of sun exposure daily without sunscreen, approximately 15–20 min. Discourage prolonged sun exposure beyond that time. • Teach the patient that excessive soda, caffeine, and other nondairy consumption may diminish absorption of dietary calcium. • Encourage adequate activity and exercise, especially weight-bearing exercise, 3–5 times per week.
• Follow administration guidelines for optimal results. (Calcium supplements and vitamin D should be taken with meals or within 1 h after meals for best absorption. Bisphosphonates should be taken on an empty stomach with a full glass of water and the patient should remain upright for 30 min to 1 h. Bisphosphonates and calcium preparations should be taken 2 h apart.)	• Teach the patient the appropriate administration guidelines for best results. Ensure that the patient is able to remain upright if bisphosphonates are used.
Minimizing adverse effects: • Monitor for GI irritation or abdominal pain. (Bisphosphonates may cause esophageal irritation and erosion. Increasing nausea, gastric, or abdominal pain should be reported immediately.)	• Instruct the patient to immediately report any new onset of nausea or any increasing or severe chest or abdominal discomfort or pain.
• Continue to monitor periodic laboratory work, especially calcium, magnesium, phosphorus, vitamin D, and creatinine as needed. Assess for signs or symptoms of hypo- or hypercalcemia. (Calcium, magnesium, phosphorus, and vitamin D levels should return to, and remain within, normal limits. Increased creatinine levels may indicate renal effects and may require discontinuation of medications.)	• Instruct the patient on the need to return periodically for laboratory work. • Instruct the patient to immediately report symptoms of hypocalcemia (muscle spasms, facial grimacing, irritability, hyperreflexes) or hypercalcemia (increased bone pain, anorexia, nausea, vomiting, constipation, thirst, lethargy, or fatigue).
• Monitor the use of vitamin D. Excessive intake may lead to toxic effects. (Fat-soluble vitamins are stored in the body and may accumulate and result in toxic levels. Monitor liver function studies and for symptoms such as nausea, vomiting, headache, fatigue, dry and itchy skin, blurred vision, or palpitations. Report any symptoms immediately.)	• Instruct the patient not to take additional or large amounts of vitamin D unless instructed by the provider. • Encourage the patient to obtain fat-soluble vitamins from natural sources through a balanced diet whenever possible.
• Increase fluid intake, avoiding caffeine or soda. (Increased fluid intake decreases the risk of renal calculi formation.)	• Encourage the patient to increase fluid intake to 2 L/day, divided throughout the day, but avoid highly caffeinated beverages and excessive soda intake.
• Monitor adherence to the recommended regimen. (Bone remodeling occurs over several months and effects may not be noted immediately. The patient may discontinue drug therapy because of a perceived lack of response.)	• Teach the patient to continue taking the drug therapy regularly to ensure full effects. Therapeutic response may take 1–3 months and effects continue after the drug has been discontinued.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Note and promptly report any new-onset thigh or groin pain, unilaterally or bilaterally. (An increased incidence of atypical fractures has been noted in some patients taking bisphosphonates, particularly with long-term use or with concurrent corticosteroid use. Thigh or groin pain has been noted to occur prior to fracture and should be reported to the provider for assessment.)	• Teach the patient to promptly report any new onset of groin or thigh pain, either unilaterally or bilaterally. • Advise the patient to review the need for continued bisphosphonate use with the healthcare provider based on bone density studies on a regular basis.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of the medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken with additional fluids, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs including:
	  • *Calcium supplements:* Take with meals or immediately after meals.
	  • *Bisphosphonates:* Take with a full glass of plain water and remain in an upright position for 30 min to 1 h after taking.

escalated until serum PTH and calcium levels return to normal values. Overtreatment may cause hypocalcemia. Nausea, vomiting, and diarrhea are common during therapy. This drug is a strong inhibitor of CYP450 enzymes and should be used with caution in patients who are receiving other drugs that are CYP450 substrates or inhibitors. Etelcalcetide, approved in 2017, is administered by the IV route, usually at the end of a hemodialysis session. The most common adverse effects are hypocalcemia, muscle spasms, diarrhea, nausea, vomiting, headache, and paresthesia.

Pathophysiology of Metabolic Bone Disease

72.4 Metabolic bone disease is characterized by abnormal bone structure.

Metabolic bone disease (MBD) is a general term that refers to a cluster of disorders that have in common defects in the structure of bone. MBDs are caused by abnormal amounts of the minerals or hormones responsible for bone homeostasis, such as calcium, phosphate, vitamin D, or PTH. Some MBDs have a genetic etiology, whereas others are iatrogenic and caused by certain drugs and therapies.

Osteoporosis: **Osteoporosis** is an MBD characterized by bone demineralization, decreased bone density, and subsequent fractures. Osteoporosis is the most prevalent MBD in the United States. This disorder is usually asymptomatic until the bones become brittle enough to fracture or for vertebrae to collapse.

Normal bone remodeling requires a balance between bone deposition (gain) and bone resorption (loss). The exact pathophysiology of osteoporosis is unknown, but there are two major theories. In the first, osteoporosis may be caused by defective osteoblasts that have an abnormally short lifespan or work less efficiently, resulting in slow bone deposition. The second and more popular theory suggests that the osteoclasts have increased activity, resorbing bone at an increased rate. The common factor between the two theories is that normal bone turnover is altered, with the rate of resorption greater than bone formation, resulting in a decrease in total bone density and an altered bone structure.

Numerous risk factors have been identified for osteoporosis. Women are 4 times more likely than men to develop this condition, and the most common risk factor associated with the development of osteoporosis is the onset of menopause. When women reach menopause, estrogen secretion declines, and bones become weak and fragile. In women with osteoporosis, fractures often occur in the hips, wrists, forearms, or spine. In some cases, a lack of dietary calcium and vitamin D contributes to bone deterioration. The metabolism of calcium in osteoporosis is illustrated in Figure 72.3.

Major risk factors for osteoporosis include the following:

- Excessive alcohol intake (more than 4 drinks per day for men or 2 for women)
- Gonadal hormone deficiency (estrogen or androgen)
- Increasing age
- Low body weight (less than 58 kg or 128 lb)
- Low calcium or vitamin D intake
- Low level of physical activity or immobilization
- Menopause
- Personal history of fracture or family history of osteoporotic fracture
- Tobacco use
- Caucasian or Asian.

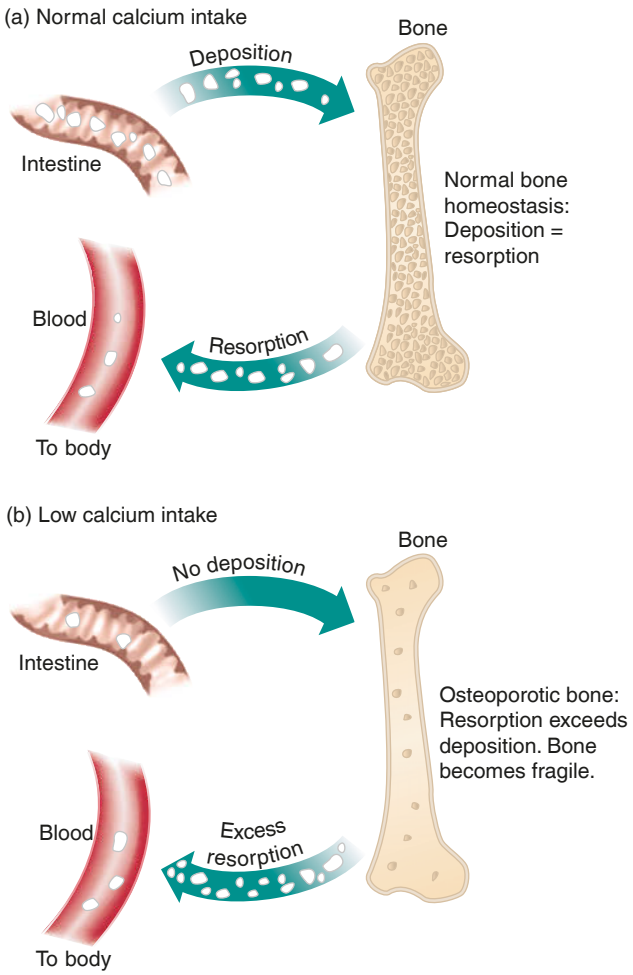

Figure 72.3 Calcium metabolism in osteoporosis.

Several methods are available for measuring bone mineral density (BMD) but the "gold standard" for the diagnosis of osteoporosis is dual-energy x-ray absorptiometry (DEXA). BMD at the spine and hip is measured and data are reported as T-scores. Positive T-scores represent the BMD values of a young adult between the ages of 30 and 35, which is the period of peak bone strength. Negative T-scores indicate some loss in BMD. Osteopenia, or a low bone mass, is present when the T-score is between –1 and –2.5. Osteoporosis is defined as a T-score of –2.5 or less. Nutritional adjustments and drug therapy are initiated when T-scores fall into the osteopenic or osteoporosis ranges.

Drug therapies for osteoporosis include calcium and vitamin D therapy, bisphosphonates, estrogen receptor modulators, parathyroid hormone analogs (abaloparatide [Tymlos] and teriparatide [Forteo]), denosumab, and calcitonin.

Osteomalacia: **Osteomalacia**, referred to as rickets in children, is a disorder characterized by softening of bones without alteration of basic bone structure. Weight-bearing stress on the softened bones causes skeletal deformities. Many factors contribute to the development of osteomalacia and rickets, but the most important is a deficiency of vitamin D and calcium. This risk factor for the disease is extremely rare in the United States, being most prevalent in older adults, premature infants, and individuals on strict vegetarian diets. Other factors that may result in the development of osteomalacia include malabsorption disorders of the small bowel, damage to the renal tubules, adverse effects of anticonvulsant therapy, hepatic impairment, or a limited exposure to sunlight.

The promotion of breastfeeding over vitamin D–fortified formulas is thought to be responsible for some cases of osteomalacia, particularly in mothers who are vitamin D deficient. In addition, the increased use of sunscreens to prevent skin cancer inhibits the formation of adequate vitamin D by sunlight. The replacement of vitamin D–fortified milk with carbonated beverages by children and teens also contributes to the possibility of rickets. Nurses need to emphasize the importance of getting enough extra dietary vitamin D to children and pregnant women. Drug therapy for children and adults consists of calcium salts and vitamin D.

Symptoms of osteomalacia include hypocalcemia, muscle weakness, muscle spasms, and diffuse bone pain, especially in the hip area. Patients may also experience pain in the arms, legs, and spine. Classic signs of rickets in children include bowlegs and a pigeon breast. Children may also develop a slight fever and become restless at night.

The standard test for diagnosing osteomalacia is to determine vitamin D status by measuring the serum levels of 25-hydroxyvitamin D. Additional tests may include bone radiographs and computed tomography (CT) scans of the vertebral column.

Paget's disease: **Paget's disease**, or osteitis deformans, is a chronic, progressive condition characterized by accelerated remodeling of the bone, producing enlarged and softened bones. With this disorder, the processes of bone resorption and bone formation occur simultaneously but at a very high rate. The rapid turnover causes new bone to be weak and brittle, resulting in deformities and fractures. Paget's disease can occur in any bone, but it most often affects the vertebrae, skull, sternum, pelvis, femur, and tibia. Paget's disease occurs with equal frequency in men and women over 40 years of age. The cause of Paget's disease is unknown.

Although many patients with Paget's disease are asymptomatic, approximately 10% experience vague, nonspecific complaints for many years. Symptoms include pain of the hips and femurs, joint inflammation, headaches, facial pain, and hearing loss if bones around the ear are affected. Nerves along the spinal column may be pinched because of the abnormal vertebral bone growth.

The evaluation of Paget's disease is based on radiographic and laboratory findings. The enzyme alkaline phosphatase (ALP) is elevated in the blood because of the extensive bone turnover. The disease is usually confirmed by early detection of this enzyme in the blood. Calcium is also liberated because of its close association with phosphate. If diagnosed early enough, symptoms can be treated successfully. If the diagnosis is made late in the progression of the disease, permanent skeletal abnormalities develop and other disorders may appear, including arthritis, kidney stones, and heart disease.

Bisphosphonates are the primary pharmacotherapy for Paget's disease. Calcitonin may be used as a second-line drug. Patients with Paget's disease should consume adequate amounts of calcium and vitamin D on a daily basis.

Pharmacotherapy of Metabolic Bone Disease

72.5 Vitamin D therapy is indicated for treating osteomalacia, hypoparathyroidism, and osteoporosis.

Inactive, intermediate, and active forms of vitamin D are available as medications. Patients' vitamin D needs vary depending on how much sunlight they receive. After age 70, the RDA of vitamin D increases from 400 units/day to 600 units/day. In severe cases of malabsorption disorders, patients may receive 50,000 to 100,000 units/day. Because vitamin D is needed to absorb calcium from the GI tract, many supplements combine vitamin D and calcium into a single tablet.

Several forms of vitamin D are available for therapy. Three of those products—ergocalciferol, cholecalciferol, and calcitriol—are identical to the forms of vitamin D that occur in nature. Each vitamin D product has a slightly different potency and pharmacokinetics. Indications for vitamin D products include the following:

- Hypocalcemia
- Hypophosphatemia
- Osteomalacia (rickets)
- Osteoporosis prophylaxis
- Parathyroid dysfunction
- Vitamin D deficiency.

Vitamin D is a fat-soluble vitamin that is stored by the body. It is possible to consume too much of this vitamin or to show signs of overdose from prescription medications. Excess vitamin D will cause calcium to leave bones and enter the blood. The signs and symptoms of hypercalcemia, such as anorexia, vomiting, excessive thirst, fatigue, and confusion, may become evident. Kidney stones may occur, and bones may fracture easily.

PROTOTYPE DRUG **Calcitriol (Calcijex, Rocaltrol)**

Classification **Therapeutic:** Vitamin D
Pharmacologic: Bone resorption inhibitor

Therapeutic Effects and Uses: Calcitriol is the active form of vitamin D. This medication is used in cases of hypocalcemia and for patients who have hypoparathyroidism. Calcitriol reduces bone resorption and is useful in treating rickets. Patients with CKD are unable to synthesize sufficient calcitriol and thus will receive this drug as replacement therapy.

The effectiveness of calcitriol depends on having an adequate amount of calcium; therefore, it is usually prescribed in combination with calcium supplements. It is available for administration via the oral (PO) route in the form of tablets and solutions. An IV solution for injection is available to treat dialysis-associated hypocalcemia.

Mechanism of Action: Calcitriol elevates serum calcium levels, decreases elevated blood levels of phosphate, and decreases bone resorption and demineralization by promoting the intestinal absorption and renal reabsorption of calcium. The rising calcium levels provide negative feedback to the parathyroid glands, reducing the secretion of PTH. Calcitriol itself also provides negative feedback to the parathyroid glands.

Pharmacokinetics:

Route(s)	PO (tablets, capsules, or solution), IV
Absorption	Readily absorbed from the GI tract
Distribution	Widely distributed; crosses the placenta; small amounts are secreted in breast milk; 99% bound to vitamin D–binding protein
Primary metabolism	Hepatic
Primary excretion	Mostly feces with small amounts in urine
Onset of action	2–6 h
Duration of action	3–5 days

Adverse Effects: The adverse effects of vitamin D therapy include symptoms of hypercalcemia, such as palpitations, anorexia, nausea, vomiting, blurred vision, photophobia, constipation, abdominal cramps, metallic taste, headache, weakness, dry mouth, thirst, increased urination, and muscle or bone pain.

Contraindications/Precautions: This drug should not be given to patients with hypercalcemia or those who have evidence of vitamin D toxicity. Caution must be used in patients with CKD who are at increased risk for vitamin D–induced hypercalcemia.

Drug Interactions: Thiazide diuretics may enhance the effects of vitamin D, causing hypercalcemia. Too much vitamin D may cause dysrhythmias in patients who are receiving digoxin. Magnesium antacids or supplements should not be given concurrently owing to an increased risk of hypermagnesemia. Orlistat (Xenical) may prevent the absorption of fat-soluble nutrients such as vitamin D. Corticosteroids inhibit the absorption of calcium, which is a major effect of vitamin D. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Vitamin D overdose results in hypercalcemia, hypercalciuria, and hyperphosphatemia. If the overdosage was recent, emesis should be induced to remove any remaining drug from the stomach. All vitamin D and calcium supplements are discontinued and the patient is placed on a low-calcium diet until the hypercalcemia resolves.

Nursing Responsibilities: Key nursing implications for patients receiving calcitriol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Osteoporosis.

Drugs Similar to Calcitriol (Calcijex, Rocaltrol)

Other forms of vitamin D for therapy include calcifediol, cholecalciferol, doxercalciferol, ergocalciferol, and paricalcitol. Doses for the vitamin D preparations are given in Table 72.4.

Calcifediol (Rayaldee): Calcifediol is an analog of vitamin D_3 that is converted to the active hormone, calcitriol, in the kidneys. Calcifediol was approved in 2016 for the treatment of secondary hyperparathyroidism in adult patients with CKD. It has the same adverse effects as calcitriol. Caution must be used to avoid overtreatment, because this may cause severe hypercalcemia. This drug is pregnancy category C.

Cholecalciferol (Delta-D): Cholecalciferol (vitamin D_3) is the form of vitamin D that is produced in the skin after exposure to ultraviolet (UV) light. It is activated by the liver and kidneys to form calcitriol. Once activated, cholecalciferol produces the same actions and adverse effects as calcitriol. It is an oral dietary supplement for the prophylaxis and treatment of vitamin D deficiency. Fosamax plus D is a combination drug containing alendronate and cholecalciferol.

Doxercalciferol (Hectorol): Doxercalciferol is an analog of vitamin D that is given by either the PO or IV route. This drug is activated by the liver alone: No kidney metabolism is necessary. Adverse effects are the same as those of calcitriol. However, caution must be taken to avoid the rapid development of hypercalcemia when this drug is administered by the IV route. Its only approved indication is for the treatment of secondary hyperparathyroidism and resultant bone disease.

Ergocalciferol (Calciferol, Drisdol): Ergocalciferol (vitamin D_2) is a natural vitamin D analog found in plants, fortified milk, eggs, and cereals. Once activated, ergocalciferol produces actions and adverse effects identical to those of calcitriol. Bile is required for its absorption, and the drug requires adequate kidney function to be metabolized to its active form. Indications for therapy with ergocalciferol are the same as those for calcitriol.

Paricalcitol (Zemplar): Paricalcitol is an analog of vitamin D that is given by either the PO or IV route. Adverse effects are the same as those of calcitriol; however, caution must be taken to avoid the rapid development of hypercalcemia when this drug is administered by the IV route. The only indication for paricalcitol is for the treatment of secondary hyperparathyroidism and resultant bone disease.

72.6 Bisphosphonates increase bone density and are used to treat osteoporosis and Paget's disease.

The most frequently prescribed drug class for osteoporosis is the **bisphosphonates**. These drugs are structural

Table 72.4 Vitamin D Preparations

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
calcifediol (Rayaldee)	PO: 30–60 mcg once daily	*Diarrhea, infection, hypertension, dizziness*
calcitriol (Calcijex, Rocaltrol)	PO: 0.25–0.50 mcg/day IV: Begin with 1–4 mcg 3 times/wk	Hypercalcemia, bone pain, lethargy, anorexia, nausea, vomiting, increased urination, hallucinations, dysrhythmias, anemia
cholecalciferol (Delta-D)	PO: 400–1000 international units/day	
doxercalciferol (Hectorol)	PO: 10 mcg, 3 times/wk IV: 4 mcg, 3 times/wk (max: 60 mcg/wk [PO]; 18 mcg/wk [IV])	
ergocalciferol (Calciferol, Drisdol)	PO: 15–25 mcg once daily IV: 4 mcg 3 times/wk	
paricalcitol (Zemplar)	IV: 0.04–0.1 mcg/kg, every other day (max: 24 mcg/kg) PO: 1–4 mcg every other day or 3 times/wk	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

analogs of pyrophosphate, which is a natural substance that inhibits bone resorption. Bisphosphonates bind to hydroxyapatite in bone and suppress osteoclast activity, thus increasing bone mass density and reducing the incidence of fractures by about 50%. Examples include etidronate (Didronel), alendronate (Fosamax), zoledronate (Reclast, Zometa), risedronate (Actonel, Atelvia), and pamidronate (Aredia), which is available as an injectable drug. Etidronate also inhibits bone demineralization that could lead to osteomalacia; the other bisphosphonates do not have this effect. In addition to treating postmenopausal osteoporosis, some of the bisphosphonates are approved to treat corticosteroid-induced osteoporosis. A summary of the indications for bisphosphonates is given in Table 72.5 and their doses are listed in Table 72.6.

The beneficial effects of bisphosphonates on bone mass density increase rapidly during the first year of therapy and plateau after 2 to 3 years. Even after discontinuation of therapy, bone density will remain increased for up to 1 year. For optimal effects, the patient must have adequate dietary consumption of calcium and vitamin D; any deficiencies should be corrected prior to initiating bisphosphonate therapy. Studies suggest that once-weekly dosing with bisphosphonates may give the same bone density benefits as daily dosing because of their extended duration of drug action.

Bisphosphonates are also preferred drugs for the pharmacotherapy of Paget's disease. For this disorder, therapy is usually cyclic, with bisphosphonates administered until serum ALP levels return to normal followed by several months without drugs. When the serum ALP level becomes elevated, therapy is begun again. The pharmacologic goals are to slow the rate of bone reabsorption and encourage the deposition of strong bone.

Several bisphosphonates are used to treat bone metastases and malignant hypercalcemia. Bone metastases are characterized by osteoclast hyperactivity, which creates "punched-out," osteolytic lesions that release large amounts of calcium into the blood. Bisphosphonates suppress osteoclast activity, thus slowing the rate of bone resorption and the rate of calcium release. Thus some of these drugs are approved for treating hypercalcemia due to malignancy. It is important to note that bisphosphonates are not antineoplastics; they have no effect on tumor cells and are given only as a palliative measure.

The most frequent adverse effects of bisphosphonates include GI symptoms such as nausea, vomiting, abdominal pain, dyspepsia, and esophageal irritation. Because these drugs are poorly absorbed from the intestinal tract, they must be taken on an empty stomach with plain water, at least 30 minutes before any other fluid, food, or medications. To avoid esophageal irritation, the patient should stay in an upright position for at least 30 minutes following the dose. Bisphosphonates are not metabolized and are excreted in the urine.

Patients taking the bisphosphonates are evaluated on a regular basis to determine if the drug is still necessary. To avoid the possibility of long-term adverse effects, these drugs are usually discontinued after several years of therapy in patients who have a low risk for fracture.

One unusual adverse effect that may occur during bisphosphonate therapy is osteonecrosis of the jaw. Symptoms include local pain and swelling, loosening of teeth, and infection at the site of the lesion. It is not clear what causes the necrosis. Discontinuing the bisphosphonate does not resolve the lesion because the drugs are incorporated in bone for many months and perhaps years.

PROTOTYPE DRUG **Alendronate (Fosamax)**

Classification
Therapeutic: Drug for osteoporosis and Paget's disease
Pharmacologic: Bisphosphonate, bone resorption inhibitor

Table 72.5 Indications for Bisphosphonates

Drug	Osteoporosis in Postmenopausal Women	Osteoporosis in Men	Glucocorticoid-Induced Osteoporosis	Paget's Disease	Hypercalcemia of Malignancy	Breast Cancer Metastases	Multiple Myeloma/Bone Metastases
alendronate (Fosamax)	X	X	X	X

ibandronate (Boniva)	X						
pamidronate (Aredia)				X	X	X	
risedronate (Actonel, Atelvia)	X	X	X	X			
zoledronate (Reclast, Zometa)	X	X		X	X		X

Table 72.6 Selected Drugs for Osteoporosis and Other Bone Disorders

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Bisphosphonates		
alendronate (Fosamax)	Osteoporosis: PO: 10 mg/day or 70 mg once weekly Paget's disease: PO: 40 mg/day for 6 months	*Nausea, dyspepsia, diarrhea, bone pain, back pain* Bone fractures, nephrotoxicity, hypocalcemia, hypophosphatemia, gastric ulcer, esophageal perforation, dysrhythmias, anemia, osteonecrosis of the jaw, atrial fibrillation
etidronate (Didronel)	PO: 5–10 mg/kg/day for 6 months or 11–20 mg/kg/day for 3 months	
ibandronate (Boniva)	PO: 2.5 mg/day or one 150-mg tablet per month, taken on the same date each month IV: 3 mg every 3 months	
pamidronate (Aredia)	IV: 15–90 mg in 1000 mL normal saline or D_5W over 4–24 h	
risedronate (Actonel, Atelvia)	PO: 5 mg/day or 35 mg once weekly at least 30 min before the first drink or meal of the day	
zoledronate (Reclast, Zometa)	IV (Zometa): 4-mg single dose infused over at least 15 min; may be repeated q3–4wk for cancer IV (Reclast): one 5-mg single dose per year, infused over at least 15 min	
Miscellaneous Drugs		
abaloparatide (Tymlos)	Subcutaneous: 80 mcg/day using a prefilled pen	*Orthostatic hypotension, dizziness, nausea, headache, fatigue* Hypercalcemia, hypercalciuria, urolithiasis, risk for osteosarcoma
calcitonin-salmon (Miacalcin)	Subcutaneous/IM: salmon, 4–8 international units/kg bid for hypercalcemia; 100 international units every 1–3 days for osteoporosis or Paget disease	*Flushing of the face and hands, pain at the injection site* Anaphylaxis
cinacalcet (Sensipar)	PO: Start with 30 mg once daily; may increase q2–4wk until target PTH of 150–300 mg/mL (max: 300 mg/day) for secondary hyperparathyroidism	*Dizziness, noncardiac chest pain, HTN, nausea, anorexia, hypocalcemia, myalgia* Hypocalcemia, seizures
denosumab (Prolia, Xgen)	Subcutaneous (Prolia): 60 mg every 6 months Subcutaneous (Xgen): 120 mg q4wk	*Fatigue, asthenia, hypophosphatemia, nausea, hypercholesterolemia, musculoskeletal pain, and cystitis* Hypocalcemia, serious infections, osteonecrosis of jaw
etelcalcetide (Parsabiv)	IV: 5-mg bolus	*Muscle spasms, diarrhea, headache, nausea, vomiting* Severe hypocalcemia, worsening heart failure, GI bleeding
raloxifene (Evista)	PO: 60 mg/day	*Hot flashes, leg cramps, peripheral edema, flu syndrome, arthralgia, sweating* Breast pain, vaginal bleeding, pneumonia, chest pain, venous thromboembolism, stroke
teriparatide (Forteo)	Subcutaneous: 20 mcg/day using a prefilled pen	*Dizziness, depression, insomnia, vertigo, rhinitis, increased cough, leg cramps, nausea, arthralgia* Syncope, angina, transient hypercalcemia, risk for osteosarcoma

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Therapeutic Actions and Uses: First approved in 1995, alendronate is the best studied drug in this class. Alendronate is approved for the following indications:

- Prevention and treatment of osteoporosis in postmenopausal women
- Treatment of glucocorticoid-induced osteoporosis in both women and men
- Treatment to increase bone mass in men with osteoporosis
- Treatment of symptomatic Paget's disease in both women and men.

Alendronate is also used off-label for treating hypercalcemia due to malignancy. Several regimens for alendronate are available: once daily (10 mg), twice weekly (35 mg), or once weekly (70 mg). Although the once weekly is more convenient, higher doses can produce more GI-related adverse effects. All doses must be taken on an empty stomach, preferably in a fasting state 2 hours before breakfast.

Therapeutic effects of alendronate may take 1 to 3 months to appear and may continue for several months after therapy is discontinued. This drug lowers serum alkaline phosphatase, which is the enzyme associated with bone turnover, without major adverse effects.

The safety and effectiveness of long-term therapy with alendronate is still being investigated. Patients should be regularly evaluated to determine the need for continued therapy, and the drug discontinued after 3 to 5 years of use in those at low risk for fractures.

Mechanism of Action: Alendronate inhibits osteoclast-mediated bone resorption to minimize loss of bone density. Its effects appear to be localized to resorption sites of active bone turnover and it does not interfere with bone mineralization.

Pharmacokinetics:

Route(s)	PO
Absorption	Less than 1% (significantly decreased by food or beverages)
Distribution	Rapid skeletal uptake; unknown if secreted in breast milk; 78% bound to plasma protein
Primary metabolism	Not metabolized
Primary excretion	50% excreted unchanged in the urine
Onset of action	3–6 weeks
Duration of action	12 weeks or more after discontinuation

Adverse Effects: The most common adverse effect of alendronate is hypocalcemia, which is usually transient and mild. Other adverse effects include diarrhea, constipation, flatulence, nausea, vomiting, GI irritation, a metallic or altered taste perception, hypocalcemia, hypophosphatemia, abdominal pain, dyspepsia, myalgia, and headache. Pathologic fractures may occur if the drug is taken longer than 3 months or in cases of chronic overdose. Although rare, this drug may cause serious esophagitis, which is why patients should remain in an upright position at least 30 minutes after receiving a dose. Osteonecrosis of the jaw has occurred spontaneously in patients taking bisphosphonates.

Contraindications/Precautions: Contraindications include patients with osteomalacia or who have hypersensitivity to this drug. Caution should be used in patients with CKD, heart failure, hyperphosphatemia, liver disease, fever or infection, active upper GI problems, and pregnancy. This drug is contraindicated in patients with abnormalities of the esophagus that delay esophageal emptying, such as stricture or achalasia, and in those who are unable to stand or sit upright for at least 30 minutes following administration of the drug.

Drug Interactions: Calcium, iron, antacids containing aluminum or magnesium, and certain mineral supplements interfere with the absorption of alendronate and have the potential to decrease its effectiveness. Patients should wait at least 30 minutes after taking alendronate before taking any other supplements or other medications. **Herbal/Food:** The patient's diet must have adequate amounts of vitamin D, calcium, and phosphates. Excessive amounts of calcium supplements or dairy products reduce alendronate absorption.

Pregnancy: Category C.

Treatment of Overdose: Hypocalcemia is an expected effect of overdose and may be treated with PO or IV calcium compounds.

Nursing Responsibilities: Key nursing implications for patients receiving alendronate are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Osteoporosis.

Drugs Similar to Alendronate (Fosamax)

Other bisphosphonates include etidronate, ibandronate, pamidronate, risedronate, and zoledronate.

Etidronate (Didronel): Etidronate was the first bisphosphonate approved in the United States in 1977. It is less selective for bone than some of the other medications in this class and is not a first-line drug. It is approved for moderate to severe Paget's disease and for hypertrophic ossification following total hip replacement or spinal cord injury. It is used off-label as an alternative to other bisphosphonates for prevention of postmenopausal and corticosteroid-induced osteoporosis. It is available by the PO route. Like all bisphosphonates, etidronate causes GI mucosa irritation and bone and joint pain. This drug is nephrotoxic and may increase the risk of dysrhythmias. This drug is pregnancy category C.

Ibandronate (Boniva): Ibandronate was approved in 2003 for the prevention and treatment of postmenopausal osteoporosis. In addition to its oral formulation, it is the only IV bisphosphonate approved for the prophylaxis of postmenopausal osteoporosis. When administered IV, injections are spaced 3 months apart. Off-label indications include Paget's disease, bone metastases from prostate cancer, and malignant hypercalcemia. Adverse effects are similar to those of other drugs in this class. This drug is pregnancy category C.

Pamidronate (Aredia): Approved in 1991, pamidronate is available by slow IV infusion for hypercalcemia, moderate to severe Paget's disease, and bone metastases due to breast cancer or multiple myeloma. It may be used off-label to treat osteoporosis and osteogenesis imperfecta. Caution must be used when treating patients with CKD or those who are receiving nephrotoxic drugs because significant renal function deterioration can occur with pamidronate, even after a single dose. Other common adverse effects are nausea, fever, constipation, and dyspnea. Pamidronate is pregnancy category D.

Risedronate (Actonel, Atelvia): Approved in 1998, risedronate is considered a first-line drug for the treatment of glucocorticoid-induced and postmenopausal osteoporosis, and it is also approved to treat symptomatic Paget's disease. It may be used off-label to treat osteolytic lesions due to multiple myeloma. Available by the PO route, it is reported to cause less GI distress than other bisphosphonates. Like other oral bisphosphonates, it is contraindicated in patients who are unable to sit upright for at least 30 minutes after drug administration or who have disorders that cause delayed esophageal emptying. Atelvia is a delayed release form of the drug that can be taken once weekly. Arthralgia, back pain, diarrhea, abdominal pain, and dyspepsia are common adverse effects. This drug is pregnancy category C.

Zoledronate (Reclast, Zometa): Originally approved in 2001, zoledronate (also called zoledronic acid) is available by the IV route to treat hypercalcemia of malignancy, multiple myeloma, and bone metastases. One advantage of Zometa is that it can be infused over 15 to 20 minutes compared to 2 to 4 hours for pamidronate. Frequent adverse effects include nausea, fatigue, anemia, bone pain, constipation, fever, vomiting, and dyspnea.

In 2007, the FDA expanded the indications for zoledronate (Reclast) to include prevention or treatment of postmenopausal osteoporosis, osteoporosis in men, and Paget's disease. A major advantage of Reclast is that its prolonged duration of action results in a once-yearly dose for Paget's disease and osteoporosis prophylaxis. Reclast is available by IV infusion, administered over at least 15 minutes. Common adverse effects include bone pain, pyrexia, nausea, headache, arthralgia, fatigue, and constipation.

Reclast and Zometa are not interchangeable and the drugs should not be administered concurrently. Zoledronate is nephrotoxic and should be used with caution in patients with CKD. Like pamidronate, zoledronate is pregnancy category D and should not be used during pregnancy.

72.7 Selective estrogen receptor modulators increase bone mass density and prevent fractures in postmenopausal women.

Selective estrogen receptor modulators (SERMs) are drugs that bind to estrogen receptors (ERs). Estrogen exerts its effects on target tissues by interacting with ERs and causing either activation or inhibition of specific cellular actions. ERs are found in the reproductive organs of both males and females where they enhance the development of reproductive tissues. But ERs are found in more than just reproductive tissues. In the cardiovascular system, ERs are responsible for lowering blood cholesterol, and in the brain, these receptors influence behavior and mood. In bone, ERs help to maintain bone mineral density.

Certain estrogens are produced by plants. These substances, called phytoestrogens, mimic the effects of natural estrogen and are thought to exert beneficial effects on the cardiovascular system and possibly protection from cancer. For example, soybeans, flax seed, and tofu are rich sources of phytoestrogens.

SERMs are medications that may activate or inhibit ERs. Thus, SERMs may be estrogen agonists or antagonists, depending on the specific drug and the tissue involved. For example, raloxifene (Evista) blocks estrogen receptors in the uterus and breast; it has no estrogen-like proliferative effects on these tissues that might promote cancer. Raloxifene does, however, have estrogen-like effects that reduce bone resorption, thus increasing bone density and reducing the likelihood of fractures. It is most effective in preventing vertebral fractures. The dose for raloxifene is shown in Table 72.6.

The other SERMs include tamoxifen, toremifene (Fareston), and bazedoxifene (Duavee). Tamoxifen and toremifene are used to treat metastatic breast cancer in postmenopausal women (see Chapter 57). Bazedoxifene is formulated in a fixed-dose combination with conjugated estrogens to manage symptoms of menopause as well as to prevent bone fractures (see Chapter 69).

PROTOTYPE DRUG **Raloxifene (Evista)**

Classification **Therapeutic:** Drug for osteoporosis prophylaxis
Pharmacologic: Selective estrogen receptor modifier

Therapeutic Effects and Uses: Approved in 1997, raloxifene is primarily used for the prevention or treatment of osteoporosis in postmenopausal women. In 2007, it was approved for the prophylaxis of invasive breast cancer in postmenopausal women at high risk for breast cancer. High risk of breast cancer is defined as at least one breast biopsy showing carcinoma or atypical hyperplasia or having a first-degree relative with breast cancer. Other factors considered are current age, number of breast biopsies, age at menarche, nulliparity, or age of first live birth. It is important for nurses and patients to understand that this drug is for the prevention, not treatment, of breast carcinoma.

Raloxifene increases bone mass density, reducing vertebral fractures. It does not appear to reduce the incidence of fractures at nonvertebral sites. Raloxifene also reduces serum total cholesterol and low-density lipoproteins (LDLs) without lowering high-density lipoproteins (HDLs) or triglycerides. Unlike estrogen, which causes proliferation of uterine and breast tissue, causing adverse effects, raloxifene is an estrogen antagonist on these tissues. Raloxifene has been used off-label to treat uterine leiomyomas,

for pubertal gynecomastia, and for the prevention of bone loss in men with prostate cancer.

Mechanism of Action: As a selective estrogen receptor antagonist or agonist, raloxifene decreases bone resorption while increasing bone mass and density by activating estrogen receptors.

Pharmacokinetics:

Route(s)	PO
Absorption	60% absorbed
Distribution	Crosses the placenta; unknown if secreted in breast milk; 95% bound to plasma protein
Primary metabolism	Hepatic; extensive first-pass metabolism
Primary excretion	Primarily in feces
Onset of action	8 weeks
Duration of action	Half-life: 28 h

Adverse Effects: The most common adverse effects of raloxifene therapy are hot flashes, leg cramps, and weight gain. Less common adverse effects include fever, arthralgia, myalgia, arthritis, depression, insomnia, chest pain, peripheral edema, decreased serum cholesterol, nausea, dyspepsia, vomiting, flatulence, GI disorders, gastroenteritis, cystitis, migraine, flulike symptoms, endometrial disorder, breast pain, and vaginal bleeding. Raloxifene may cause fetal harm when administered to a pregnant woman. **Black Box Warning:** Raloxifene increases the risk of venous thromboembolism and death from strokes. Women with a history of venous thromboembolism should not take this drug.

Contraindications/Precautions: This drug is contraindicated during lactation and pregnancy and in women who may become pregnant. Patients with a history of venous thromboembolism and those who are hypersensitive to raloxifene should not take this drug. Raloxifene should be discontinued 72 hours before prolonged immobilization is anticipated due to risk of thromboembolic events.

Drug Interactions: Concurrent use with warfarin may decrease prothrombin time (PT). Decreased raloxifene absorption will result from concurrent use with ampicillin or cholestyramine. Use of raloxifene with other highly protein-bound drugs (e.g., ibuprofen, indomethacin, diazepam) may interfere with binding sites. Patients should not take cholesterol-lowering drugs or ERT concurrently with this medication. **Herbal/Food:** Black cohosh has estrogenic effects and may interfere with the actions of raloxifene.

Pregnancy: Category X.

Treatment of Overdose: Overdose with raloxifene is uncommon and symptoms are given supportive treatment.

Nursing Responsibilities: Key nursing implications for patients receiving raloxifene are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Osteoporosis.

Drugs Similar to Raloxifene (Evista)

The other SERMs are discussed in previous chapters: tamoxifen and toremifene in Chapter 57 and bazedoxifene with conjugated estrogens in Chapter 69.

CONNECTION Checkpoint 72.2

From what you learned in Chapter 57, what are the indications for pharmacotherapy with tamoxifen? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

72.8 Calcitonin and several miscellaneous drugs are used for osteoporosis and other metabolic bone diseases.

Several miscellaneous drugs are used to treat MBDs. Although they act by different mechanisms, they are presented together in this section because each is the only drug in its class.

Calcitonin-salmon (Miacalcin): Calcitonin is a hormone that is produced and secreted by the thyroid gland in response to elevated serum calcium levels. This hormone directly inhibits osteoclasts. The function of calcitonin is to lower serum calcium levels by decreasing bone resorption and increasing the urinary excretion of calcium. It acts in direct opposition to PTH and vitamin D.

As a drug calcitonin is obtained from salmon and is approved for the treatment of osteoporosis in women who are more than 5 years postmenopause. Because calcitonin is less effective for reducing osteoporosis-related fractures than the bisphosphonates, it is considered a second-line treatment. The dose for calcitonin is given in Table 72.6.

In addition to treating osteoporosis, calcitonin is indicated for Paget's disease and hypercalcemia. In Paget's disease calcitonin slows the rate of bone turnover and decreases the incidence of bone pain. It is most effective in treating hypercalcemia caused by hyperparathyroidism or prolonged immobility or that accompanies certain malignancies.

Calcitonin is available by subcutaneous or IM injection. In 2016, the intranasal forms of calcitonin were removed from the market. Subcutaneous injections are initially given as a daily dose then decreased to 2 to 3 times per week. Adverse effects of calcitonin include nausea, injection-site inflammation, and generalized flushing of the face and hands. This drug is pregnancy category C.

CONNECTIONS: Using Research in Practice

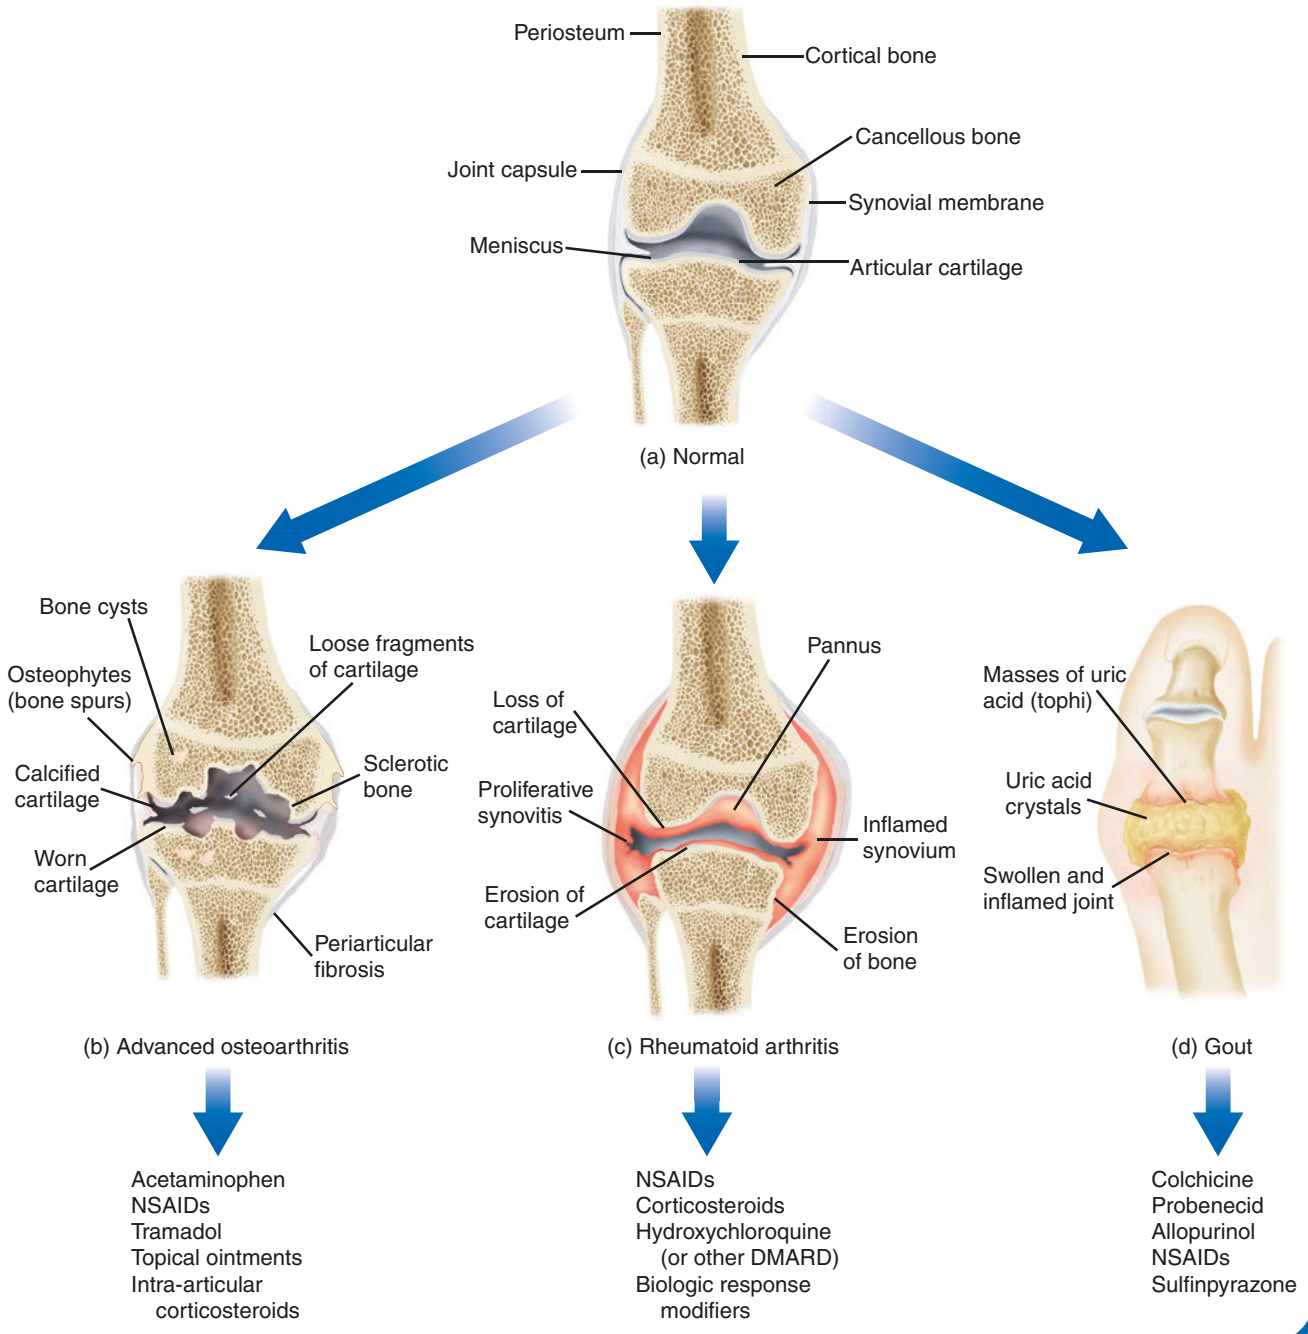
Predicting Bone Loss

Several studies have investigated the effects of ethnicity on the development of bone loss. There has been no clear association for both men and women between ethnicity and bone loss even when controlling for other factors such as body mass index (BMI), fat versus lean body mass, and socioeconomic status (Jackson & Mysiw, 2014). Exceptions have been noted, and women, especially Asian women who take bisphosphonates for long durations, were found to have a higher rate of femoral shaft fractures (Lo et al., 2014). In a study of men and differences in bone loss, Araujo et al. (2014) found that men with higher incomes had less BMD loss than those with low or moderate incomes. This may be due, in part, to increased options for diet and exercise related to income. Physical activity, history of or current smoking, and BMI are also risk factors that predict fracture risk. Finally, it appears that hip geometry measurements obtained during DEXA imaging, such as the size, shape, and angle of the femur, may also help predict fracture risk (Broy et al., 2015).

DEXA screening remains a definitive measure of bone loss and of estimating fracture risk and can provide information on both bone density and hip geometry measurements. Other non-DEXA screening tools have also been found to be effective at estimating risk of fracture. They include the World Health Organization's fracture risk assessment tool (FRAX), the men's osteoporosis risk estimation score (MORES), and the osteoporosis self-assessment screening tool (OST), and these can be used with or without DEXA to predict risk (Cass, Shepherd, Asirot, Mahajan, & Nizami, 2016; Kanis et al., 2015, 2016; Pang & Inderjeeth, 2014). In addition to DEXA and fracture risk assessment tools, Najafi, Dahlberg, and Hansson (2016) recommend the use of balance measures such as standing on one leg with eyes closed.

Denosumab (Prolia, Xgen): Approved in 2010, denosumab is used to prevent bone fractures in postmenopausal women and to prevent skeletal-related events in patients with bone metastases with solid tumors. It is considered a first-line drug for osteoporosis prevention in patients at high risk for fracture. Denosumab is given by subcutaneous injection, either every 4 weeks (Xgen) or every 6 months (Prolia). The drug is a monoclonal antibody classified as a RANKL inhibitor. RANKL is a protein that binds to the RANK receptor on osteoblasts. Once bound, RANKL promotes the removal of calcium from bone. By inhibiting this action, denosumab helps to maintain bone mineral density and prevent fractures due to osteoporosis or bone metastases. Common adverse effects include fatigue, asthenia, hypophosphatemia, nausea, hypercholesterolemia, musculoskeletal pain, and cystitis. Because the drug can cause severe hypocalcemia, serum calcium levels should be monitored regularly and calcium supplements and vitamin D administered as necessary. Some patients also experience osteonecrosis of the jaw. This drug is pregnancy category C and is contraindicated during pregnancy.

Parathyroid hormone analogs: Abaloparatide (Tymlos) and teriparatide (Forteo) are forms of human PTH produced by recombinant DNA technology. Their only approved indication is for the treatment of osteoporosis in men and postmenopausal women. These drugs are reserved for patients with a high risk of bone fractures. The actions of the PTH analogs are identical to those of endogenous PTH. Unlike other medications that simply reduce bone resorption, the PTH analogs also stimulate the production of new bone. These actions increase bone mass density and reduce the incidence of fractures. Both drugs are given daily by the subcutaneous route and are available as prefilled pen injectors. Both teriparatide (approved in 2002) and abaloparatide (approved in 2017) carry a black box warning that PTH analogs cause osteosarcomas in laboratory animals. Because of this, they should not be used in patients with an increased risk for osteosarcoma. The black box warning also states that the PTH analogs should not be used for more than 2 years during a patient's lifetime. Teriparatide may be used off-label to treat hypoparathyroidism and corticosteroid-induced osteoporosis. Teriparatide is well tolerated, with dizziness and leg cramps being the most frequent adverse effects. Abaloparatide has no pregnancy rating. Teriparatide is rated as pregnancy category C.



Pathophysiology and Pharmacotherapy of Joint Disorders

72.9 Osteoarthritis is treated with a combination of analgesics and nonpharmacologic therapies.

A simple classification of joint disorders places them into two categories: noninflammatory and inflammatory. The most common of the noninflammatory disorders is osteoarthritis. Common inflammatory joint disorders such as rheumatoid arthritis and gout are covered in Sections 72.10 and 72.11, respectively. These joint conditions are frequent indications for pharmacotherapy, with joint pain being common to all disorders. Analgesics and anti-inflammatory drugs are important components of pharmacotherapy. A few additional drugs are specific to the particular joint pathology. Pharmacotherapy Illustrated 72.1 shows the types of joint pathology and their drug therapy.

Pharmacotherapy Illustrated 72.1

Joint Disorders

Osteoarthritis (OA) is a progressive, degenerative joint disease caused by the breakdown of articular cartilage. It is the most common cause of disability in the United States, affecting over 30 million people. Weight-bearing joints such as the knee, vertebral column, and hip are most commonly affected. The hands are also affected because they are frequently used. OA may be classified as idiopathic or secondary. Idiopathic OA, the most common type, has no known cause but is associated with increasing age. The causes of secondary OA include trauma, mechanical stress, inflammation of the joint structures, neurologic disorders, use of certain medications, and joint instability. Excessive weight contributes to the development of OA, particularly in the knee and hip. Other risk factors associated with OA include decreased estrogen in menopausal women, excessive growth hormone, and increased PTH.

As cartilage thins in the affected joints, there is less padding and, eventually, the underlying bone is affected. The bone thickens in the exposed areas, forming bone spurs and cysts that narrow the joint space. As these growths enlarge, small pieces may break off, leading to inflammation of the synovial membrane and a loss of lubricating fluid. This leads to further pain, inflammation, and destruction of the synovial membrane lining the joint. The affected joint becomes unstable and more susceptible to injury, with partial joint dislocations and other deformities that are common in advanced disease being seen.

The onset of OA is usually gradual, with pain and stiffness in one or more joints being the first manifestations. The patient with OA typically describes a deep, aching, localized pain, which is usually aggravated by movement and relieved by rest. Pain at night may be accompanied by paresthesias. As the disease advances, the range of motion (ROM) of the joint decreases; this is often accompanied by complaints of progressive pain. Bone enlargement can increase joint size; flexion contractures contribute to joint instability. It is important to note that OA is not accompanied by the degree of inflammation associated with other forms of arthritis. The joints of a patient with OA are characteristically hard and cool to palpation. A patient with OA is shown in Figure 72.4. The diagnosis of OA is typically made through a medical history, physical examination, and routine x-rays.

Nonpharmacologic therapies are an essential component of OA management. Walking, nonimpact aerobics, and passive ROM exercises are important to maintain joint flexibility. Improving muscle strength, especially of the quadriceps muscle, will help patients improve their ability to perform ADLs. Bracing may help keep joints positioned correctly and relieve pain. Knowledge of proper body mechanics and posture may offer some benefit. Patients who are obese should consider a weight loss program, especially if weight-bearing joints such as the hip and knee are affected. Weight loss has been associated with decreased pain and disability. Surgical procedures such as joint replacement and reconstructive surgery may become necessary when other methods are ineffective.

Figure 72.4 Patient with osteoarthritis.
Courtesy of JPC-PROD/Shutterstock.

The goals of pharmacotherapy for OA include reducing pain and inflammation and minimizing disability. The initial treatment for most patients is acetaminophen. Acetaminophen is inexpensive, participates in few drug–drug interactions, and has fewer serious adverse effects than other analgesics. For patients whose pain is unrelieved by acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), including naproxen and ibuprofen derivatives, are usually given. Because high doses of NSAIDs can result in GI bleeding and affect platelet aggregation, patients must be carefully monitored. Aspirin is no longer recommended because the high doses needed to produce pain relief in patients with OA may cause GI bleeding. Tramadol (Ultram) has become a popular drug for the treatment of moderate to severe pain. Opioids such as codeine may be combined with acetaminophen for severe pain. The student should refer to Chapter 25 for a complete discussion of the actions and adverse effects of analgesics.

In acute cases, intra-articular corticosteroid injections may be used. With intra-articular injections, a long-acting corticosteroid such as triamcinolone is injected directly into the joint space of the affected joint. Pain relief generally lasts 3 months following the injection. Although this procedure relieves pain on a temporary basis, it can speed the destruction of cartilage if it is performed more frequently than every 4 to 6 months.

Many patients use topical medications, including salicylates (Aspercreme and Sportscreme), capsaicin (Capzasin), and counterirritants (Bengay and Icy Hot), which are sold OTC as creams, gels, sprays, patches, or ointments, to relieve OA pain. These therapies are well tolerated and produce few adverse effects. These products should not be used more than 4 times daily and should be discontinued if irritation occurs.

Another drug therapy option for patients with moderate OA who do not respond adequately to analgesics includes hyaluronate sodium (Hyalgan), a chemical normally found in high amounts within the synovial fluid. Administered by injection directly into the knee joint, this drug replaces or supplements the body's natural hyaluronic acid, which deteriorates as a result of the inflammation of OA. Treatment consists of one injection per week for three to five injections. Hyalgan helps provide a barrier that prevents friction and further inflammation of the joint by coating the articulating cartilage surface. Information that is given to the patient prior to administration should include adverse effects such as pain or swelling at the injection site and the avoidance of any strenuous activities for approximately 48 hours after injection.

CONNECTIONS: Complementary and Alternative Therapies

Glucosamine and Chondroitin for Osteoarthritis

Description

Many patients use OTC herbal medicines to relieve the pain and inflammation associated with OA. Two of the most commonly used agents are glucosamine and chondroitin.

History and Claims

Glucosamine is a natural substance that is an important building block of cartilage. With aging, glucosamine is lost with the natural thinning of cartilage. As cartilage wears down, the joints lose their normal cushioning ability, resulting in the pain and inflammation of OA. Chondroitin is another substance that forms part of the matrix between cartilage cells.

The use of glucosamine is thought to reduce cartilage breakdown and improve cartilage production and repair. Chondroitin is another dietary supplement purported to repair cartilage damaged by inflammation or injury.

Standardization

Glucosamine is made from the crushed shells of shrimps, lobsters, and crabs, although non-shellfish forms are available for patients allergic to shellfish. It is available as oral tablets, capsules, or in powder form, with a typical dose being 1.5 g/day. Chondroitin is derived from bovine or shark cartilage and is also taken orally, with doses in the range of 800 to 1200 mg/day.

Evidence

Typical of many other specialty supplements, research regarding the effectiveness of chondroitin and glucosamine has delivered mixed results. In most European countries, these two supplements are prescribed for the symptomatic treatment of knee OA (Henrotin, Marty, & Mobasheri, 2014). In the United States, large research trials have not demonstrated significant improvement in pain in patients who took chondroitin for osteoarthritis, and there is insufficient evidence to suggest that glucosamine improves joint structure (Center for Complementary and Integrative Health, 2016).

Glucosamine and chondroitin supplements are known to interact with warfarin (Coumadin), increasing the risk of bleeding, and some studies suggest that large doses may cause renal damage. As with all supplements, patients should be encouraged to talk with their healthcare provider about using the supplement and at what dosage.

72.10 Pharmacotherapy for rheumatoid arthritis includes analgesics, anti-inflammatory drugs, corticosteroids, and disease-modifying antirheumatic drugs.

Rheumatoid arthritis (RA) is a chronic, progressive autoimmune disease that causes inflammation of the joints. It is characterized by disfigurement and inflammation of multiple joints. RA is less common than OA, with RA affecting over 2 million people in the United States. Typically RA occurs at an earlier age than OA, with the incidence of RA increasing up to age 70. It is important to differentiate between the two types of arthritis because the treatments are very different.

In RA, autoantibodies known as rheumatoid factors attack the individual's tissues, activating complement and drawing leukocytes into the area, where they attack the cells of the synovial membranes and blood. Inflammation first occurs in the synovial membranes, which line joint cavities, then progresses to the surrounding articular cartilage. The damaged synovial membrane swells and the persistent inflammation spreads and damages the surrounding blood vessels, ligaments, and tendons. The swelling also causes hemorrhage, coagulation, and deposits of fibrin within the joints. This ultimately leads to scar tissue formation that immobilizes the joint.

The exact etiology of RA is not known, but it is likely a combination of environmental and genetic factors. Female reproductive hormones may influence the development of RA because it affects women about 3 times more frequently than men. Infectious organisms, such as the Epstein-Barr virus, may play a role in an individual developing the autoimmune processes seen with RA.

The course of RA is variable and the rate at which joint deformities develop is not consistent. Disease progression is typically fastest during the first 6 years, slowing thereafter. The onset is typically insidious, though it may be acute if precipitated by a stressor, such as infection. The patient with early RA typically experiences morning joint stiffness, swelling, pain, and generalized fatigue. The joints may be slightly reddened, warm, and tender to palpation. The pattern of joints involved is usually symmetric. The upper extremity joints are often involved, beginning with the hands and wrists, as well as the joints of the toes, ankles, and knees. As the disease worsens, the morning stiffness can extend several hours into the day and occur with any periods of prolonged rest. The persistent inflammation causes deformities of the joints and the supporting ligaments, tendons, and muscles, making activity painful. Muscle weakness and decreased ROM may be apparent. Most or all synovial joints are eventually affected. A patient with RA is shown in Figure 72.5.

PharmFACT

Genetic factors account for 50% of the risk for developing rheumatoid arthritis. Disease concordance in identical twins is 15% to 20%, which suggests that nongenetic factors also play an important role (Smith, 2017).

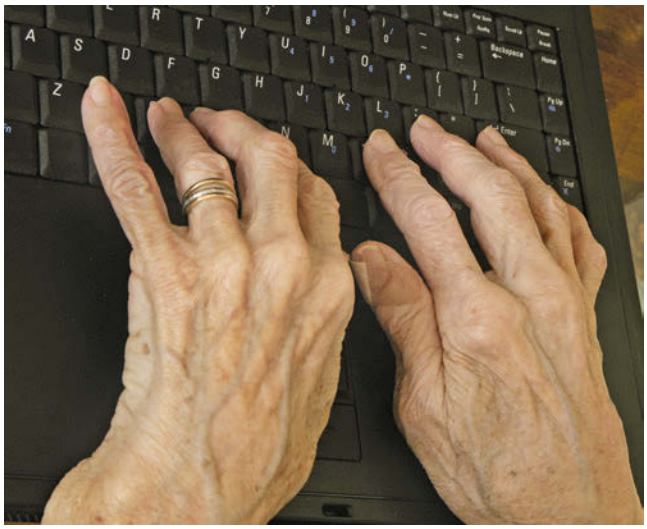


Figure 72.5 Patient with rheumatoid arthritis.
Courtesy of Lee319/Shutterstock.

Joint manifestations in RA typically precede systemic manifestations, which are associated with advancing disease. Extreme fatigue, anorexia, weight loss, anemia, and low-grade fever are common. Rheumatoid nodules may develop in the subcutaneous tissue of the forearm, toes, and fingers and in the viscera surrounding the heart, lungs, dura, and intestinal tract. Inflammation of the blood vessels can result in vasculitis. Respiratory complications, including pleurisy, pneumonitis, and fibrosis, are common as well as cardiac complications such as pericarditis and myocarditis.

Diagnosis of RA is based on the patient's history, physical examination, and diagnostic tests. Laboratory tests that are helpful in supporting a diagnosis of RA include elevations in the serum rheumatoid factor, erythrocyte sedimentation rate (ESR), antinuclear antibody titers, and serum immunoglobulin levels. Routine x-rays are used to determine the degree of structural joint damage.

Like OA, nonpharmacologic therapies are an essential component of RA management. ROM and joint and muscle strengthening exercises are important if the patient is to continue performing normal ADLs. Psychologic counseling may be helpful to help the patient deal with a potentially debilitating disease. Braces, splints, canes, and walkers can assist in ambulation. Loss of excess weight can help take the stress off inflamed joints. Proper rest helps reduce pain.

The primary goals of RA pharmacotherapy are to manage inflammation, reduce pain, and maximize physical abilities. Pharmacotherapy for the relief of pain associated with RA includes the same classes of analgesics used for OA. Therapy is begun with NSAIDs, because these drugs relieve both pain and inflammation. NSAIDs that are used to treat RA are usually given in doses that are higher than those for the patient with OA. Aspirin is not recommended for long-term therapy due to its adverse effects on the GI system and platelet aggregation. Acetaminophen is effective at relieving pain and fever but has no anti-inflammatory actions. Although the analgesics relieve symptomatic pain, they have little effect on disease progression.

Corticosteroids may be considered for moderate or severe RA. Because of their potent anti-inflammatory action, the goal of therapy with corticosteroids is to relieve the symptoms associated with RA flare-ups. They are not used for prolonged therapy because of their long-term adverse effects, which include a greater susceptibility to infections, poor wound healing, and osteoporosis. Severe rebound symptoms can occur if these medicines are abruptly discontinued. For these reasons, corticosteroids, when used, are given at the lowest daily doses possible.

The progression of tissue damage characteristic of RA can be slowed or modified with a diverse group of drugs called **disease-modifying antirheumatic drugs (DMARDs)**. These drugs modify immune and inflammatory responses. They have been found to reduce mortality rates, improve symptoms, and enhance the quality of life in patients with RA. Doses of DMARDs are listed in Table 72.7. The medications are grouped as follows:

- Nonbiologic DMARDs
- Biologic DMARDs (anti–tumor necrosis factor [TNF] drugs)
- Biologic DMARDS (non–anti-TNF drugs).

The choice of a specific DMARD depends on the experiences of the healthcare provider and the response of the patient to therapy. Many rheumatologists consider methotrexate to be the first-line therapy for the initial treatment of RA. It acts quickly, has a relatively favorable safety profile, is low cost, and slows the progression of the disease. A once-weekly subcutaneous formulation of methotrexate (Otrexup) was approved in 2013 for severe RA that has not responded to other forms of therapy. Other nonbiologic DMARDs considered for initial therapy include hydroxychloroquine (Plaquenil) and sulfasalazine (Azulfidine). Risks of toxicity with these drugs is among the lowest associated with DMARDs. Nonbiologic DMARDs such as azathioprine (Azasan, Imuran) and leflunomide (Arava) have more adverse effects than other DMARDs, but may be used in combination with some of the biologic therapies.

Biologic therapies are a newer DMARD therapy for the treatment of RA. These drugs block steps in the inflammatory response, reduce joint inflammation, and slow the progression of joint damage. Adalimumab (Humira), etanercept (Enbrel), certolizumab pegol (Cimzia), golimumab (Simponi), and infliximab (Remicade) are tumor necrosis factor (TNF) antagonists. TNF is a naturally occurring cytokine produced by macrophages and activated T cells that mediates inflammation and modulates cellular

Table 72.7 Selected Disease-Modifying Antirheumatic Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Nonbiologic DMARDS		
azathioprine (Azasan, Imuran)	PO: 1 mg/kg/day once or in divided doses bid for 6–8 wk (max: 2.5 mg/kg/day) Maintenance dose: 1–2.5 mg/kg/day as a single dose or divided	*Chills, fever, malaise, myalgia* Myelosuppression, hepatotoxicity, lymphoproliferative disorders
hydroxychloroquine (Plaquenil)	PO: 400–600 mg/day for 4–12 wk, then 200–400 mg once daily Maintenance dose: 10–20 mg/day	*Anorexia, nausea, vomiting, headache, and personality changes* Retinopathy, agranulocytosis, aplastic anemia, seizures
leflunomide (Arava)	PO: 100-mg loading dose for 3 days, then 20 mg/day	*Diarrhea, elevated hepatic enzymes, alopecia, rash* Hepatotoxicity, immunosuppression
methotrexate (Otrexup, Rheumatrex, Trexall)	PO: 7.5 mg once/wk or 2.5 mg q12h for 3 doses once/wk (max: 20 mg/wk) Subcutaneous (Otrexup): 10–25 mg once weekly	*Headache, glossitis, gingivitis, mild leukopenia, nausea* Ulcerative stomatitis, myelosuppression, aplastic anemia, hepatic cirrhosis, nephrotoxicity, sudden death, pulmonary fibrosis, teratogenicity
sulfasalazine (Azulfidine)	PO: 500–1000 mg/day (max: 3 g/day)	*Headache, anorexia, nausea, vomiting* Anaphylaxis, Stevens–Johnson syndrome (SJS), agranulocytosis, leukopenia, reversible oligospermia
Biologic DMARDs (Anti-TNF Drugs)		
adalimumab (Humira)	Subcutaneous: 40 mg every other week	*Local reactions at the injection site (pain, erythema, myalgia), nasopharyngitis* Serious infection, sepsis, and invasive fungal infections, lupus-like syndrome, positive antinuclear antibodies, tumor lysis syndrome, heart failure exacerbations, SJS, increased malignancies, neutropenia.
certolizumab pegol (Cimzia)	Subcutaneous: 400 mg initially and at wk 2 and 4, followed by 200 mg every other week	
etanercept (Enbrel)	Subcutaneous: 25 mg twice weekly; or 0.08 mg/kg or 50 mg once weekly	
golimumab (Simponi)	Subcutaneous: 50 mg once monthly (for RA) or 100 mg q4wk (for ulcerative colitis)	
infliximab (Remicade)	IV: 3 mg/kg at wk 0, 2, and 6, then q8wk	
Biologic DMARDs (Non–Anti-TNF Drugs)		
abatacept (Orencia)	IV: 500–1000 mg given at 0, 2, and 4 wk, then q4wk thereafter	*Local reactions at the injection site (pain, erythema, myalgia), nasopharyngitis* Serious infection, sepsis, and invasive fungal infections, tumor lysis syndrome, neutropenia, increased malignancies (tofacitinib), anaphylaxis, hypotension (rituximab), bowel obstruction and perforation (rituximab, tocilizumab, tofacitinib)
anakinra (Kineret)	Subcutaneous: 100 mg/day	
rituximab (Rituxan)	IV: 1000 mg q2wk for a total of 2 doses (give a corticosteroid 30 min prior to infusion)	
sarilumab (Kevzara)	Subcutaneous: 150 mg/1.14 mL or 200 mg/1.14 mL using a prefilled syringe	
tocilizumab (Actemra)	IV: 4–8 mg/kg every other week Subcutaneous: 162 mg every week or every other week	
tofacitinib (Xeljanz)	PO: 5 mg bid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

immune responses. Elevated levels of TNF are found in the synovial fluid of patients with RA. Certolizumab pegol (Cimzia) and golimumab (Simponi) are newer generation TNF blockers. Anakinra (Kineret) and abatacept (Orencia) are biologic drugs that block actions of interleukins in inflammatory pathways. The biologic drugs appear to be effective and relatively nontoxic but they are expensive (about $20,000 per year); thus they are normally not prescribed until conventional therapy has been attempted and failed. Combinations of biologic and nonbiologic drugs may be effective for patients unresponsive to monotherapy.

PROTOTYPE DRUG Adalimumab (Humira)

Classification **Therapeutic:** Antirheumatic drug, antimalarial
Pharmacologic: Disease-modifying antirheumatic drug

Therapeutic Effects and Uses: Initially introduced to treat RA in 2002, adalimumab was the first fully human monoclonal antibody approved by the FDA. Since then it has become one of the best selling drugs in history. Indications for the drug have expanded to

include psoriatic arthritis, ankylosing spondylitis, polyarticular juvenile idiopathic arthritis, Crohn's disease, hidradenitis suppurativa, ulcerative colitis, chronic plaque psoriasis, and uveitis. Amjevita is a biosimilar drug approved in 2016 for seven indications of adalimumab. A biosimilar is a biologic drug that is substantially similar in clinical properties.

Adalimumab is administered by the subcutaneous route, usually every other week. Doses differ by indication. The drug is available in a single-use pen injection system for home administration.

Mechanism of Action: Adalimumab blocks the inflammatory activity of TNF. High levels of TNF are often found in patients with inflammatory disorders such as RA.

Pharmacokinetics:

Route(s)	Subcutaneous
Absorption	Peak levels occur in about 5 days
Distribution	Unknown
Primary metabolism	Unknown
Primary excretion	Unknown
Onset of action	4–5 weeks
Duration of action	10–20 days

Adverse Effects: The most common adverse effects are injection-site pain, upper respiratory infection, increased creatine phosphate, headache, and rash. **Black Box Warning:** Due to its ability to suppress the immune system, patients are at increased risk for the development of serious infections and malignancies. Latent infections such as tuberculosis and hepatitis B virus may become reactivated. Leukemias, lymphomas, and other malignancies have been reported with TNF blockers. Although rare, fatal cases of hepatosplenic T-cell lymphoma have been documented with TNF blockers.

Contraindications/Precautions: There are no contraindications. As a precaution, patients should be monitored for the development of infections or malignancies.

Drug Interactions: Adalimumab should not be administered concurrently with the TNF blockers anakinra or abatacept. Administration of live vaccines should be avoided. Concurrent use with other immunosuppressants should be avoided or carefully monitored to avoid an increased risk for serious infections. **Herbal/Food:** Echinacea should be avoided because it may decrease the immunosuppressive effects of adalimumab.

Pregnancy: Category B

Treatment of Overdose Treatment is supportive.

Nursing Responsibilities: Key nursing implications for patients receiving adalimumab are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Rheumatoid Arthritis and Osteoarthritis.

Other DMARDS for Rheumatoid Arthritis

The first- and second-choice DMARDs are described next. Gold salts (Auranofin, Aurothioglucose, gold sodium thiomalate) and penicillamine (Cuprimine, Depen) are DMARDs that are rarely used and the student should refer to a drug guide for information. Cyclosporine and azathioprine are immunosuppressants that occasionally are used as DMARDs. They are described in Chapter 42.

TNF Blockers: The TNF blockers include the monoclonal antibodies adalimumab, certolizumab, etanercept, golimumab, and infliximab. Although each of these drugs is unique, they have similar actions and adverse effects. The most common adverse effects are injection-site reactions such as pain, swelling, and bruising. Other adverse effects include upper respiratory tract infection, neutropenia, and rare cases of central nervous system (CNS) demyelinating disorders such as multiple sclerosis. Also, some of these medications may worsen or cause heart failure. Because they are potent immunosuppressants, all pose an increased risk for serious infections and malignancy. These drugs carry a black box warning that reactivation of latent infections such as tuberculosis may occur. The warning also includes an increased risk for lymphoma and other malignancies, especially when used in children and adolescents treated for juvenile RA. All TNF blockers are pregnancy category B.

- **Adalimumab (Humira):** See the prototype feature above.
- **Certolizumab pegol (Cimzia).** Certolizumab was approved in 2008 for the treatment of moderate to severe RA, ankylosing spondylitis, psoriatic arthritis, and Crohn's disease unresponsive to safer medications. The drug is given as a subcutaneous injection, usually every other week.
- **Etanercept (Enbrel).** Approved in 1998, etanercept is approved for the treatment of moderate to severe RA, psoriatic RA in adults, polyarticular juvenile RA in children ages 2 and older, ankylosing spondylitis, and plaque psoriasis. Etanercept is administered by the subcutaneous route twice a week. Concurrent use of etanercept with sulfasalazine may result in leukopenia.
- **Golimumab (Simponi).** Golimumab was approved in 2009 for the management of moderate to severe RA, active psoriatic RA in adults, and active ankylosing spondylitis in adults. More recently, the drug was approved to treat moderate to severe ulcerative colitis

that cannot be managed by first-line medications. Golimumab is usually combined with methotrexate and is given as a subcutaneous injection once a month.

- **Infliximab (Remicade).** Originally approved in 1998, infliximab is indicated for moderate to severe RA, psoriatic RA, ankylosing spondylitis, Crohn's disease, ulcerative colitis, and plaque psoriasis. For RA infliximab is usually combined with methotrexate and is given as an IV infusion over several hours, followed by subsequent injections in weeks 2 and 6 and every 8 weeks thereafter. Acetaminophen and diphenhydramine (Benadryl) are given prior to infusion to decrease the symptoms of infusion reaction such as chest pain, tachycardia, shortness of breath, and lightheadedness.

Abatacept (Orencia): Abatacept was approved in 2005 for the treatment of moderate to severe RA in adults and for juvenile idiopathic RA in children ages 6 and older. The drug acts by inhibiting the actions of T cells, which are often hyperactive in patients with RA. It is administered as an IV infusion, usually every 2 to 4 weeks. Headache, upper respiratory tract infection, and nausea are common adverse effects. Like other immunosuppressants, there is an increased risk of serious infections or reactivation of latent infections. The risk for malignancies may also be increased. Although abatacept is sometimes used in combination with other DMARDs, it should not be administered concurrently with TNF blockers due to a high incidence of serious infections. This drug is pregnancy category C.

Anakinra (Kineret): Approved in 2001, anakinra inhibits interleukin-1 (IL-1), an important chemical mediator of inflammation. It is approved for RA that has not responded to one or more DMARDs. A major disadvantage of this drug is that it must be given daily by the subcutaneous route. Injection-site reactions such as pain, swelling, edema, and bruising occur more often than with the other drugs in its class. Ice and hydrocortisone cream are recommended to diminish the pain, along with site rotation. Upper respiratory infections and influenza symptoms occur in many patients. The manufacturer recommends that anakinra not be administered concurrently with TNF inhibitors such as etanercept due to an increased risk of infections. Anakinra is pregnancy category B.

Hydroxychloroquine (Plaquenil) Approved in 1955, hydroxychloroquine is approved for the treatment of RA. This drug is also used for the prophylaxis and treatment of malaria, but chloroquine (Aralen) is the preferred drug for this parasitic infection (see Chapter 53). It may be used to treat systemic lupus erythematosus in patients who have not responded well to other anti-inflammatory drugs. Hydroxychloroquine therapy for 3 to 6 months is required to achieve therapeutic effects. For full effectiveness, hydroxychloroquine is most often prescribed concurrently with salicylates and glucocorticoids. The primary adverse effects of hydroxychloroquine are GI related, such as anorexia, weight loss, nausea, and vomiting. Possible ocular effects include blurred vision, photophobia, diminished ability to read, and blacked-out areas in the visual field. Hydroxychloroquine is pregnancy category C.

Leflunomide (Arava): Approved in 1998, leflunomide is a DMARD with a unique mechanism of action. It inhibits an enzyme in mitochondria that is responsible for the synthesis of pyrimidines, which are building blocks for DNA and ribonucleic acid (RNA). The result is an inhibition in B-cell and T-cell function. Reduced cytokine and antibody production by these cells reduces inflammation and joint destruction. After a loading dose for 3 days, this drug is given PO once daily. Leflunomide has an exceptionally long half-life, and it can be detected in the blood as long as 2 years after discontinuation. If toxicity occurs, the administration of cholestyramine for 11 days can clear most leflunomide from the body. Common adverse effects include diarrhea, nausea, vomiting, headache, and alopecia. Leflunomide is hepatotoxic and liver function must be regularly monitored during therapy. The possibility of pregnancy should be excluded before therapy is begun because this drug is pregnancy category X.

Methotrexate (Otrexup, Rheumatrex, Trexall): Methotrexate is prescribed for a number of proliferative and inflammatory diseases, including various carcinomas and leukemias, immunosuppression following kidney transplantation, severe psoriasis, and RA. Methotrexate is a folic acid antagonist, and a potent immunosuppressant. Gastric irritation and stomatitis are the most frequent adverse effects; these are minimized by the concurrent use of folic acid. Patients, particularly those who are older, obese, or have diabetes or CKD, need to be monitored for hepatotoxicity, bone marrow suppression, and pneumonitis. The possibility of pregnancy should be excluded before therapy is begun because this drug is pregnancy category X. A prototype feature for methotrexate may be found in Chapter 57.

Rituximab (Rituxan): Rituximab (Rituxan) is a monoclonal antibody originally approved in 1997 as an antineoplastic drug. The drug binds to CD20, a surface protein present on B lymphocytes involved in certain leukemias and lymphomas. Once bound, rituximab lyses the tumor cells. Later, it was discovered that B lymphocytes also play a major role in producing the severe inflammation associated with RA. In 2006, rituximab was approved to treat moderate to severe RA that has not responded to therapy with TNF blockers. For RA, the drug is administered concurrently with methotrexate. Common adverse effects include upper respiratory tract infection, urinary tract infection, and bronchitis. Rituximab can produce adverse

effects such as serious infections, life-threatening dysrhythmias, and tumor lysis syndrome. This drug is pregnancy category C.

Sarilumab (Kevzara): Approved in 2017, sarilumab acts by blocking receptors for interleukin-6 (IL-6), a substance secreted by immune cells that promotes inflammation and activates the immune response. It may be used as monotherapy or in combination with other DMARDs such as methotrexate to treat moderate to severe RA in patients who have not responded to one or more DMARDS. This drug may cause neutropenia; therefore, it should be avoided if an active infection is present. The drug is not recommended for patients with active hepatic disease. Sarilumab does not have a pregnancy rating.

Sulfasalazine (Azulfidine): Sulfasalazine is a sulfonamide and, having been approved in 1950, one of the oldest drugs for RA. It is also approved for juvenile RA, Crohn's disease, and ulcerative colitis. It is available as an enteric-coated tablet that must be taken 3 to 4 times daily. Its beneficial effects are noted quickly, often after 4 weeks of therapy. GI complaints such as nausea, vomiting, anorexia, diarrhea, and abdominal pain occur in a significant number of patients taking this drug, and these may cause discontinuation of therapy. The adverse GI effects are better tolerated if therapy starts with a low dose that is gradually increased. Headache; blood dyscrasias, especially leukopenia; and skin rashes are also frequent. Regular monitoring of CBCs for bone marrow suppression should be conducted. Patients with allergies to sulfur or other sulfonamides should not receive sulfasalazine. Concurrent administration with iron supplements or antibiotics should be avoided because doing so diminishes the absorption of sulfasalazine. Sulfasalazine is pregnancy category B.

Tocilizumab (Actemra): Tocilizumab was approved in 2010 for the treatment of moderate to severe RA in adults and for juvenile idiopathic arthritis in children ages 2 and older. Like sarilumab, tocilizumab acts by inhibiting IL-6 and may be used as monotherapy or in combination with other DMARDs such as methotrexate. It is administered by either the IV or subcutaneous route. Headache, upper respiratory tract infection, hypertension (HTN), and increased liver enzymes are common adverse effects. Like other immunosuppressants, the risk of serious infections or reactivation of latent infections is increased. Tocilizumab therapy should not be initiated if the absolute neutrophil count (ANC) is less than 2000/mm^3, if the platelet count is below 100,000/mm^3, or if liver enzymes are elevated (1.5 times normal). This drug is pregnancy category C.

Tofacitinib (Xeljanz): Tofacitinib is a newer biologic DMARD, approved in 2013 to treat RA that has not responded adequately to methotrexate therapy. This drug acts by inhibiting Janus kinase (JAK). JAKs are enzymes that signal the immune system to release certain cytokines that cause inflammation. By blocking the signaling pathway, JAK inhibitors (sometimes called Jakinibs) reduce the progress and clinical symptoms of RA. Like some other biologic therapies, tofacitinib carries a black box warning that its use may result in serious infections and that the existence of latent tuberculosis should be excluded prior to therapy. The black box warning also notes that lymphoma and other malignancies have developed in patients taking this drug. Tofacitinib is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Rheumatoid Arthritis and Osteoarthritis

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including musculoskeletal, GI, cardiovascular, neurologic, endocrine, hepatic, or kidney disease. Obtain a drug history including allergies, current prescription and OTC drugs and herbal preparations; alcohol use; or smoking. Be alert to possible drug interactions.
- Obtain a history of any current symptoms or pain and their effect on ADLs. Assess for inflammation, nodules, deformities, as well as location, and note the presence of pain or discomfort, time of day of occurrence, on movement, or at rest. Assess effects on sleep.
- Obtain a dietary history and the effect of the disease on the ability to obtain food sources, cooking, and eating. Assess adequacy of fluid intake.
- Obtain baseline weight and vital signs.
- Evaluate appropriate laboratory findings (e.g., CBC, sedimentation rate, hepatic and renal function studies, rheumatoid factor, coagulation panels, bleeding time, electrolytes, glucose, lipid profile).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., symptoms of acute inflammation are diminished or absent, pain is diminished or absent, ability to carry out ROM and ADLs has increased).
- Continue monitoring vital signs and level of pain.
- Continue to monitor laboratory studies as ordered.
- Assess for and promptly report adverse effects: symptoms of GI bleeding (dark or tarry stools, hematemesis, coffee-ground emesis, or blood in the stool), abdominal pain, severe tinnitus, dizziness, drowsiness, lightheadedness, palpitations, tachycardia, HTN, increased respiratory rate and depth, pulmonary congestion, edema, diminished urine output, fever, infections, visual effects (blurred vision, photophobia, blacked-out areas in the vision field).

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished inflammation, pain, stiffness, improved ROM, and ability to carry out ADLs should continue to improve.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures, e.g., a balance between low-impact activity and rest, application of warm or cool compresses, or warm showers prior to activity. • Teach the patient to promptly report increasing pain, stiffness, and decreased ability to carry out ADLs. Hospitalization may be required during acute exacerbations dependent on the severity of symptoms.
• Continue to assess fluid and nutrition intake. (Inflammation, pain, and deformities may make eating and drinking difficult. Dietitian consultation may be required.)	• Encourage the patient to eat small, nutrient-dense foods with adequate fluids frequently throughout the day to maintain nutrition and hydration as well as to conserve energy. The family or caregiver may need to prepare meals, and a dietary consult may be useful.
• Continue to monitor CBC, sedimentation rate, RA factor, hepatic and renal laboratory values, glucose, electrolytes, and lipid levels.	• Instruct the patient on the need to return for periodic laboratory testing.
Minimizing adverse effects: • Instruct the patient to promptly report any worsening inflammation or pain, increased joint involvement, or overall worsening of symptoms. (Drugs for RA treat the symptoms and slow the progression of the disease but are not a cure. Acute exacerbations may require hospitalization and a change in the medication regimen.)	• Instruct the patient to promptly report any continued inflammation, pain, increased joint involvement, or general worsening of symptoms.
• Continue to monitor periodic laboratory work: CBC, coagulation panels, bleeding time, electrolytes, glucose, hepatic and renal function tests, and lipid levels. (Aspirin, salicylates, and NSAIDs affect platelet aggregation and should be monitored when used long term or if excessive bleeding or bruising is noted. Corticosteroids may affect electrolytes, glucose, and lipid levels. DMARDs may cause hemolysis, agranulocytosis, or aplastic anemia. **Lifespan:** Age-related physiologic differences may place the older adult at greater risk for adverse hepatic, renal, or cardiac effects.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor for abdominal pain, black or tarry stools, blood in the stool, hematemesis, coffee-ground emesis, dizziness, lightheadedness, or hypotension, especially if associated with tachycardia. (NSAIDs and glucocorticoids may cause GI irritation and bleeding.)	• Instruct the patient to immediately report any signs or symptoms of GI bleeding. • Teach the patient to take the drug with food or milk to decrease GI irritation. Enteric-coated tablets should be swallowed whole without chewing, crushing, or breaking. Alcohol use should be avoided or eliminated.
• Monitor for tinnitus, difficulty hearing, lightheadedness, or difficulty with balance and report promptly. (NSAIDs and salicylates may be ototoxic and cause hearing loss.)	• Instruct the patient to immediately report any signs or symptoms of ringing, humming, buzzing in ears, difficulty with balance, dizziness, vertigo, or nausea.
• Monitor urine output and renal function studies periodically. Weigh the patient on corticosteroids daily and report weight gain of 1 kg (2 lb) or more in a 24-h period or more than 2 kg (5 lb) per week, or increasing peripheral edema. (NSAIDs and salicylates may be nephrotoxic. Patients on long-term or high-dose therapy should monitor urine output and have periodic renal function studies. Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses.)	• Instruct the patient on NSAIDs and salicylates to report any changes in the quantity of urine output, darkening of urine, or edema promptly. • Teach the patient on NSAIDs and salicylates to increase fluid intake, especially if fever is present. • Instruct the patient to weigh self daily, ideally at the same time of day. The patient should report a weight gain of more than 1 kg (2 lb) in a 24-h period or more than 2 kg (5 lb) per week, or increasing peripheral edema.
• Observe for skin rashes, fever, stomatitis, flulike symptoms, or general malaise. (Bone marrow suppression may occur with corticosteroids or DMARDs and result in an increased risk of infection.)	• Teach the patient to immediately report any flulike symptoms, fever, mouth irritation or soreness, or skin rashes.
• Periodically monitor vision in patients on NSAIDs or DMARDs. Immediately report unusual changes in visual acuity, blurred or diminished vision, reports of spots in vision, difficulty reading, blacked-out areas of the vision field, or changes to color sense to the provider. (NSAIDs may cause blurred or diminished vision, decreased color sense, diplopia, or scotomas. DMARDs may cause significant retinal changes with blurred vision, difficulty reading, photophobia, or blacked-out areas of the vision field.)	• Teach the patient on NSAIDs or DMARDs to obtain eye examinations twice yearly or more frequently as instructed by the provider. Immediately report any sudden changes in vision.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken with food or meals or with additional fluids, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

CONNECTION Checkpoint 72.3

Chloroquine (Aralen) and hydroxychloroquine (Plaquenil) are very similar, and both may be used to treat malaria. From what you learned in Chapter 53, what organism causes malaria? Describe how these drugs are used for prophylaxis of malaria. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Gout and Hyperuricemia

72.11 Gout is treated with drugs that decrease joint pain and inflammation and lower uric acid levels.

Gout is a form of acute arthritis caused by an accumulation of uric acid (urate) crystals in the joints and other body tissues, causing inflammation. Between 1% and 3% of the U.S. population are affected by gout. Of patients with gout 90% are men, who first manifest symptoms between the ages of 30 and 60; women are affected after menopause.

Gout may be classified as primary or secondary. Primary gout is caused by genetic errors in the metabolism of purines. Uric acid is a waste product created by the metabolic breakdown of the nucleic acids DNA and RNA. The kidneys are responsible for excreting uric acid. High levels of uric acid crystals may result from an increased metabolism of nucleic acids or the reduced excretion of uric acid by the kidneys. Primary gout may therefore be viewed as an imbalance in the handling of uric acid by the body. The production of uric acid crystals exceeds the excretion capability of the kidneys. Primary gout is inherited as an X-linked trait; males inherit the disorder through female carriers.

Secondary gout is caused by diseases or drugs that increase the metabolic turnover of nucleic acids or that interfere with the excretion of uric acid. Some examples of drugs that may cause gout include thiazide diuretics, aspirin, cyclosporine, and alcohol, when ingested on a chronic basis. Conditions that can cause secondary gout include diabetic ketoacidosis, hypothyroidism, multiple myeloma, CKD, and diseases associated with a rapid cell turnover such as leukemia, hemolytic anemia, and polycythemia.

The primary diagnostic criterion for gout is the serum uric acid level. **Hyperuricemia** is defined as a serum uric acid level of 7 mg/dL. Patients with mild hyperuricemia are asymptomatic. Once the level of uric acid rises to saturation levels in body fluids, urate crystals form and symptoms appear, usually with a sudden onset.

Acute gouty arthritis occurs when needle-shaped uric acid crystals accumulate in joints, resulting in extremely painful, red, and inflamed tissue. Attacks have a sudden onset, often occur at night, and may be triggered by ingestion of alcohol, dehydration, stress, injury to the joint, or fever. Gouty arthritis most often occurs in the big toes, heels, ankles, wrists, fingers, knees, or elbows and may be accompanied by an elevated temperature. With chronic gout, bumps called tophi, or deposits of sodium urate crystals in the subcutaneous tissue, may be present, particularly on the outer ear, arms, and fingers. Deposits of urate crystals in the kidneys may lead to the development of urinary calculi and kidney failure. Nephrolithiasis occurs in 10% to 25% of patients with gout and is more likely to occur in patients with low fluid intake and when the urine is acidic.

Gout may be difficult to diagnose because early symptoms may be vague. Although most people with gout have hyperuricemia, the serum levels of uric acid may be normal even during an acute attack. To confirm a diagnosis, a synovial fluid analysis may be performed to evaluate for the presence of uric acid crystals or to rule out synovial fluid infection as the cause of the symptoms.

In its early phases, treatment of gout is very successful. The goals of gout pharmacotherapy are threefold:

- Termination of acute episodes
- Prevention of future gout attacks
- Avoidance of the formation of gout complications, such as tophi and kidney stones.

Combination therapy using anti-inflammatory drugs and uric acid inhibitors such as probenecid (Probalan), febuxostat (Uloric), and allopurinol (Lopurin, Zyloprim) is the mainstay of gout therapy. Uric acid inhibitors block the accumulation of uric acid in the blood or uric acid crystals within the joints. When uric acid accumulation is blocked, the symptoms associated with gout diminish. These drugs are most effective when taken within the first 12 hours of an acute attack. About 80% of the patients using uric acid inhibitors experience GI complaints such as abdominal cramping, nausea, vomiting, and diarrhea. Drugs for gout are listed in Table 72.8.

NSAIDs are the preferred drugs for treating the pain and inflammation of acute episodes of gout. Commonly used NSAIDs include indomethacin (Indocin) and naproxen (Naprosyn), which are taken PO every day. Aspirin should be avoided because it can increase uric acid levels and worsen symptoms. Corticosteroids may be used to treat exacerbations of acute gout, particularly when the symptoms are in a single joint and the medication can be delivered intra-articularly. The most commonly used corticosteroid is prednisone. Most patients report that symptoms improve within a few hours of treatment and that an acute episode terminates within a week.

Prophylaxis of gout includes dietary management, avoidance of drugs that worsen the condition, and therapy with antigout medications. Patients should avoid high-purine foods such as organ meats, legumes, alcoholic beverages, mushrooms, and oatmeal because these foods form

Table 72.8 Drugs for Gout

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
allopurinol (Lopurin, Zyloprim)	PO (primary): 100 mg/day (max: 800 mg/day) PO (secondary): 200–800 mg/day IV: 200–400 mg/m^2/day	*Drowsiness, skin rash, diarrhea* Severe skin reactions, bone marrow depression, hepatotoxicity, kidney failure
colchicine (Colcrys)	PO for prophylaxis: 0.5 mg once or twice daily PO for gout flare: 1.2 mg followed by another dose of 0.6 mg 1 h later	*Nausea, vomiting, diarrhea, GI upset* Bone marrow depression, aplastic anemia, leukopenia, thrombocytopenia, agranulocytosis, severe diarrhea, nephrotoxicity
febuxostat (Uloric)	PO: 40–80 mg once daily	*Liver enzyme elevation, nausea, arthralgia, rash* Thromboembolism, gout flare
lesinurad (Zurampic)	PO: 200 mg once daily	*Headache, influenza, increased blood creatinine, gastroesophageal reflux disease.* Acute kidney failure, major cardiovascular events
pegloticase (Krystexxa)	IV: 8 mg q2wk	*Gout flare, nausea, ecchymosis, nasopharyngitis* Anaphylaxis, infusion reaction, worsening heart failure
probenecid (Probalan)	PO: 250 mg bid for 1 wk, then 500 mg bid (max: 3 g/day)	*Nausea, vomiting, headache, anorexia, flushed face* Anaphylaxis, severe skin reactions, hepatotoxicity, anemia, aplastic anemia, leukopenia

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

nucleic acids when they are metabolized. Patients should avoid aspirin, niacin, and diuretics because their use can precipitate an acute episode of gout. Renal complications may be avoided by adequate fluid intake and consumption of a low-protein diet.

PROTOTYPE DRUG Colchicine (Colcrys)

Classification **Therapeutic:** Antigout drug
Pharmacologic: Anti-inflammatory drug

Therapeutic Effects and Uses: Colchicine is a natural product obtained from the autumn crocus, which is grown in gardens and found in meadows throughout the United States and Canada. It has been used for centuries as a natural product. Although first available by prescription prior to 1938, colchicine was not officially approved by the FDA until 2009. The trade-name form, Colcrys, is approved for the treatment and prophylaxis of acute gout flares and for familial Mediterranean fever.

Although NSAIDs have largely replaced colchicine as first-line therapy, it is prescribed for some patients with acute gouty arthritis. It is much more effective if taken within 24 hours of the onset of symptoms. Colchicine has several off-label indications that include amyloidosis, Paget's disease, hepatic cirrhosis, and Mediterranean fever.

Although colchicine has no analgesic properties, patients experience pain relief due to the reduction in inflammation. Low doses of colchicine may be used as prophylactic therapy for gouty arthritis in patients with normal or slightly elevated serum uric acid levels. Should the patient note the onset of an acute episode, the dose can be increased until symptoms subside. It is important to understand, however, that colchicine does not inhibit uric acid synthesis and does not promote uric acid excretion. Thus, if the patient has escalating serum uric acid levels, allopurinol and sulfinpyrazone are the preferred drugs for prophylaxis (see Section 72.12). Patients who are on colchicine prophylaxis therapy may discontinue the drug after they have been symptom free for a year and have normal serum uric acid levels. In some patients, discontinuation may precipitate an acute gout episode.

Mechanism of Action: Colchicine inhibits the migration of neutrophils into the area of inflammation. This drug reduces the inflammation associated with acute gouty arthritis by inhibiting the synthesis of microtubules, which are the subcellular structures responsible for helping white blood cells infiltrate an area.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Widely distributed; concentrated in leukocytes, kidney, liver, spleen, and intestinal tract
Primary metabolism	Hepatic
Primary excretion	Feces
Onset of action	12 h
Duration of action	Half-life: variable (1.7–20.9 h)

Adverse Effects: The most significant adverse effects of colchicine are GI related and these may occur in up to 80% of patients. Adverse effects include nausea, vomiting, abdominal pain, anorexia, and diarrhea. This drug may cause bone marrow toxicity, and aplastic anemia, leukopenia, thrombocytopenia, or agranulocytosis may occur. Additional adverse effects include hepatotoxicity, mental confusion, azotemia, proteinuria, hematuria, and oliguria. Severe irritation and tissue damage may occur if the IV formulation leaks around the injection site.

Contraindications/Precautions: This drug is contraindicated in patients with a known hypersensitivity to colchicine, and in those with CKD, pregnancy, or GI, hepatic, or cardiac impairment. Patients with blood dyscrasias should not receive colchicine. Colchicine should be used with caution in older adults and debilitated patients, or in patients with an early manifestation of GI, renal, hepatic, or cardiac disease.

Drug Interactions: Concurrent use with NSAIDs may increase the risk of serious GI symptoms. Colchicine may exhibit additive bone marrow toxicity with cyclosporine, phenylbutazone, and other drugs that adversely affect bone marrow. Erythromycin may increase serum colchicine levels. Loop diuretics may decrease colchicine effects. Alcohol or products that contain alcohol may cause skin rashes and result in additive liver damage. Colchicine may increase a patient's sensitivity to CNS depressants. Colchicine may also directly interfere with the absorption of vitamin B_{12}. **Herbal/Food:** Alcohol and foods that are rich in purines, including salmon, sardines, and organ meats, should be avoided. Foods that cause the urine to become more alkaline, such as milk, fruits, carbonated drinks, most vegetables, molasses, and baking soda, may increase the risk of kidney stones.

Pregnancy: Category C (PO) or D (IV).

Treatment of Overdose: Overdoses (including unintentional ingestion of autumn crocus) may cause severe GI distress, shock, paralysis, delirium, respiratory failure, and death. Treatment is symptomatic and may include gastric lavage and hemodialysis.

Nursing Responsibilities: Key nursing implications for patients receiving colchicine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Gout.

Drugs Similar to Colchicine (Colcrys)

Colchicine is the only drug in this class.

PharmFACT

Pseudogout is a type of arthritis that can cause symptoms similar to gout but involves accumulation of a different type of crystal: calcium pyrophosphate. The patient is treated with analgesics or anti-inflammatory drugs; no therapy is available to dissolve these types of crystals (Saadeh, 2016).

72.12 Hyperuricemia is treated with drugs that reduce serum levels of uric acid.

Many patients with increased uric acid levels are asymptomatic. In most cases, pharmacotherapy is not indicated for asymptomatic patients. For patients with repeated acute episodes of chronic gout, however, prophylactic pharmacotherapy should be used to lower serum uric acid levels. Prophylaxis may be obtained by blocking the formation of uric acid or by increasing its excretion.

Allopurinol (Lopurin, Zyloprim) is a preferred drug for gout *prophylaxis*. Allopurinol acts by inhibiting **xanthine oxidase**, which is the enzyme responsible for the formation of uric acid. Blocking the synthesis of uric acid will lower serum uric acid levels, thus preventing gout. It is also used in patients with CKD or those who have renal obstruction caused by uric acid stones.

Uricosurics are drugs that increase the rate of excretion of uric acid by blocking its reabsorption in the kidney. These drugs are most effective in preventing hyperuricemia associated with chronic gout and should not be used to treat acute attacks of gouty arthritis. The uricosuric drugs have no analgesic or anti-inflammatory properties. Probenecid (Probalan) is an older uricosuric drug used for gout prophylaxis. This drug may precipitate acute gout during the period of initial therapy because it mobilizes uric acid that has been stored in the body. Concurrent administration of colchicine can help prevent this adverse effect.

Lesinurad is a newer uricosuric that offers fewer adverse effects and drug interactions than probenecid. It is approved only in combination with a xanthine oxidase inhibitor such as allopurinol. Drugs for hyperuricemia and gout are listed in Table 72.8.

Acute hyperuricemia can occur following antineoplastic therapy as part of a serious condition called tumor lysis syndrome when cancer cells are broken down. The massive load of uric acid crystals can result in acute kidney failure and possibly death. Rasburicase (Elitek) is a recombinant form of the enzyme urate oxidase, which can lower serum uric acid levels when given IV to patients receiving antineoplastic therapy.

PROTOTYPE DRUG **Allopurinol (Lopurin, Zyloprim)**

Classification **Therapeutic:** Antigout drug
Pharmacologic: Xanthine oxidase inhibitor

Therapeutic Effects and Uses: Allopurinol is an older drug that was approved in 1966 for gout and its complications. It controls the hyperuricemia that causes severe gout and reduces the possibility of flare-ups of acute gouty

attacks. It is also approved to prevent recurrent nephrolithiasis due to calcium oxalate stones in patients with elevated uric acid levels. It may be used prophylactically to reduce the severity of the hyperuricemia associated with antineoplastic and radiation therapies, both of which increase plasma uric acid levels by promoting nucleic acid degradation. This drug takes 1 to 3 weeks to bring serum uric acid levels to within the normal range.

Allopurinol is available by the PO and IV routes. IV administration is usually reserved for patients with high uric acid levels resulting from cancer chemotherapy. In 2017 Duzallo, a fixed-dose combination of allopurinol and lesinurad, was approved to treat symptomatic gout.

Mechanism of Action: Allopurinol reduces uric acid formation by selectively inhibiting the action of xanthine oxidase, which is the enzyme responsible for the formation of uric acid. Lowering the formation of uric acid prevents hyperuricemia. Unlike the uricosuric drugs, allopurinol does not increase the renal excretion of uric acid.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	80–90% absorbed in the GI tract
Distribution	Widely distributed; secreted in breast milk; less than 1% bound to plasma proteins
Primary metabolism	Hepatic to the active metabolite oxypurinol
Primary excretion	Primarily renal
Onset of action	24–48 h
Duration of action	1–3 weeks after drug is discontinued

Adverse Effects: The most frequent and serious adverse effects are dermatologic, including micropapular rash, rare cases of fatal toxic epidermal necrolysis, and Stevens–Johnson syndrome. A rare, sometimes fatal, hypersensitivity syndrome may occur and includes a skin rash, fever, hepatitis, leukocytosis, eosinophilia, and progressive kidney failure. Other adverse effects include drowsiness, headache, vertigo, nausea, vomiting, malaise, diarrhea, cataracts, retinopathy, and thrombocytopenia.

Contraindications/Precautions: Contraindications include hypersensitivity to allopurinol and idiopathic hemochromatosis. Use cautiously in patients with CKD or impaired hepatic function, history of peptic ulcers, lower GI tract disease, bone marrow depression, and pregnancy.

Drug Interactions: Alcohol may inhibit the renal excretion of uric acid. Ampicillin and amoxicillin may increase the risk of skin rashes. An enhanced anticoagulant effect may be seen with the use of warfarin, and toxicity risks increase for azathioprine, mercaptopurine, cyclophosphamide, and cyclosporine. An increased hypoglycemic effect may be seen with chlorpropamide. The risk of ototoxicity is increased when allopurinol is used with thiazides and angiotensin-converting enzyme (ACE) inhibitors. Aluminum antacids taken concurrently with allopurinol may decrease its effects. An increased effect may be seen with phenytoin, theophylline, and anticancer drugs, necessitating the need for altered doses of these medications. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with allopurinol is rare. There is no specific treatment for an overdose and the patient is treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving allopurinol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Gout.

Drugs Similar to Allopurinol (Lopurin, Zyloprim)

Additional drugs for gout prophylaxis and hyperuricemia include febuxostat, lesinurad, pegloticase, and probenecid. Sulfinpyrazone is a uricosuric medication than has been discontinued in the United States.

Febuxostat (Uloric): An alternative to allopurinol, febuxostat was approved in 2009 for the chronic management of hyperuricemia in patients with gout. The drug acts by inhibiting xanthine oxidase and offers the convenience of once-daily dosing. Unlike some of the other medications in this class, febuxostat exhibits little nephrotoxicity or dermatologic toxicity. Liver function tests should be monitored periodically to prevent the development of hepatotoxicity. It should not be administered concurrently with drugs metabolized by xanthine oxidase such as mercaptopurine or azathioprine because these drugs could accumulate to toxic levels. Febuxostat is pregnancy category C.

Lesinurad (Zurampic): Lesinurad is a uricosuric medication approved in 2015. It is indicated when pharmacotherapy has been unable to lower uric acid to target levels by the use of a xanthine oxidase inhibitor alone. Lesinurad is more selective at blocking uric acid transporters in the kidney than probenecid, thus it produces fewer drug interactions. It must be administered concurrently with a xanthine oxidase inhibitor such as allopurinol. It is important for the patient to remain well hydrated during therapy. This drug contains a black box warning that acute kidney failure has occurred with this medication. Lesinurad has not been assigned a pregnancy rating.

Pegloticase (Krystexxa): Approved in 2010, pegloticase is a synthetic enzyme that metabolizes uric acid to an inert substance. It is used to lower uric acid levels in patients

with chronic gout who have not responded well to conventional therapies. It is administered over a 2-hour period by IV infusion, once every 2 weeks. The drug has a black box warning that anaphylaxis may occur during and after the infusion, and emergency equipment should be readily available to address such a reaction. Patients should also be pretreated with antihistamines and corticosteroids. Other common adverse effects include gout flares at the initiation of therapy, infusion reactions, nausea, ecchymosis, nasopharyngitis, and worsening of heart failure. This drug is pregnancy category C.

Probenecid (Probalan): Probenecid is an older drug approved in 1951 that inhibits the reabsorption of uric acid in the kidneys, thus increasing its renal excretion. Given PO, it is effective for prophylaxis but will not terminate acute gout episodes. Probenecid should be taken with meals to decrease gastric irritation. Several combination drugs that contain probenecid and colchicine are available for long-term maintenance therapy. Adverse effects are generally minor and include headache, nausea, vomiting, and anorexia. This drug is pregnancy category C.

Unrelated to its use in treating gout, probenecid blocks the transport of organic acids in the renal tubule. When given concurrently with antibiotics such as penicillins or cephalosporins, the serum levels of antibiotics will be boosted, making them more effective. Because of its effect on renal transport mechanisms, probenecid has the potential to interact with virtually any acidic drug. A drug guide should be consulted when administering probenecid to patients who are taking multiple medications.

The mobilization of uric acid may also cause or worsen kidney stones due to the increased amount of uric acid being excreted by the kidneys. To prevent these adverse effects of early therapy, the uricosurics are started at low doses and increased gradually over several weeks. During this initial therapy, the urine may be made more alkaline by the administration of sodium bicarbonate to prevent uric acid crystals from forming.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Gout

Assessment

Baseline assessment prior to administration:

- Understand the reason the drug has been prescribed in order to assess for therapeutic effects (e.g., decreasing acute inflammatory stage, preventing recurrence).
- Obtain a complete health history including musculoskeletal, GI, cardiovascular, neurologic, endocrine, hepatic, or kidney disease.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, or smoking. Be alert to possible drug interactions.
- Obtain a history of any current symptoms and their effect on ADLs. Assess for inflammation and location, and note any pain or discomfort on movement or at rest.
- Obtain a dietary history, noting correlations between food intake and increase in symptoms. Assess fluid intake.
- Obtain baseline weight and vital signs.
- Evaluate appropriate laboratory findings (e.g., uric acid level, CBC, hepatic and renal function studies, urinalysis).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., symptoms of acute inflammation are diminished or absent, no return of symptoms).
- Continue monitoring vital signs and urine output.
- Continue to monitor uric acid level, CBC, hepatic and renal studies.
- Assess for and promptly report adverse effects: nausea, vomiting, abdominal pain, skin rash, pruritus, paresthesia, diminished urine output, fever, or infections.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Review the dietary history with the patient, noting any correlation between diet and symptoms, especially after ingestion of purine-containing foods (e.g., salmon, sardines, organ meats, alcohol, mushrooms, legumes, oatmeal). Avoid large doses of vitamin C. (Gout may occur due to overproduction or underexcretion of uric acid or a combination of both. Correlating symptoms to intake of high-purine foods assists in determining the most effective drug therapy. Large doses of vitamin C may acidify the urine, leading to formation of uric acid stones.)	• Encourage the patient to keep a food diary, noting any occurrence or increasing of symptoms related to food or beverage intake. • Teach the patient to limit intake of high-purine foods and to limit or eliminate alcohol consumption.
• Increase fluid intake to 2–4 L/day. Monitor urine output and obtain periodic urinalysis. (Increased fluid intake will help increase uric acid excretion and prevent urinary uric acid crystal formation or renal calculi.)	• Teach the patient to increase fluid intake to 2–4 L/day, taken throughout the day.
• Continue to monitor serum and urinary uric acid levels, and note improvement in symptoms of acute inflammation, gouty tophi, and improved movement with less pain in affected joints. (As uric acid levels decrease, inflammation due to uric acid crystals should improve.)	• Encourage the patient to maintain consistent drug dosing to ensure that uric acid levels are diminishing. • Instruct the patient on the need to return for periodic laboratory testing and urinalysis.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Monitor serum and urinary uric acid levels and symptoms associated with acute inflammatory period. (Decreased uric acid levels should decrease the amount of inflammation. Continued or increasing inflammation may indicate a need for additional antigout or anti-inflammatory medication.)	• Instruct the patient to promptly report any continued inflammation, pain, increased joint involvement, or general worsening of symptoms.

• Monitor daily weight and urinary output. Record intake and output in the hospitalized patient. Immediately report any flank pain to the provider. (Uric acid excretion may cause urate crystal formation in the kidneys with resulting kidney impairment. Daily weight is an accurate measure of overall body fluid volume and any gain of over 1 kg [2 lb] per day should be reported. Flank pain may indicate the presence of renal calculi.)	• Instruct the patient to:
	  • Report any diminished urine output or changes in urine appearance, and to return periodically for urinalysis.
	  • Weigh self daily at the same time and report any weight gain of over 1 kg (2 lb) in a 24-h period to the healthcare provider.
	  • Immediately report any flank pain to the provider.

• Continue to monitor periodic hepatic and renal laboratory work. (**Lifespan:** Age-related physiologic differences may place the older adult at greater risk for hepatic and nephrotoxicity.)	• Instruct the patient on the need to return periodically for laboratory work.
• Decrease intake of purine-containing foods (e.g., salmon, sardines, organ meat, mushrooms, legumes, oatmeal, and alcohol). Avoid large doses of vitamin C. (Intake of high-purine foods and alcohol may increase production of uric acid. Large doses of vitamin C may acidify the urine, leading to formation of uric acid stones.)	• Teach the patient to avoid high-purine foods, decrease or eliminate alcohol consumption, and avoid increased vitamin C intake or supplementation. Provide dietitian consult as needed.
• Observe for skin rashes, fever, stomatitis, flulike symptoms, or general malaise. (Bone marrow suppression may occur with antigout drugs and result in leukopenia and an increased risk of infection. Severe dermatologic reactions are possible and any skin rashes, especially with the appearance of blisters and discoloration, should be reported immediately.)	• Teach the patient to immediately report any flulike symptoms, fever, mouth irritation or soreness, or skin rashes.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taken on an empty stomach or with meals or additional fluids, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs including taking medications at the first sign of a gout attack. • Colchicine should be taken on an empty stomach. Other antigout medications should be taken with food or meals.

Understanding Chapter 72

Key Concepts Summary

72.1 Adequate levels of calcium in the body are necessary to transmit nerve impulses, to prevent muscle spasms, and for proper bone health.

72.2 Calcium balance is regulated by parathyroid hormone, calcitonin, and vitamin D.

72.3 Hypocalcemia and hypercalcemia are treated with nutritional adjustments or with pharmacotherapy.

72.4 Metabolic bone disease is characterized by abnormal bone structure.

72.5 Vitamin D therapy is indicated for treating osteomalacia, hypoparathyroidism, and osteoporosis.

72.6 Bisphosphonates increase bone density and are used to treat osteoporosis and Paget's disease.

72.7 Selective estrogen receptor modulators increase bone mass density and prevent fractures in postmenopausal women.

72.8 Calcitonin and several miscellaneous drugs are used for osteoporosis and other metabolic bone diseases.

72.9 Osteoarthritis is treated with a combination of analgesics and nonpharmacologic therapies.

72.10 Pharmacotherapy for rheumatoid arthritis includes analgesics, anti-inflammatory drugs, corticosteroids, and disease-modifying antirheumatic drugs.

72.11 Gout is treated with drugs that decrease joint pain and inflammation and lower uric acid levels.

72.12 Hyperuricemia is treated with drugs that reduce serum levels of uric acid.

CASE STUDY: Making the Patient Connection

Remember the patient "Charlene Coleman" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Charlene Coleman is a 65-year-old Black woman who is generally in good health. She has scheduled a routine checkup visit with her healthcare provider. While assessing Charlene's vital signs, height, and weight, the nurse notes a significant deviation from the data recorded during last year's visit. Apparently, the patient has lost 2.5 cm (1 in.) in height during the last year. When the nurse shares this information, Charlene states, "I have always been short. You should see my mother who is much shorter than I am. But lately, my clothes just don't seem to fit. I haven't lost any weight, but my pant legs drag on the ground. Is it possible that I'm actually getting shorter?"

Critical Thinking Questions

1. As the nurse, how would you respond to the patient's statement?
2. As you talk with Charlene, she asks you, "Is there any way to slow my declining height?" What could you recommend?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

A female patient, age 56, has been ordered methotrexate (Otrexup, Rheumatrex, Trexall) and etanercept (Enbrel) for treatment of severe RA. She wants her daughter to administer the etanercept because of limitations due to arthritis-related deformities in her hands. The daughter is worried about giving her mother the medication.

1. How is etanercept (Enbrel) given? How often?
2. What instructions should the nurse give the daughter about administering this medication?
3. What potential adverse effects may occur in addition to those related to the injection itself?
4. What is the drug classification for methotrexate? What are potential adverse effects for this drug?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient who has been prescribed alendronate (Fosamax) demonstrates an understanding of how to correctly take the medication when stating:
    1. "I will take my medication prior to eating my lunch or dinner."
    2. "I will take my medication immediately before bedtime or at 9 p.m."
    3. "I will take my medication with a full glass of water 30 minutes before breakfast."
    4. "I should lie flat for at least 30 minutes after I take this medication."

2. Which of the following symptoms would alert the nurse to the possibility of the development of toxicity to methotrexate (Otrexup, Rheumatrex, Trexall)?
   1. Headache, dizziness, and blurred vision
   2. Hematuria, hiccoughs, and jaundice
   3. Stomatitis, constipation, and dyspepsia
   4. Jaundice, ascites, and edema formation

3. The patient asks the nurse to explain how colchicine (Colcrys) works. The nurse would base the response on which physiologic principle?
   1. It increases the deposits of uric acid in the synovial spaces of the joints.
   2. It reduces the pain associated with joint inflammation from gouty arthritis.
   3. It prevents the accumulation of uric acid crystals in the joints.
   4. It increases renal excretion of uric acid crystals.

4. Which laboratory findings would the nurse monitor to determine if pharmacotherapy is helping a patient taking calcium supplementation for osteomalacia?
   1. Increasing serum calcium and increasing phosphate levels
   2. Increasing serum calcium and decreasing phosphate levels
   3. Decreasing serum calcium and increasing phosphate levels
   4. Decreasing serum calcium and decreasing phosphate levels

5. Which assessment findings in a patient who is receiving calcitriol (Rocaltrol) should the nurse immediately report to the prescriber?
   1. Muscle weakness, nausea, and vomiting
   2. Diarrhea, abdominal pain, and stomatitis
   3. Bone pain, joint stiffness, and fever
   4. Photosensitivity, tinnitus, and bone pain

6. A patient with rheumatoid arthritis will begin treatment with adalimumab (Humira). Which of the following statements related to this therapy is correct? (Select all that apply.) Adalimumab:
   1. May lower immune response and increase the risk of infections and malignancies.
   2. Is associated with osteoporosis and baseline and periodic dual-energy x-ray absorptiometry (DEXA) scans should be conducted.
   3. May reactivate latent TB.
   4. May cause local injection-site irritations such as pain and bruising.
   5. Must be taken daily for up to 6 months.

"I hate the way my skin looks. I know people are just staring at my face and not really listening to me."
Patient "Danny McBride"

Chapter 73
Pharmacotherapy of Dermatologic Disorders

Chapter Outline

- Anatomy of the Integumentary System
- Classification of Skin Disorders
- Pharmacotherapy of Skin Infections
  Scabicides and Pediculicides
  PROTOTYPE *Permethrin (Acticin, Elimite, Nix), p. 1369*
- Pharmacotherapy of Acne and Rosacea
  PROTOTYPE *Tretinoin (Avita, Retin-A, Others), p. 1373*
- Pharmacotherapy of Dermatitis
- Pharmacotherapy of Psoriasis
- Pharmacotherapy of Minor Skin Burns
  PROTOTYPE *Benzocaine (Americaine, Anbesol, Others), p. 1384*
- Pharmacotherapy of Alopecia

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the structure and functions of the skin and associated structures.
2. Explain the process by which superficial skin cells are replaced.
3. Explain how skin diseases are classified.
4. Describe the drug therapies for bacterial, fungal, viral, and parasitic infections of the skin.
5. Explain the etiology, pathogenesis, and pharmacotherapy for acne vulgaris, rosacea, dermatitis, and psoriasis.
6. Outline the stepwise approach to treating psoriasis.
7. Describe the prevention and management of minor burns.
8. Explain the pharmacotherapy of alopecia.
9. Describe the nurse's role in the pharmacologic management of dermatologic disorders.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Apply the nursing process to the care of patients receiving pharmacotherapy for dermatologic disorders.

Key Terms

acne vulgaris, 1370
comedolytics, 1373
comedones, 1372
dermatitis, 1376

rhinophyma, 1373
rosacea, 1373
scabicides, 1369
seborrhea, 1370
urticaria, 1367

The integumentary system consists of the skin, hair, nails, sweat glands, and sebaceous glands. The largest and most visible of all organs, healthy skin provides an effective barrier between the outside environment and the body's internal tissues, helps to regulate body temperature, and assists in maintaining fluid and electrolyte balance. At times, however, environmental conditions damage the skin, or conditions within the body change, resulting in unhealthy skin. Some of these changes can even lead to systemic changes that affect tissues outside the integumentary system. When this occurs, pharmacotherapy may be utilized to improve the skin's condition. The purpose of this chapter is to examine the broad scope of skin disorders and the drugs used for skin pharmacotherapy.

Anatomy of the Integumentary System

73.1 Three layers of skin, known as the epidermis, dermis, and subcutaneous layers, provide effective barrier defenses for the body.

To understand the actions of dermatologic drugs, it is necessary to have a thorough knowledge of the structure of the skin. The skin comprises three primary layers: the epidermis, dermis, and subcutaneous layers, as illustrated in Figure 73.1. The epidermis is the visible, outermost layer that constitutes only about 5% of the skin depth. The middle layer is the dermis, which accounts for about 95% of the entire skin thickness. The subcutaneous layer lies beneath the dermis. Some textbooks consider the subcutaneous layer as being separate from the skin and not one of its layers. Each layer of skin is distinct in form and function and provides the basis for how drugs are injected or topically applied.

Epidermis: The epidermis consists of epithelial cells with either four or five sublayers depending on its location. The five layers from the innermost to outermost are the stratum basale (also referred to as the stratum germinativum), stratum spinosum, stratum granulosum, stratum lucidum, and the strongest layer, the stratum corneum. The stratum corneum is referred to as the "horny layer" because of the abundance of the protein keratin, a water-insoluble material secreted by keratinocytes, which is also found in the hair, hooves, and horns of many mammals. Keratin gives the skin its tough, protective seal, forming a barrier that repels bacteria and foreign matter. Most substances cannot penetrate it. The largest amount of keratin is found in those areas subject to mechanical stress, for example, the soles of the feet and the palms of the hands.

The deepest epidermal sublayer, the stratum basale, supplies the epidermis with new cells after older superficial cells have been damaged or lost through normal wear. Over time, these newly created cells migrate from the stratum basale to the outermost layers of the skin. As these cells are pushed to the surface, they are flattened and covered with keratin. The outermost skin layer, called the stratum corneum, is composed of these dead cells. On average, it takes a cell about 2 to 3 weeks to move from the stratum basale to the body surface.

Specialized cells within the deeper layers of the epidermis, called melanocytes, secrete the dark pigment melanin. Melanin forms a protective shield, which protects the keratinocytes and the nerve endings in the dermis from the sun's ultraviolet (UV) rays. The number and type of melanocytes determine the overall pigment of the skin and determine racial differences in skin tone. Darker skin tones are not caused by an increased number of melanocytes, but by the amount of the pigment melanin that is contained in each cell. The more melanin, the darker the skin color. Freckles, birthmarks, and age spots are caused by the production of melanin. In areas where the melanocytes are destroyed, there are milk-white areas of depigmented skin referred to as vitiligo.

The junction of the epidermis and the dermis is an area of many ridges and furrows called the rete ridges. This area anchors the epidermis to the dermis. The epidermis does not have a separate blood supply. It receives its nutrients by diffusion in the rete ridges from the many blood vessels in the dermis. This surface also provides for the ripples seen on the skin surface, which on the fingertips are called fingerprints.

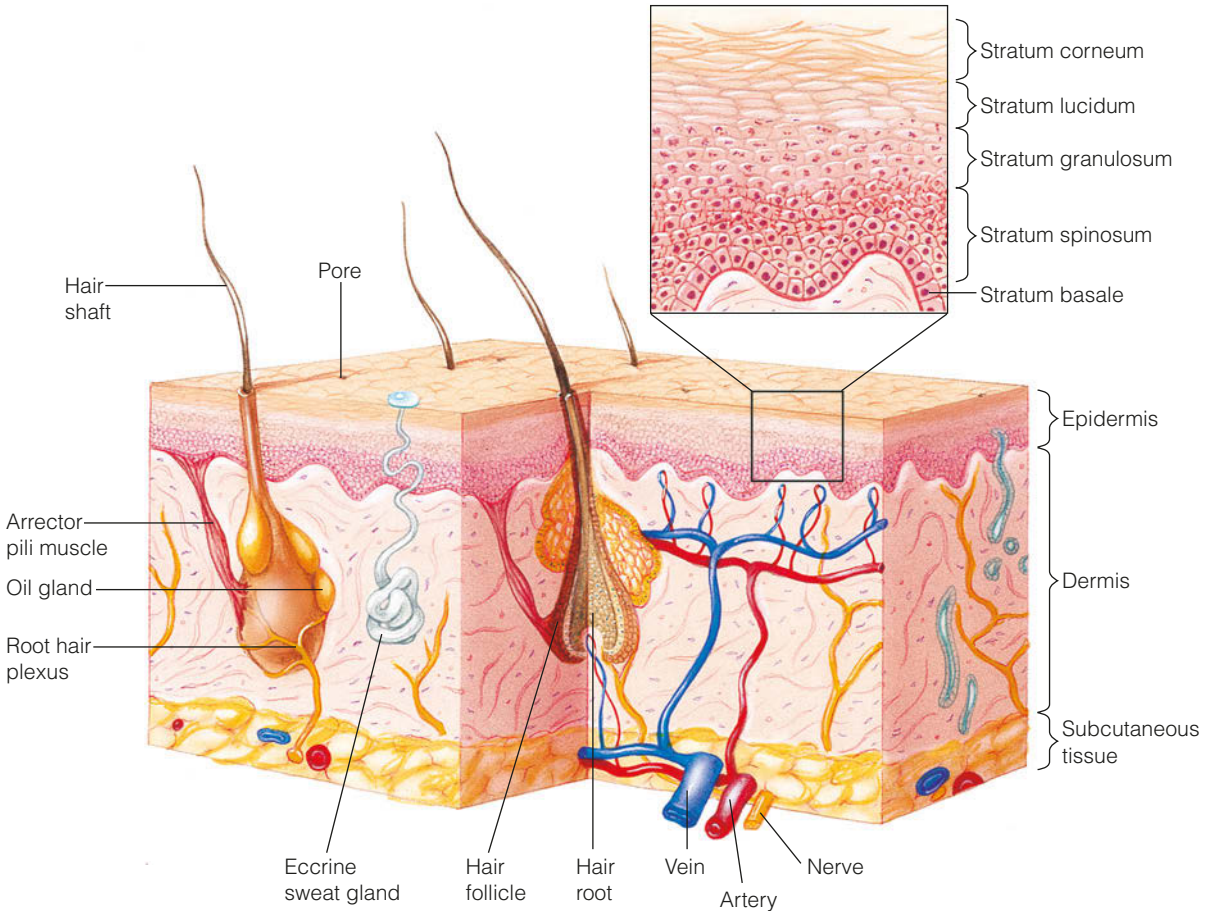

Figure 73.1 Anatomy of the skin.

Dermis: The second primary layer of skin, called the dermis, is a layer of connective tissue that contains no cells. The dermis is composed of collagen fibers and elastic fibers that give the skin both flexibility and strength. It provides a foundation for the epidermis and accessory structures such as hair and nails. Most sensory nerves that transmit the sensations of touch, pressure, temperature, pain, and itch are located within the dermis, as well as the oil glands and sweat glands. A vast network of lymph and capillary vessels is found within the dermis.

Subcutaneous tissue: Beneath the dermis is the subcutaneous tissue, or hypodermis, which lies over muscle and bone. It consists mainly of adipose tissue, which cushions, insulates, and serves as an energy reserve in the event that extra calories are needed to fuel the body. The amount of subcutaneous tissue varies in an individual and is determined by body area, sex, age, nutritional status, and heredity. Many blood vessels pass through the fatty layer and extend into the dermis, forming capillary networks that supply nutrients and remove wastes.

Skin appendages: Hair follicles are located in the dermis. Hair growth varies by race, gender, age, and heredity. Individual hairs vary in both structure and rate of growth, depending on their location. Composed primarily of dead cells, hair consists of a root that begins in the bulb of the hair follicle and grows from the dermis outward. The hair shaft is the portion that projects through the epidermis and exits the skin. Hair growth occurs in cycles; a growth phase is followed by a resting phase during which hair is shed from the body. Stressors can alter the growth cycle and cause temporary hair loss. Permanent baldness is genetic in origin and is seldom influenced by stressors. Hair color is genetically determined by an individual's rate of melanin production within the hair shaft.

The sebaceous glands are distributed over the entire skin surface, except for the palms of the hand and the soles of the feet. Most sebaceous glands are directly connected to the hair follicles; the glands of the eyelids, nipple areolae, and genitalia are freestanding. Sebaceous glands produce sebum, which is emptied into the space between the hair follicle and shaft. Sebum lubricates and softens the skin and hair and reduces water loss from the skin surface in low humidity. Sebum also is mildly bacteriostatic. The secretion of sebum is stimulated by hormones, especially androgens.

The skin has two types of sweat glands: apocrine and eccrine. The apocrine glands are directly connected to the hair follicles and are mainly found in the axillary, perineal,

nipple areolae, and umbilical areas. The interaction of skin bacteria with the milky secretions of apocrine glands causes distinct body odor. The eccrine glands are found over the entire skin surface. Their ducts open directly onto the skin surface and are not associated with hair follicles. The secretions of the eccrine glands are an important factor in the regulation of body temperature. Sweat is released from the eccrine glands in response to elevated body temperature or ambient temperature and is under control of the sympathetic nervous system.

Classification of Skin Disorders

73.2 The etiology of skin disorders may be classified as infectious, inflammatory, or neoplastic.

Of the many types of skin disorders, some have vague, generalized signs and symptoms, and others have specific and easily identifiable causes. **Urticaria** is a hypersensitivity response that is characterized by hives and is often accompanied by pruritus, or itching. Allergies to foods often manifest as urticaria. **Pruritus** is a general condition that is associated with dry, scaly skin or a parasite infestation. Pruritus may also be a sign of serious systemic pathology, such as cholestatic disease and uremia. A substantial number of drugs have urticaria or pruritus listed as potential adverse effects. Local **erythema** or redness accompanies inflammation and many other skin disorders. Inflammation is a characteristic of burns and trauma to the skin.

Skin disorders are diverse and difficult to classify because some conditions have overlapping components. For example, lesions that are characteristic of acne may be inflamed and become infected. One simple method, which is summarized in Table 73.1, is to group the disorders into the following categories:

- **Infectious.** Bacterial, fungal, viral, and parasitic infections of the skin and mucous membranes are relatively common and are frequent indications for anti-infective pharmacotherapy. A brief overview of anti-infectives most frequently prescribed for skin conditions is presented in Section 73.3, with further emphasis on parasitic infections in Section 73.4. Greater detail on the individual anti-infective drugs may be found in Chapters 46 through 54.
- **Inflammatory.** Inflammatory disorders encompass a broad range of pathology that includes acne, dermatitis, burns, and psoriasis. The pharmacotherapy of inflammatory skin disorders includes many of the drugs discussed in Chapter 41, such as corticosteroids.
- **Neoplastic.** Malignant tumors include malignant melanoma and basal cell carcinoma, which are treated with the therapies described in Chapter 57. Warts are a type of benign tumor.

Systemic disease processes that occur in the body may manifest as dermatologic signs and symptoms. Skin abnormalities, including color, size, type, and character of surface lesions, and skin turgor and moisture may have systemic causes such as chronic kidney disease (CKD), liver impairment, cardiovascular insufficiency, metastatic tumors, recent injury, and poor nutritional status.

Although there are many skin disorders, some warrant only localized or short-term pharmacotherapy. Examples include lice infestation, sunburn with minor irritation, and acne. Eczema, dermatitis, and psoriasis are more serious disorders that require extensive and more prolonged therapy.

Pharmacotherapy of Skin Infections

73.3 When the integrity of the skin is compromised, microbes can gain entrance and cause infections that require anti-infective therapy.

The skin is normally populated with microorganisms or flora that includes a diverse collection of bacteria, fungi,

Table 73.1 Classification of Skin Disorders

Type	Examples
Infectious	Bacterial infections: boils, impetigo, infected hair follicles
	Fungal infections: ringworm, athlete's foot, jock itch, nail infection
	Parasitic infections: ticks, mites, lice
	Viral infections: cold sores, fever blisters (herpes simplex), chickenpox, warts, shingles (herpes zoster), measles (rubeola), and German measles (rubella)
Inflammatory	Injury and exposure to the sun
	Combination of overactive glands, increased hormone production, and/or infection such as acne and rosacea
	Disorders with itching, cracking, and discomfort such as atopic dermatitis, contact dermatitis, seborrheic dermatitis, stasis dermatitis, and psoriasis
Neoplastic	Skin cancers: squamous cell carcinoma, basal cell carcinoma, and malignant melanoma
	Benign neoplasms include keratosis and keratoacanthoma

and viruses. The skin is very dry, and keratin is a poor energy source for microbes. Although perspiration provides a wet environment, its high-salt content discourages microbial growth. Furthermore, the outer layer is continually being sloughed off, and the microorganisms leave with the dead skin.

Bacterial skin diseases may occur when the skin is punctured or cut, or when the outer layer is abraded through trauma or removed through severe burns. Some bacteria also infect hair follicles. The most common bacterial infections of the skin are caused by *Staphylococcus* and *Streptococcus,* which are normal skin inhabitants. *Staphylococcus aureus* is responsible for furuncles (boils), carbuncles (abscesses), and other pus-containing lesions of the skin. Both *S. aureus* and *Streptococcus pyogenes* can cause impetigo, which is a superficial skin disorder that commonly occurs in school-age children. Cellulitis is an acute skin and subcutaneous tissue infection caused by *Staphylococcus* and *Streptococcus.* Folliculitis, an infection of hair follicles usually caused by *S. aureus*, is often called a "hot-tub" infection because it is acquired when water in these types of tubs is not adequately treated with chlorine.

Although many skin bacterial infections are self-limiting, some are serious enough to require pharmacotherapy. When possible, topical drugs are applied directly to the infection site. Topical medications offer the advantage of causing fewer adverse effects, and many are available over the counter (OTC) for self-treatment. If the infection is deep within the skin, affects large regions of the body, or has the potential to enter the systemic circulation, oral (PO) or parenteral therapy is indicated. Furthermore, the incidence of methicillin-resistant *S. aureus* (MRSA) skin infections is increasing. MRSA often requires pharmacotherapy with two or more antibiotics. Some of the more common topical antibiotics for skin infections include the following:

- Bacitracin ointment
- Erythromycin ointment (Eryderm, others)
- Gentamicin cream and ointment
- Metronidazole cream and lotion
- Mupirocin (Bactroban)
- Neomycin with polymyxin B (Neosporin), cream and ointment
- Tetracycline.

Fungal infections of the skin or nails such as tinea pedis (athlete's foot) and tinea cruris (jock itch) commonly occur in warm, moist areas covered by clothing. Tinea capitis (ringworm of the scalp) and tinea unguium (ringworm of the nails) are also common. These pathogens are responsive to therapy with topical OTC antifungals such as undecylenic acid (Cruex, Desenex, others). More serious fungal infections of the skin and mucous membranes, such as *Candida albicans* infections that occur in immunocompromised patients, require systemic antifungals (see Chapter 52). Clotrimazole (Lotrimin, Mycelex, others) and miconazole (Micatin) are common antifungals available as creams and lotions that are used for a variety of dermatologic mycoses. Oral fluconazole (Diflucan) is indicated for more serious fungal infections of the skin.

Certain viral infections can manifest with skin lesions. Childhood viral infections that affect the skin include varicella (chickenpox), rubeola (measles), and rubella (German measles). Usually, these infections are self-limiting and nonspecific, so treatment is directed at controlling the extent of skin lesions. Viral infections with skin lesions in adults include herpes zoster (shingles) and herpes simplex (cold sores and genital lesions). Pharmacotherapy of severe or persistent viral skin lesions may include topical or PO antiviral therapy with acyclovir (Zovirax) or other antivirals.

CONNECTION Checkpoint 73.1

From what you learned in Chapter 52, what is onychomycosis and what types of drugs are used to treat it? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Scabicides and Pediculicides

73.4 Scabicides and pediculicides are used to treat parasitic skin infestations.

Common skin parasites include mites and lice. Scabies is an eruption of the skin caused by the female mite *Sarcoptes scabiei*, which burrows into the skin to lay eggs that hatch in about 5 days. Scabies mites are barely visible without magnification. Scabies lesions most commonly occur between the fingers, on the extremities, in axillary and gluteal folds, around the trunk, and in the genital area. The major symptom is intense pruritus; vigorous scratching may lead to secondary infections. Scabies is easily spread through skin-to-skin contact and from mites living in upholstery, shared beds, and bath linens. Diagnosis is made by visual inspection of the burrows and confirmed by microscopic scrapings of the mite's ova or fecal pellets.

Over 3 million new cases of lice infestation or pediculosis are treated each year in the United States. Lice are larger than mites, measuring from 1 to 4 mm in length. They are readily spread by sharing infected hats, hairbrushes, bedding, or clothes, or by close personal contact. These parasites require human blood for survival and die within 24 hours without the blood of a human host. Lice (singular: louse) often infest the pubic area or the scalp and lay eggs, referred to as **nits**, which attach to body hairs. Head lice are referred to as *Pediculus humanus capitis*, body lice as *Pediculus humanus corporis,* and pubic lice as *Phthirus pubis*. The pubic louse is referred to as a "crab louse," because it looks like a tiny crab when viewed under the

microscope. Individuals with pubic lice will sometimes say that they have "crabs." Pubic lice may produce sky-blue macules on the inner thighs or lower abdomen. The bite of the louse and the release of its saliva into the wound both lead to intense pruritus, followed by vigorous scratching. Secondary infections can result from scratching.

The treatment of skin parasites consists of using **scabicides**, which are drugs that kill mites, or **pediculicides**, which are drugs that kill lice. Some drugs are effective against both mites and lice. The choice of drug depends on where the infestation is located as well as other factors such as age, pregnancy, or breastfeeding.

The preferred drug for lice is permethrin, a chemical derived from chrysanthemum flowers and formulated as a 1% liquid (Nix). This drug is considered the safest agent, especially for infants and children. Pyrethrin (RID, others) is a related product that also is obtained from the chrysanthemum plant. Permethrin and pyrethrin, which are also widely used as insecticides on crops and livestock, kill lice and their eggs on contact. These drugs are effective in 97% to 99% of patients, although a repeat application may be needed. Adverse effects are generally minor and include stinging, itching, or tingling. If two treatments of pyrethrin-based medications fail to eliminate the infestation, lindane or malathion (Ovide) may be prescribed. Resistant lice are most likely to appear in patients who have received multiple treatments with pyrethrin-based shampoos.

Permethrin is also a first-line drug for scabies. The 5% cream (Elimite) is applied to the entire skin surface and allowed to remain for 8 to 14 hours before bathing. A single application cures 95% of patients, although itching may continue for several weeks as the dead mites are eliminated from the skin. Crotamiton (Eurax) is an alternative scabicide that is available by prescription as a 10% cream. If the scabies is unresponsive to topical medications, the antiparasitic drug ivermectin (Sklice) may be administered as a single oral dose.

All scabicides and pediculicides must be used strictly as directed, because excessive use can cause serious systemic effects and skin irritation. Drugs for the treatment of lice or mites must not be applied to the mouth, open skin lesions, or eyes, because this will cause severe irritation.

PROTOTYPE DRUG Permethrin (Acticin, Elimite, Nix)

Classification **Therapeutic:** Antiparasitic
Pharmacologic: Scabicide, pediculicide

Therapeutic Effects and Uses: Nix is marketed as a cream, lotion, or shampoo to kill head and crab lice and mites and to eradicate their ova. A 1% lotion is approved for lice and a 5% lotion for mites. The medication should be allowed to remain on the hair and scalp 10 minutes before removal. Patients should be aware that penetration of the skin by mites causes itching, which lasts up to 2 or 3 weeks even after the parasites have been killed.

Successful elimination of parasitic infections should include removing the nits with a nit comb, washing bedding, and cleaning or removing objects that have been in contact with the head or hair.

Mechanism of Action: Permethrin affects the nervous system of the parasite, causing paralysis. Because lice are dependent on blood for survival, they die within 24 to 28 hours. It has ectoparasitic and ovicidal activity against *P. humanus capitis*, *P. pubis*, *S. scabiei* (scabies), ticks, mites, and fleas.

Pharmacokinetics:

Route(s)	Topical: 5% and 1% formulations
Absorption	Less than 2% is absorbed through intact skin
Distribution	Stored in body fat
Primary metabolism	Hepatic
Primary excretion	Urine
Onset of action	10 min
Duration of action	14 days

Adverse Effects: Permethrin causes few systemic effects. Local reactions may occur and include pruritus, rash, transient tingling, burning, stinging, erythema, and edema of the affected area.

Contraindications/Precautions: Contraindications include hypersensitivity to pyrethrins, chrysanthemums, sulfites, or other preservatives. Permethrin should be used cautiously on inflamed skin, in those with asthma, or in lactating women.

Drug Interactions: No clinically significant interactions have been documented.

Pregnancy: Category B.

Treatment of Overdose: No specific treatment for overdose with permethrin has been reported. Flush eyes well with water if the medicine unintentionally gets into the eyes.

Nursing Responsibilities: Key nursing implications for patients receiving permethrin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Lice or Mite Infestation.

Drugs Similar to Permethrin (Acticin, Elimite, Nix)

Other drugs for parasitic skin infections include crotamiton, ivermectin, lindane, malathion, and pyrethrin.

Crotamiton (Eurax): Crotamiton is a scabicide and antipruritic that is used to eradicate *S. scabiei* and relieve

itching. Available as a 10% cream or lotion, this drug should not be applied to skin that is acutely inflamed, raw, or has weeping surfaces. It should not be instilled into the eyes or mouth. If this drug comes in contact with the eyes, they must be flushed thoroughly with water. Adverse effects may include skin irritation, rash, and erythema. This drug is pregnancy category C.

Ivermectin (Sklice): Ivermectin is a drug first approved by the U.S. Food and Drug Administration (FDA) to treat helminthic infections. It is a preferred drug treating river blindness, a debilitating infection in many developing countries. In 2012, ivermectin (Sklice) was approved as a 0.5% lotion for head lice in patients 6 months of age and older. Sklice is applied to dry hair and rinsed off with water after 10 minutes. A single application is usually sufficient. Side effects are minor and include dry scalp and eye irritation if the eyes are exposed to the drug. This drug is pregnancy category C.

Lindane: Lindane is a scabicide and pediculicide in a 1% lotion or shampoo form that is applied directly to the skin to be absorbed by parasites and ova (nits), resulting in their death. This drug is used for treatment of head and crab lice and scabies infestations. Lindane should not be applied to skin that has open cuts or to mucous membranes, eyes, or face. It should be used cautiously in infants and patients with a history of seizures, human immunodeficiency virus (HIV) infections, and alcoholism. Gloves should be worn when applying the medication to reduce exposure to the skin. Although effective, this drug penetrates the skin and may cause significant adverse effects. Lindane has a black box warning that states that the drug is indicated for patients who are unresponsive to safer therapies because seizures and deaths have been reported with repeated applications. The warning also states that the drug is contraindicated in premature infants and in individuals with uncontrolled seizure disorders. Additional adverse effects include dizziness, tremors, seizures, and death. This drug is pregnancy category C.

Malathion (Ovide): Available as a 0.5% lotion, malathion kills lice and ova by poisoning the nervous system of the parasite. It is contraindicated in children under the age of 6. Care must be taken to keep this drug out of the eyes during treatment because it can cause conjunctivitis. One treatment is all that is needed when using this medication. Because the solution contains alcohol, it is flammable and needs to be kept away from any heat source such as hair dryers or cigarettes. Malathion is very toxic if swallowed. This drug is pregnancy category B.

Pyrethrin (RID): Pyrethrin is a pediculicide solution or shampoo that poisons the parasite's nervous system, resulting in paralysis and death. Pyrethrin may require a repeat application a week after the first dose. Contraindications include skin infections, abrasions, lactation, and sensitivity to the solution components. Pyrethrin is usually formulated with 4% piperonyl butoxide because this combination results in greater parasite killing. Pyrethrin should be used with caution in ragweed-sensitized patients, infants, and children. This medication is applied to infested areas that are wet, allowing it to stay in place for at least 10 minutes. The areas are then washed and rinsed with warm water. For shampoo applications, the hair is shampooed as usual then a fine-toothed comb is used to remove the lice and eggs from the hair. This drug is pregnancy category C.

Pharmacotherapy of Acne and Rosacea

73.5 The pharmacotherapy of acne includes treatment with benzoyl peroxide, retinoids, and antibiotics; pharmacotherapy for rosacea includes retinoids and metronidazole.

Acne vulgaris and rosacea are two disorders that produce similar appearing lesions on the face. Although the two conditions have some visual similarities and share a few common treatments, the pharmacotherapy of the disorders is very different.

Acne Vulgaris

Acne vulgaris, a disorder of the hair follicles and sebaceous glands, is a common condition that affects 80% of adolescents. Although acne occurs most often in teenagers, it is not unusual to find patients with acne who are older than 30 years, which is a condition referred to as mature acne or acne tardive. Acne vulgaris is more common in men but tends to persist longer in women. Acne affects approximately 17 million people in the United States, making it one of the most common skin conditions encountered by the nurse.

Although the precise cause of acne is unknown, several factors that are associated with acne vulgaris include abnormal formation of keratin that blocks oil glands and **seborrhea**, the overproduction of sebum by oil glands. The bacterium *Propionibacterium acnes* grows within oil gland openings and changes sebum to an acidic and irritating substance. As a result, small inflamed bumps appear on the surface of the skin. Other factors associated with acne include androgens, which stimulate the sebaceous glands to produce more sebum. This is clearly evident in teenage boys and in patients who are administered testosterone. Studies have indicated that dietary factors do not promote acne. Remissions tend to occur in the summer, perhaps due to more exposure of the skin to the UV rays from sunlight.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Lice or Mite Infestation

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including dermatologic and social history of recent exposure.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Assess skin areas to be treated for signs of infestation (e.g., lice or nits in hair, reddened track areas between webs of fingers, around belt, or elastic lines), irritation, excoriation, or drainage.
- Obtain baseline height, weight, and vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased visible infestation, nits are removed, skin healing is visible).
- Assess for adverse effects: localized tingling, pruritus, stinging, or burning. Promptly report any severe skin reactions or edema.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor the appropriate medication administration for optimal results. Monitor the affected area after treatment over the next 1–2 wk to ensure that the infestation has been eliminated. (Appropriate administration will optimize therapeutic effects and limit the need for retreatment.)	• Teach the patient, family, or caregiver the appropriate administration techniques.
Minimizing adverse effects: • Monitor the area of infestation over the next 1–2 wk. Reinfestations will usually appear within 1 wk and need to be retreated at that time. (Most treatments are highly effective when administered correctly. Retreatment may be needed depending on the type of infestation.)	• Instruct the patient, family, or caregiver to continue to assess the area daily for 1–2 wk and contact the healthcare provider for a second prescription if reinfestation is noted.
• Monitor family members, caregivers, or sexual contacts for infestation. Bedding and personal objects should be cleansed before reuse. (Reinfestation may recur if those in close contact with the patient are infested. Close contacts should be treated at the same time as the patient. Brushes, combs, and bedding should be washed before reuse. Vacuum cloth that cannot be washed. Children's toys that cannot be washed may be placed in a plastic bag and sealed for 2 wk. Lice and mites perish quickly once separated from a human host food source.)	• Instruct the patient, family, or caregiver to wash bedding, clothing used currently, combs, and brushes in soapy water and dry thoroughly. Vacuum furniture or fabric that cannot be cleaned to remove any errant vermin. Dry clean hats or caps that cannot be washed. Seal children's toys in plastic bags for 2 wk if they cannot be washed.
• Monitor skin condition in areas that have been treated. Promptly report any irritation, broken skin, erythema, rashes, or edema. (Skin reactions are relatively uncommon but may occur. Allergic reactions should be reported promptly.)	• Teach the patient, family, or caregiver to report any redness, swelling, itching, excoriation, or burning to the healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., use exactly as directed or per package directions. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient, family, or caregiver about the drug:
	  • Wash hair or shower to remove any residual creams or gels before applying the drug. Dry thoroughly.
	  • Apply the drug per package directions and allow it to remain in the hair or on the skin for the prescribed length of time (usually 10 minutes). Most packages contain enough drug for one treatment, although a second package may be required if the hair is long. Do not allow the drug to come in contact with eyes.
	  • Dry thoroughly after showering or shampooing the drug out of the hair or skin.
	  • Comb through the hair with a small-toothed comb to remove any remaining dead lice, nits, or nit casings.
	  • If eyelashes are infested, apply a thin coat of petroleum jelly to eyelashes once a day for 1 wk. Comb through using a small-toothed comb to remove any dead lice, nits, or nit casings.
	  • Check hair, webbings of fingers and toes, belt, or elastic waistbands for signs of reinfestation over the next week. If needed, a second application of the drug can be used after 1 wk.

PharmFACT

Although many young people believe that indoor tanning helps to clear up acne, there is no scientific evidence to support this claim. Indoor tanning is responsible for about 400,000 cases of skin cancer in the United States each year. Even one tanning session can increase the risk of developing squamous cell carcinoma by 67% and basal cell carcinoma by 29% (American Academy of Dermatology, n.d.).

Acne lesions are most frequently distributed on the face, chest, and back and include open and closed **comedones**. Blackheads, or open comedones, occur when sebum has plugged the oil gland, causing it to become black because of the presence of melanin granules. Whiteheads, or closed comedones, develop just beneath the surface of the skin and appear white rather than black. Some closed comedones may rupture, resulting in an inflammatory response. The result is seen as papules, inflammatory pustules, and cysts. Mild papules and cysts drain on their own without treatment. Deeper lesions can cause scarring of the skin. Acne is graded as mild, moderate, or severe, depending on the number and type of lesions present.

The goals of acne therapy are to treat existing lesions and to prevent or lessen the severity of future recurrences. Severe acne can cause permanent scarring of the face. Treatment for acne is directed toward the pathogenesis of the lesion and there are multiple treatment options. The regimen used depends on the extent and severity of the acne and the response of each individual patient. Mechanisms of action of antiacne medications include the following:

- Inhibit sebaceous gland overactivity
- Reduce bacterial colonization
- Prevent follicles from becoming plugged with keratin
- Reduce inflammation of lesions.

Many of the medications used for acne and related disorders are available OTC. Mild acne is treated by topical therapy with drugs such as benzoyl peroxide, topical antibiotics, and salicylic acid. Moderate to severe acne is treated with increasing strengths of tretinoin and the use of systemic antibiotics. Because of their increased toxicity, prescription medications are reserved for more severe, persistent cases. These drugs are listed in Table 73.2.

Benzoyl peroxide (Clearasil, Fostex, others) is the most common topical OTC medication for acne. Benzoyl peroxide has a **keratolytic** effect, which helps to treat acne by loosening dry skin and causing an increased shedding of the outer layer of the epidermis. In addition, this drug suppresses sebum production and exhibits antibacterial effects against *P. acnes*. Benzoyl peroxide is available as a topical lotion, cream, or gel in various percentage concentrations. Typically the patient applies benzoyl peroxide once daily and, in many instances, this is the only treatment needed. The drug is very safe, with local redness, irritation, and drying being the most common adverse effects. Although the symptoms might worsen during the early weeks of therapy, the skin usually adjusts quickly to its use. Other keratolytic drugs that are available by prescription are used for severe acne and include benzoyl peroxide with erythromycin (Benzamycin) and benzoyl peroxide with sulfur (Sulfoxyl).

In 2014 the FDA issued a drug safety communication regarding the use of OTC acne products containing benzoyl peroxide and salicylic acid. The communication warns that these drugs may cause rare, but potentially life-threatening allergic reactions. Symptoms of this reaction include throat tightness; difficulty breathing; feeling faint; or swelling of the eyes, face, lips, or tongue. The allergic reaction may occur immediately or several days after initiating therapy. New users are urged to test the product on a small patch of skin for 3 days. If no discomfort occurs, the drug may be safely applied.

Table 73.2 Drugs for Acne

Drug	Remarks
adapalene (Differin)	Retinoid-like compound used to treat acne formation
azelaic acid (Azelex, Finacea)	For mild to moderate inflammatory acne
benzoyl peroxide (Clearasil, Fostex, others)	Keratinolytic available OTC: sometimes combined with erythromycin (Benzamycin) or clindamycin (BenzaClin) for acne caused by *P. acnes*
clindamycin and tretinoin (Veltin, Ziana)	Combination product with an antibiotic and a retinoid in a gel base; for mild to moderate acne
ethinyl estradiol (Estinyl)	Oral contraceptives are sometimes used for acne; for example, ethinyl estradiol plus norgestimate (Ortho Tri-Cyclen-28)
isotretinoin (Accutane)	For severe acne with cysts or acne formed in small, rounded masses; pregnancy category X
sulfacetamide sodium (Cetamide, Klaron, others)	For sensitive skin; sometimes combined with sulfur to promote peeling, as in the condition rosacea; also used for conjunctivitis
tazarotene (Avage, Tazorac)	A retinoid drug that may also be used for plaque psoriasis; has antiproliferative and anti-inflammatory effects
tetracyclines	Antibiotics; refer to Chapter 48
tretinoin (Avita, Retin-A, others)	To prevent clogging of pore follicles; also used for the treatment of acute promyelocytic leukemia and wrinkles

Retinoids are a class of drug closely related to vitamin A. They are used in the treatment of inflammatory skin conditions, dermatologic malignancies, and acne. The topical formulations are often the first-line drugs for mild to moderate acne characterized by inflammatory cysts. Drugs in this class are called **comedolytics** because they prevent and break up the formation of clogged pores. Tretinoin (Avita, Retin-A, others) is an older drug with comedolytic action that decreases comedone formation and increases extrusion of comedones from the skin. Tretinoin also has the ability to improve photodamaged skin and is used for wrinkle removal. Other retinoids include isotretinoin (Accutane), a PO vitamin A metabolite medication that aids in reducing the size of sebaceous glands, thereby decreasing oil production and the occurrence of clogged pores. Therapy with retinoids may require 8 to 12 weeks to achieve maximum effectiveness. Common reactions to retinoids include burning, stinging, and sensitivity to sunlight. Adapalene (Differin) is a third-generation retinoid that causes less irritation than the older drugs. Epiduo is a topical drug that contains both adapalene and benzoyl peroxide. Additional retinoid-like drugs and the related compounds that are used to treat acne are listed in Table 73.2.

Antibiotics are prescribed to lessen the severe redness and inflammation associated with moderate to severe acne, especially when the acne is inflammatory and results in cysts and pustules. Oral doxycycline (Vibramycin, others), minocycline, and tetracycline, which are administered in small doses over a long period, have been the traditional antibiotics used in acne therapy. Due to their effects on teeth formation, tetracyclines should not be used in children younger than age 8. Erythromycin and clindamycin are frequently used topically and have a low incidence of adverse effects. Antibiotics are not comedolytic and resistance can develop with continued therapy. Benzamycin is a prescription product that contains erythromycin and benzoyl peroxide.

Oral contraceptives (OCs) that contain ethinyl estradiol and norgestimate are also used in pubertal girls to help clear the skin of acne by suppressing sebum production and reducing skin oiliness. Hormonal therapy is used when antibiotic therapy has proved ineffective. OCs are most effective for young women when the acne begins somewhat later than usual and tends to flare up at certain times in the menstrual cycle. Estrogen is not administered to male patients because of undesirable adverse effects, such as breast enlargement and decrease in body hair. For the actions and contraindications of oral contraceptives, see Chapter 70.

CONNECTION Checkpoint 73.2

Retinoids are derivatives of vitamin A. From what you learned in Chapter 61, what type of vitamin is vitamin A? What are some signs of toxicity due to excess amounts of this vitamin? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Rosacea

Rosacea is an inflammatory skin disorder of unknown etiology with lesions affecting mainly the face. Unlike acne, which most commonly affects teenagers, rosacea is a progressive disorder with an onset between 30 and 50 years of age. Rosacea is characterized by small papules or inflammatory bumps without pus that swell, thicken, and become painful. These lesions typically occur in the middle third of the face, including the forehead, nose, cheeks, and chin. The face takes on a reddened or flushed appearance with accompanying telangiectasia (dilation of small blood vessels). With time the redness becomes more permanent, and lesions resembling acne appear. The soft tissues of the nose may thicken, resulting in a reddened, bulbous, irregular swelling called **rhinophyma**. Disorders of the eye frequently accompany rosacea, particularly conjunctivitis, itching, edema, and keratitis.

Rosacea is exacerbated by factors such as sunlight, stress, increased temperature, and medications that dilate facial blood vessels, including alcohol, spicy foods, skin care products, and hot beverages. Rosacea affects more women than men, although men more often develop rhinophyma. Learning and avoiding the environmental triggers that worsen the symptoms of the condition may prevent rosacea flares.

The two most effective treatments for rosacea are topical metronidazole (MetroGel, MetroCream) and azelaic acid (Azelex, Finacea). Benzoyl peroxide may be applied as needed. Alternative medications include topical tretinoin (Avita, Retin-A, others), clindamycin (Cleocin-T, ClindaMax), and sulfacetamide. Tetracycline antibiotics are of benefit to patients with rosacea who have multiple pustules or ocular involvement. Severe, resistant cases may respond to isotretinoin (Accutane). Newer topical therapies include brimonidine (Mirvaso), oxymetazoline (Rhofade), and ivermectin (Soolantra), which are used to reduce the persistent redness of facial rosacea.

PROTOTYPE DRUG **Tretinoin (Avita, Retin-A, Others)**

Classification **Therapeutic:** Antiacne drug
Pharmacologic: Retinoid

Therapeutic Effects and Uses: Approved as a topical drug in 1971, tretinoin is a natural derivative of vitamin A. This drug is indicated for the early treatment and control of mild to moderate acne vulgaris. Renova is a topical form of tretinoin that is approved to treat fine facial wrinkles and hyperpigmentation associated with photodamaged skin. Tretinoin has antineoplastic actions; a PO form is approved to treat acute promyelocytic leukemia (APL) and may be prescribed off-label for skin malignancies.

Symptoms take 4 to 8 weeks to improve, and maximum therapeutic benefit may take 5 to 6 months. Because

of potentially serious adverse effects, this drug is most often reserved for cystic acne or severe keratinization disorders.

Mechanism of Action: The principal action of tretinoin is regulation of skin growth and turnover. As cells from the stratum germinativum grow toward the surface, skin cells are lost from the stratum pore openings, and their replacement is slowed. Tretinoin reverses retention hyperkeratosis and comedone formation, which are the primary events in acne pathology. The drug increases the permeability of the skin and supports conversion of follicular epithelium into a less sturdy and almost fragile condition. Tretinoin also decreases oil production by reducing the size and number of oil glands.

Pharmacokinetics:

Route(s)	Topical, PO
Absorption	Minimally absorbed from intact skin; well absorbed PO
Distribution	Secreted in breast milk; more than 95% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal; small amounts in feces
Onset of action	Unknown
Duration of action	Half-life: 0.5–2 h

Adverse Effects: Nearly all patients who use topical tretinoin will experience local effects such as redness, scaling, erythema, crusting, and peeling of the skin with temporary hypopigmentation or hyperpigmentation. Skin irritation can be severe and cause discontinuation of therapy; a lower strength solution may be necessary to limit the severity of these adverse effects. Dermatologic adverse effects resolve once therapy is discontinued. Oral therapy can also cause adverse skin effects.

For treatment of APL, very high oral doses are used and adverse effects are more serious than with topical therapy. The most common effects with PO therapy include bone pain, fever, headache, nausea, vomiting, rash, stomatitis, pruritus, sweating, and ocular disorders. Other adverse effects may include hyperlipidemia, shivering, hemorrhage, pain, dizziness, paresthesias, anxiety, insomnia, depression, cerebral hemorrhage, intracranial hypertension (HTN), hallucinations, dysrhythmias, flushing, hypotension or HTN, heart failure, visual disturbances, abdominal pain, diarrhea, constipation, dyspepsia, gastrointestinal (GI) hemorrhage, kidney impairment, dysuria, and acute kidney failure. **Black Box Warning:** Patients with APL are at high risk for serious adverse effects. About 25% of patients develop retinoic acid-APL syndrome, which is a serious condition characterized by fever, weakness, fatigue, dyspnea, weight gain, peripheral edema, respiratory insufficiency, and pneumonia. About 40% of patients develop a rapidly evolving leukocytosis, which is associated with a high risk of life-threatening complications. There is a high risk that infants will be severely deformed if this drug is administered during pregnancy.

Contraindications/Precautions: Contraindications for topical administration include eczema, exposure to sunlight or UV rays, sunburn, hypersensitivity to this drug or vitamin A preparation, and children less than 12 years of age. This drug should be used cautiously in patients who are in an occupation necessitating considerable sun exposure or weather extremes or in patients with hepatic disease. This drug may cause birth defects and is contraindicated during lactation, pregnancy, or suspected pregnancy. Pregnancy testing is advised before starting therapy in female patients of childbearing age. Oral tretinoin is contraindicated in patients who have hepatic disease, leukopenia or neutropenia, or who are hypersensitive to the drug.

Drug Interactions: Topical acne keratinolytics (sulfur, resorcinol, benzoyl peroxide, and salicylic acid) may increase inflammation and peeling; topical products that contain alcohol or menthol may cause stinging. Additive phototoxicity can occur if tretinoin is used concurrently with other phototoxic drugs such as tetracyclines, fluoroquinolone, or sulfonamides. Use of this medication with hypoglycemic drugs may lead to a loss of glycemic control and cardiovascular risk, because tretinoin raises serum triglyceride levels. Hepatotoxic drugs may cause additive liver impairment if used concurrently with PO tretinoin. **Herbal/Food:** The PO absorption of tretinoin is increased if taken with a high-fat meal.

Pregnancy: Category C (topical) and D (PO).

Treatment of Overdose: Overuse of the topical drug will lead to excessive skin drying and peeling. Symptoms of PO overdose are nonspecific and resolve with symptomatic treatment.

Nursing Responsibilities: Key nursing implications for patients receiving tretinoin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Acne and Related Skin Conditions.

Drugs Similar to Tretinoin (Avita, Retin-A, Others)

Other antiacne drugs include adapalene, azelaic acid, isotretinoin, and tazarotene.

Adapalene (Differin): Approved in 1996, adapalene is a topical acne drug that modulates the inflammation, epithelial keratinization, and differentiation of follicular cells. It is very similar to the retinoids but is reported to produce less skin irritation. Optimal results may take up to

12 weeks of therapy. Patients must be cautious with sun exposure because this drug can increase the potential for sunburn. Other adverse effects include local burning, pruritus, scaling, and peeling. Only minimal amounts of adapalene are absorbed through the skin. Safety of this drug in patients under age 12 has not been established. This drug is pregnancy category C.

Azelaic acid (Azelex, Finacea): Approved in 1995, azelaic acid is a natural product found in wheat, rye, and barley. Azelaic acid is a topical therapy that is effective for the treatment of mild to moderate acne by suppressing the growth of *P. acnes* and decreasing the proliferation of keratinocytes. It is also approved for the topical treatment of inflammatory pustules associated with rosacea. Only 4% is absorbed systemically. Adverse effects are typical of other topical antiacne drugs: local burning, pruritus, scaling, and peeling. Safety of this drug in patients under age 12 has not been established. This drug is pregnancy category B.

Isotretinoin (Accutane): Approved in 1982, isotretinoin is a PO retinoid that is the most effective drug for severe, inflammatory acne. Therapy may require several months for optimal benefit. Off-label uses include rosacea, psoriasis, and the treatment of squamous cell carcinoma of the skin. Because of potentially serious adverse effects, this drug is usually used when other therapies fail to produce satisfactory results. Isotretinoin carries a black box warning that it causes birth defects (category X), which can occur after even short courses of therapy. The warning further states that the drug has special requirements for distribution that require patients, healthcare providers, and pharmacists to register and adhere to the iPledge Program, a pregnancy risk management program. Before starting therapy, the patient must submit to two negative pregnancy tests and sign a statement of understanding about the drug's adverse effects. Each subsequent month, the pharmacist must document receipt of a negative pregnancy test and verify that two forms of effective contraception are being utilized by the patient. Males must also register with the iPledge Program because small amounts of isotretinoin are found in semen and could potentially cause birth defects in a pregnant partner. Other common adverse effects include cheilitis, epistaxis, xerostomia, hair loss, eczema, elevated serum lipid levels, myalgia, and arthralgia. Clinical depression, psychosis, and aggression have been reported.

Tazarotene (Avage, Tazorac): Approved in 1997, tazarotene is a topical retinoid derivative of vitamin A that is used for the treatment of acne, fine facial wrinkles, and psoriasis. Patients become sensitive to the sun's UV light and need to wear protective sunscreen and clothing when using this drug. Adverse effects are similar to those of topical tretinoin: local burning, stinging, erythema, and general skin irritation. This drug is metabolized in the skin to an active metabolite; small amounts are absorbed systemically. Safety of this drug in patients under age 12 has not been established. Tazarotene is pregnancy category X.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Acne and Related Skin Conditions

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including dermatologic, hepatic, or kidney disease; psychiatric disorders; pregnancy; or breastfeeding.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], lipid profiles, hepatic or renal function laboratory tests).
- Obtain baseline vital signs.
- Assess the patient's ability to receive and understand instructions. Include the family or caregiver as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., skin is clearing of acne lesions).
- Continue periodic monitoring of CBC, lipid profiles, glucose, and hepatic function tests if on a PO drug.
- Monitor vital signs at each healthcare visit.
- Monitor eye health periodically with eye examinations every 6 months while on PO drug therapy.
- Assess for adverse effects: localized skin irritation, erythema, pruritus, dry or peeling skin; dry mouth, eyes, or nose may occur if on the PO drug. Immediately report any sudden or significant changes in mood, especially depression or suicidal thoughts in patients on PO isotretinoin.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor appropriate medication administration for optimal results. (Topical treatment areas should show signs of improvement within 2–4 wk but may require up to 3–4 months of treatment. PO treatment is usually successful within one course and a second course may be delayed for several weeks to monitor continuing improvement.)	• Teach the patient appropriate administration techniques. • Advise the patient that significant improvement may take several weeks but some improvement should be noticed within a few days of treatment.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Monitor the area under topical treatment for excessive dryness and irritation. (Overcleansing or overdrying of the skin may make the condition worse. If other drying products such as benzoyl peroxide were used before treatment, a brief recovery period may be needed to avoid excessive skin irritation.)	• Teach the patient to gently cleanse the skin using a non-oily soap and avoiding vigorous scrubbing. If excessive dryness occurs, use a non-oily lotion to areas of dryness.
• Monitor patients on isotretinoin for emotional health or changes in mood. (Depression, including with suicidal ideations, has been noted as an adverse effect.)	• Instruct the patient, family, or caregiver to immediately report any signs of decreased mood, affect, depression, or expressed suicidal thoughts to the healthcare provider.
• Monitor CBC, lipid levels, and hepatic function laboratory values periodically for patients on PO medication. (Lipid levels may increase in up to 70% of patients on PO acne therapy. Hepatic toxicity is an adverse effect of PO drugs.)	• Instruct the patient to return periodically for laboratory tests. • Teach the patient to report any symptoms of abdominal or right upper quadrant discomfort or pain, yellowing of the skin or sclera, fatigue, anorexia, darkened urine, or clay-colored stools immediately.
• Monitor for vision changes. (Corneal opacities or cataracts are an adverse effect of PO antiacne medications. Dryness of eyes during treatment is common. Night vision may be diminished during treatment.)	• Instruct the patient to maintain regular eye examinations and to report any changes in visual acuity, especially with night driving. • Teach the patient that artificial tear solutions may assist in relieving eye dryness. Consult the healthcare provider if dryness is severe or increases.
• Monitor the patient's exposure to sun and UV light. Use oil-free sunscreen of SPF 15 or higher prior to any sun exposure. (Drying, skin sensitivity, and peeling skin are possible adverse effects of antiacne and antiwrinkle medications, especially for patients on tretinoin. Protection from sun exposure is essential to prevent increasing skin damage.)	• Teach the patient to use sunscreens of SPF 15 or higher and to wear protective clothing and hats to avoid sun exposure to areas under treatment for acne or wrinkles. • Teach the patient that UV light therapy from a healthcare provider is monitored, and tanning beds are not a substitute. Tanning beds should be avoided unless specifically ordered by the healthcare provider.

• Monitor adherence with iPledge requirements for patients on isotretinoin. (iPledge is required of all patients on isotretinoin before receiving a prescription or refills of the drug. It includes educational information and requires the patient to ensure that all requirements to prevent teratogenic effects have been met.)	• Instruct the patient on isotretinoin of the requirements of the iPledge mandatory program to ensure continued prescriptions, including:
	  • Women of childbearing age must use two methods of birth control while on the drug.
	  • Women of childbearing age must have two negative pregnancy tests 1 month before, during, and after drug therapy, conducted at certified laboratories. The results of these tests are submitted by the healthcare provider, along with a description of the two types of birth control used by the patient.
	  • Male patients must verify that they will use a barrier method of birth control and will not donate blood while on the drug.

Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., topical drug used appropriately, iPledge program is followed. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Gently cleanse the affected skin twice daily with non-oily soap, avoiding excessive or vigorous scrubbing.
	  • Apply a thin layer of topical cream or lotion to the affected area after cleansing the skin. Keep the drug out of the eyes. Allow to dry and avoid contact with clothing, towels, or bedding to avoid staining or bleaching.
	  • For PO medications, take in the morning, and if twice-a-day dosing is ordered, take the second dose approximately 8 h after the first.

Pharmacotherapy of Dermatitis

73.6 The most effective treatment for dermatitis is topical corticosteroids, which are classified by their potency.

Dermatitis is a general term that refers to superficial inflammatory disorders of the skin. General symptoms include local redness, pain, and pruritus. Intense scratching may lead to **excoriation**, which are scratches that break the skin surface and fill with blood or serous fluid to form crusty scales. A wide variety of factors can cause dermatitis, with different types of symptoms occurring depending on the causative agent. The three most common types that respond to topical pharmacotherapy are atopic, contact, and seborrheic. Dermatitis may be acute or chronic.

PharmFACT

About 37% of young children with severe eczema also have a food allergy. Many children no longer have eczema by the time they enter grade school (American College of Allergy, Asthma and Immunology, n.d.).

Atopic dermatitis, or **eczema**, is a chronic, inflammatory skin disorder with a genetic predisposition. Patients who present with eczema often have a family history of asthma and hay fever as well as allergies to a variety of irritants such as cosmetics, lotions, soaps, pollens, food, pet dander, and dust. About 75% of patients with atopic dermatitis have had an initial onset before 1 year of age. In those babies predisposed to eczema, breastfeeding seems to offer protection, because it is rare for a breastfed child to develop eczema before the introduction of other foods. In infants and small children, lesions usually begin on the face and scalp, and then progress to other parts of the body. A frequent and prominent symptom in infants is the appearance of red cheeks.

Contact dermatitis can be caused by a hypersensitivity response, resulting from exposure to specific natural or synthetic allergens such as plants, chemicals, latex, drugs, metals, or foreign proteins. Accompanying the allergic reaction may be various degrees of cracking, bleeding, or small blisters. See Figure 73.2.

Seborrheic dermatitis is a form of eczema that can affect patients at any age. The exact cause of seborrheic dermatitis is unknown, but hormone levels, coexisting fungal infections, nutritional deficiencies, and immunodeficiency states are associated with the disease. Seborrheic dermatitis presents as greasy, not dry, scales that affect the scalp, central face, and anterior chest, often presenting as scalp scaling, or dandruff. Other symptoms may include redness of the nasolabial fold, particularly during times of stress; blepharitis; otitis externa; and acne vulgaris. In infants, thick, greasy scales on the vertex of the scalp, commonly known as cradle cap, are seen. These scales can become more widespread, with the central face, forehead, and ears being affected.

Pharmacotherapy of dermatitis is symptomatic and involves lotions and ointments to control itching and skin flaking. Antihistamines may be used to control inflammation and reduce itching, and analgesics or topical anesthetics may be prescribed for pain relief. Atopic dermatitis can be controlled, but not cured, by medications. Part of the management plan must include the identification and elimination of allergic triggers that cause flare-ups.

Topical corticosteroids are the most effective treatment for controlling the inflammation and itching of dermatitis. Creams, lotions, solutions, gels, and pads that contain corticosteroids are specially formulated to penetrate deep into the skin layers. These dermatologic drugs are classified by potency, as listed in Table 73.3. The high-potency medications are used to treat acute flare-ups and are limited to 2 to 3 weeks of therapy. The medium-potency formulations are for more prolonged therapy of chronic dermatitis. The low-potency corticosteroids are prescribed for children.

Figure 73.2 Dermatitis.
Courtesy of Librakv/Fotolia.

Long-term corticosteroid use may lead to irritation, redness, hypopigmentation, and thinning of the skin. High-potency formulations are not advised for the head or neck regions because of potential adverse effects. If absorption occurs, topical corticosteroids may produce undesirable systemic effects, including adrenal insufficiency, mood changes, serum imbalances, and loss of bone mass, as discussed in Chapter 68. To avoid serious adverse effects, careful attention must be given to the amount of corticosteroid applied, the frequency of application, and how long it should be used. For most patients with dermatitis, topical corticosteroids have minimal adverse effects.

Patients with persistent atopic dermatitis that does not respond to corticosteroids may benefit from PO immunosuppressants, such as cyclosporine. This drug is generally used for the short-term treatment of severe disease. The topical calcineurin inhibitors pimecrolimus 1% (Elidel) and tacrolimus 0.03%, 0.1% (Protopic) are available for patients older than 2 years of age. These medications may be used on all skin surfaces (including the face and neck) because they have fewer adverse effects than the topical corticosteroids. Adverse effects include burning and stinging on broken skin. Pimecrolimus and tacrolimus are not approved for long-term therapy because of a small risk of skin cancer and lymphoma. They are reserved for patients who have not responded to topical corticosteroids. When using these

Table 73.3 Selected Topical Corticosteroids for Dermatitis and Related Symptoms

Generic Name	Strength (%)	Trade Name
Very High Potency		
betamethasone dipropionate, augmented, cream	0.05	Diprolene
clobetasol propionate	0.05	Temovate
diflorasone diacetate	0.05	Maxiflor
halobetasol	0.05	Ultravate
High Potency		
amcinonide	0.1	Cyclocort
fluocinonide	0.025	Lidex
halcinonide	0.1	Halog
Medium Potency

fluocinolone acetonide	0.025	Synalar
flurandrenolide, cream	0.025	Cordran
fluticasone propionate, cream	0.05	Cutivate
hydrocortisone valerate	0.2	Westcort
mometasone furoate	0.1	Elocon
prednicarbate	0.1	Dermatop
triamcinolone acetonide	0.025–0.1	Aristocort, Kenalog
Low Potency		
alclometasone dipropionate	0.05	Aclovate
desonide	0.05	Desonate, DesOwen, Verdeso
dexamethasone	0.1	—
hydrocortisone	0.25–1	Cortizone, Hycort

drugs, occlusive dressings should not be used because this promotes absorption of the drug and can increase the risk of systemic toxicity. The immunosuppressants are presented in Chapter 42.

Other alternatives to corticosteroids for atopic dermatitis include doxepin (Zonalon), crisaborole (Eucrisa), and dupilumab (Dupixent). When given PO doxepin is used to treat depression; however, Zonalon cream is indicated for atopic dermatitis. Some of the drug is absorbed across the skin, causing drowsiness in about 20% of patients. Applied topically, crisaborole is an anti-inflammatory drug approved in 2016 to treat atopic dermatitis.

The approval of dupilumab in 2017 has led to a new approach to treating persistent atopic dermatitis that has not responded to other therapies. This drug is a monoclonal antibody that targets the interleukin-4 (IL-4) receptor pathway. By blocking the binding of IL-4 (and to some extent IL-13), the drug prevents the release of inflammatory cytokines. It is administered by the subcutaneous route every other week. The most common adverse effects are injection-site reactions and conjunctivitis.

CONNECTIONS: Treating the Diverse Patient

The Role of Genetics in Dermatitis and Psoriasis

As more is learned about the role genetics plays in the response to drug therapy, it is clear that genetics also influences skin reactions such as atopic dermatitis, psoriasis, and drug-induced skin reactions (Borroni, 2015; Dhingra et al., 2014; Sukasem, Puangpetch, Medhasi, & Tassaneeyakul, 2014). Activated T cells and cytokines such as interleukins have been shown to play a role in skin defenses and skin reactions. Differences have also been shown to exist in the numbers and activation of cytokines between children and adults, and between racial groups (Leung, 2015). Gaining a better understanding of the role genetic factors play in the development of skin conditions will help to refine treatment options, particularly with the biologic response modifiers, and to develop new approaches to therapy (Miyagaki & Sugaya, 2015).

Topical therapy for seborrheic dermatitis primarily consists of antifungals and low-dose topical corticosteroids, depending on the location affected. The first-line therapy for seborrheic dermatitis that affects the scalp should be topical corticosteroids. These may be administered as a shampoo, topical solution, or a lotion applied to the scalp. A typical regimen for an adult would be to use a topical corticosteroid once or twice daily with the use of a medicated shampoo 2 to 3 times per week. Shampoos that contain selenium sulfide (Selsun), salicylic acid, zinc pyrithione, or an antifungal azole are most often used. Once-daily antifungal medication with fluconazole (Diflucan), ketoconazole (Nizoral), or ciclopirox (Loprox) combined with 2 weeks of once-daily desonide (DesOwen) is recommended for seborrheic dermatitis of the face and ears.

CONNECTION Checkpoint 73.3

Topical applications of corticosteroids are used for a variety of conditions. What are some indications for corticosteroids given by the following routes of administration: aerosol inhalation (see Chapter 44), intranasal (see Chapter 45), and intra-articular (see Chapter 72)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Psoriasis

73.7 Psoriasis is a chronic, inflammatory disease that is treated with topical and systemic medications.

Psoriasis is a chronic, inflammatory skin disorder that affects 1% to 2% of the population and appears with

greater frequency in people of European ancestry. The onset of psoriasis is generally established by 20 years of age, although it may occur throughout the lifespan.

Although the etiology of psoriasis is incompletely understood, it appears to have both genetic and autoimmune components. About 33% to 50% of the cases have a genetic basis, with a close family member also having the disorder. When one identical twin presents with psoriasis, the other twin has a 70% probability of also acquiring the disease. The immune nature of psoriasis is supported by the discovery that activated T lymphocytes (T cells) migrate to the dermis and release cytokines such as tumor necrosis factor (TNF) that increase the production of skin cells and cause inflammation. Furthermore, suppressing T-cell function through the use of immunosuppressants or biologic therapies improves symptoms of psoriasis.

Specific environmental triggers worsen psoriasis, including stress, smoking, alcohol, climate changes, and infections. In addition, certain drugs, including angiotensin-converting enzyme (ACE) inhibitors, beta-adrenergic blockers, tetracyclines, and nonsteroidal anti-inflammatory drugs (NSAIDs), act as triggers. People with psoriasis seem to improve in warmer climates, where there is more exposure to sunlight.

When psoriasis occurs, both the dermis and epidermis become thickened from an extremely fast skin turnover rate, with skin cells reaching the surface in 4 to 7 days instead of the normal 2 to 3 weeks. This rapid proliferation time does not allow for cell maturation and keratinization to occur, giving the skin lesions their characteristic appearance. The typical psoriatic lesions are characterized by red, raised patches of skin covered with flaky, thick, silver scales called **plaques**. Plaques are ultimately shed from the surface while the underlying skin becomes inflamed and irritated. If the scales are scraped away, the dark-red base of the lesion is exposed, producing multiple bleeding points. Lesions vary in size and are usually present on the scalp, elbows, knees, extensor surfaces of the arms and legs, sacrum, hands, and occasionally around the nails (Figure 73.3). The face is rarely affected. When psoriasis affects the nails, a yellow or brown discoloration may result, and the nail itself may separate from the nail bed, thicken, and crumble. The various forms of psoriasis are described in Table 73.4.

Figure 73.3 Psoriasis.
Courtesy of Casi/Fotolia.

The goal of psoriasis pharmacotherapy is to reduce erythema, plaques, and scales to improve the cosmetic appearance of the patient, leading to the ability to perform normal lifestyle activities. This is accomplished by reducing epidermal cell turnover and promoting healing of the psoriatic lesions. The choice of therapy depends on the type and extent of the disease and the history of response to a previous treatment of psoriasis. A number of prescription and OTC drugs are available for the treatment of psoriasis and are listed in Table 73.5. Therapy is often conducted

Table 73.4 Types of Psoriasis

Form of Psoriasis	Description	Most Common Location of Lesions	Comments
Guttate (droplike) or eruptive psoriasis	Lesions smaller than those of psoriasis vulgaris	Upper trunk and extremities	More common in early-onset psoriasis; can appear and resolve spontaneously a few weeks following a streptococcal respiratory infection
Psoriasis vulgaris	Lesions are papules that form into erythematous plaques with thick, silver or gray plaques that bleed when removed; plaques in dark-skinned individuals often appear purple	Skin over scalp, elbows, and knees; lesions possible anywhere on the body	Most common form; requires long-term specialized management
Psoriatic arthritis	Resembles rheumatoid arthritis	Fingers and toes at the distal interphalangeal joints; can affect the skin and nails	About 20% of patients with psoriasis also have arthritis
Psoriatic erythroderma or exfoliative dermatitis	Generalized scaling; erythema without lesions	All body surfaces	Least common form
Pustular psoriasis	Eruption of pustules; presence of fever	Trunk and extremities; can appear on the palms, soles, and nail beds	Average age of onset is 50 years

Table 73.5 Selected Drugs for Psoriasis and Related Disorders

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Topical Medications		
calcipotriene (Dovonex)	Topical: Apply a thin layer to the lesions 1–2 times/day up to 8 wk	*Burning, stinging, folliculitis, itching, dry skin, hyperpigmentation* No serious adverse effects
coal tar (Balnetar, Cutar, others)	Topical: Apply to affected areas 1–4 times/day	*Folliculitis, irritation, photosensitivity* No serious adverse effects
salicylic acid (Neutrogena, Salex, others)	Topical: Apply to affected areas tid–qid in concentrations ranging from 2% to 10%	*Erythema, pruritus, stinging of the skin* No serious adverse effects
tazarotene (Tazorac)	Acne: Apply a thin film to the clean, dry area daily Plaque psoriasis: Apply thin film daily in the evening	*Pruritus, burning, stinging, skin irritation, transient worsening of psoriasis, skin peeling, photosensitivity* Hypertriglyceridemia, teratogenicity
Systemic Medications		
acitretin (Soriatane)	PO: 25–50 mg/day with the main meal	*Dry mouth, alopecia, cheilitis, dry skin, dry mucous membranes* Increased triglycerides and cholesterol, paresthesias, rigors, arthralgia, skin peeling, pseudotumor cerebri, depression, elevated liver function tests, teratogenicity
adalimumab (Humira)	Subcutaneous: 40 mg every other week	*Upper respiratory infection, local reactions at the injection site (pain, erythema, myalgia)* Malignancies, serious infections, worsening heart failure
alefacept (Amevive)	IM: 15 mg once weekly for 12 wk	*Nausea, vomiting, diarrhea, pharyngitis, dizziness, cough, pruritus* Malignancies, serious infection, hepatotoxicity, lymphopenia
apremilast (Otezla)	PO: Begin with 10 mg/day and increase over a 6-day period to 30 mg bid	*Diarrhea, nausea, headache* Depression, weight loss
brodalumab (Siliq)	Subcutaneous: 210 mg at wk 0, 2, and 4 followed by 210 mg q2wk	*Arthralgia, headache, fatigue, diarrhea, injection site reactions* Neutropenia, serious infections, suicidal ideation
cyclosporine (Gengraf, Neoral, Sandimmune)	PO: 1.25 mg/kg bid (max: 4 mg/kg/day)	*Hirsutism, tremor, vomiting, headache, pruritus, nausea, diarrhea* HTN, myocardial infarction (MI), nephrotoxicity, hyperkalemia, gingival enlargement, paresthesias, hepatotoxicity, infection
etanercept (Enbrel)	Subcutaneous: 50 mg twice weekly (given 3–4 days apart) Maintenance dose: 50 mg/wk	*Local reactions at the injection site (pain, erythema, myalgia), abdominal pain, vomiting, nasopharyngitis* Serious infections, lupus-like syndrome, positive antinuclear antibodies, heart failure exacerbations
guselkumab (Tremfya)	Subcutaneous: 100 mg at wk 0 and 4 followed by 100 mg q8wk	*Upper respiratory infection, headache, arthralgia, diarrhea, injection-site reactions* Serious infections
infliximab (Remicade)	IV: 5 mg/kg given as an induction dose at 0, 2, and 6 wk followed by a maintenance dose of 5 mg/kg q8wk thereafter	*Infections, headache, abdominal pain* Infusion-related reactions, invasive fungal infections, malignancies, hepatotoxicity, lupus-like syndrome
ixekizumab (Taltz)	Subcutaneous: 160 mg at wk 0, followed by 80 mg at wk 2, 4, 6, 8, 10, and 12 followed by 80 mg q4wk	*Local reactions at the injection site, upper respiratory infections, nausea* Serious infections, hypersensitivity, worsening of inflammatory bowel disease
methotrexate (Otrexup, Rheumatrex, Trexall)	PO: 2.5–5 mg bid for 3 doses each week (max: 25–30 mg/wk) Subcutaneous (Otrexup): 10–25 mg once weekly	*Headache, glossitis, gingivitis, mild leukopenia, nausea* Ulcerative stomatitis, myelosuppression, aplastic anemia, hepatic cirrhosis, nephrotoxicity, sudden death, pulmonary fibrosis, acute renal failure, teratogenicity
secukinumab (Cosentyx)	Subcutaneous: 150–300 mg at wk 0, 1, 2, 3, and 4 followed by 300 mg q4wk	*Nasopharyngitis, diarrhea, upper respiratory tract infection* Serious infections, hypersensitivity reactions
ustekinumab (Stelara)	Subcutaneous: 45–90 mg initially and 4 wk later, followed by 45–90 mg q12wk	*Nasopharyngitis, upper respiratory tract infection, headache, and fatigue* Malignancies, serious infections

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

in a stepwise manner. Psoriasis is a lifelong disease and there is no pharmacologic cure.

PharmFACT

Psoriasis affects more than 8 million Americans. More than 30% of these patients will experience their first episode before age 20 (National Psoriasis Foundation, n.d.).

Topical Drugs

Corticosteroids: Topical corticosteroids are a first-line therapy for the initial treatment of psoriasis. These drugs are effective, inexpensive, and relatively safe. When they are applied to psoriatic lesions, topical corticosteroids suppress cell division, reduce inflammation, relieve pruritus, and delay the movement of keratinocytes that are associated with fast skin turnover. Choosing the correct strength of corticosteroid and the most effective vehicle base are important aspects of treatment because the effectiveness of a topical steroid depends on its potency and ability to be absorbed into the skin. Initial therapy may begin with a high-potency drug to obtain rapid clearing of the lesions. High-potency medications are also used for acute flare-ups for 2 to 3 weeks. The high-potency formulations are best applied to the areas thickest with plaque, such as the hands or feet, and should not be used on the face and genital areas. For chronic maintenance therapy, the patient is switched to moderate- and low-potency corticosteroids because they have a lower potential for adverse effects.

Occlusive dressings may be applied to increase the effectiveness of the corticosteroid. A simple way to enhance drug penetration is to apply the steroid directly to the skin followed by warm, moist dressings and an occlusive outer wrap. Wraps may be large plastic bags, vinyl jogging suits, or rolls of tubular plastic. Care should be taken that the wraps not be left in place longer than 8 hours. The skin should be inspected for atrophy, striae, hypopigmentation, and telangiectasias, which are all adverse effects of topical corticosteroid therapy.

Repeated use of topical corticosteroids will result in tolerance. To delay tolerance, doses of the high-potency drugs are kept as low as possible. Some healthcare providers discontinue corticosteroids after an adequate response has been obtained and switch to a different therapy such as coal tar for several weeks.

When large areas of the body have psoriatic lesions, topical corticosteroid therapy can be expensive and involve some systemic risk. The larger the area treated, the greater the absorbed doses. The student should refer to Chapter 68 for a discussion of the adverse effects of systemic corticosteroid therapy.

Coal tar: Coal tar may be used as monotherapy or in combination with other psoriasis medications. The drug inhibits deoxyribonucleic acid (DNA) synthesis, arrests abnormal cell growth, and reduces inflammation. Coal tar is inexpensive and available as a solution, gel, lotion, and shampoo. Coal tar preparations, however, are messy, staining, and have a foul odor. The use of coal tar is considered a second-line therapy except for shampoos, which can treat scalp lesions.

Calcipotriene (Dovonex): Approved in 1993, calcipotriene is a derivative of vitamin D that is available as a cream for use on the body and as a solution for the scalp. The drug binds to vitamin D receptors in the skin, suppresses cellular proliferation, and decreases cellular turnover in the psoriatic plaques. Symptomatic improvement is seen in 2 to 3 weeks. Calcipotriene is an effective alternative to topical corticosteroids. Only about 6% of a topical dose is absorbed systemically. Its most common adverse effect is local irritation. It is not recommended for use by patients over age 65, who have an increased incidence of adverse effects with the drug, or by pregnant and lactating women (category C). Its use may produce hypercalcemia if applied over large areas of the body or if used in higher than recommended doses. Phototherapy of excessive exposure to UV light should be avoided due to the potential for increased tumor incidence. This drug is pregnancy category C.

Salicylic acid: Salicylic acid is a keratinolytic that has been used as an OTC remedy to treat various skin conditions, including psoriasis, acne, dandruff, warts, and dermatitis. It is the active metabolite of aspirin and has been available for over 100 years. Salicylic acid removes the outer layers of skin, allowing improved penetration of other dermatologic drugs. The drug is pregnancy category C.

Tazarotene (Tazorac): Approved in 1997, tazarotene (Tazorac) is a vitamin A retinoid that causes sloughing of the scales covering the psoriatic plaques. Available as an ointment or gel, this drug is applied once daily in the evening. Tazarotene is also approved for facial wrinkles and acne. Because this drug is pregnancy category X, its use is contraindicated during pregnancy.

Systemic Drugs

Some patients have severe psoriasis that is resistant to topical therapy. Because systemic drugs have the potential to cause serious adverse effects, they are generally used when topical drugs and phototherapy fail to produce an adequate response. In some cases, they may be used for a few weeks to produce a rapid improvement in symptoms before beginning topical therapy.

Acitretin (Soriatane): Acitretin is a PO retinoid that is approved for severe, resistant psoriasis. Two to three months of therapy may be required for significant symptomatic improvement. Approved in 1997, acitretin acts like other retinoids to inhibit keratin formation and skin

inflammation. This drug is very effective at eliminating psoriatic lesions. However, the lesions return soon after therapy is discontinued. The most serious adverse effect is teratogenicity (category X). At least two negative pregnancy tests should be obtained before beginning therapy, and the patient should use effective birth control for 3 years after discontinuing the drug. Many adverse effects occur frequently during therapy, including cheilitis, hair loss, dry skin, pruritus, rash, epistaxis, bleeding gums, and joint pain. The active metabolite of acitretin, etretinate (Tegison), was withdrawn from the market in 1998 due to high toxicity. The patient should refrain from drinking alcohol during acitretin therapy because this converts more of the drug to its toxic metabolite.

Apremilast (Otezla): Approved in 2014, apremilast is used to treat psoriatic arthritis and plaque psoriasis. The drug inhibits the enzyme phosphodiesterase-4, which results in a reduction in several different proinflammatory mediators. It is the first drug approved for psoriasis that acts by this mechanism. Apremilast is considered an option for patients who have not responded to phototherapy or systemic therapy with other drugs. Patients with a history of depression, suicidal behavior, or weight loss should be monitored regularly while on apremilast therapy. This drug is pregnancy category C.

Cyclosporine (Gengraf, Neoral, Sandimmune): Cyclosporine is an immunosuppressant that is presented as a prototype drug in Chapter 42. The drug acts by suppressing T-cell functions. It is effective at providing rapid relief from the symptoms of psoriasis and is often combined with other drugs, such as calcipotriene, to provide for a lower dose and reduced toxicity. Due to the potential for serious adverse effects such as nephrotoxicity, hepatotoxicity, and increased risk for infections and neoplasia, cyclosporine is used for extensive psoriasis when other treatment methods have failed.

Methotrexate (Otrexup, Rheumatrex, Trexall): Methotrexate is one of the most frequently prescribed systemic drugs for severe psoriasis. An older drug approved in 1953, methotrexate is used in the treatment of a variety of disorders, including carcinomas and rheumatoid arthritis, in addition to being prescribed for psoriasis. For psoriasis, methotrexate inhibits the rapid proliferation of cells in the skin. It is administered either once weekly or twice daily for 3 days each week. In 2013 a new formulation of the drug, Otrexup, was approved that permits a once-weekly subcutaneous injection for patients with severe psoriasis. Improvement is noted after several weeks of therapy but maximum effects may take 2 to 3 months. For resistant lesions, methotrexate may be combined with phototherapy or alternated with other systemic drugs. Methotrexate is discussed as a prototype drug in Chapter 57.

Biologic therapies: An understanding of the role of the immune system in the pathogenesis of psoriasis has led to the use of biologic therapies to treat patients with moderate to severe disease. Biologic drugs suppress the hyperactive inflammatory and immune responses characteristic of psoriasis by several different mechanisms. Adalimumab (Humira), etanercept (Enbrel), and infliximab (Remicade) inhibit TNF. Apremilast (Otezla) produces an anti-inflammatory effect by blocking the enzyme phosphodiesterase-4. Ixekizumab (Taltz), secukinumab (Cosentyx), ustekinumab (Stelara), guselkumab (Tremfya), and brodalumab (Siliq) are newer drugs that inhibit interleukins. Alefacept (Amevive) inhibits T-cell activation.

The biologic therapy medications induce general immunosuppression, and patients are at an increased risk for infection, including reactivation of latent infections such as tuberculosis. In addition brodalumab, one of the newest biologic therapies, has a black box warning regarding the potential for suicidal ideation. Healthcare providers and pharmacies must receive special certification to dispense brodalumab. Major disadvantages of biologic drugs are that they are not available in PO formulations and their annual costs may exceed $20,000 per year.

Nonpharmacologic therapy: Phototherapy with ultraviolet-A (UVA) and ultraviolet-B (UVB) light is used in cases of severe debilitating psoriasis. Phototherapy with UVA is combined with methoxsalen, a drug from a chemical family known as the psoralens. The concurrent use of UVA and the drug is called PUVA therapy. **Psoralens** are PO or topical drugs that produce a photosensitive reaction when exposed to UV light. This reaction reduces the number of psoriatic lesions, but unpleasant adverse effects such as headache, nausea, and skin sensitivity occur that may limit the effectiveness of PUVA therapy. Treatments are limited to 2 to 3 times per week, and an interim period of 48 hours between treatments is necessary. Because of the strong photosensitizing properties of the psoralens, patients must wear dark glasses during treatment and for the remainder of the day. The use of PUVA has been associated with an increased risk for cataract development.

The second type of phototherapy is with narrow-band UVB light, which is less hazardous than UVA therapy. The wavelength of UVB is similar to that of sunlight, and it reduces the lesions that cover a large area of the body that normally resist topical treatments. It is usually used in conjunction with topical coal tar. If access to a light treatment unit is not feasible, natural sunlight may be used. The use of commercial tanning beds is not recommended for the patient with psoriasis.

All UV treatments may cause acute sunburn reactions, including generalized redness with edema and tenderness as well as the development of long-term effects of actinic keratosis, premature aging of the skin, and skin cancers.

Immunosuppressant drugs such as cyclosporine are not used in conjunction with PUVA therapy, because they increase the risk of skin cancer.

Pharmacotherapy of Minor Skin Burns

73.8 The pharmacotherapy of sunburn includes prevention with sunscreens and treatment with lotions, topical anesthetics, and analgesics.

Sunburn results from overexposure of the skin to UV light and is associated with light skin complexions, prolonged exposure to the sun during the more hazardous hours of the day (10 a.m. until 3 p.m.), and lack of protective clothing when outdoors. Chronic sun exposure can result in serious conditions, including eye injury, cataracts, and skin cancer.

Minor, first-degree burns affect only the outer layers of the epidermis. Excessive exposure to UV light, however, injures the dermis and dilates the capillaries, leading to redness, tenderness, edema, and occasional blister formation. In addition to producing local skin damage, sun overexposure releases toxins that may produce systemic effects. The signs and symptoms of sunburn include erythema, intense pain, nausea, vomiting, chills, edema, and headache. These symptoms usually resolve within a matter of hours or days, depending on the severity of the exposure. Once sunburn has occurred, medications can only alleviate the symptoms; they do not speed recovery time.

The best treatment for sunburn is prevention. Sunscreens are liquids or lotions applied for chemical or physical protection. Chemical sunscreens absorb the spectrum of UV light that is responsible for most sunburns. Chemical sunscreens include those that contain benzophenone for protection against UVA rays, and those that work against UVB rays such as cinnamates, para-aminobenzoic acid (PABA), and salicylates. Physical sunscreens such as zinc oxide, talc, and titanium dioxide reflect or scatter light to prevent the penetration of both UVA and UVB rays. Parsol is another sunscreen product that is being used more frequently as a key ingredient in lip balm.

The effectiveness of a sunscreen is indicated by its SPF. An SPF of 8 means the product offers 8 times more protection than using no sunscreen. Patients with skin that sunburns easily should use products with an SPF of 15 or greater. Waterproof sunscreens are meant to withstand 8 minutes of exposure to water. People tend to apply sunscreen too infrequently and in layers that are too thin. To be effective, sunscreen must be applied generously and often during the exposure period.

Treatment for sunburn consists of addressing symptoms with soothing lotions, rest, prevention of dehydration, and topical anesthetics, if needed. Treatment is usually done on an outpatient basis. Topical anesthetics for minor burns include benzocaine (Solarcaine), dibucaine (Nupercainal), lidocaine (Xylocaine), and tetracaine HCl (Pontocaine). Aloe vera is a popular natural therapy for minor skin irritations and burns. Hydrocortisone cream may decrease pain and swelling and assist in the healing of

CONNECTIONS: Complementary and Alternative Therapies

Aloe Vera

Description

Numerous products on the market, including soaps, lotions, creams, and sunscreens, are aimed at the consumer who is seeking the healing properties of aloe vera gel. Healthcare providers have also recommended aloe vera gel to treat dermatitis, burns, and a variety of skin disorders.

History and Claims

Aloe vera is derived from the gel inside the leaf of the aloe plant, which is a member of the lily family. Aloe vera contains over 70 active substances, including antioxidants, minerals, vitamins, and enzymes. These substances are supposed to kill a variety of microorganisms, decrease pain, and reduce localized inflammation. Aloe vera also has value for its moisturizing and wound healing properties. It has been used medicinally for thousands of years. Early mention is made of aloe's use in ancient Sumer in 2200 BC, where it was proclaimed a plant of great healing power.

Standardization

Aloe vera has not been evaluated by the FDA for safety, effectiveness, or purity.

Evidence

Like other herbal products, controlled research studies demonstrating the effectiveness of aloe vera are lacking. The gel is most often used topically, although it may be taken orally. The yellow latex component of aloe produces a strong laxative effect and intense cramping may occur; the drug is not recommended to be taken orally for this reason (National Center for Complementary and Integrative Health, 2016). The antimicrobial actions of aloe vera extracts have been clearly demonstrated (Stanley, Ifeanyi, & Eziokwu, 2014). While it is known that whole-leaf aloe vera extract has demonstrated carcinogenic outcomes, less is known about the long-term effects of the gel, used topically or orally (Guo & Mei, 2016). Until more rigorous clinical trials have been conducted, nurses should advise patients wanting to use aloe vera, particularly the PO form, to discuss it with their healthcare provider.

damaged tissue. These same drugs may also provide relief from minor pain due to insect bites and pruritus. In more severe cases, PO analgesics and anti-inflammatory medications such as aspirin or ibuprofen may be indicated.

PROTOTYPE DRUG **Benzocaine (Americaine, Anbesol, Others)**

Classification **Therapeutic:** Topical anesthetic
Pharmacologic: Local anesthetic (ester type), antipruritic

Therapeutic Effects and Uses: Approved in 1938, benzocaine inhibits the conduction of nerve impulses from sensory nerve endings, producing surface anesthesia. It is indicated for the temporary relief of pain and discomfort in patients with pruritic skin problems, minor burns and wounds, and insect bites. It is available in a variety of delivery forms, including sprays, lotions, gels, and lozenges. Several products are available OTC to treat pain due to toothaches, dentures, or canker sores. Because of its short duration of action, it must be applied 3 to 4 times a day.

Mechanism of Action: Benzocaine produces surface anesthesia by inhibiting the conduction of nerve endings.

Pharmacokinetics:

Route(s)	Topical
Absorption	Minimally absorbed from intact skin
Distribution	Unknown
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	1 min
Duration of action	15–20 min

Adverse Effects: Adverse effects include sensitization in susceptible individuals, allergic reactions, and anaphylaxis. Because it is poorly absorbed, systemic adverse effects are rarely observed.

Contraindications/Precautions: Contraindications include hypersensitivity to benzocaine or other PABA derivatives or to any of the components in the formulation. Caution should be used in patients with a history of drug sensitivity to ester-type anesthetics, denuded skin, or severely traumatized mucosa, and in children under 6 years.

Drug Interactions: Benzocaine may antagonize the antibacterial activity of sulfonamides.

Pregnancy: Category C.

Treatment of Overdose: Overdose with topical benzocaine is unlikely.

Nursing Responsibilities:

- Assess the sunburn, including the location, portion of body surface area, edema, erythema, and blistering.
- Assess for systemic symptoms such as fever, chills, weakness, and shock. These may occur following severe exposure, or when the sunburn affects a large portion of the body surface area.
- Obtain a thorough history, including sunburn and tanning history, the amount of time the patient usually spends in the sun, how easily the patient burns, and the type of sun protection used. If the patient uses a sunscreen, obtain the SPF rating.
- Obtain an allergy history and use of OTC products or home remedies to treat the sunburn.
- If topical anesthetics or ointments are ordered, assess the skin for secondary infections for which these medications are contraindicated.
- For patients using the medication for the first time, conduct a trial application on a small area of skin to assess for an allergic reaction. If no adverse effects occur within 30 to 60 minutes, the medication may be applied to the entire area of sunburn.
- Report any serious sunburn in children under age 6 to the healthcare provider.

Lifespan and Diversity Considerations:

- The drug should not be used for children under 1 year of age except on direction of the healthcare provider.

Patient and Family Education:

- Avoid applying the medication to open or infected areas of skin.
- Report severe, persistent pain.
- Avoid additional sun exposure while receiving treatment.
- Prevent sunburn in the future by wearing protective clothing such as long-sleeved shirts and large-brim hats, and by using sunscreen with an SPF of 15 or greater.
- Follow the directions regarding use and reapplication of sunscreen after swimming or sweating.
- Refrigerate topical lotions so they will provide a soothing, cooling effect when applied.
- Increase hydration after sunburning to aid in cooling the skin. Avoid excessive cool bathing, which may dry the skin further.
- Do not apply benzocaine to infants and young children.

Drugs Similar to Benzocaine (Americaine, Anbesol, Others)

Benzocaine is the only drug in its class that is used for minor burns.

Pharmacotherapy of Alopecia

73.9 Several drugs are able to stimulate moderate hair regrowth in patients with male- and female-pattern alopecia.

Alopecia is the loss of hair, resulting in baldness. Male-pattern baldness is the most common cause of hair loss in men and is genetically determined. Men affected by this type of alopecia typically experience a loss of hair at the temples, followed by a recession of the hairline and baldness at the crown.

Two drugs are currently available to promote hair regrowth in patients with male-pattern baldness: topical minoxidil (Rogaine) and PO finasteride (Propecia, Proscar). Neither drug was originally developed for baldness. Although their exact mechanisms of action are unknown, it is thought that these drugs work by stimulating the epithelial cells within the hair follicle. They are most successful in patients with recent onset of symptoms or who are less than 50 years of age. About 40% of patients who are treated 2 to 3 times daily for a year will experience moderate regrowth of hair. For both drugs, hair regrowth stops when the drug is discontinued.

Hair loss in women differs from hair loss in men and varies by ethnicity. A common type of alopecia in Caucasian women, female-pattern hair loss, typically begins in the early 20s and 30s, with progressive thinning and loss of hair on the top of the scalp but not the back. These women typically do not have a receding hairline. The hair also becomes finer as individual hairs become smaller, resulting in less dense hair. Some women with this pattern of hair loss may have elevated androgen levels or diabetes that requires treatment. Topical minoxidil is currently the only hair regrowth treatment approved for women by the FDA. Applied to the scalp twice daily, it stimulates hairs that are actively growing to have more robust growth.

Women of African descent have a different type of alopecia called central centrifugal alopecia. This type also results in hair loss on the top of the scalp, but it is different from the female-pattern hair loss in that the hair follicles are destroyed. Topical minoxidil is used in this group to stimulate growth in the unaffected hair follicles, whereas anti-inflammatory medications are used to decrease the destruction of the hair follicles.

Minoxidil (Rogaine): Oral minoxidil (Loniten) was first approved for HTN in 1979. Approval to market the topical solution for hair loss occurred in 1996. The drug is rubbed onto the scalp twice daily. Although minoxidil is a potent vasodilator, this mechanism is likely not involved in its effectiveness as a hair regrowth agent. The exact mechanism of action is unknown. Only 2% of a topical dose is absorbed systemically; therefore, this route does not affect blood pressure. Various brands of minoxidil include 2% Rogaine for Women, 2% Rogaine for Men Regular Strength, and 5% Rogaine for Men Extra Strength. An off-label use is to treat chemotherapy-induced alopecia. In patients who are receiving chemotherapy, hair regrowth occurs at a faster rate with minoxidil use. Response rates vary however, and over half of patients treated do not experience significant regrowth. The drug has no significant adverse effects. This drug is pregnancy category C. Caution should be taken to keep the solution out of the reach of children. One teaspoon of the solution contains the amount of a daily adult antihypertensive dose.

Finasteride (Propecia, Proscar): Proscar was approved for benign prostatic hyperplasia (BPH) in 1992. Propecia was later approved to treat male-pattern baldness in 1997. The dose used for treating BPH is 5 times higher than that used for baldness. Unlike minoxidil, finasteride is a PO medication. This drug is thought to act by reducing the amounts of dihydroxytestosterone (DHT) in hair follicles, thus slowing hair loss. It is less effective than minoxidil at promoting hair regrowth. At the low doses used for hair regrowth, adverse effects are uncommon. It is not approved for use in women. This drug is pregnancy category X. Pregnant women should not touch this drug because it may harm a male fetus if absorbed.

CONNECTION Checkpoint 73.4

From what you learned in Chapter 71, describe the mechanism by which finasteride reduces symptoms of BPH. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Understanding Chapter 73

Key Concepts Summary

73.1 Three layers of skin, known as the epidermis, dermis, and subcutaneous layers, provide effective barrier defenses for the body.

73.2 The etiology of skin disorders may be classified as infectious, inflammatory, or neoplastic.

73.3 When the integrity of the skin is compromised, microbes can gain entrance and cause infections that require anti-infective therapy.

73.4 Scabicides and pediculicides are used to treat parasitic skin infestations.

73.5 The pharmacotherapy of acne includes treatment with benzoyl peroxide, retinoids, and antibiotics; pharmacotherapy for rosacea includes retinoids and metronidazole.

73.6 The most effective treatment for dermatitis is topical corticosteroids, which are classified by their potency.

73.7 Psoriasis is a chronic, inflammatory disease that is treated with topical and systemic medications.

73.8 The pharmacotherapy of sunburn includes prevention with sunscreens and treatment with lotions, topical anesthetics, and analgesics.

73.9 Several drugs are able to stimulate moderate hair regrowth in patients with male- and female-pattern alopecia.

CASE STUDY: Making the Patient Connection

Remember the patient "Danny McBride" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Danny McBride is a 17-year-old high school student in his senior year. He is active in lacrosse and baseball but is finding that his skin is breaking out more often lately and is becoming discouraged at the frequency. He feels it has started to affect his social life, so his parents make an appointment with a dermatologist. The healthcare provider diagnoses Danny's skin condition as acne vulgaris and prescribes tretinoin (Retin-A).

Critical Thinking Questions

1. What would you tell Danny about his condition? Include what acne is, who is prone to develop it, and what methods of treatment have been found to be beneficial.
2. What are some reasons why Danny's acne outbreaks may have increased at this time?
3. What will you teach Danny about the application of tretinoin and adverse effects that may occur?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Stephanie Caldera, age 36, is seen by her healthcare provider for scaling patches on her forearms, elbows, and lower legs. She is diagnosed with psoriasis vulgaris and the provider prescribes betamethasone cream (Diprosone). Stephanie asks the nurse, "What is psoriasis? I look so awful! Is it contagious?"

1. How should the nurse respond?
2. What specific instructions should Stephanie be given about the application of the betamethasone cream?
3. Stephanie's psoriasis has not been responsive to betamethasone and she is prescribed calcipotriene (Dovonex). What teaching does Stephanie receive about this new prescription?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. An important inclusion in a teaching plan prepared for the patient who is taking permethrin (Nix) is:
   1. Nix can be applied after body lotion is applied.
   2. All body hair, including eyelashes and eyebrows, can be treated with lindane.
   3. Lice cannot live outside the body.
   4. In addition to hair shafts, examine the inner thigh areas, gluteal folds, and pubic areas for lice.
2. A patient is being treated with a course of topical desoximetasone (Topicort) for atopic dermatitis. In planning teaching for this patient, which adverse effects would the nurse anticipate?
   1. Burning and stinging of the skin in the affected area
   2. Development of localized pruritus and hives
   3. Hair loss in the application area
   4. Worsening of acne vulgaris

3. The patient reports using benzoyl peroxide (Benzac) for treatment of acne. The nurse notes that the action of this drug includes which of the following? (Select all that apply.)
   1. Sebum suppression
   2. Antimicrobial effect
   3. Keratolytic effect
   4. Microdermal abrasion
   5. Sunscreen activity

4. A patient has been prescribed topical tretinoin (Retin-A) for treatment of acne unresponsive to over-the-counter products. What essential information should the nurse include in the patient's teaching?
   1. Wash the face thoroughly 3 times a day with an antiacne soap while using this medication.
   2. Plan to expose the involved skin areas to sunlight for a minimum of 15 minutes each day.
   3. Use only mild soaps, warm water, and pat the skin dry to avoid excessive irritation.
   4. Alternate the topical tretinoin (Retin-A) with benzoyl peroxide on an every-other-day rotation for best results.

5. Benzocaine (Americaine) has been recommended to a 17-year-old patient for treatment of a mild sunburn. What should the patient be taught about using this product?
   1. It may be used on superficial and partial-thickness sunburns.
   2. Warming the lotion under warm water will prevent a chilled sensation when applied.
   3. A small test area should be used if the drug has not been used before to assess for allergy.
   4. Cover the treated area with a light dressing wrapped in plastic wrap to keep it from rubbing off.

6. A patient who has been prescribed isotretinoin (Accutane) must comply with the iPledge Program because of the risk of _____ effects.

Chapter 74
Pharmacotherapy of Eye and Ear Disorders

Chapter Outline

- Anatomy of the Eye
- Pathophysiology of Glaucoma
- Pharmacotherapy of Glaucoma
  - Prostaglandins
    - **PROTOTYPE** *Latanoprost (Xalatan), p. 1393*
  - Autonomic Drugs
    - **PROTOTYPE** *Timolol (Betimol, Timoptic, Others), p. 1396*
  - Carbonic Anhydrase Inhibitors
  - Osmotic Diuretics
- Pharmacotherapy for Eye Examinations
  - Anticholinergics
  - Sympathomimetics
- Pharmacotherapy for Other Eye Conditions
  - Lubricants
  - Vasoconstrictors
- Anatomy of the Ear
- Pharmacotherapy with Otic Preparations
  - Antibiotics
  - Cerumenolytics

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the major anatomic structures of the eye.
2. Identify the primary risk factors associated with glaucoma.
3. Compare and contrast open-angle and closed-angle glaucoma.
4. Explain the two major mechanisms by which drugs reduce intraocular pressure.
5. Identify examples of drugs that dilate or constrict pupils, relax ciliary muscles, constrict ocular blood vessels, or moisten eye membranes.
6. Identify the types of ear conditions that could benefit from pharmacotherapy.
7. Describe the nurse's role in the nonpharmacologic and pharmacologic management of eye and ear disorders.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to the care of patients receiving pharmacotherapy for eye and ear disorders.

tonometry, 1392

The senses of vision and hearing are the primary means for us to communicate with the world around us. Disorders that affect the eye and ear can result in problems with self-care, mobility, safety, and communication. The eye is vulnerable to a variety of conditions, many of which can be prevented, controlled, or reversed with proper pharmacotherapy. The first part of this chapter covers drugs that are used for the treatment of glaucoma and those used routinely by ophthalmic healthcare providers. The remaining part of this chapter presents drugs that are used for the treatment of common ear disorders, including infections, inflammation, and the buildup of earwax.

Anatomy of the Eye

74.1 Knowledge of basic eye anatomy is fundamental to understanding eye disorders and their pharmacotherapy.

Knowledge of basic ocular anatomy is key to understanding eye disorders and their pharmacotherapy. The important structures of the eye are shown in Figures 74.1 and 74.2.

The wall of the eye contains three layers, known as tunics. The outermost fibrous tunic is composed of the cornea and the sclera. The cornea is the transparent layer that covers the anterior portion of the eye. It has no blood

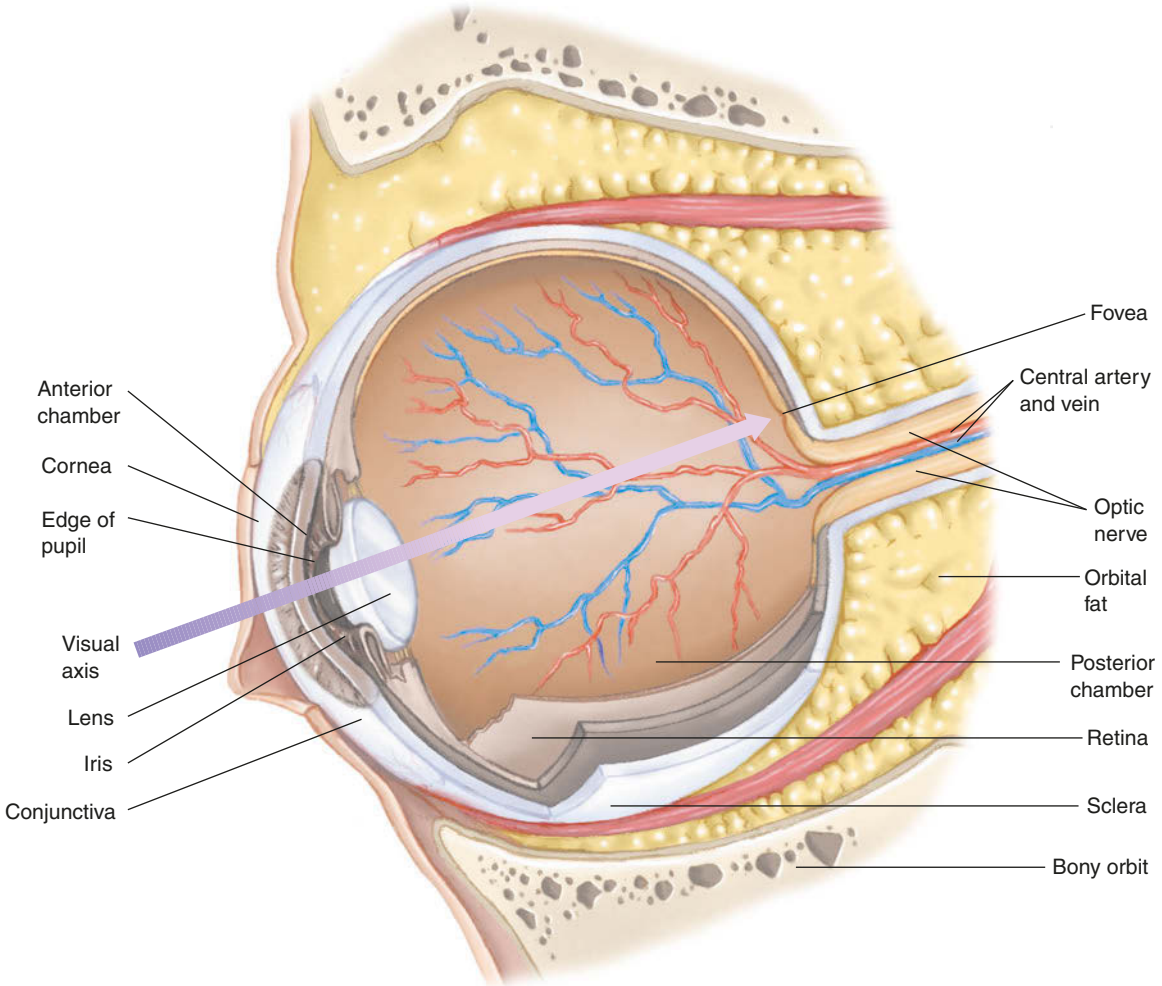

Figure 74.1 Anatomy of the interior of the eye.

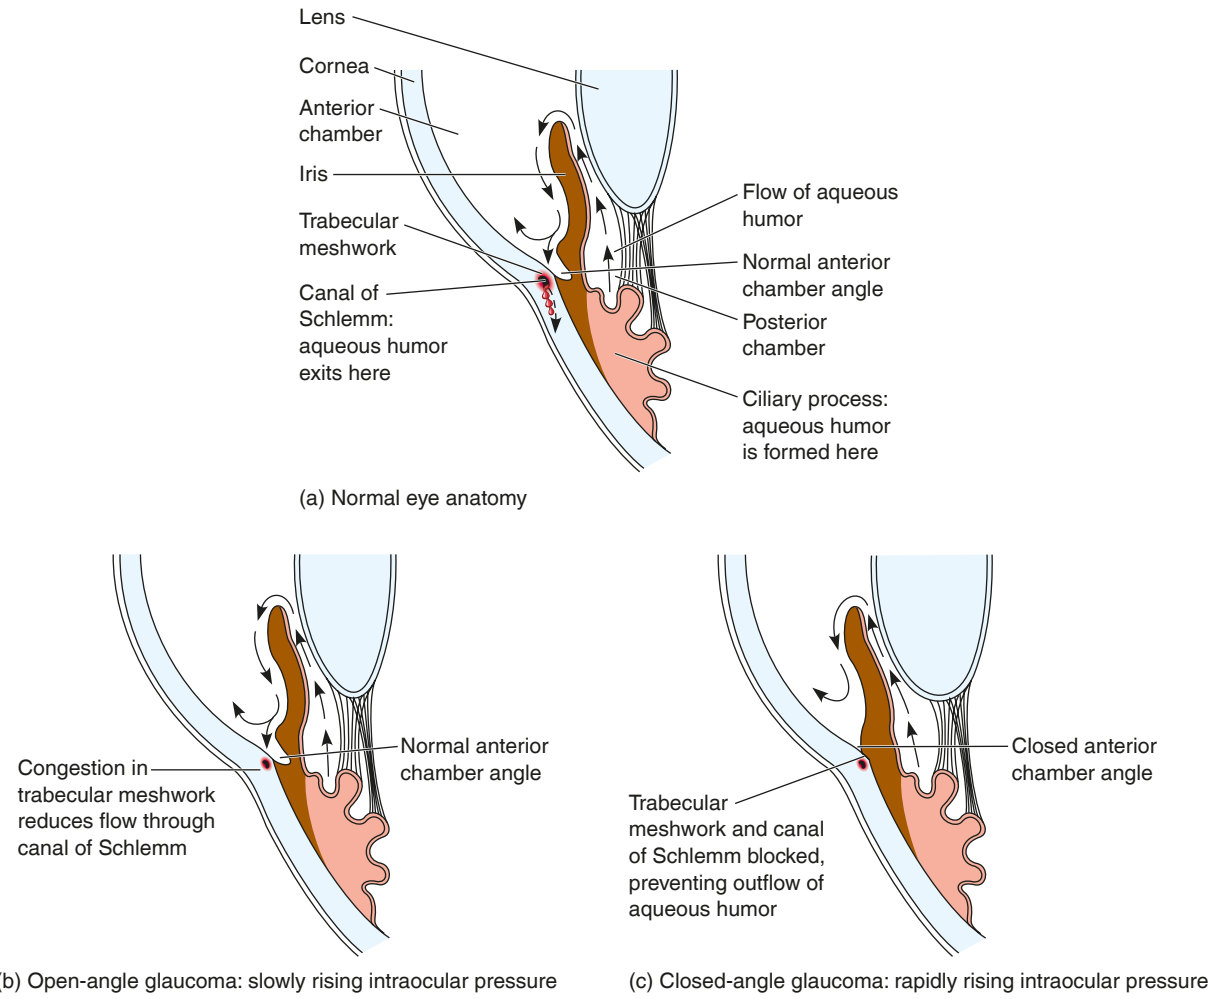

Figure 74.2 (a) In a healthy eye, aqueous humor is formed in the ciliary process and drains through the canal of Schlemm. (b) In chronic open-angle glaucoma, the anterior chamber angle remains open, but drainage of aqueous humor through the canal of Schlemm is impaired. (c) In acute closed-angle glaucoma, the angle of the iris and anterior chamber narrows, obstructing the drainage of aqueous humor through the canal of Schlemm.

vessels and receives nutrients from the fluid lying behind the cornea, or aqueous humor. It is continuous with the sclera, which is the thick, white, opaque portion covering the posterior portion of the eye. The vascular tunic is the middle layer of the eye, which is rich in blood vessels. The vascular tunic contains specialized structures that include the iris and ciliary body. The innermost layer is the neural tunic or retina, which contains the photoreceptors for vision.

The interior of the eye is divided into two cavities. The largest portion of the interior of the eye is the posterior cavity, which is filled with a gel-like substance called vitreous humor that helps the eyeball to maintain its shape and keep the retina in place.

The anterior cavity is smaller but is very important from a pharmacologic perspective. This cavity is separated into two chambers by the lens. The anterior chamber extends from the cornea to the iris; the posterior chamber lies between the iris and the lens. In front of the lens is the pigmented iris, which is made up of smooth muscle fibers that change the diameter of the pupil. The pupil is the central opening that allows light to enter. These muscle fibers are under control of the sympathetic nervous system. Pupil constriction is the result of parasympathetic stimulation, and its dilation is a sympathetic response.

The anterior cavity is filled with **aqueous humor**, a thin fluid that slowly circulates to bring nutrients to the area and remove wastes. The aqueous humor is secreted by cells in a muscular structure called the ciliary body. Once secreted, the aqueous humor flows from the posterior chamber through the pupil and into the anterior chamber. Within the anterior chamber and around the periphery is a network of spongy connective tissue, or trabecular meshwork, that contains an opening called the canal of Schlemm (scleral venous sinus). The aqueous humor drains into the canal of Schlemm and out of the anterior chamber into the venous system, thus completing its circulation. Under normal circumstances, the rate of aqueous humor production is equal to its outflow, maintaining intraocular pressure (IOP) within a normal range. Interference with either the

production or outflow of aqueous humor, however, can lead to an increase in IOP.

The conjunctiva, eyebrows, eyelashes, eyelids, and lacrimal apparatus that produce tears all serve to protect the eye. Infection and inflammatory responses are common conditions in these supporting structures. Redness, edema, and itching are common symptoms.

Pathophysiology of Glaucoma

74.2 The two principal types of glaucoma, closed-angle glaucoma and open-angle glaucoma, are characterized by increased intraocular pressure.

Glaucoma is a condition that is characterized by gradual loss of peripheral vision, usually accompanied by increased IOP. Glaucoma occurs when the IOP becomes high enough to cause optic nerve damage, leading to visual field loss and possible progression to blindness. Although the median IOP in the population is 15 to 16 mmHg, this pressure varies greatly with age, daily activities, and even time of day. As a rule, IOPs that are consistently above 21 mmHg are considered abnormal. Many patients, however, tolerate IOPs in the mid to high 20s without damage to the optic nerve. IOPs that are above 30 mmHg require treatment because they are associated with a high risk for permanent vision changes. Some patients of Asian descent may experience glaucoma at "normal" IOP values, below 21 mmHg.

PharmFACT

Blindness from glaucoma is 6 to 8 times higher in African Americans than Caucasians. After cataracts, it is the leading cause of blindness among African Americans (Glaucoma Research Foundation, 2017).

Glaucoma affects more than 3 million people over the age of 40 in the United States. It is the leading cause of preventable blindness worldwide. Primary glaucoma usually occurs without an identifiable cause and is most frequently found in people older than 60 years of age. In some cases, glaucoma is associated with genetic factors; it can be congenital in infants and children. Glaucoma can also be secondary to eye trauma, infection, diabetes, inflammation, hemorrhage, tumor, or cataracts. Some medications may contribute to the development or progression of glaucoma, including the long-term use of corticosteroids, some antihypertensives, antihistamines, and antidepressants. Other major risk factors associated with glaucoma include hypertension (HTN), migraines, refractive disorders with high degrees of nearsightedness or farsightedness, and normal aging.

Diagnosis of glaucoma can be difficult because it sometimes occurs so gradually that patients do not experience symptoms or seek medical attention until late in the disease process. **Tonometry** is a primary ophthalmic technique that tests for glaucoma by measuring IOP. Patients with unusually thick or thin corneas may have false negatives or false positives during tonometry. Patients who have had Lasik surgery, which removes corneal tissue to correct myopia, may appear to have normal IOPs, yet have glaucoma. Gonioscopy uses a gonioscope to measure the angle in the eye where the iris meets the cornea and is useful in distinguishing between open-angle and closed-angle glaucoma. Visual field testing (perimetry) assesses the degree of central visual field narrowing and peripheral vision loss. Funduscopic examinations look at retinal field changes that accompany glaucoma.

The two major types of primary glaucoma are closed-angle glaucoma and open-angle glaucoma, as shown in Figure 74.2. Both disorders result from the same problem: a buildup of aqueous humor in the anterior cavity. This buildup is caused either by an excessive production of aqueous humor or by a blockage of its outflow. In either case, IOP increases, leading to progressive damage to the optic nerve. As the optic nerve degenerates, the patient will first notice a loss of visual field, then a loss of central visual acuity, and eventually total blindness. The major differences between closed-angle glaucoma and open-angle glaucoma include how quickly the IOP develops and whether there is narrowing of the anterior chamber angle between the iris and cornea.

Closed-angle glaucoma, also called acute- or narrow-angle glaucoma, accounts for only 5% of all primary glaucoma. The incidence is higher in older adults and in individuals of Asian descent. It is typically caused by the normal thickening of the lens and may develop gradually over several years. This type of glaucoma is usually unilateral and is often associated with conditions that result in dilation of the pupil, such as stress, impact injury, or medications. Closed-angle glaucoma occurs when the pressure inside the anterior chamber increases suddenly because the iris is being pushed over the area where the aqueous humor normally drains into the trabecular network and the canal of Schlemm. The displacement of the iris is due in part to the dilation of the pupil or accommodation of the lens, causing the angle between the posterior cornea and the anterior iris to narrow or close.

Signs and symptoms of closed-angle glaucoma are caused by acute obstruction of the outflow of aqueous humor from the eye and include dull to severe eye and facial pain, headaches, seeing colored halos around bright lights, a bulging iris, and a sudden change in visual acuity. The affected eye may appear reddened and the pupil may be nonreactive. Ocular pain may be so severe that it causes nausea and vomiting. Once the outflow is totally

closed, closed-angle glaucoma constitutes a medical emergency and laser or conventional surgery is indicated for the preservation of sight. Surgical options include iridectomy, laser trabeculoplasty, trabeculectomy, and drainage implants.

Open-angle glaucoma is the most common type of glaucoma, accounting for more than 90% of the cases. Its cause is unknown and many patients are asymptomatic. It is usually bilateral, with the elevated IOP developing over years. Open-angle glaucoma is named as such because the anterior chamber angle is normal; the iris does not completely cover the trabecular meshwork and canal of Schlemm. They remain open with their flow being partially obstructed. This leads to the gradual development of increased IOP with slow degeneration of the optic nerve, resulting in a gradual loss of vision. Most patients with open-angle glaucoma can be successfully treated with medications.

Pharmacotherapy of Glaucoma

74.3 The primary goal of glaucoma pharmacotherapy is to prevent damage to the optic nerve by lowering intraocular pressure.

When glaucoma is diagnosed and treated early in the course of the disease, permanent vision disability can usually be prevented. Some healthcare providers initiate pharmacotherapy in all patients with an IOP greater than 21 mmHg. Because of the expense of pharmacotherapy and potential adverse drug effects, other healthcare providers will instead carefully monitor the patient through regular follow-up examinations and wait until the IOP rises to 28 to 30 mmHg before initiating treatment. If signs of optic nerve damage or visual field changes are evident, the patient is treated regardless of the IOP.

Once pharmacotherapy has been initiated, reevaluation is performed after 2 to 4 months to assess for therapeutic effectiveness. Some of the antiglaucoma drugs take 6 to 8 weeks to reach peak effect. If the therapeutic goals are not achieved with a single drug, it is common to add a second medication from a different class to the regimen to produce an additive decrease in IOP. Some of the drugs may continue to have effects on the eye for 2 to 4 weeks after being discontinued.

Maintaining patient adherence with the medication regimen is a key factor in preventing progressive vision impairment. It is essential for the nurse to determine any factors that could decrease adherence, such as insufficient financial resources, lack of knowledge about the disease, inability to properly instill the medication, or difficulty remembering the dosing schedule. The patient diagnosed with glaucoma may experience fear and anxiety about potential blindness and disability. Accurate and thorough teaching for the patient and family or caregiver should be directed at how the disease can be managed with the correct use of the medications.

Many drugs are available to treat glaucoma. These medications work by one of two mechanisms: increasing the outflow of aqueous humor at the canal of Schlemm or decreasing the formation of aqueous humor at the ciliary body. Many antiglaucoma drugs produce these effects by modifying actions of the autonomic nervous system.

Although topical drugs are most commonly prescribed, oral (PO) medications may be used for severe glaucoma. Drugs for glaucoma, which are listed in Table 74.1, include the following classes:

- Prostaglandins
- Autonomic drugs, including beta-adrenergic blockers, alpha$_2$-adrenergic agonists, cholinergic agonists, and nonselective sympathomimetics
- Carbonic anhydrase inhibitors
- Osmotic diuretics.

74.4 Prostaglandin analogs are the first-line drugs for treating high intraocular pressure because of their long durations of action and high safety profiles.

Prostaglandin analogs are often the preferred drugs for glaucoma because they have long durations of action, allowing for once-daily dosing, and produce fewer adverse effects than the beta-adrenergic blockers. They may be used as monotherapy or combined with drugs from other classes to produce an additive reduction in IOP in patients with resistant glaucoma.

Prostaglandin analogs lower IOP by increasing the outflow of aqueous humor. Latanoprost (Xalatan), which is available as a 0.005% eyedrop solution, is one of the most commonly used prostaglandin analogs. Other ocular prostaglandins include bimatoprost (Lumigan) and travoprost (Travatan Z). An occasional adverse effect of these medications is heightened pigmentation, which turns a blue iris to a more brown color. Many patients experience thicker and longer eyelashes. These drugs cause local irritation, stinging of the eyes, and redness during the first month of therapy. Because of these effects, prostaglandins are normally administered just before bedtime.

PROTOTYPE DRUG **Latanoprost (Xalatan)**

Classification **Therapeutic:** Drug for glaucoma
Pharmacologic: Prostaglandin analog

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration in 1996, latanoprost is a prostaglandin analog believed to reduce IOP by increasing the outflow of aqueous humor for patients with

Table 74.1 Selected Drugs for Glaucoma

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Prostaglandins		
bimatoprost (Lumigan)	1 drop of 0.03% solution daily in the evening	*Increased length and thickness of eyelashes, darkening of the iris, stinging, sensation of foreign body in the eye* Respiratory infection, flu, angina, muscle or joint pain
latanoprost (Xalatan)	1 drop of 0.005% solution daily in the evening	
tafluprost (Zioptan)	1 drop of 0.0015% solution daily in the evening	
travoprost (Travatan Z)	1 drop of 0.004% solution daily in the evening	
Beta-Adrenergic Blockers		
betaxolol (Betoptic)	1 drop of 0.5% solution bid	*Local burning and stinging, blurred vision, headache* Conjunctival hyperemia, angina, anxiety, bronchoconstriction, hypotension, dysrhythmias
carteolol (Ocupress)	1 drop of 1% solution bid	
levobunolol (Betagan)	1–2 drops of 0.25–0.5% solution 1–2 times/day	
metipranolol (OptiPranolol)	1 drop of 0.3% solution bid	
timolol (Betimol, Timoptic, others)	1–2 drops of 0.25–0.5% solution 1–2 times/day Gel (salve): apply daily	
Alpha$_2$-Adrenergic Agonists		
apraclonidine (Iopidine)	1 drop of 0.5% solution bid	*Local itching and burning, blurred vision, dry mouth, headache, eye discharge* Allergic conjunctivitis, conjunctival hyperemia, hypotension, bulbar conjunctival follicles
brimonidine (Alphagan P)	1 drop of 0.1–0.15% solution in the affected eye tid, 8 h apart	
Cholinergic Agonists		
carbachol (Isopto Carbachol)	1–2 drops of 0.75–3% solution in the lower conjunctival sac up to 3 times/day	*Induced myopia, reduced visual acuity in low light, eye redness, headache* Salivation, tachycardia, hypotension, bronchospasm, sweating, nausea, vomiting, retinal detachment (pilocarpine)
echothiophate iodide (Phospholine Iodide)	1 drop of 0.03–0.25% solution 1–2 times/day	
pilocarpine (Isopto Carpine, Pilopine)	Acute glaucoma: 1 drop of 1–2% solution every 5–10 min for 3–6 doses Chronic glaucoma: 1 drop of 0.5–4% solution q4–12h	
Sympathomimetics		
dipivefrin (Propine)	1 drop of 0.1% solution q12h	*Local burning and stinging, blurred vision, headache, photosensitivity* Tachycardia, HTN
Carbonic Anhydrase Inhibitors		
acetazolamide (Diamox)	PO: 250 mg 1–4 times/day	*For topical medications: blurred vision, bitter taste, dry eye, blepharitis, local itching, sensation of foreign body in the eye, headache* For PO medications: diuresis, electrolyte imbalances, blood dyscrasias, flaccid paralysis, hepatic impairment
brinzolamide (Azopt)	1 drop of 1% solution tid	
dorzolamide (Trusopt)	1 drop of 2% solution in the affected eye(s) tid	
methazolamide (Neptazane)	PO: 50–100 mg bid–tid	
Osmotic Diuretics		
isosorbide (Ismotic)	PO: 1–3 g/kg 1–2 times/day	*Orthostatic hypotension, facial flushing, headache, palpitations, anxiety, nausea* Severe headache, electrolyte imbalances, edema
mannitol (Osmitrol)	IV: 1.5–2 mg/kg as a 15–25% solution over 30–60 min	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

open-angle glaucoma and ocular HTN. The recommended dose is one drop in the affected eye(s) in the evening. It is used to treat open-angle glaucoma.

Mechanism of Action: Latanoprost reduces elevated IOP in patients with open-angle glaucoma. Latanoprost is a prodrug that is metabolized to its active form in the cornea, reaching its peak effect in about 12 hours.

Pharmacokinetics:

Route(s)	Ophthalmic solution
Absorption	Through the cornea
Distribution	Enters systemic distribution in small amounts
Primary metabolism	Metabolized in the aqueous humor to its active form

Primary excretion	Renal
Onset of action	3–4 h with peak effect at 8–12 h
Duration of action	Unknown

Adverse Effects: Adverse effects include ocular symptoms such as conjunctival edema, tearing, dryness, burning, pain, irritation, itching, sensation of a foreign body in the eye, photophobia, or visual disturbances. The eyelashes on the treated eye may grow thicker or darker. Changes may occur in the pigmentation of the iris of the treated eye and in the periocular skin. Rare, systemic adverse effects include headaches, rashes, flulike symptoms, and abnormal liver function tests.

Contraindications/Precautions: Contraindications include hypersensitivity to the drug or another component in the solution, pregnancy, lactation, intraocular infection, or conjunctivitis. It should not be administered to patients with closed-angle glaucoma. The safety of this drug has not been demonstrated in children.

Drug Interactions: Latanoprost interacts with the preservative thimerosal: If used concurrently with other eyedrops that contain thimerosal, precipitation may occur. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with the ophthalmic solution is unlikely.

Nursing Responsibilities: Key nursing implications for patients receiving latanoprost are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Glaucoma.

Drugs Similar to Latanoprost (Xalatan)

Bimatoprost, tafluprost, and travoprost are other prostaglandin analogs used for glaucoma.

Bimatoprost (Lumigan): Approved in 2001, bimatoprost is a synthetic prostaglandin analog indicated for the treatment of open-angle glaucoma. It is usually used when the patient has not responded adequately to other antiglaucoma drugs. In 2008, a newer formulation of this drug, Latisse, was approved to treat hypotrichosis, a condition of having too few eyelashes. Use of bimatoprost can cause a gradual increase in the development of brown pigmentation in the iris, which may be irreversible, and includes an increase in pigmentation of the eyelid. Other adverse effects include blurred vision, eye discomfort, ocular pruritus, conjunctivitis, dry eye, light intolerance, and tearing. It is available as a 0.01% or 0.03% solution applied once daily in the evening. This drug is pregnancy category C.

Tafluprost (Zioptan): When approved in 2012, tafluprost became the first antiglaucoma prostaglandin completely free of preservatives. Preservatives sometimes cause allergic reactions in susceptible patients and may worsen ocular surface disorders such as dry eye syndrome. The actions, effectiveness, and side effects of tafluprost are equivalent to those of other prostaglandins.

Travoprost (Travatan Z): Approved in 2001, travoprost is approved for the treatment of open-angle glaucoma. Travoprost has been found to be more effective in African Americans than in non–African Americans. Like bimatoprost, travoprost is used when other drugs have failed to produce a satisfactory response. Use of this drug can cause a gradual increase in the development of brown pigmentation in the iris, which may be irreversible, and includes an increase in pigmentation of the eyelid and growth of the eyelashes. Conjunctival hyperemia has been reported in 35% to 50% of patients treated with travoprost. Some other adverse effects include blurred vision, eye discomfort, ocular pruritus, dry eye, light intolerance, and tearing. It is available as a 0.004% solution, applied once daily in the evening. This drug is pregnancy category C.

CONNECTION Checkpoint 74.1

Several prostaglandins are used for their actions on uterine smooth muscle. From what you learned in Chapter 70, what are the primary indications for the prostaglandins carboprost (Hemabate), dinoprostone (Cervidil), and mifepristone (Mifeprex)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

74.5 Drugs that affect the autonomic nervous system are sometimes prescribed to treat glaucoma.

Several structures within the eye are activated by the sympathetic and parasympathetic divisions of the autonomic nervous system. As such, a significant number of autonomic drugs have been used to treat glaucoma and to aid in ophthalmic examinations of the eyeball.

- Sympathetic activation (or parasympathetic division blockade): Muscles of the iris contract to dilate the pupil; the ciliary muscle relaxes to enhance distance vision.
- Parasympathetic activation (or sympathetic division blockade): Muscles of the iris contract to constrict the pupil; the ciliary muscle contracts to enhance near vision.

The most frequently used autonomic drugs are the beta-adrenergic antagonists or blockers. Alpha$_2$-adrenergic agonists, cholinergic agonists, and nonselective sympathomimetics play minor roles, as discussed next. Prior to reading this section, the student may want to review Chapter 12 to brush up on the terminology and anatomy of the autonomic nervous system.

Beta-adrenergic blockers: Before the discovery of the prostaglandin analogs, beta-adrenergic blockers were the preferred drugs for open-angle glaucoma. These drugs decrease the production of aqueous humor by the ciliary body in the affected eye and can lower IOP by 20% to 30%. Five beta-adrenergic blockers are available as ophthalmic solutions: betaxolol (Betoptic), carteolol (Ocupress), levobunolol (Betagan), metipranolol (OptiPranolol), and timolol (Betimol, Timoptic, others). These drugs generally produce fewer adverse ocular effects than cholinergic agonists or sympathomimetics. In most patients, the topical administration of beta blockers does not result in significant systemic absorption. Should absorption occur, however, adverse systemic effects may include bronchoconstriction, dysrhythmias, and hypotension. Because of the potential for adverse systemic effects, these drugs should be used with caution in patients with asthma, bradycardia, or heart failure. Tolerance will develop with long-term use in about 25% of patients who take these drugs.

Alpha$_2$-adrenergic agonists: Alpha$_2$-adrenergic agonists lower IOP by decreasing the production of aqueous humor and increasing its absorption. Only two alpha$_2$-adrenergic agonists are currently approved: apraclonidine and brimonidine. Apraclonidine (Iopidine) is infrequently used but may be prescribed for the prevention or short-term therapy of postoperative increases in IOP. Brimonidine (Alphagan P) is more commonly prescribed, either as monotherapy or as an adjunct in combination with a beta-adrenergic blocker, for the long-term treatment of open-angle glaucoma or glaucoma secondary to uveitis, which is an inflammation of the middle layer of the eyeball. Alpha$_2$-adrenergic agonists may be used in combination with other antiglaucoma drugs to cause additive reduction in IOP. Combigan is an ophthalmic solution that consists of brimonidine and timolol.

Alpha$_2$-adrenergic agonists are contraindicated in closed-angle glaucoma because the pupil dilation that results would worsen the condition. The most significant adverse effect, and one that is a frequent cause for discontinuation of therapy, is an allergic-type reaction that causes sensation of a foreign body, itching, and hyperemia. Other adverse effects include headache, drowsiness, dry mucosal membranes, blurred vision, and irritated eyelids. These drugs produce few cardiovascular or pulmonary adverse effects. Rare systemic adverse effects may occur, including nervousness, anxiety, and muscle tremors. Patients should immediately notify their healthcare provider if they experience acute eye pain, because this may signal the onset of closed-angle glaucoma.

Cholinergic agonists (miotics): Drugs that directly activate cholinergic receptors in the eye produce **miosis**, or constriction of the pupil, and contraction of the ciliary muscle. These actions physically stretch the trabecular meshwork to allow greater outflow of aqueous humor and a lowering of IOP. Pilocarpine (Isopto Carpine, Pilopine) is the most commonly prescribed antiglaucoma drug in this class. The cholinergic agonists are applied topically to the eye 4 times daily. Because of their greater toxicity and frequent dosing, these drugs are normally used only in patients with open-angle glaucoma who do not respond to other drugs. Local effects include headache, induced myopia, and decreased vision in low light. Systemic absorption can result in hypotension, vomiting, diuresis, bronchoconstriction, diaphoresis, and abdominal pain with diarrhea. Toxic effects include vertigo, bradycardia, tremors, syncope, and cardiac dysrhythmias. Other actions of the cholinergic agonists are presented in Chapter 13.

A second group of cholinergic agonists, the cholinesterase inhibitors, act indirectly to lower IOP. They produce essentially the same actions as the direct-acting drugs but exhibit a higher incidence of adverse effects. Cholinesterase inhibitors such as echothiophate cause cataracts in a significant percentage of patients and are used only in those who are resistant to therapy with other drugs.

CONNECTION Checkpoint 74.2

Cholinergic agonists such as pilocarpine activate muscarinic receptors. From what you learned in Chapter 13, what effect do muscarinic agonists have on lacrimation and how is this used therapeutically?

Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.

Nonselective sympathomimetics: Nonselective sympathomimetics activate the sympathetic nervous system to produce **mydriasis** (pupil dilation) and increase the outflow of aqueous humor, resulting in a lower IOP. They are not as effective as the beta-adrenergic blockers or the prostaglandin analogs. Medications in this class include epinephrine and dipivefrin, which are converted to epinephrine in the eye. Both are administered topically for open-angle glaucoma and are contraindicated in closed-angle glaucoma. Epinephrine will increase blood pressure and the heart rate if it reaches the systemic circulation; thus the drug is contraindicated in patients with unstable cardiovascular disease. Sympathomimetics also produce a high frequency of ocular adverse effects, including tearing, burning, hyperemia, and stenosis of the nasolacrimal duct. Because of the potential for systemic adverse effects, these medications are third-choice drugs for glaucoma.

PROTOTYPE DRUG **Timolol (Betimol, Timoptic, Others)**

Classification **Therapeutic:** Drug for glaucoma
Pharmacologic: Miotic, beta-adrenergic antagonist

Therapeutic Effects and Uses: Approved in 1978, timolol is a nonselective beta-adrenergic blocker available

as a 0.25% or 0.5% ophthalmic solution. Its primary indication is chronic open-angle glaucoma. It may also be used for aphakic glaucoma (high IOP in patients with no lens), secondary glaucoma, and ocular HTN. The usual dose is one drop in the affected eye(s) twice a day. Timoptic XE allows for once-daily dosing. Treatment may require 2 to 4 weeks to reach the maximum therapeutic effect.

Timolol is available in several formulations. Cosopt is an antiglaucoma drug that combines timolol with dorzolamide, a topical carbonic anhydrase inhibitor. Combigan is an ophthalmic solution of timolol with brimonidine, an alpha-adrenergic agonist. Timolol is also available in tablets (Blocadren), which are prescribed to treat mild HTN.

Mechanism of Action: Timolol topically lowers the elevated and normal IOP by reducing the formation of aqueous humor and possibly increasing outflow. It affects both $beta_1$ and $beta_2$ receptors.

Pharmacokinetics:

Route(s)	Eye solution or gel
Absorption	Small amounts reach the systemic circulation from topical application
Distribution	Secreted in breast milk
Primary metabolism	80% metabolized in the liver to inactive metabolites
Primary excretion	Renal
Onset of action	30 min
Duration of action	12–24 h

Adverse Effects: The most common adverse effects from ophthalmic administration are local burning and stinging on instillation. Vision may become temporarily blurred. In most patients absorption is not significant enough to cause adverse systemic effects as long as timolol is applied correctly. If absorption occurs, hypotension or dysrhythmias are possible.

Contraindications/Precautions: Although little is absorbed through ocular administration, this drug should be used with caution in certain patients. Timolol is contraindicated in patients with asthma, severe chronic obstructive pulmonary disease (COPD), sinus bradycardia, second- or third-degree atrioventricular block, heart failure, cardiogenic shock, or hypersensitivity to the drug. Safety in children has not been established.

Drug Interactions: Drug interactions may result if significant systemic absorption occurs. Timolol should be used with caution in patients who are taking other beta blockers owing to additive cardiac effects. Concurrent use with anticholinergics, nitrates, reserpine, methyldopa, or verapamil could lead to hypotension and bradycardia. Epinephrine use could lead to HTN followed by severe bradycardia. When given by the ocular route, timolol will produce additive lowering of IOP when given concurrently with other antiglaucoma drugs. **Herbal/Food:** There are no known herbal or food interactions with this drug.

Pregnancy: Category C.

Treatment of Overdose: Overdose with ophthalmic solution is unlikely but could result in systemic symptoms such as reduced heart rate and bronchospasm.

Nursing Responsibilities: Key nursing implications for patients receiving timolol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Glaucoma.

Drugs Similar to Timolol (Betimol, Timoptic, Others)

Other beta-adrenergic blockers with ophthalmic indications include betaxolol, carteolol, levobunolol, and metipranolol. Levobetaxolol (Betaxon) is an ophthalmic beta blocker that has been discontinued in the United States.

Betaxolol (Betoptic): Approved in 1985, betaxolol is a selective $beta_1$-adrenergic receptor blocker. This drug reduces IOP by decreasing the production of aqueous humor. Betaxolol is indicated for intraocular HTN and chronic open-angle glaucoma. A tablet form of this drug (Kerlone) is available to treat HTN. Although only small amounts are absorbed from ophthalmic administration, this drug should be used cautiously in patients with heart failure and if used concurrently with a systemic beta-adrenergic blocker. Ocular irritation and tearing are frequent adverse effects. This drug is pregnancy category C.

Carteolol (Ocupress): Carteolol is a nonselective beta-adrenergic blocker that competes for available beta receptor sites and is used for the treatment of chronic open-angle glaucoma. Both $beta_1$ and $beta_2$ receptors are inhibited. Adverse effects and contraindications are the same as those of other ophthalmic beta blockers. This drug is pregnancy category C.

Levobunolol (Betagan): Approved in 1985, levobunolol is a nonselective beta-adrenergic blocker that is indicated for the treatment of intraocular HTN and chronic open-angle glaucoma. Because small amounts may reach the systemic circulation, caution needs to be practiced when using this drug in patients with asthma, COPD, bradycardia, thyroid conditions, diabetes, and abnormal blood glucose levels. Tolerance can develop with long-term use. Ocular irritation is a frequent, transient adverse effect. This drug is pregnancy category C.

Metipranolol (OptiPranolol): Approved in 1989, this drug is a nonselective beta-adrenergic blocker used for the treatment of elevated IOP and chronic open-angle glaucoma. It

is available as a 0.3% solution that is applied to the affected eye(s) twice daily. Small amounts may be absorbed systemically. Contraindications are the same as those of other ophthalmic beta blockers. Ocular irritation is a frequent, transient adverse effect. Although rare, uveitis has been associated with metipranolol use. If this occurs, this drug should be discontinued because uveitis can cause an increase in IOP. This drug is pregnancy category C.

Miscellaneous Drugs for Treating Glaucoma

74.6 Carbonic anhydrase inhibitors and osmotic diuretics are occasionally used for treating glaucoma.

Although prostaglandin analogs and beta-adrenergic blockers are the two most frequently prescribed classes for lowering IOP, some patients may experience adverse effects from these drugs or have particularly resistant glaucoma. Two additional classes, the carbonic anhydrase inhibitors and the osmotic diuretics, are not routinely prescribed.

Carbonic anhydrase inhibitors: Carbonic anhydrase inhibitors interfere with the synthesis of carbonic acid, which decreases the production of aqueous humor and reduces IOP. They are used as long-term therapy in patients with open-angle glaucoma when prostaglandin inhibitors, beta blockers, and other autonomic drugs have not been effective.

Drugs in this class are divided into topical or oral formulations. Dorzolamide (Trusopt) is used topically to treat open-angle glaucoma, either as monotherapy or in combination with other medications. Dorzolamide and other topical carbonic anhydrase inhibitors, including brinzolamide (Azopt), are well tolerated and produce few significant adverse effects other than photosensitivity. PO formulations such as acetazolamide (Diamox) are very effective at lowering IOP in both open-angle and closed-angle glaucoma but are rarely used because they produce more adverse systemic effects than drugs from other classes. These adverse effects include lethargy, nausea, vomiting, depression, paresthesias, and drowsiness. Patients must be cautioned when taking these medications because they contain sulfur and may cause allergic reactions. Because the oral formulations are diuretics and can reduce IOP quickly, serum electrolytes should be monitored during treatment. A prototype feature for acetazolamide is presented in Chapter 32.

Osmotic diuretics: Osmotic diuretics are occasionally used preoperatively and postoperatively with ocular surgery or as emergency treatment of acute closed-angle glaucoma attacks. Examples include isosorbide (Ismotic), urea, and mannitol (Osmitrol). Because they have the ability to quickly reduce plasma volume, these drugs are effective in reducing the formation of aqueous humor, thereby reducing IOP. Adverse effects include headache, tremors, dizziness, dry mouth, fluid and electrolyte imbalances, and thrombophlebitis or venous clot formation near the site of intravenous (IV) administration. A prototype feature for mannitol is presented in Chapter 32.

CONNECTION Checkpoint 74.3

Mannitol is given by the IV route under controlled conditions. From what you learned in Chapter 32, describe the mechanism of action of osmotic diuretics. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Glaucoma

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including ophthalmologic, respiratory, cardiovascular, and endocrine disease.
- Assess visual acuity and visual fields. Assess for the presence of eye pain, visual disturbances such as halos around lights, diminished foggy vision, or loss of peripheral vision.
- Assess for history of recent eye trauma or infection.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Obtain baseline vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., IOP remains below 21 mmHg, no changes in visual acuity or fields).
- Assess for adverse effects: conjunctival edema, tearing, dryness, burning, pain, irritation, itching, sensation of foreign body in the eye, or photophobia. Severe visual disturbances or eye pain should be reported to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor visual acuity, vision fields, and IOP. (IOP should remain less than 21 mmHg or per parameters set by healthcare provider. Visual acuity and fields remain intact.)	• Instruct the patient to immediately report changes in vision, eye pain, light sensitivity, halos around lights, or headache to the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Monitor appropriate administration of the drug to avoid extraocular effects. (Eyedrops should be instilled into the conjunctival sac and the lacrimal duct area held with gentle pressure for one full minute to prevent drug leakage into the nasopharynx with possible systemic effects. PO drugs should be taken consistently throughout the day with no doses omitted.)	• Teach the patient the proper administration techniques for eyedrops. PO medications should be taken as regularly throughout the day as possible and with consistent dosing.
• Monitor IOP periodically. (Consistent readings above 21 mmHg may indicate worsening disease or improper use of drug therapy.)	• Instruct the patient about the importance of returning for and maintaining regular eye examinations.
• Monitor for increasing eye redness, pain, light sensitivity, or changes in visual acuity. (Eye changes or pain may indicate worsening disease, infection, or adverse drug effects.)	• Instruct the patient to avoid touching the eyedrop tip to the conjunctival sac when instilling eyedrops. Immediately report any increasing redness, eye pain, eye drainage, or changes in vision.
• Remove contact lenses before administering ophthalmic solutions. Avoid use of other eyedrops or ointments unless approved by the healthcare provider. (Contact lenses may hinder eye solution from fully reaching all eye surfaces or may absorb solution, resulting in higher than expected amounts in the eye over time. Other eye solutions may interact with or counteract the effects of the prescribed solution.)	• Instruct the patient to remove contact lenses prior to administering eyedrops and wait at least 15 min before reinserting them. • Instruct the patient to seek the healthcare provider's advice before using any other eye solution.
• Monitor vital signs periodically for signs of systemic absorption of ophthalmic preparations. (Ophthalmic drugs such as beta blockers or cholinergic drugs may result in hypotension, bradycardia, or respiratory distress due to bronchospasm if the drug is absorbed systemically. Ensure that the patient is administering drops appropriately if changes in blood pressure are noted. **Lifespan:** Monitor older adults frequently for hypotension related to systemic absorption to prevent falls.)	• Teach the patient to return to the healthcare provider periodically for monitoring. Assess blood pressure once per week (e.g., at supermarket pharmacy counter sphygmomanometer) and report any blood pressure less than 90/60 mmHg or per parameters set by the healthcare provider. Immediately report any dizziness, lightheadedness, headache, palpitations, syncope, or difficulty breathing.
• Provide for eye comfort such as an adequately lighted room. (Ophthalmic drugs such as beta blockers used in the treatment of glaucoma can cause miosis and difficulty seeing in low light levels.)	• Caution the patient about driving or other activities in low-light conditions or at night until the effects of the drug are known.
• Monitor adherence to the treatment regimen. (Nonadherence with drug therapy may result in the total loss of vision.)	• Teach the patient the importance of adhering to the medication schedule as prescribed. • Address any concerns the patient may have about cost or discomfort related to drug therapy, and provide appropriate referrals (e.g., social service agency) as needed.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., appropriate instillation of eyedrops followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Remove contact lenses if worn.
	  • Gently pull down on the lower eyelid, anchoring the hand against the cheekbone.
	  • Tilt the head back; steadying the hand on the forehead as needed, drop prescribed numbers of drops into the conjunctival sac. Do not drop solution directly onto the eye surface.
	  • Close the eye gently. Hold light pressure on the tear duct for one full minute to retain the solution.
	  • Do not reinsert contact lenses for a minimum of 15 min after eyedrop instillation, or as directed.

Pharmacotherapy for Eye Examinations

74.7 Drugs that are routinely used for eye examinations include mydriatics, cycloplegics, diagnostic dyes, and local anesthetics.

Various drugs are used to enhance diagnostic eye examinations and during ophthalmic surgery. Mydriatic drugs cause sympathetic activation that relaxes the ciliary muscle, causing dilation of the pupil and thus allowing for better visualization of retinal structures. Cycloplegic drugs not only dilate the pupil but also paralyze the ciliary muscle and prevent the lens from moving during assessment. Mydriatics and cycloplegics are often used in combination to achieve the maximum pupil dilation needed for surgery or during funduscopic examinations. Examples of drugs used for eye examinations include

anticholinergics, such as atropine (Isopto Atropine) and tropicamide (Mydriacyl, Tropicacyl), and sympathomimetics, such as phenylephrine (Mydfrin, Neo-Synephrine). Mydriatic, cycloplegic, and other drugs for eye conditions are listed in Table 74.2.

Mydriatics cause intense photophobia and pain in response to bright light. Mydriatics can worsen glaucoma by impairing aqueous humor outflow and thereby increasing IOP. In addition, strong concentrations of anticholinergics have the potential to have systemic effects on the central nervous system (CNS) and cause confusion, unsteadiness, or drowsiness. **Cycloplegics** can cause severe blurred vision and loss of near vision. Scopolamine, an anticholinergic often used to prevent motion sickness, can cause blurred vision due to cycloplegia, as well as angle-closure glaucoma attacks. The response to mydriatics and cycloplegics can last from 3 hours up to several days. The patient should be taught to wear sunglasses and that the ability to drive, read, and perform visual tasks may be affected during treatment.

Diagnostic drugs are used to help locate lesions or foreign bodies within the eye and to provide some local anesthesia. Fluorescein sodium is a dye used in assessing the cornea and fitting contact lenses. Scratches may turn bright green; foreign bodies are surrounded by a green halo. Areas where the conjunctiva is damaged show an orange-yellow discoloration. Fluorescein sodium with benoxinate (Fluress) adds local anesthesia, making it useful for the identification and removal of foreign bodies from the cornea.

Local anesthetics are used to prevent the pain associated with diagnostic and surgical procedures, suturing and removal of foreign bodies, and ocular injections. The drugs used include proparacaine (Alcaine, Ophthaine) and tetracaine. Application consists of one to two drops applied to the affected eye. Anesthesia typically occurs within 20 seconds and lasts for 10 to 20 minutes. Adverse effects of their use include local irritation, including conjunctivitis. Systemic effects are rarer, but CNS excitation has been known to occur. The nurse must be careful to protect the patient's eye from injury while anesthetized, or corneal damage may occur.

Table 74.2 Miscellaneous Drugs Used for the Eye

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Mydriatics: Sympathomimetics		
phenylephrine (Mydfrin, Neo-Synephrine)	1 drop of 2.5% or 10% solution before eye examination	*Eye pain, photosensitivity, eye irritation, headache* HTN, tremor, dysrhythmias
Cycloplegics: Anticholinergics		
atropine (Isopto Atropine, others)	Uveitis: 1–2 drops of 1% solution up to 4 times daily; also give 1–2 drops 1 h prior to eye examination	*Eye irritation and redness, dry mouth, local burning or stinging, headache, blurred vision, photosensitivity, eczematoid dermatitis (scopolamine and tropicamide)* Somnolence, tachycardia, convulsions, mental changes, keratitis, increased IOP (homatropine)
cyclopentolate (Cyclogyl, Pentolair)	1 drop of 0.5–2% solution 40–50 min before eye examination	
homatropine (Isopto Homatropine, others)	1–2 drops of 2% or 5% solution before eye examination Uveitis: 1–2 drops of 2–5% solution bid–tid up to q3–4h as needed	
scopolamine (Isopto Hyoscine)	1–2 drops of 0.25% solution 1 h before eye examination	
tropicamide (Mydriacyl, Tropicacyl)	1–2 drops of 0.5–1% solution before eye examination	
Anesthetics		
lidocaine (Akten)	2 drops of 3.5% gel in affected eye, reapplied as needed	*Stinging, corneal erosion, headache, slowed healing of corneal abrasions* Anaphylactic reactions
proparacaine (Alcaine, Ophthaine)	1 drop of 0.5% solution in affected eye q5–10min for 5–7 doses	
tetracaine	1–2 drops of a 0.5% solution or 1.25–2.5 cm of ointment in the lower conjunctival sac	
Lubricants		
lanolin alcohol (Lacri-lube)	Apply a thin film to the inside of the eyelid	*Temporary burning or stinging, eye itching or redness, headache* No serious adverse effects
polyvinyl alcohol (Liquifilm, others)	1–2 drops tid–qid prn	
Vasoconstrictors		
naphazoline (Albalon Allerest, Clear Eyes, others)	1–3 drops of 0.1% solution q3–4h prn	*Temporary burning or stinging, eye itching or redness, headache* No serious adverse effects
oxymetazoline (OcuClear, Visine LR)	1–2 drops of 0.025% solution qid	
phenylephrine (Neo-Synephrine)	1–2 drops of 0.12% solution up to 4 times/day	
tetrahydrozoline (Murine Plus, Visine, others)	1–2 drops of 0.05% solution bid–tid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTIONS: Community-Oriented Practice

Improper Eyedrop Administration

Most adults will use eyedrops occasionally to treat dry eyes, allergy conditions, or as a prescribed treatment for more serious eye conditions. In a study of post–cataract surgery patients who did not regularly use eyedrops, An, Kasner, Samek, and Lévesque (2014) found that less than 8% of patients self-administered eyedrops correctly. Despite only 31% of patients reporting difficulty with self-administration, the most common problems observed were failure to wash hands before self-administration (78%), contaminating the bottle tip (57.4%), missing the eye (31.5%), and instilling an incorrect number of drops (64%). The authors also found that self-administration improved significantly after the patients were provided instruction in the proper instillation techniques. To improve therapeutic outcomes and patient safety, adequate patient education is vital.

Pharmacotherapy for Other Eye Conditions

74.8 Numerous pharmacologic drugs are used to treat minor eye irritation and redness.

Drugs for minor eye irritation and dryness come from a broad range of classes. Some drugs lubricate only the eye's surface, whereas others are designed to penetrate and affect a specific area of the eye.

Dry eye disease (or syndrome) is a condition in which the patient secretes either an insufficient amount of tears or poor quality tears. Common in older adults, this condition is worsened by certain medications such as decongestants or antihistamines, or by environmental conditions such as wind or dry climate. Long-term use of contact lenses and refractive surgeries (Lasik) can decrease tear production.

Minor dry eye disease is treated with lubricants such as artificial tears. Artificial tear drugs are topical preparations of methyl or vinyl cellulose. These drops can be instilled as often as every hour. A wide variety of over-the-counter (OTC) preparations are available, including eyedrop solutions, ointments, and inserts.

Two prescription drugs are available to treat dry eye disease. Cyclosporine ophthalmic emulsion (Restasis) stimulates the production of tears in patients whose tear production is suppressed by ocular inflammation. It is most effective when used in combination with artificial tear replacement and is administered as one drop in the affected eye(s) twice daily. Cyclosporine is presented as a prototype immunosuppressant in Chapter 42.

Approved in 2016, lifitegrast (Xiidra) is an ophthalmic solution that blocks certain inflammatory cytokine interactions on the surface of the eye. This reduces dry eye discomfort. It is administered as one drop daily in each eye. Side effects are minor and include local irritation, dysgeusia (distorted sense of taste), and decreased visual acuity.

Minor eye irritation is a frequent condition that is often treated with vasoconstrictors. Common vasoconstrictors include phenylephrine (Neo-Synephrine), naphazoline (Clear Eyes, others), and tetrahydrozoline (Murine Plus, Visine, others). The adverse effects of the vasoconstrictors are usually minor and include blurred vision, tearing, headache, and rebound vasodilation with redness.

Infection and inflammatory responses are common conditions in the supporting structures of the eye and may result from foreign bodies, bacteria, or viruses. Allergies and irritants such as tobacco smoke are also common sources of inflammation. Redness, edema, and itching are common symptoms. The anti-infectives used to treat eye infections are the same drugs used to treat infections in other areas of the body. Applied topically they carry the common adverse effects of conjunctivitis and local skin and eye irritation. Examples of eye infections that are treated with anti-infective medications include:

- **Blepharitis.** Inflammation of the edges of the eyelids that is commonly seen in older adults and those with dry eyes.
- **Conjunctivitis.** Inflammation or infection of the lining of the eyelids. Bacterial conjunctivitis is often caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Viral conjunctivitis is highly contagious and treatment is symptomatic.
- **Chalazion and styes.** A chalazion is a lump or cyst along the edge of an eyelid. Hordeolum, or an external stye, is a blockage of the sebaceous glands at the base of the eyelashes. A chalazion or hordeolum may become infected and require the use of ocular antibiotics.
- **Keratitis.** An inflammation of the cornea that may also be caused by trauma or dryness of the cornea from decreased lubrication. If left untreated, corneal scarring with impaired vision may result.

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketorolac (Acular, Acuvail), can be used to treat conjunctivitis and other inflammatory conditions. They are also used to reduce inflammation postoperatively and the symptoms associated with seasonal allergies. Topical corticosteroids are also very effective at reducing inflammation in the eye, although they should not be administered if an infection is suspected. The most common adverse effects of topical corticosteroids are cataracts, glaucoma, mydriasis, and ptosis. Cycloplegics can also be used to treat ocular pain caused by almost any inflammatory condition, except glaucoma.

Several medications, including antihistamines, mast cell stabilizers, and combination antihistamine–mast cell stabilizers, are used to decrease the redness and itching associated with allergic conjunctivitis. Systemic antihistamines

Table 74.3 Drugs for the Treatment of Allergic Conjunctivitis

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Mast Cell Stabilizers		
cromolyn (Crolom)	1–2 drops of 4% solution q4–6h	*Dry mouth, headache, nausea, sneezing, nasal symptoms, and transient eye stinging and burning*
lodoxamide (Alomide)	1–2 drops of 0.1% solution qid	
nedocromil (Alocril)	1–2 drops of 2% solution bid	Bronchospasm, angioedema, anaphylaxis
Antihistamines		
alcaftadine (Lastacaft)	1 drop of 0.25% solution once daily	*Fatigue, dizziness, dry mouth, headache, pharyngitis, cough, bitter taste, rhinitis*
azelastine (Optivar)	1 drop of 0.05% solution bid	
bepotastine (Bepreve)	1 drop of 1.5% solution bid	No serious adverse effects
cetirizine (Zerviate)	1 drop of 0.24% solution bid	
emedastine (Emadine)	1 drop of 0.05% solution qid	
epinastine (Elestat)	1 drop of 0.05% solution bid	
ketotifen (Alaway, Zaditor)	1 drop of 0.025% solution q8–12h	
olopatadine (Patanol)	1 drop of 0.1% solution bid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

may be used but they may cause ocular dryness, which could aggravate symptoms. Topical mast cell stabilizers, with or without an antihistamine, are the preferred treatment for allergic conjunctivitis because they do not cause further drying of the eyes. Olopatadine (Patanol) and ketotifen (Alaway, Zaditor) are combination antihistamine–mast cell stabilizers. Ketotifen is available OTC. Drugs for the treatment of allergic conjunctivitis are listed in Table 74.3.

Anatomy of the Ear

74.9 Knowledge of basic ear anatomy is fundamental to understanding ear disorders and pharmacotherapy.

The ear has two major sensory functions: hearing and maintenance of equilibrium and balance. The three structural areas of the ear—the external, middle, and inner ear—carry out these functions, as shown in Figure 74.3.

The external ear consists of the pinna, which is the visible portion of the ear, and the external auditory canal. The external auditory canal transmits sound waves to the tympanic membrane, or eardrum. This canal is lined with numerous ceruminous glands that protect the canal and help keep the tympanic membrane pliable. The tympanic membrane separates the external ear from the middle ear. The middle ear consists of a bony cavity containing the three ossicles, called the malleus, incus, and stapes, that transmit sound waves to the inner ear. The eustachian tube provides a connection between the middle ear and the nasopharynx. It permits equalization of pressure in the middle ear by allowing air to enter or leave the middle ear cavity and for the drainage of secretions. Its mucosa is continuous with the mucosal lining of the throat, providing a means for infectious organisms to enter the middle ear from the nose and throat. The inner ear consists of the semicircular canals, the vestibule, and the cochlea. The cochlea is the main organ of hearing, whereas the semicircular canals and vestibule are responsible for balance and equilibrium.

Pharmacotherapy with Otic Preparations

74.10 Otic preparations treat infections, inflammation, and earwax buildup.

Otic medications commonly used to treat ear infections, inflammation, and wax buildup are shown in Table 74.4. Otitis, or inflammation of the ear, is a common indication for pharmacotherapy. **Otitis externa**, commonly called swimmer's ear, is an inflammation with or without infection of the skin in the external auditory canal. The acute form is bacterial in origin and most often due to *Pseudomonas aeruginosa* or *S. aureus*. It is associated with water exposure, high humidity, and a history of ear trauma generally from sharp or small objects. Chronic otitis externa is most often caused by a fungal infection or an allergic response usually associated with cosmetics, hair products, or devices placed within the ear canal. The typical presentation is that of acute-onset ear pain associated with pruritus, swelling, and tenderness to the touch or with movement. A greenish white drainage may accompany symptoms. Hearing impairment may result if the swelling is sufficient to obstruct the auditory canal.

Treatment of otitis externa focuses on reducing pain and inflammation, usually with topical corticosteroids, antibiotics, and analgesics, as needed. Neomycin, gentamicin, and ciprofloxacin (Cipro otic) are the most commonly used topical otic antibiotics. Mild fungal infections can be treated with a 90% to 95% alcohol solution; more advanced disease may be treated with topical 1% clotrimazole (Lotrimin) or tolnaftate (Tinactin). If swelling obstructs the external canal, an ear

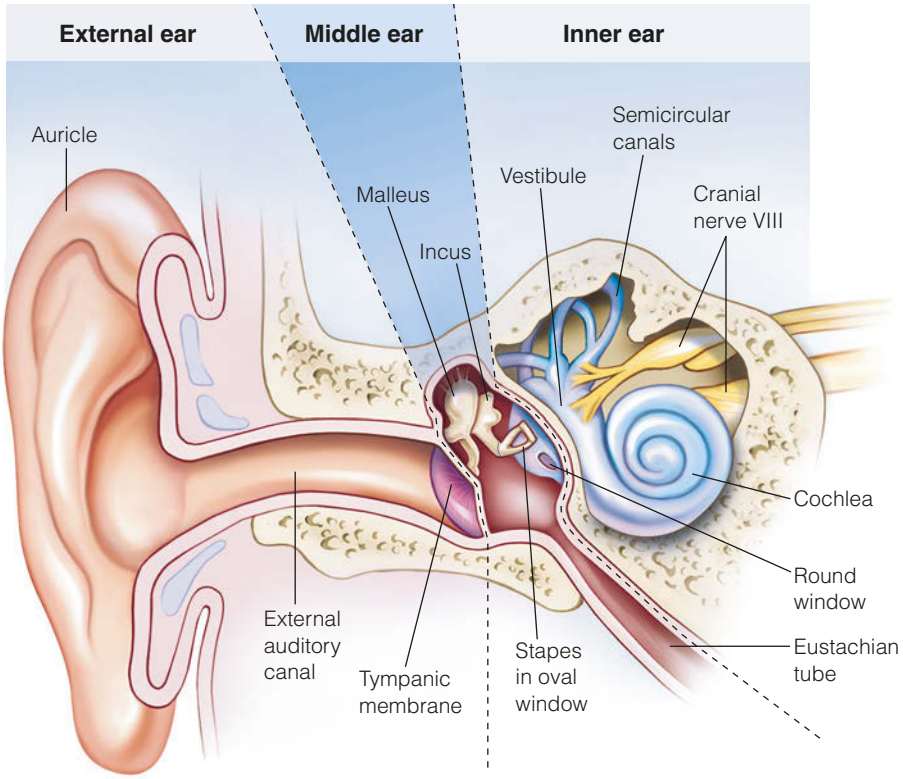

Figure 74.3 Anatomy of the ear.

wick may be placed past the blockage and the drops applied to the end. The use of systemic antibiotics may be necessary in cases when outer ear infections are extensive, such as with cellulitis or lymph node involvement.

PharmFACT

Otitis externa has a peak incidence of 7 to 12 years of age and occurs most commonly in the summer months. Although called swimmer's ear, the condition may also be caused by cleaning and scratching the ear canal with cotton swabs or paper clips (Waltzman, 2017).

Otitis media, which is inflammation of the middle ear, is a common disorder that affects infants and young children, although people of any age may be affected. Among children 75% experience at least one episode of otitis media by their third birthday, and almost half of these children will have three or more ear infections during that time.

There are three common types of otitis media: acute, chronic, and serous. Acute otitis media and chronic otitis media are similar. An infectious agent, most often a viral upper respiratory infection, results in pathogens being introduced into the middle ear through the eustachian tube, leading to swelling and inflammation of the ossicles

Table 74.4 Otic Preparations

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
acetic acid and hydrocortisone (Acetasol HC, VoSoL HC)	3–5 drops q4h–qid for 24 h, then 5 drops tid–qid	*Ear irritation, local stinging or burning, dizziness*
carbamide peroxide (Debrox)	1–5 drops of 6.5% solution bid for 4 days	Allergic reactions (antibiotics)
ciprofloxacin-dexamethasone (Ciprodex)	4 drops in the affected ear bid for 7 days	
ciprofloxacin-hydrocortisone (Cipro HC)	3 drops of the suspension instilled into the affected ear bid for 7 days	
ofloxacin (Floxin otic)	5–10 drops in the affected ear once daily for 7 days	
polymyxin B, neomycin, and hydrocortisone (Cortisporin) colistin, neomycin, thonzonium bromide and hydrocortisone (Cortisporin TC)	3–5 drops in the affected ear tid–qid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

of the middle ear. Bacterial infection with *S. pneumoniae*, *H. influenzae*, and *Streptococcus pyogenes* causes most cases. Otitis media may also be associated with allergies or eustachian tube dysfunction. Acute otitis has a duration of less than 3 weeks; chronic otitis follows repeated episodes and has a longer duration of symptoms. Sometimes the eardrum ruptures, and pus drains out of the ear. More commonly, the pus and mucus remain in the middle ear due to the swollen and inflamed eustachian tube. This is called middle ear effusion or serous otitis media. After the acute infection has passed, the effusion may remain and become chronic, lasting for weeks, months, or even years.

Otitis media is treated with a course of systemic, rather than topical, antibiotics. Amoxicillin, at a dose of 80 to 90 mg/kg/day, is prescribed for most children. For patients who have symptoms of a more severe illness and in those for whom additional coverage for β-lactamase–positive *H. influenzae* and *Moraxella catarrhalis* is desired, therapy is initiated with high-dose amoxicillin-clavulanate. For patients with mild penicillin allergy, a cephalosporin may be considered. If the penicillin allergy is more severe, azithromycin or clarithromycin can be used. In the patient who is vomiting or cannot otherwise tolerate oral medication, a single dose of parenteral ceftriaxone has been shown to be effective.

CONNECTIONS: Preparing for Advanced Practice

Otitis Media

Case

Aadila, a 3-year-old, is brought to the clinic by her mother because she has been experiencing a low-grade fever of 38°C (100.5°F) for 2 days. The fever is accompanied by reports of left ear pain that has been awakening her. Both Aadila and her mom look exhausted, and Aadila has been extremely fussy during the visit. Mom tells you that Aadila has had upper respiratory infection symptoms including rhinorrhea, nasal congestion, and a nonproductive cough for 1 week, although the symptoms have started to resolve. She did not have any fever before the ear pain started. The child has had no changes in eating or elimination patterns. Mom has not tried any medications, but has been putting warm compresses over the ear, which seems to relieve some pain. Aadila has no significant medical history and has had only one other ear infection when she was 9 months old. She is fully immunized. Her temperature is 37.7°C (100°F). The physical examination revealed the only abnormalities to be slight redness of the throat, a nose full of thick green mucus, a pearly gray right tympanic membrane with positive light reflex and visible bony landmarks; an erythematous and bulging left tympanic membrane with diminished light reflex and bony landmarks not visualized. No drainage was observed and no pain on palpation of the mastoid bone was noted. Should Aadila be treated with antibiotics? Should she be treated for pain management?

Discussion

The chief symptom of otitis media is ear pain with an accompanying sense of fullness in the ear. Headaches are common, along with malaise and nausea. The patient may experience tinnitus or popping sounds when yawning or swallowing. Acute otitis media (AOM) is often difficult to detect because most children affected by this disorder do not yet have sufficient speech and language skills to tell someone what is bothering them. Common signs include the following:

- Unusual irritability
- Difficulty sleeping
- Tugging or pulling at one or both ears
- Fever
- Purulent or bloody drainage from the ear
- Loss of balance
- Unresponsiveness to quiet sounds, or other signs of hearing difficulty such as sitting too close to the television or being inattentive.

The American Academy of Pediatrics and the American Academy of Family Physicians released an updated clinical practice guideline for the treatment of AOM in 2013 that highlights the causes of and treatment options for AOM (Lieberthal et al., 2013). The decision to place a patient on antibiotics or to observe is based on the child's age, diagnostic certainty, and illness severity, remembering that viruses are the most common cause of upper respiratory tract infection in children. Deferring antibacterial treatment for children over 6 months of age with nonsevere illness for 48 to 72 hours and limiting management to symptomatic relief is appropriate. All children under 6 months of age should receive antibiotic therapy regardless of illness severity. Amoxicillin remains first-line therapy for children who have not received amoxicillin within the past 30 days. Amoxicillin/clavulanate is recommended if amoxicillin has been taken within the past 30 days, if concurrent conjunctivitis is present, or if the child has a history of recurrent AOM unresponsive to amoxicillin.

Symptomatic pain management, especially during the first 24 hours of an episode of AOM, should be part of the care plan, regardless of the use of antibiotics. Symptomatic relief involves the use of analgesics, such as acetaminophen, or NSAIDs, such as ibuprofen (for children over 6 months of age), to relieve pain and reduce fever. Patients with severe pain may require therapy with opioid analgesics such as codeine. A 7-day course of a corticosteroid is often combined with antibiotics when severe inflammation is present. Antihistamines or decongestants may be used to decrease mucus production and fluid levels in the middle ear (Lieberthal et al., 2013).

Otitis interna, or labyrinthitis, is an inner ear infection that may occur as the result of chronic otitis media or as part of a viral systemic infection, including mononucleosis or an upper respiratory infection. Of all ear infections, otitis interna is the most difficult to treat because the blood–labyrinth barrier makes it difficult for systemic medications to reach the affected areas. **Mastoiditis**, or inflammation of the mastoid sinus, is frequently the result of chronic or inadequately treated bacterial otitis media or an otitis interna infection. The infection moves into the bone and surrounding structures of the ear. Symptoms of pain, hearing loss, and tenderness typically appear 2 to 3 weeks after an episode of otitis media. Mastoiditis can be a serious problem. If left untreated, it can result in hearing loss.

The treatment of acute mastoiditis involves aggressive antibiotic therapy. IV gentamicin or ticarcillin may be used initially. Therapy may be adjusted once culture and sensitivity results have been obtained. Therapy is continued for at least 14 days. If the antibiotics are not effective and symptoms persist, surgery such as a mastoidectomy or meatoplasty may be indicated.

Cerumen (earwax) softeners are also used for proper ear health. When cerumen accumulates, it narrows the ear canal and may interfere with hearing. **Cerumenolytics** may be needed to loosen and remove impacted cerumen from the ear canal. Use of these agents usually involves the instillation of an earwax softener and then a gentle lavage of the wax-impacted ear with tepid water using an irrigating syringe to gently insert the water. An instrument called an ear loop may be used to help remove earwax but should be used only by healthcare providers who are skilled in using it. There are three types of cerumen-softening preparations: water based, oil based, and nonwater oil based. Water-based preparations include solutions of triethanolamine, 3% hydrogen peroxide, 10% sodium bicarbonate, and saline or water. The nonwater oil-based preparation available in the United States includes the OTC drug carbamide peroxide (Debrox). Oil-based preparations include household olive, mineral, and almond oils and commercially prepared combinations, such as Cerumol, Earex, and Otocerol. Research has shown that the water-based and nonwater oil-based agents have equal effectiveness.

CONNECTION: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Otitis

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic disease.
- Assess hearing and balance. Obtain audiology screening as needed.
- Assess for history of recent infections, swimming, condition of external ear canal, presence of drainage, and tympanic membrane assessment.
- Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Obtain baseline vital signs.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., infection is clearing, or hearing is maintained).
- Assess for adverse effects: localized irritation or burning, dizziness, vertigo, nausea, or vomiting. Severe ear pain, increased drainage, fever, increasing dizziness, vertigo, nausea, and vomiting should be immediately reported to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Monitor hearing and balance. Obtain audiology screening periodically as needed. (Hearing remains within the patient's baseline assessment parameters, no dizziness or vertigo is noted.)	• Instruct the patient to immediately report severe ear pain, increased drainage, fever, increasing dizziness, vertigo, nausea, vomiting, or tenderness in or around the ear to the healthcare provider.
Minimizing adverse effects: • Monitor appropriate administration of the drug to avoid adverse effects. (Eardrops should be administered into the ear canal without dropping the solution directly on the tympanic membrane, which may induce vertigo.)	• Teach the patient the proper administration techniques for eardrops.
• Monitor hearing periodically in patients with chronic otitis with effusion. (Otitis media with effusion may lead to hearing loss and speech or language impairment, especially in young children.)	• Instruct the patient, family, or caregiver on the importance of returning for and maintaining regular hearing examinations.
• Monitor balance and for changes in gait or ambulation. (Dizziness or vertigo may cause intolerance to activity and increase the risk for falls. **Lifespan:** Monitor older adults more frequently for dizziness to prevent falls.)	• Instruct the patient to immediately report any increasing dizziness or vertigo. Assist the patient with ambulation if dizziness is present to prevent falls. If dizziness occurs at home, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes.
• Provide for ear comfort such as warm, moist compresses to the outer ear. (Warm, moist compresses to the outer ear may increase circulation to the local area and ease ear discomfort.)	• Teach the patient to apply warm but not hot compresses to the external ear for approximately 15–20 min as needed for discomfort.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration, e.g., appropriate instillation of eardrops, followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the drug following appropriate guidelines:
	  • Warm eardrop solution by placing in or under warm but not hot water. The bottle may be placed in a plastic bag to protect the label before warming. *Never* warm eardrops in the microwave.
	  • Have the patient lie supine with the ear to be treated uppermost. Gently pull the pinna down and back for children under age 3, up and back for children over age 3, adolescents, and adults.
	  • Instill the number of drops ordered into the ear canal, taking care not to drop the solution directly onto the eardrum but allowing it to slide down the side of the ear canal.
	  • Gently massage the area in front of the ear (tragus) to promote thorough administration of the drop unless pain is severe.
	  • Have the patient continue lying down for 5–10 min to ensure complete absorption of the eardrop. A small piece of cotton may be placed at the entrance to the ear canal if any solution returns upon arising.

Understanding Chapter 74

Key Concepts Summary

74.1 Knowledge of basic eye anatomy is fundamental to understanding eye disorders and their pharmacotherapy.

74.2 The two principal types of glaucoma, closed-angle glaucoma and open-angle glaucoma, are characterized by increased intraocular pressure.

74.3 The primary goal of glaucoma pharmacotherapy is to prevent damage to the optic nerve by lowering intraocular pressure.

74.4 Prostaglandin analogs are the first-line drugs for treating high intraocular pressure because of their long durations of action and high safety profiles.

74.5 Drugs that affect the autonomic nervous system are sometimes prescribed to treat glaucoma.

74.6 Carbonic anhydrase inhibitors and osmotic diuretics are occasionally used for treating glaucoma.

74.7 Drugs that are routinely used for eye examinations include mydriatics, cycloplegics, diagnostic dyes, and local anesthetics.

74.8 Numerous pharmacologic drugs are used to treat minor eye irritation and redness.

74.9 Knowledge of basic ear anatomy is fundamental to understanding ear disorders and pharmacotherapy.

74.10 Otic preparations treat infections, inflammation, and earwax buildup.

CASE STUDY: Making the Patient Connection

Remember the patient "Therese Duclos" from the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Therese Duclos, a 65-year-old African American woman, visits her ophthalmologist with reports of blurry vision and not being able to see well at night while driving. Her health history includes adult-onset diabetes for the past 10 years and osteoporosis since age 55. Her medical regimen includes diet control for the diabetes and Boniva monthly. She denies any injury to her eyes and last had an eye checkup 1 year ago.

Critical Thinking Questions

1. What factors are present in Mrs. Duclos's health history that you identify as predisposing conditions for the development of primary open-angle glaucoma?
2. Therese needs to learn the proper administration of eyedrops. What teaching would you provide to ensure that the skill will be performed correctly?
3. What would be possible effects from systemic absorption if the patient were taking beta-adrenergic drops (e.g., timolol, carteolol)? Prostaglandin drops (e.g., latanoprost, bimatoprost)? Cholinergic agonists (e.g., carbachol, pilocarpine)?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Zachary, a 4-year-old boy, is experiencing pain in his right ear. His mother takes him to the healthcare provider and he is diagnosed with otitis media. Zachary is prescribed ciprofloxacin with dexamethasone (Ciprodex) otic drops to be instilled in his right ear twice a day for a week. To ensure that the mother is knowledgeable in this form of administration, the nurse will teach her about the proper technique. Create a patient information sheet for a parent who needs to administer eardrops.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is teaching a patient about a new eyedrop prescription for timolol (Timoptic) for treatment of open-angle glaucoma. The patient has a history of seasonal allergies and hypertension. What is an important administration technique to stress for this patient?
   1. Take any eyedrops for allergies 5 minutes before administering the timolol drops.
   2. Do not use the timolol drops while concurrently taking allergy medication.
   3. The timolol drops may temporarily worsen seasonal allergies.
   4. Gently put pressure on the inner canthus (tear duct) for 1 minute after instilling the timolol drop.

2. The nurse is providing health teaching to a patient who has been prescribed latanoprost (Xalatan) for open-angle glaucoma. While harmless, the nurse would caution the patient about which potential nonocular effects of the drug? (Select all that apply.)
   1. Darkening and thickening of the upper eyelid
   2. Darkening and thickening of eyelashes
   3. A lightening of iris color and a slight darkening of the sclera
   4. A slight darkening of the iris color
   5. A permanent bluish tint to the conjunctiva

3. Pilocarpine (Isopto Carpine) has been ordered for a patient with closed-angle glaucoma who has not responded well to other drugs. Pilocarpine causes _____, which stretches the trabecular meshwork, allowing a greater outflow of aqueous humor and lowering intraocular pressure.

4. The nurse is teaching a 25-year-old patient about the administration of ciprofloxacin with hydrocortisone (Cipro) for otitis. In which order will the nurse instruct the patient to use the drug?
   1. Gently massage the area in front of the ear.
   2. Pull the earlobe upward and back.
   3. Allow the drop to fall into the ear canal flowing down the side.
   4. Remain with the treated ear in an uppermost position for 5 minutes.

5. The nurse is teaching a patient with otitis about a prescription for polymyxin B, neomycin, with hydrocortisone (Cortisporin). The patient should be instructed to immediately report which symptom?
   1. Mild itching in the outer ear canal
   2. Gradually decreasing pain
   3. Slight dizziness after instilling the eardrop
   4. Increasing pain, particularly in the area around the ear

6. The nurse is instilling drops of phenylephrine (Neo-Synephrine) into the patient's eye before cataract surgery. Phenylephrine is used prior to cataract surgery because it causes _____, allowing visualization of the operative area.

Chapter 75
Emergency Preparedness: Bioterrorism and Management of Poisoning

Chapter Outline

- Emergency Preparedness, Bioterrorism, and Nursing
- Biologic Agents
  - Anthrax
  - Botulism
  - Pneumonic Plague
  - Tularemia
  - Viruses
- Chemical and Physical Agents
  - Chemical Toxins
  - Ionizing Radiation
- Management of Poisoning
  - Drugs Used in the Management of Poisoning
    - **PROTOTYPE** *Activated Charcoal (CharcoAid), p. 1418*
  - Ion Trapping
  - Chelating Drugs
    - **PROTOTYPE** *Edetate Calcium Disodium (Calcium EDTA), p. 1419*
    - **PROTOTYPE** *Dimercaprol (BAL in Oil), p. 1419*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Discuss the role of professional nursing in emergency preparedness and the management of poisoning.
2. Discuss the purpose, function, and components of the Strategic National Stockpile.
3. Identify the types of agents that might be used for a bioterrorist attack.
4. Compare and contrast the various chemical agents that can be used as poisons.
5. Explain the risks associated with ionizing radiation emitted from a nuclear terrorist attack.
6. Describe the five general principles of treating acute poisoning.
7. Identify the drugs important in emergency preparedness and management of poisoning.
8. Compare the pharmacologic management of biologic, chemical, radiologic, nuclear, and explosive agents in emergency preparedness.
9. Discuss the management of poisoning by the poison control center, including minimizing poison absorption and enhancing poison removal.
10. Apply the nursing process to the care of patients receiving pharmacotherapy for poisoning or overdose.

Strategic National Stockpile (SNS), 1412
tularemia, 1413

Emergency preparedness is the ability to respond swiftly and effectively to an unexpected event that may impact human health. The unexpected event may be a natural disaster caused by severe weather, an unintentional chemical spill, or a purposeful terrorist attack on the public. Nurses have an essential role in assessing and recognizing poisoning and taking appropriate interventions to save lives. Sometimes, specific drugs are necessary to counter the effects of biologic hazards and minimize the loss of life in emergency situations. This chapter focuses on the role of pharmacology in emergency preparedness as related to bioterrorism and management of poisoning.

Emergency Preparedness, Bioterrorism, and Nursing

75.1 Emergency preparedness has become an essential competency for all healthcare professionals.

Emergency preparedness has been an emerging role of professional nursing for many years. In the past, however, most training focused on emergency management for natural disasters, catastrophic incidents, or infectious epidemics. Often nurses responded to victims at the location of the disaster or incident. Today, nurses must learn how to respond to mass casualty incidents and potential disasters that can result from agents that are biologic, chemical, radiologic, nuclear, or explosive in nature. Standard emergency triage may be reversed, focusing on patients with the best chance to live.

Nurses may be among the first responders to victims who arrive at emergency departments (EDs), clinics, healthcare provider offices, or school health settings. They must be prepared to assess and recognize when someone has been exposed to potential hazards and to take appropriate actions. Failure to do so could lead to an epidemic or major loss of life. Examples include patients who present to the healthcare setting with symptoms of anthrax, avian flu, or severe acute respiratory syndrome (SARS).

Since the terrorist attacks of September 11, 2001, Americans are more concerned with threats of terrorism and are more aware of emergency preparedness than ever before. Increased efforts to safeguard the general populace remain at an all-time high. Healthcare providers must continually update their knowledge of emergency management and think more globally in dealing with patients whose illness presents in a less typical way. Knowledge of treatment modalities related to bioterrorism has become a basic competency required of all healthcare providers.

75.2 Bioterrorism is the intentional release of a virus or microorganism to cause human harm.

The past two decades have brought the acts and effects of terrorism to the forefront of discussion in this and other countries. Terrorism is generally defined as the systematic use of terror, violence, or intimidation to achieve a desired purpose or end. The U.S. Federal Criminal Code describes terrorism as activities that involve life-threatening acts intended to coerce or intimidate a given population. Terrorists use chemical, nuclear, radiologic, explosive, or biologic hazards to commit violent and intimidating crimes against general and special targeted populations.

Bioterrorism is the intentional release of an infectious agent for the purpose of causing harm to a large number of people. In the United States, governmental agencies such as the Centers for Disease Control and Prevention (CDC) and the Department of Defense provide education to prepare the general public for possible bioterrorism events. In the wrong hands, simple and easily obtained toxic agents could be disseminated for public harm. However, of greatest concern is the use of highly infectious diseases such as anthrax, smallpox, hemorrhagic viruses, and plague, or toxic agents such as nerve gas, cyanide, and chlorinated agents as well as nuclear and radiation threats. Table 75.1 provides the CDC list of biologic threats and their potential impact on the health of the general public.

75.3 Nurses may have the first opportunity to recognize and initiate a response to bioterrorism.

Nursing has a rich history in emergency preparedness. Florence Nightingale began defining the role of nursing in emergency preparedness as early as the Crimean War. Throughout many wars and disasters, nurses have honed their assessment and critical care skills to support people in need and improve healthcare outcomes. The Civil War was a time when nurses worked together with leaders like Clara

Table 75.1 Categories of Infectious Agents

Category	Description	Examples
A	Agents that pose a significant risk to national security because they • can easily be disseminated or transmitted person to person; • result in high mortality rates with potential for major public health impact; • might cause public panic and social disruption; and • require special action for public health preparedness.	Anthrax (*Bacillus anthracis*) Botulism (*Clostridium botulinum* toxin) Plague (*Yersinia pestis*) Smallpox (*Variola major*) Tularemia (*Francisella tularensis*) Viral hemorrhagic fevers such as Marburg, Ebola, Lassa, and Machupo
B	Second highest priority agents include those that • are moderately easy to disseminate; • result in moderate morbidity and low mortality rates; and • require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance.	Brucellosis (*Brucella* species) Epsilon toxin of *Clostridium perfringens* Food safety threats such as salmonella, Shigella, and *Escherichia coli* Glanders (*Burkholderia mallei*) Melioidosis (*Burkholderia pseudomallei*) Psittacosis (*Chlamydia psittaci*) Q fever (*Coxiella burnetii*) Ricin toxin from *Ricinus communis* Staphylococcal enterotoxin B Typhus fever (*Rickettsia prowazekii*) Viral encephalitis Water safety threats such as *Vibrio cholerae* and *Cryptosporidium parvum*
C	Third highest priority agents include emerging pathogens that could be engineered for mass dissemination in the future because of • availability; • ease of production and dissemination; and • potential for high morbidity and high mortality rates and major health impact.	Hantaviruses Nipah virus (NiV)

From *Emergency Preparedness & Response: Bioterrorism Agents/Diseases,* CDC, n.d. Retrieved from https://fas.org/biosecurity/resource/documents/CDC_Bioterrorism_Agents.pdf.

Barton to establish the American Red Cross, with nursing becoming a special service in 1909. In World War II, nurses became a defined group within the military, and the Cadet Nurse Corps was established. These wartime nurses learned triage, provided trauma care, and administered penicillin to save many lives. Nurses have played a major role in providing emergency assistance in natural disasters such as earthquakes, tornados, hurricanes, floods, and tsunamis. The challenges have now expanded to include bioterrorism, toxins, radiation, and mass casualty emergencies.

Today emergency preparedness has come to the forefront of professional nursing practice. Established through a grant in 2004 in collaboration with the U.S. Department of Homeland Security, the National Nurse Emergency Preparedness Initiative (NNEPI) advances the education and policy related to emergency preparedness for professional nurses.

In 2001, the International Nursing Coalition for Mass Casualty Education was established, defining emergency preparedness competencies for registered nurses responding to mass casualty incidents (MCIs). Now known as the Nursing Emergency Preparedness Education Coalition (NEPEC), the coalition identified a set of general core competencies that provides guidelines for the role of professional nurses in responding to MCIs. Competencies identified included the ability to adequately assess the situation and victims of an MCI and to have the technical and communication skills required to function as an effective member of the response team. Under technical skills, nurses must demonstrate safe administration of medications and immunizations and have knowledge of nursing interventions for adverse medication events. This is but one area of professional nursing practice where knowledge of pharmacology is important to nursing emergency preparedness.

For more than 30 years The Joint Commission has required accredited hospitals to meet standards in disaster planning. In the late 1990s, The Joint Commission added standards that address possible bioterrorism and emergency management. State and federal agencies have developed updated emergency preparedness plans that include bioterrorism. Nurses are part of the collaborative developed by healthcare professionals to respond immediately to a community emergency. Key roles for nurses include education, resources, referrals, diagnosis, treatment, and planning. Pharmacology for emergency preparedness has a role in each of these.

75.4 The Strategic National Stockpile has large quantities of medicine to protect the public if a health emergency arises.

When a health emergency such as a biologic or chemical attack, flu outbreak, or earthquake occurs, the response

must be rapid to minimize health consequences and protect the American public. Due to the unexpected nature of such an incident, shortages in medical supplies, equipment, and drugs may occur. The **Strategic National Stockpile (SNS)** is a national repository of antibiotics, chemical antidotes, antitoxins, antiviral drugs, life support medications, intravenous (IV) administration equipment, airway maintenance supplies, and surgical material for use in a declared biologic or terrorism incident or other major health emergency. The CDC manages the SNS to ensure immediate availability and deployment of essentials to any state. These antibiotics, vaccines, and medical supplies are free to the population affected by the adverse event.

One of the two components of the SNS is a Push Package, which includes preassembled caches of drugs, antidotes, and medical supplies that broadly cover a nonspecific emergency for use in early hours. Stored strategically, deployment can be accomplished within 12 hours. The SNS program ensures that the medical materials stock is rotated and kept within potency shelf-life limits. The second component is vendor-managed inventory (VMI) packages that contain additional supplies that can be more event specific and ship within 24 to 36 hours. This plan is designed to minimize local hospital stockpiling of bioterrorism pharmaceuticals that have expiration dates and can be costly.

Parts of the SNS were deployed for relatively recent health threats. In 2005, SNS response teams were sent to support state efforts in responding to hurricanes Rita and Katrina on the Gulf Coast. Part of the SNS antiviral inventory was used to help state efforts to control the H1N1 swine influenza outbreak in 2009.

Biologic Agents

75.5 Highly infectious bacteria or viruses could be used as bioterrorist threats.

The U.S. government takes the threat of bioterrorism seriously and has implemented a program to prepare the public for such catastrophes. Six biologic agents are considered category A threats (see Table 75.1), meaning they could cause enough mortality and morbidity damage to interfere with the social functioning of a large city or populated area. These six threats are anthrax, botulism toxin, pneumonic plague, smallpox, tularemia, and viral hemorrhagic fevers. Knowing the agents most likely to be used in a terrorist event allows the professional nurse to plan and to prepare for emergencies of this nature. The nurse can be an effective member of the emergency team who is responding to the widespread panic and life-threatening illnesses caused by an attack of bioterrorism.

Anthrax is an acute infectious disease that results from exposure to the spore-forming bacterium *Bacillus anthracis*. The spore produces a toxin that can be fatal to the host. Although microbiologist Robert Koch confirmed the bacterial nature of anthrax in 1876, anthrax has plagued the world for many centuries, even in biblical times. Anthrax infection is found among hoofed animals such as cattle, sheep, goats, pigs, bison, antelopes, and elephants. It was recognized as a potential biologic weapon in World War I, and several countries were suspected of experimenting with its use as a weapon in World War II. In 1995, Iraq admitted producing anthrax as a biologic weapon. U.S. military personnel were vaccinated before deployment to the Gulf War areas.

In the fall of 2001, following the terrorist attacks on the World Trade Center, five people died from exposure to anthrax in what most believe were purposeful acts of bioterrorism. In total, 19 confirmed and 4 suspected cases occurred across the United States in Connecticut, Florida, Maryland, New Jersey, New York, Pennsylvania, Virginia, and the District of Columbia. Over 32,000 people were treated for possible exposure, many of whom were postal workers, between October 8 and November 9, 2001. Lives were lost, government workers and U.S. citizens were critically threatened, and agency operations such as the U.S. Postal Service were interrupted for weeks.

Anthrax poisoning can occur by ingestion, absorption through an open wound on the skin, or inhalation, which is the most dangerous route. The method of transmission affects the symptoms demonstrated. Table 75.2 summarizes the clinical picture of anthrax. Anthrax infects by releasing two toxins, edema toxin and lethal toxin. Both cause necrosis and exudate accumulation and symptoms such as pain, edema, and restricted activity. The anthrax-binding receptor binds with a human cell, allowing the bacterial toxins to enter. Anthrax produces heat and chemically resistant spores, which can remain viable in soil for many years. These are dangerous because they have the potential for inhalation infection for humans. Left untreated, inhalation anthrax is usually deadly. In the anthrax attacks in the United States in fall 2001, anthrax was delivered as a fine powder. This form of anthrax is easily inhaled and adheres to almost any surface.

Several drugs can be used to treat anthrax. Ciprofloxacin (Cipro) is the primary antibiotic used with a prophylaxis oral (PO) dose of 500 mg every 12 hours for 60 days. If anthrax exposure is confirmed, the patient is immediately administered IV treatment with 400 mg every 12 hours. Anthrax can also be treated with other antibiotics such as penicillin, ampicillin, vancomycin, erythromycin, tetracycline, and doxycycline. Inhalation anthrax exposure may necessitate the combined use of ciprofloxacin and doxycycline but must be done immediately to avoid death. The public should be discouraged from seeking the prophylactic use of antibiotics in cases where anthrax exposure has not been confirmed. Indiscriminate, unnecessary use of antibiotics can be expensive, can cause significant adverse

Table 75.2 Clinical Manifestations of Anthrax

Type	Description	Symptoms
Cutaneous anthrax	Most common but least complicated form of anthrax; almost always curable if treated within the first few weeks of exposure; results from direct contact of contaminated products with an open wound or cut	Small skin lesions develop and turn into black scabs; inoculation takes less than 1 wk; cannot be spread by person-to-person contact
Gastrointestinal anthrax	Rare form of anthrax; without treatment, can be lethal in up to 50% of cases; results from eating anthrax-contaminated food, usually meat	Sore throat, difficulty swallowing, cramping, diarrhea, and abdominal swelling
Inhalation anthrax	Least common but the most dangerous form of anthrax; can be successfully treated if identified within the first few days after exposure; results from inhaling anthrax spores	Initially, fatigue and fever for several days, followed by persistent cough and shortness of breath; without treatment, death can result within 4–6 days

effects, and can promote the appearance of resistant bacterial strains. A prototype feature for ciprofloxacin can be found in Chapter 49.

Two newer medications have been developed to treat inhalation anthrax. In 2015, the U.S. Food and Drug Administration (FDA) approved Anthrasil, an immune globulin preparation prepared from the plasma of people vaccinated against anthrax. The globulin preparation contains antibodies that neutralize toxins produced by the anthrax bacteria. Anthrasil carries a black box warning that thrombosis may occur when using immune globulin products. In 2016, the FDA approved obiltoxaximab (Anthim), the first monoclonal antibody for treating anthrax. Obiltoxaximab neutralizes toxins secreted by the anthrax bacteria. The drug carries a black box warning that it may cause hypersensitivity reactions, including anaphylaxis. Neither Anthrasil nor Anthim have antibacterial activity; therefore, they must be used in combination with antibacterial drugs.

CONNECTION Checkpoint 75.1

From what you learned in Chapter 49, name the antibiotic class to which ciprofloxacin belongs and describe its mechanism of bacteriocidal action. Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.

Although anthrax immunization was approved by the FDA 30 years ago, it has not been widely used because of the extremely low incidence of this disease in the United States. The vaccine is effective only if given prior to exposure. The anthrax vaccine causes the body to make protective antibodies, thus preventing the onset of disease and its symptoms. Immunization for anthrax consists of 5 subcutaneous doses given over 18 months. Annual booster injections of the vaccine are recommended. At this time, the CDC recommends vaccination for only select populations who might be exposed to large amounts of anthrax on the job. This includes certain laboratory or remediation workers, some military personnel, and those handling animals or animal products (CDC, 2017).

Controversy is ongoing regarding the safety of the anthrax vaccine and whether it is truly effective in preventing the disease. Until these issues are resolved, the use of anthrax immunization will likely remain limited to select groups. Vaccines and the immune response are discussed in more detail in Chapter 43.

Botulism is caused by *Clostridium botulinum*, an organism that secretes a potent toxin that paralyzes the muscles after an individual is poisoned. Respiratory failure and paralysis may force a patient to be on a ventilator for weeks or months. As a biologic weapon, botulism could be transmitted in air, food, or water. Treatment includes immediate administration of an antitoxin and assisted ventilation until patients are able to function independently. The antitoxin should be given as soon as possible and never delayed pending the microbiologic testing. Trivalent botulinum antitoxin is available through state departments of health or the CDC. A pentavalent toxoid vaccine for botulism prophylaxis is available as an investigation drug through the Department of Defense.

Pneumonic plague is a life-threatening infectious lung disease that occurs after breathing *Yersinia pestis*, a bacterium found on rodents and their fleas that is responsible for the bubonic plague. It is highly contagious and can be deadly if untreated within 24 hours of contact. As a biologic agent, *Y. pestis* could be spread by aerosol over the population. Within 1 to 6 days of exposure, the patient would be infectious to everyone he or she has come in contact with during that time. This makes the plague difficult to contain. Symptoms include fever and weakness, rapid development of pneumonia, chest pain with shortness of breath, cough, and bloody sputum. Without immediate treatment, respiratory failure will result followed by shock and death. Treatment with antibiotics must occur within 24 hours and last for at least 7 days to prevent death from the infection. The primary antibiotic for *Y. pestis* infection is doxycycline 100 mg twice a day or ciprofloxacin 500 mg twice a day for 7 days. There is no vaccine approved in the United States for this bacterium at the present time.

Caused by the organism *Francisella tularensis*, **tularemia** is a serious infectious disease found in rodents, rabbits, and hares. Cases have been reported in almost every state, although overall the infection is rare in the United States. *F. tularensis* is one of the most infectious bacteria known

and survives at low temperatures for weeks in hay, straw, moist soil, or in the bodies of decaying animals. As a biologic weapon the most casualties would be with aerosol release in an area of high population, causing hemorrhagic inflammation of the respiratory airway. Treatment includes IV therapy with streptomycin as the preferred drug, with parenteral gentamicin being an alternative. Aminoglycosides should be used for 10 days. Tetracyclines and chloramphenicol can be used for at least 14 days but have a higher rate of relapse and treatment failure. In mass casualty incidents, oral doxycycline for 14 to 21 days and ciprofloxacin for 10 days are preferred for adults and children. Antibiotics for treating tularemia are included in the SNS. An attenuated (live) vaccine is available as an investigational drug and is under review by the FDA.

A major viral biologic threat is the variola virus, better known as **smallpox**. This serious, contagious disease is fatal in up to 30% of cases. Although believed to be eradicated, with the last case in the United States occurring in 1949 and in Somalia in 1977, the virus may still be stockpiled in laboratories across the world for use as a biologic weapon. Generally, personal contact is needed to spread this disease, but only a few viral droplets spread through the air or on contaminated objects are needed to produce the disease. Humans are the only carriers. Unvaccinated populations are at risk.

Vaccination is the only known treatment for smallpox. The vaccination gives immunity for 3 to 5 years and is effective if given prior to exposure to the virus or up to 3 days postexposure. Smallpox vaccinations are contraindicated for certain groups such as pregnant or lactating women; children under 1 year old; people with impaired immune systems, such as those with human immunodeficiency virus (HIV) or leukemia; people with atopic dermatitis or eczema; or anyone with an allergy to a component in the vaccine. Although serious adverse effects are very rare, vaccines can cause death. A mutation in the virus would render the vaccine ineffective, so mass vaccinations for smallpox are not considered prudent at this time. People at risk such as law enforcement, healthcare professionals, or military personnel might need vaccination if exposed to the virus. The U.S. government maintains enough vaccinations for the public in the event of an outbreak.

Viral hemorrhagic fevers, which are caused by a number of virus families, can cause severe physical damage affecting multiple organ systems. Usually these viruses damage the circulatory system, resulting in hemorrhage. The host can be the cotton rat and deer mouse but some, such as Ebola or Marburg, have unknown hosts. There is no cure or vaccine for these viruses and patients are treated with supportive therapy, such as fluid and electrolytes, and management of complications. Ribavirin is an antiviral drug that has shown some success in treating Lassa fever. CDC researchers in the Viral Special Pathogens Branch work with these hemorrhagic fever viruses, which are considered a biosafety level 4. This class consists of exotic agents that can be transmitted by aerosol and pose a high risk of life-threatening disease.

Chemical and Physical Agents

75.6 There are 13 categories of toxic chemicals that could cause mass casualties if released into the environment.

Chemical warfare agents have been used since World War I, but few drug antidotes exist today. Many treatments provide minimal help other than to relieve some symptoms and provide comfort following exposure. Whether a chemical is released by terrorists, enemy military, or by industry in a chemical release accident the result is the same: A hazardous chemical is released into the environment that may harm the health of the public. The CDC has classified hazardous chemicals into the following categories:

- **Biotoxins.** Poisons from plants or animals
- **Vesicants and blister agents.** Agents that severely blister the skin, respiratory tract, or eyes on contact
- **Blood agents.** Poisons that are absorbed into the circulation
- **Acids and caustics.** Chemicals that burn the eyes, skin, or lining of the respiratory tract on contact
- **Pulmonary and choking agents.** Chemicals that irritate the lungs and cause swelling and choking
- **Incapacitating agents.** Chemicals that alter consciousness, making it difficult for the patient to think clearly
- **Long-acting anticoagulants.** Chemicals that produce uncontrolled bleeding by preventing clotting
- **Metals.** Agents that are metallic poisons
- **Nerve agents.** Poisons that impair nervous system functioning
- **Organic solvents.** Chemicals that damage living tissue by dissolving fats and oils
- **Tear gas or mace.** Agents used for riot or crowd control by law enforcement or for self-defense; irritate the eyes and the respiratory tract, resulting in incapacitation
- **Toxic alcohols.** Chemicals that damage vital organs such as the heart, kidneys, and nervous system
- **Vomiting agents.** Chemicals that induce nausea and vomiting.

Table 75.3 lists well-known chemical agents and their symptoms and treatments. The primary chemical hazards related to pharmacology are nerve agents. Individuals who breathe nerve gas experience convulsions and loss of consciousness, which result in respiratory failure within minutes. The antidote for nerve gas is the anticholinergic drug atropine.

Table 75.3 Chemical Agents and Treatments

Agent	Signs and Symptoms	Decontamination	Persistence
Nerve Agents			
Tabun (GA)	Salivation Lacrimation Urination Defecation Gastric disturbances Emesis	Remove contaminated clothing. Flush with a soap and water solution for patients. Flush with large amounts of a 5% bleach and water solution for objects.	1–2 days if heavy concentration
Sarin (GB)			1–2 days will evaporate with water
Soman (GD)			Moderate, 1–2 days
V agents (VX)			High, 1 wk if heavy concentration; as volatile as motor oil
Vesicants (Blister Agents)			
Sulfur mustard (H)	Acts first as a cell irritant, then as a cell poison. Conjunctivitis, reddened skin, blisters, nasal irritation, inflammation of throat and lungs.	Remove contaminated clothing. Flush with soap and water solution for patients. Flush with large amounts of a 5% bleach and water solution for objects.	Very high, days to weeks
Distilled mustard (HD)			
Nitrogen mustard (HN 1,3)			
Mustargen (HN 2)			Moderate
Lewisite (L)	Immediate pain with blisters later.		Days, rapid hydrolysis with humidity
Phosgene oxime (CX)	Immediate pain with blisters later—necrosis equivalent to second- and third-degree burns.		Low, 2 h in soil
Chemical Asphyxiants (Blood Agents)			
Hydrogen cyanide (AC)	Cherry red skin or ~30% cyanosis. Patients may appear to be gasping for air. Seizures prior to death. Effect is similar to asphyxiation but is more sudden.	Remove contaminated clothing. Flush with a soap and water solution for patients. Flush with large amounts of 5% bleach and water solution for objects.	Extremely volatile, 1–2 days
Cyanogen chloride (CK)			Rapidly evaporates and disperses
Arsine (SA)			Low

75.7 Ionizing radiation produces immediate and long-term effects on human tissue.

Bioterrorists may use nuclear bombs or attack nuclear facilities that could cause mass casualty deaths at the point of impact and create residual ionizing radiation for miles around the site. Some radioisotopes emit radiation for decades and even centuries. Smaller scale radiation could occur with the release of solid or liquid nuclear material into public areas or a dirty bomb, which explodes with radioactive powder or pellets, contaminating the area.

Radiation sickness occurs after exposure to ionizing radiation and can last from hours to days. Initial symptoms include nausea, vomiting, and diarrhea with later symptoms of weight loss, anorexia, fatigue, and suppression of the bone marrow. When exposed to large amounts of radiation or to small amounts over many decades, patients tend to develop certain malignancies such as leukemia or thyroid cancer.

Except for supportive therapies, the only recognized treatment available to counter the thyroid uptake of radiation is ingestion of potassium iodine (KI) before or immediately after exposure. One of the radioisotopes produced by a nuclear explosion is iodine-131 (^{131}I). Because iodine is naturally concentrated in the thyroid gland, ^{131}I will immediately enter the thyroid and damage thyroid cells. For example, following the Chernobyl nuclear disaster, the incidence of thyroid cancer in the Ukraine jumped from 4 to 6 cases per million people to 45 cases per million. If taken prior to, or immediately following, a nuclear incident, KI can prevent up to 100% of the radioactive iodine from entering the thyroid gland. It is effective even if taken 3 to 4 hours after radiation exposure. Generally, a single 130-mg dose is necessary for adults.

Unfortunately, KI protects only the thyroid gland from ^{131}I. It has no protective effects on other body tissues, and it offers no protection against the dozens of other harmful radioisotopes generated by a nuclear explosion. As with vaccines and antibiotics, the stockpiling of KI by local healthcare agencies or individuals is not recommended.

CONNECTION Checkpoint 75.2

From what you learned in Chapter 67, describe the therapeutic use of ^{131}I in treating thyroid disease. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

The most serious nuclear incident in the United States occurred at the Three Mile Island nuclear plant in Pennsylvania in 1979. No injuries or deaths occurred and the average estimated dose of radiation to the public around the plant was 1 millirem, which is an amount equivalent to one sixth of a chest x-ray (U.S. Nuclear Regulatory Commission, 2014).

Management of Poisoning

75.8 The general management of poisoning includes contacting the poison control center or emergency medical services as soon as possible.

Virtually any chemical may cause poisoning if taken in excessive amounts. The body has a remarkable capacity to tolerate a wide variety of chemicals and has physiologic mechanisms to detoxify and rapidly eliminate many of them. Toxicity results when the body's detoxification and excretion abilities are exceeded. Toxic effects may appear immediately or they may appear decades after the initial exposure.

PharmFACT

During the past decade, as the death rates for the top leading causes of death, such as heart disease and cancer, have substantially decreased, the death rate associated with opioid pain medication has increased. From 1999 to 2014, more than 165,000 people in the United States have died from overdoses related to opioid pain medication (Dowell, Hagerich, & Chou, 2016).

Medications are the most frequently involved substances in poisonings for all age groups. Household cleaning compounds comprise a second large group of poisonings, with cosmetics being close behind. Although exposure to poisons may occur by any route, ingestion accounts for over 75% of all poisoning cases. Swallowing dangerous substances is common among children with curious minds who put strange substances into their mouths. Most poisonings present with low levels of toxicity, but some can result in fatalities, such as the ingestion of gun-bluing agents used to maintain the color of gun barrels. Signs and symptoms of ingested poisons include abdominal cramping or stomach pain, nausea, vomiting, diarrhea, sleepiness or loss of consciousness, bottles or containers of poisons close by, or odor, stains, or burns around the mouth.

Poisoning from medications may be unintentional or intentional (suicide). Acetaminophen is a common toxin because so many analgesic medications contain this drug. Although legal for adults, alcohol is a potential poison and its abuse is a major health problem in the United States. Ingestion of alcohol, along with certain prescribed medications, amphetamines, hallucinogens, or inhaled substances such as solvents or glue can create life-threatening situations. Symptoms of drug overdose include confusion, elevated heart rate, drowsiness, enlarged or dilated pupils, and hallucinations. Other medications that cause frequent poisonings include iron, calcium channel blockers, and tricyclic antidepressants.

When a specific antidote is available, it is administered as soon as the poisoning is diagnosed (Table 75.4). In the vast majority of poisoning cases, there is no specific antidote. General therapies such as activated charcoal, peritoneal dialysis, hemodialysis, and gastric lavage have only limited effectiveness. In some cases, they are totally ineffective. Emergency physicians and nurses are generally faced with treating individual symptoms either because the poison is unknown or because there is no antidote. The

Table 75.4 Specific Antidotes

Poison	Antidote
acetaminophen	acetylcysteine (Cetylev, Mucomyst)
anticholinergic drugs	physostigmine (Antilirium)
benzodiazepines	flumazenil (Romazicon)
beta-adrenergic blockers	glucagon
calcium channel blockers	calcium, IV insulin in high doses with IV glucose
carbamates	atropine, pralidoxime (Protopam)
digoxin (Lanoxin)	digoxin immune Fab (Digibind)
ethylene glycol (antifreeze, brake fluid, coolants)	ethanol, fomepizole (Antizol)
heavy metals	chelating drugs
iron	deferoxamine (Desferal)
isoniazid (INH)	pyridoxine (vitamin B_6)
methanol	ethanol, fomepizole (Antizol)
methemoglobin-forming drugs (some local anesthetics, nitrates, nitrites, phenacetin, sulfonamides)	methylene blue
opioids	naloxone (Narcan)
organophosphates	atropine, pralidoxime (Protopam)
tricyclic antidepressants	sodium bicarbonate

strategy for treatment of acute poisoning consists of five general principles:

- **Topical decontamination.** Removal of contaminated clothing, flushing of the skin or eyes
- **Prevention of absorption.** Administration of adsorbents (activated charcoal), whole-bowel irrigation, induction of vomiting, and gastric lavage
- **Neutralization.** Administration of acids or bases
- **Increase in the rate of excretion.** Administration of diuretics, peritoneal or hemodialysis, and ion trapping
- **Antidotes and symptomatic therapy.** Administration of specific antidotes and support of vital functions.

Treatment for ingested poisons depends on the age and physical size of the patient and the time between swallowing and presenting for medical intervention. Any information about the poisoning that can be obtained from the patient, family, or caregiver can be helpful, such as the type of poison that was swallowed, when it was ingested, and how much was swallowed. Following are some specific interventions for managing the patient poisoned by ingestion:

- Do not implement the package instructions for poisoning without consulting the American Association of Poison Control Centers or an appropriate healthcare provider. Preferred therapy may have changed since the packaging was printed.
- Contact the poison control center if the poisoning is the result of taking too much or the wrong medication was taken.
- Provide fresh air to the individual if the poison was inhaled.
- Remove contaminated clothes if the poison came in contact with the individual's skin. Take care not to spread contamination from the poisoned clothes to the surrounding environment. Flush the skin with water for 15 to 20 minutes to dilute or remove the poison.
- Rinse the eyes with running water for 15 to 20 minutes if contacted by poison.
- Do not induce vomiting by gagging or tickling the back of the throat.
- Do not give ipecac syrup. Though once considered a routine procedure, this method of poison management is now considered ineffective. Discourage parents from keeping ipecac syrup in the home. There is no evidence that syrup of ipecac actually helps improve the outcome in poisoning cases. Furthermore, the administration of syrup of ipecac can delay the administration of more effective treatments, such as activated charcoal or antidotes.
- Do not give milk or water unless directed to do so by the poison center. Though once thought to dilute the poison, fluids can liquefy dry poison and send it more rapidly to the small intestine. The exception to this is caustic or corrosive poisons.

CONNECTION Checkpoint 75.3

From what you learned in Chapter 43, which of the following vaccines would be considered a subunit vaccine: polio, HBV, MMR, varicella, tetanus, HPV. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: Using Research in Practice

Emerging Strategies to Combat Bioterrorism

Antibiotics and vaccinations have long been the mainstay of treating bioterrorism where infectious agents are weaponized and released. As antibiotic resistance becomes an increasing global crisis, different drugs will be needed to treat the highly infectious agents used in a bioterrorism attack. The use of pre- and postexposure vaccinations may also be problematic if sufficient quantities of the vaccine cannot be made quickly.

Two recent areas of research seek to provide newer strategies to combat the release of biologic agents. Current research is investigating the use of existing FDA-approved drugs, and what is known about their chemical structures, to treat bioterrorism agents. For example, chloroquine, a drug that has been used to treat malaria, appears to have efficacy against viral biologic agents such as dengue and chikungunya (Madrid et al., 2013). Drugs without anti-infective properties are also being studied. Chlorpromazine, a phenothiazine antipsychotic and antiemetic, has been shown to have activity against some strains of *Salmonella*, and the tetracyclic antidepressant maprotiline has demonstrated activity against *Francisella*, a causative agent in tularemia (Dean & van Hoek, 2015). Although existing drugs may not be found useful for treating a biologic agent directly, what is being learned about the chemical compounds that they include and their anti-infectant properties may lead to new treatments.

Should a biologic agent be released, developing sufficient quantities of vaccine to protect the population is also a concern. Traditional methods of producing vaccines to meet a growing demand based on reemergence and spread of infectious diseases are hindered by the amount of time needed to produce the vaccine, safety concerns, and limited scalability. Recent research has begun to focus on the viability of using plant products to produce subunit vaccines (those developed through recombinant DNA technology) to provide rapid scalability of vaccine production (Streatfield, Kushnir, & Yusibov, 2015). Further study of such products is needed, but this line of research stands to benefit both the ability to fight bioterrorism agents and to increase the availability of common vaccines.

75.9 Activated charcoal is effective at adsorbing (binding) most poisons if administered within 60 minutes of ingestion.

Activated charcoal has been used as an adsorbent for acute poisoning for almost 200 years. Activated charcoal is the only FDA-approved poison-adsorbent drug. Although activated charcoal is effective in the treatment of many poisons, it is not beneficial when given to individuals with lithium, iron, or cyanide poisoning or strong acid or alkali ingestion.

PROTOTYPE DRUG **Activated Charcoal (CharcoAid)**

Classification **Therapeutic:** Antidote
Pharmacologic: Adsorbent drug

Therapeutic Effect and Uses: Activated charcoal consists of organic material such as coal, wood, or vegetables that have been carbonized, reduced, and dried to a charcoal-like substance. It is then activated by exposing it to steam, carbon dioxide, or other oxidizing chemicals at extremely high temperatures. The activation drives off impurities and reduces the particle size so that the surface area of the charcoal is very large.

This drug effectively adsorbs toxins in the intestinal tract, thus preventing their systemic absorption. Adsorption is the process of a drug physically binding to the charcoal. As a general-purpose emergency antidote, it is used in the treatment of poisonings from most drugs and chemicals. To be most effective, the charcoal should be administered within 1 hour of oral ingestion. Normally, a single dose is administered, although some poisons benefit from multiple doses. The general dosage is 5 to 10 times the estimated weight of the poison ingested.

Activated charcoal can also be used off-label to adsorb intestinal gases in the treatment of dyspepsia, flatulence, and distention. It is sometimes used topically as a deodorant for foul-smelling wounds and ulcers.

Mechanism of Action: Activated charcoal (carbon) is a chemically inert, odorless, tasteless, fine black powder. It acts by binding (adsorbing) toxic substances, thereby inhibiting their gastric absorption, enterohepatic circulation, and bioavailability.

Pharmacokinetics:

Route(s)	PO or via nasogastric tube
Absorption	Not absorbed
Distribution	Not distributed systemically
Primary metabolism	Not metabolized
Primary excretion	Fecal
Onset of action	Rapid
Duration of action	Unknown

Adverse Effects: Vomiting may occur when given by rapid ingestion and at high doses. Constipation and diarrhea have also been reported.

Contraindications/Precautions: Activated charcoal is not effective for poisonings by cyanide, mineral acids, caustic alkalis, organic solvents, iron, ethanol, or methanol ingestion. This drug should not be used in patients at a decreased level of consciousness or with a diminished gag reflex due to the risk of pulmonary aspiration. Activated charcoal also should not be used in individuals with central nervous system depression, coma, or gastrointestinal (GI) obstruction.

Drug Interactions: Activated charcoal will decrease absorption of all other oral medications. Oral medication should not be given for at least 2 hours after administration of activated charcoal. **Herbal/Food:** Milk and dairy products may decrease the effectiveness of activated charcoal.

Pregnancy: Category C.

Nursing Responsibilities: Key nursing implications for patients receiving activated charcoal are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Poisoning or Overdose.

Drugs Similar to Activated Charcoal (CharcoAid)

Activated charcoal is the only drug in this class.

75.10 Ion trapping with forced diuresis may be helpful for some poisonings.

One procedure that is occasionally used in acute poisoning is ion trapping through forced diuresis. Because most drugs are either weak acids or weak bases, changing the urine pH can be used to enhance the elimination of some drugs. For example, if the urine is made alkaline, the acidic drugs are trapped in the renal tubules and their elimination in urine is increased. The opposite effect applies for alkaline drugs.

Forced alkaline diuresis may be used to increase the excretion of acidic drugs like salicylates and phenobarbital, and forced acid diuresis has been used to eliminate amphetamines, quinine, and strychnine. When forced alkaline diuresis is employed, a diuretic such as furosemide along with IV sodium bicarbonate will make the urine more alkaline. Forced alkaline diuresis is specifically recommended when rhabdomyolysis (the rapid breakdown of skeletal muscle tissue) occurs.

Ascorbic acid is used for forced acid diuresis. In past decades, ammonium chloride was used for forced acid diuresis; however, due to its toxicity its use has greatly diminished. Research studies indicate that ion trapping through forced diuresis produces only a slight increase in the renal clearance of the drug and is rarely done in practice.

75.11 Chelating agents are capable of forming bonds with heavy metals.

Human exposure to metals has risen dramatically in the past 50 years as a result of an increase in the use of heavy metals in industrial processes and products. **Chelation therapy** is the use of drugs to detoxify poisonous metals such as mercury, arsenic, and lead by converting them to a chemically inert form that can be easily excreted. The compound formed by a chelating drug and a metal is called a chelate. Chelating drugs are most frequently administered intravenously or intramuscularly depending on the agent and the type of poisoning. Chelation was introduced during World War I originally as an antidote to arsenic-based poison gas.

The mechanism of action of chelation therapies involves the chelating drug "latching onto" and removing positively charged metals from the body. Once the amino acid binds with the metal or poison, it can be eliminated from the body by the kidneys. Two chelating drugs are described in this chapter. Many times both medications are given to the individual who is experiencing heavy metal poisoning.

PROTOTYPE DRUG **Edetate Calcium Disodium (Calcium EDTA)**

Classification **Therapeutic:** Drug for heavy metal poisoning
Pharmacologic: Chelating drug

Therapeutic Effects and Uses: Approved in 1953, edetate calcium disodium is a chelating drug that binds with heavy metals such as lead to form a soluble complex that can be excreted by the kidneys, thereby ridding the body of the poisonous substance. Although usually used for acute poisoning, this drug can also remove lead that is stored in fat, bone, or other locations. Edetate calcium disodium is administered by the IV or intramuscular (IM) routes. This drug is generally used in combination with dimercaprol (BAL) in the treatment of lead encephalopathy or when the blood lead level exceeds 100 mcg/dL.

The off-label uses of edetate calcium disodium include the treatment of poisoning from other heavy metals such as chromium, manganese, nickel, zinc, and possibly vanadium, and removal of radioactive and nuclear fission products such as plutonium, yttrium, and uranium. However, this drug is not effective in treating poisoning from arsenic, gold, or mercury.

Mechanism of Action: As a chelating drug, Calcium EDTA combines with metals to form stable, nonionizing soluble complexes that can be readily excreted by the kidneys. Action is dependent on the ability of the heavy metal to displace the weakly bound calcium in the drug molecules.

Pharmacokinetics:

Route(s)	IV/IM
Absorption	Rapidly absorbed
Distribution	Distributed to extracellular fluid; does not enter the cerebrospinal fluid
Primary metabolism	Not metabolized
Primary excretion	Chelated lead is excreted in urine; 50% is excreted in 1 h
Onset of action	Peak chelation: 24–48 h
Duration of action	Half-life: 20–60 min IV, 90 min IM

Adverse Effects: Calcium EDTA may produce renal damage such as proteinuria and microscopic hematuria. Treatment-induced nephrotoxicity is dose dependent and may be reduced by ensuring adequate diuresis before therapy begins. Patients should be monitored for cardiac rhythm irregularities and other electrocardiogram (ECG) changes during IV therapy. Additional cardiovascular effects include hypotension and thrombophlebitis.

Many patients experience febrile reaction (excessive thirst, fever, chills, severe myalgia, arthralgia, GI distress) or histamine-like reactions (flushing, throbbing headache, sweating, sneezing, nasal congestion, lacrimation, postural hypotension, tachycardia). **Black Box Warning:** Patients with lead encephalopathy and cerebral edema may experience a lethal increase in intracranial pressure if the drug is given by IV infusion. The IM route is preferred for these patients.

Contraindications/Precautions: Edetate calcium disodium is contraindicated in patients with severe kidney disease, anuria, or oliguria. IV administration is contraindicated in patients with lead encephalopathy because of a possible increase in intracranial pressure.

Drug Interactions: No clinically significant interactions have been identified. **Herbal/Food:** None known.

Pregnancy: Category C.

Nursing Responsibilities: Key nursing implications for patients receiving edetate calcium disodium are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Poisoning or Overdose.

PROTOTYPE DRUG **Dimercaprol (BAL in Oil)**

Classification **Therapeutic:** Antidote
Pharmacologic: Chelating drug

Therapeutic Effects and Uses: Given by the IM route, dimercaprol is a chelating drug that neutralizes the effects of various heavy metals such as arsenic, gold, and mercury. The drug forms stable, nontoxic intermediates with these metals so they are more easily excreted in the

urine and bile. Dimercaprol is also used as an adjunct to EDTA in the treatment of lead encephalopathy. Off-label uses include chromium dermatitis and ocular and dermatologic manifestations of arsenic poisoning. Some studies indicate that dimercaprol may be used as an adjunct to penicillamine to increase the rate of copper excretion in Wilson's disease. Wilson's disease is a rare genetic disorder in which copper builds up in the liver and is released into other parts of the body.

Mechanism of Action: Dimercaprol forms ring complexes with some heavy metals, such as arsenic, gold, and mercury, preventing or reversing the binding of metallic cations to body proteins.

Pharmacokinetics:

Route(s)	IM only
Absorption	Well absorbed
Distribution	Distributed mainly in intracellular spaces, including the brain; highest concentration is in the liver and kidneys
Primary metabolism	Unknown
Primary excretion	Urine and feces
Onset of action	Peak: 30–60 min
Duration of action	Half-life: unknown

Adverse Effects: About 50% of patients who receive high therapeutic doses have minor reactions, including nausea, vomiting, fatigue, restlessness, apprehension, headache, burning sensation of the mouth, throat, and eyes, lacrimation, blepharospasm, salivation, tingling of extremities, a feeling of constriction in the chest muscle, diffuse pain and muscle spasm, hypertension (systolic and diastolic), and tachycardia. Most patients report pain at the injection site.

Contraindications/Precautions: Dimercaprol is contraindicated in individuals with hepatic insufficiency (with the exception of postarsenic jaundice); severe kidney disease; or poisoning due to cadmium, iron, selenium, or uranium. Because dimercaprol is formulated in peanut oil, patients with a hypersensitivity to peanut products should not receive this drug. This drug should be used cautiously in patients with hypertension, oliguria, G6PD deficiency, and preexisting chronic kidney disease (CKD).

Drug Interactions: Dimercaprol should not be given when iron, cadmium, selenium, or uranium poisoning is suspected. When this drug is given in the presence of these poisonings, it forms toxic complexes. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Nursing Responsibilities: Key nursing implications for patients receiving dimercaprol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Poisoning or Overdose.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Poisoning or Overdose

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including musculoskeletal, GI, cardiovascular, neurologic, endocrine, hepatic, or kidney disease.
- Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, alcohol use, and smoking. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs, and assessment of cardiopulmonary status.
- Evaluate appropriate laboratory findings (e.g., hepatic and renal function studies, complete blood count [CBC], and urinalysis).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration and care:

- Assess for desired therapeutic effects (e.g., cardiopulmonary status is maintained, symptoms related to poison or drug overdose are diminishing, level of consciousness is maintained or improving).
- Continue monitoring vital signs and urine output.
- Continue to monitor hepatic and renal studies, CBC, urinalysis, and other drug-specific laboratory values.
- Assess for and promptly report adverse effects: worsening respiratory distress, decreasing level of consciousness, agitation, confusion, vomiting, diminished urine output, or dysrhythmias.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Administer antidotes, activated charcoal, or chelating agents as appropriate for drug overdose or poisoning once the substance is identified. (Commonly known antidotes include acetylcysteine for acetaminophen, flumazenil for benzodiazepines, sodium bicarbonate for cyclic antidepressants, amyl nitrate for cyanide, naloxone for opioids, and osmotic diuretics for methanol and ethylene glycol.)	• Explain the purpose and expected outcome of antidotes administered to the patient, family, or caregiver. • When no antidote exists for the poisonous substance, inform the patient, family, or caregiver what supportive care will be provided.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Maintain airway and provide supplemental oxygen as needed. (Patients with an overdose or poisoning may be unable to maintain a patent airway, leading to respiratory arrest and death. Intubation also protects against possible aspiration.)	• Instruct the patient to notify the healthcare provider if difficulty breathing or swallowing occurs.
• Monitor cardiopulmonary status. (Cardiac dysrhythmias and pulmonary edema may result from overdose of many poisons, including barbiturates, sedatives, hypnotics, and tranquilizers. **Lifespan:** Age-related physiologic differences or undetected cardiac disease may place the older adult at greater risk for adverse effects from Calcium EDTA.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring.
• Administer IV fluids as ordered. (Crystalloid solutions are used to treat hypovolemia, which may occur because of compromised circulatory status.)	• Instruct the patient, family, or caregiver to report burning, swelling, or discomfort at the IV site.
• Continue to monitor hepatic and renal function laboratory values, CBC, and electrolytes. Administer concentrated dextrose solution (D_5W) as ordered. (Hypoglycemia may occur due to acute poisoning or overdose with agents such as ethanol and salicylates. Nephrotoxicity and hepatotoxicity may occur related to the poisoning or overdose or related to adverse effects of the treatment. **Lifespan:** Age-related physiologic differences may place older adults at greater risk for nephrotoxicity and hepatotoxicity.)	• Explain to the patient, family, or caregiver the need for frequent laboratory work. • Instruct the patient, family, or caregiver to report symptoms of hypoglycemia such as nervousness, anxiety, hunger, shakiness, perspiration, dizziness, or lightheadedness.
• Monitor urinary output. (Observe for changes in urine character and color. Myoglobin may be present if rhabdomyolysis occurs as a result of overdose, causing a cola-colored or rust-brown appearance to the urine.)	• Instruct the patient, family, or caregiver to report any diminished urine output or changes in urine appearance.
• If ordered, insert a nasogastric tube, aspirate fluid for analysis, and perform gastric lavage. (Aspiration and lavage removes drugs that may remain in the stomach, preventing further absorption. Aspirate may be sent to the laboratory for analysis of the drugs ingested to provide identification for appropriate treatment.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for the nasogastric tube and procedure.
• Continue administration of activated charcoal, chelating agents, or antidotes as ordered. (Activated charcoal absorbs drugs from gastric content to prevent systemic absorption. Chelating agents bind heavy metal toxins to remove them from the body.)	• Explain the purpose and expected outcome of activated charcoal, chelating agent, or antidote if administered. • Inform the patient, family, or caregiver that stools may become temporarily black if activated charcoal has been used.
• Prepare the patient for dialysis procedures as ordered. (Peritoneal dialysis or hemodialysis removes poisons from the system and is used when levels are potentially lethal; otherwise the toxin may be metabolized to a more lethal substance.)	• Explain the rationale for peritoneal dialysis or hemodialysis to the patient, family, or caregiver.
• Assess for suicidal ideation and refer to a mental health professional as appropriate. (A psychiatric consultation should be ordered for patients who demonstrate suicidal ideations or behaviors.)	• When suicidal ideation is present and poisoning is self-inflicted, explain the reason for referral to a mental health professional.
• Assess learning needs and provide education related to poisoning and overdose. (Poisoning may often be prevented by personal and public education efforts.)	• Instruct the patient, family, or caregiver on the importance of maintaining a safe environment to prevent recurrence of unintentional poisonings.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of the medication therapy.

Understanding Chapter 75

Key Concepts Summary

75.1 Emergency preparedness has become an essential competency for all healthcare professionals.

75.2 Bioterrorism is the intentional release of a virus or microorganism to cause human harm.

75.3 Nurses may have the first opportunity to recognize and initiate a response to bioterrorism.

75.4 The Strategic National Stockpile has large quantities of medicine to protect the public if a health emergency arises.

75.5 Highly infectious bacteria or viruses could be used as bioterrorist threats.

75.6 There are 13 categories of toxic chemicals that could cause mass casualties if released into the environment.

75.7 Ionizing radiation produces immediate and long-term effects on human tissue.

75.8 The general management of poisoning includes contacting the poison control center or emergency medical services as soon as possible.

75.9 Activated charcoal is effective at adsorbing (binding) most poisons if administered within 60 minutes of ingestion.

75.10 Ion trapping with forced diuresis may be helpful for some poisonings.

75.11 Chelating agents are capable of forming bonds with heavy metals.

CASE STUDY: Making the Patient Connection

Remember the ED nurse "Carol Boler" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

As an ED nurse in a busy urban hospital, Carol Boler participates in frequent emergency practice drills to be prepared for mass casualty events and acts of bioterrorism. Although there have been no incidents yet, she knows that with a military base nearby, there is a chance that such an incident could occur. She is working with unit staff to plan a series of staff education meetings to discuss bioterrorism threats.

Critical Thinking Questions

1. When discussing the bioterrorism threat with a group of staff nurses, which information regarding smallpox should be included?
2. Identify the nursing assessments and interventions that the nurse should initiate when a patient is exposed to anthrax.
3. Discuss the mode of transmission and symptoms associated with *Y. pestis* exposure.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

As a school nurse, you have been asked to speak to a group of mothers about unintentional poisonings in young children.

1. Outline the information you need to present to this audience.
2. What recommendations should you give to the group about the use of ipecac syrup?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is suspected of having been exposed to ionizing radiation. Which nursing intervention would have the greatest priority?
    1. Provide supportive care for nausea, vomiting, and diarrhea.
    2. Limit the patient's exposure to ultraviolet light.
    3. Avoid contamination of self through limited exposure to the patient.
    4. Administer antiradiation medications as indicated.
2. The patient is exhibiting the symptoms of *Yersinia pestis* exposure. Which pharmacologic therapy would most likely be used in the treatment of this patient?
    1. Doxycycline
    2. Trivalent botulinum antitoxin
    3. Ribavirin
    4. Atropine sulfate

3. The nurse has received a telephone call from an anxious mother of an 18-month-old child. In a panicked voice, the mother states, "I just discovered that my baby has swallowed an unknown amount of household cleanser." Which instruction would be appropriate for the nurse to give?
   1. "Consult the package instructions for information concerning poisoning."
   2. "Force your child to vomit using a mixture of warm water and raw eggs."
   3. "Call 911 to take your child immediately to the nearest emergency department or healthcare agency."
   4. "If your child develops seizures or difficulty breathing, call the healthcare provider."

4. Activated charcoal is ordered for a patient who unintentionally overdosed on prescription medications. The nurse would question the order for activated charcoal for the patient with which condition?
   1. Acute hepatitis and cirrhosis
   2. Chronic kidney disease
   3. Decreased level of consciousness
   4. Anxiety and nervousness

5. The nurse knows that the mechanism of action for chelating therapy is:
   1. Removal of positively charged metals.
   2. Deactivation of chemical reaction.
   3. Increased liver metabolism.
   4. Decreased glomerular filtration.

6. Which of the preadministration assessment parameters would the nurse consider before administering edetate calcium disodium (Calcium EDTA) to a patient?
   1. Bowel sounds
   2. Urinary output
   3. Visual acuity
   4. Skin turgor

Appendix A
Answers to Chapter Review

Chapter 1

1 Answer: 3 Rationale: Indications are the conditions for which a particular drug is approved. Options 1, 2, and 4 are incorrect. A description of how a drug works on its target organs and cells is called the mechanism of action. The dosage is the amount of the drug that is given. The conditions whereby the drug should be avoided are contraindications. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

2 Answer: 3 Rationale: Like the original reference product drug, biosimilars are derived from living cells, such as yeast or bacteria. They are not exact, duplicate copies of the original medication, but have comparable effectiveness and safety. Options 1, 2, and 4 are incorrect. Because it is not an exact duplicate copy of the original drug, it cannot be considered a generic drug. It is not in a different therapeutic or chemical class because it differs little from the reference product. It must still be evaluated by the FDA, and demonstrate that the biosimilar differs very little from the approved reference product, before it is approved. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 1, 2, 4 Rationale: Monitoring patient response to drug therapy, teaching the patient about self-administration and how to monitor drug effects, and verifying drugs currently being used by the patient are all key nursing responsibilities. Options 3 and 5 are incorrect. The prescribing provider weighs alternative treatment options, but may not consider all available options due to many variables such as cost or complexity of treatment. Whereas the best option to treat a patient's condition will be chosen, the "ideal drug" does not exist because each patient's outcomes from drug therapy will be affected by many variables. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 1, 2, 3, 4 Rationale: Physiologic responses to drug therapy are affected by a patient's age, gender, race, body mass, and health status. Many diseases such as diabetes have genetic origins. Familial history of disease conditions may reflect potential problems in the patient. Option 5 is incorrect because not having medical insurance is not a physiologic variable that would affect drug therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 2 Rationale: Antihypertensive indicates the therapeutic classification of the drug by describing its usefulness in lowering blood pressure. Options 1, 3, and 4 are incorrect. Beta-adrenergic antagonists, diuretics, and calcium channel blockers all focus on how the drug works, rather than on what therapeutic effects occur. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 4 Rationale: Motrin and Advil are trade names for the generic drug ibuprofen. Options 1, 2, and 3 are incorrect. No error is noted because "ibuprofen" is the generic name for Advil and Motrin, both trade names. Each drug has only one generic name but may have different trade names, depending on the company that manufactures the drug. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 2

1 Answer: 2 Rationale: The FDA requires that drug manufacturers demonstrate both the safety and effectiveness of pharmaceutical products. Options 1, 3, and 4 are incorrect. All drugs have potential reactions and adverse effects. Many factors determine the cost of a drug, and newly approved drugs may be the most expensive and not fully covered by healthcare insurance plans. Not all drugs have been tested in diverse populations, and women, minority ethnic groups, children, and older adults are often underrepresented in drug research studies. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

2 Answer: 2 Rationale: Phase 2 of the clinical investigation relies on studying patients with the disease to be treated. Options 1, 3, and 4 are incorrect. Phase 1 studies use small groups of healthy participants. Phase 3 studies use large numbers of participants with the condition being treated by the drug. Phase 4 is considered postmarketing surveillance after the drug has been approved. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

3 Answer: 2 Rationale: Most drug testing occurs using adult, white, non-Hispanic men, which may limit the generalization of the results to other populations. Options 1, 3, and 4 are incorrect. Drug testing is seldom performed on children, women, or older adults. Although many drugs are tested using animals, effectiveness in animals does not always verify that the drug will be effective in humans. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

4 Answer: 4 Rationale: Telephone orders are not permissible under federal law for Schedule II controlled substances. Options 1, 2, and 3 are incorrect. Refill prescriptions are usually not any more or less expensive than the original prescription. The number of listeners is irrelevant. Prescriptions are not confirmed or verified by the DEA. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

5 Answer: 1 Rationale: The more likely a drug's potential for abuse and dependency, the stricter the regulation to control access to the substance. Options 2, 3, and 4 are incorrect. The cost and production difficulty do not influence the degree of regulation. Adverse effects and drug or food interactions do not dictate the level of regulatory control. The length of time taken to confirm that a drug is effective does not affect the degree of regulation. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

6 Answer: 1, 2, 3 Rationale: Adverse drug reactions may continue to be discovered well after the FDA approval process as larger groups of patients take the drug. Any reaction should be noted in the patient's chart, the provider notified, and an Adverse Event Report filed with the FDA when adverse reactions are noted. Options 4 and 5 are incorrect. Healthcare providers are responsible for reporting adverse reactions as they occur and should not wait for the FDA to send a recall notice. Many factors influence a patient's reaction to medications and each patient may not have the same exact reaction to the medication. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

Chapter 3

1 Answer: 2 Rationale: Although taking a larger dose of a medication usually results in a greater therapeutic response, the response also depends on the drug's plasma concentration. If a toxic level is reached from too large a dose, the drug will have adverse effects instead of a better therapeutic response. Options 1, 3, and 4 are incorrect because they are true statements. The liquid form of a drug will be absorbed faster than its tablet form. Food decreases the absorption rate of most drugs. Patients should always consult a healthcare provider if unexpected adverse effects develop. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1 Rationale: Infants do not develop a mature microsomal enzyme system until they are a year old and therefore do not metabolize drugs very efficiently. Options 2, 3, and 4 are incorrect. Pregnancy does not significantly affect drug metabolism. The concern with pregnant patients is primarily focused on alterations in distribution due to the fetal–placental barrier. The presence of kidney stones would not influence drug metabolism. Hypertension is not a factor that directly results in abnormal metabolism. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3 Rationale: Peristalsis is the wavelike muscular contraction of the gastrointestinal tract that propels stomach and intestinal contents through the system. An increase in this activity would decrease the time that drugs would remain in the GI system and therefore decrease absorption. Options 1, 2, and 4 are incorrect. Excretion for most drugs occurs mostly through the kidneys, lungs, and glands. Peristalsis would not reduce excretions of medications. A delay in peristalsis would prolong absorption time, and peristalsis is not involved in the distribution of drugs to their target sites. Cognitive Level: Applying; Patient Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 3 Rationale: Inhaled drugs produce an immediate therapeutic response. Options 1, 2, and 4 are incorrect. Inhaled medication can be used at any time during the day and is not restricted to the morning. Doses for inhaled drugs are small compared to orally ingested medications, and because these drugs go directly to the lung surface area and are readily absorbed, very little of the substance is lost due to metabolism. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 4 Rationale: The length of time a drug concentration remains in the therapeutic range is its duration of action. Patients with hepatic impairment do not effectively metabolize drugs, which increases the duration of action. Options 1, 2, and 3 are incorrect. In patients with hepatic disease, the duration of action most likely will increase since drug metabolism is impaired. Although the duration of action is extended, the effects of the drug are not improved. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 2, 4 Rationale: A therapeutic drug level that is in the acceptable range indicates that the drug is at a minimally effective concentration but not at a toxic level. Because each patient's response to a drug is unique, the nurse should continue monitoring the patient throughout the drug's use. Options 1, 3, and 5 are incorrect. Because individual patient responses to drugs can be highly variable, adverse effects, toxicities, or even no effect may occur at levels within the therapeutic range. For that reason, the drug dose may need to be adjusted throughout therapy. Therapeutic effectiveness of a drug depends on many factors and the therapeutic range of a drug is the level between minimally effective and toxic levels. It is not an indicator of how effective a drug will be in treating an individual condition. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 4

1 Answer: 1, 2, 3, 5 Rationale: One of the critical determinants of the effectiveness of drug therapy is a physical examination. Nurses will utilize assessment skills to ascertain whether the drug is being effective. In many cases, a patient's vital signs may indicate the effectiveness of a drug such as a decrease in body temperature, a change in blood pressure and pulse, or improved respiratory status. The effects of many drugs are monitored by diagnostic laboratory values such as white blood cell counts, cultures, and various electrolyte values. *Efficacy* is the term that describes the ability of a drug to produce the desired therapeutic effect. Option 4 is incorrect. The dosage time does not directly evaluate the effectiveness of drug therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 1 Rationale: The therapeutic index is the ratio between the therapeutic dose of a drug and the toxic dose and is used as a measure of the relative safety of the drug. The higher the therapeutic index is, the safer the drug. Options 2, 3, and 4 are incorrect. A drug may be labeled "dangerous" for many reasons other than the therapeutic index, including potential for abuse. The higher the therapeutic index is, the less risk of drug toxicity. A high degree of safety does not signify the degree of effectiveness. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 1 Rationale: A dose–response curve is a graphic representation that shows the relation between the amount of a drug administered and the extent of response it produces. Options 2, 3, and 4 are incorrect. A dose–response curve does not illustrate the toxic effects related to a drug or any specific population or graphically present the duration of action of a drug. Serum drug levels must be measured to determine the peak serum drug level. It is unique to each patient and the dose–response curve only represents a maximum (toxic) dose level. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

4 Answer: 4 Rationale: The TD_{50} measures the median toxicity dose. This information indicates the dose that will produce a given toxicity in 50% of a group of patients. Options 1, 2, and 3 are incorrect. Effectiveness, dose response, and receptor subtypes are not represented by the TD_{50} level. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 2 Rationale: Antagonists bind to receptors and block the effects of an endogenous chemical or another drug by competing with receptor binding sites or inhibiting the drug effect. As an antagonist, benztropine would block the effects of neostigmine and the neostigmine would exhibit a lesser effect. Options 1, 3, and 4 are incorrect. A drug that produces an effect after binding with a receptor is an agonist. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1 Rationale: Potency is a reflection of a drug's ability to bind to a receptor. Options 2, 3, and 4 are incorrect. Efficacy and the affinity of a drug to bind to a receptor are separate variables from potency. Metabolism is a function of pharmacokinetics, not pharmacodynamics. First-pass effect is a phenomenon that occurs during enteral absorption and does not affect drug affinity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation.

Chapter 5

1 Answer: 1 Rationale: Collecting additional information will provide the prescriber with knowledge about the type and severity of the reaction to that specific drug and will assist in determining the appropriateness of the order. Options 2, 3, and 4 are incorrect. The nurse should gather additional information from

the patient or family member before notifying the prescriber. A medication is never administered to a patient when allergic sensitivity is suspected until further investigation into the type and severity of the reaction has been completed. Although documentation of the event may be in the patient's medical record, the reaction may not have been documented or may have occurred after the last healthcare visit. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 1 Rationale: As the dose increases, the risk for adverse effects also increases. The patient should be closely observed for the onset of adverse effects whenever the dose of the drug is increased. Options 2, 3, and 4 are incorrect. Although adverse effects are sometimes noted after the first dose, they may occur at any time during drug administration. Although some adverse effects are common when a drug is given PO, others are more common when given by other routes, such as IV or IM. The timing of medication is not a factor associated with dose-related adverse effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 4 Rationale: Promoting adequate hydration may significantly reduce the risk of renal damage produced by drug therapies. Options 1, 2, and 3 are incorrect. Avoiding direct sunlight is appropriate teaching for patients receiving drugs that cause photosensitivity or phototoxicity. Consuming potassium-enriched foods will not reduce the risk of drug-induced nephrotoxicity, nor will avoiding alcohol consumption. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 3 Rationale: Urticaria or hives, with raised, itchy areas of skin, is often a sign of an allergic reaction. Options 1, 2, and 4 are incorrect. Angioedema is a notable swelling around the eyes and lips and sometimes of the hands and feet that occurs beneath the skin instead of on the surface. SJS is characterized by a flulike period of fever, sore throat, and headache followed by the sudden development of circular lesions that cover the majority of the skin. Photosensitivity occurs when a drug renders the skin susceptible to damage by sunlight. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 2 Rationale: The function of the bone marrow is to produce blood cells. When drugs cause bone marrow toxicity, the condition manifests as a decrease in all blood cell types. Options 1, 3, and 4 are incorrect. Muscle and bone pain are most often associated with muscle toxicity. Bone marrow toxicity is not related to a decline in an individual's range of motion. Liver enzymes are not typically affected by bone marrow toxicity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 3 Rationale: The presence of right upper quadrant pain and anorexia are early symptoms often associated with drug-induced liver damage. Options 1, 2, and 4 are incorrect. Black, "furry" tongue or infections elsewhere are not related to liver damage. A sudden drop in blood pressure is orthostatic hypotension. Unusual and uncontrolled movements are neurologic-related effects. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 6

1 Answer: 4 Rationale: When medication orders are given via telephone, it is critical for the nurse to repeat the order verbatim to the prescriber. Options 1, 2, and 3 are incorrect. Whenever possible it is best for the prescriber to write an order for medication, but this is not always possible. It is correct for the nurse to attempt to comfort the patient using a number of nursing interventions for pain. However, the nurse is required to consult the prescriber when a change in the patient's status occurs, regardless of the time. The nurse is responsible for contacting the prescriber and relaying clinical findings and assessment. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

2 Answer: 1 Rationale: Whenever a medication order is unclear, the nurse should always contact the prescriber, and then have the order rewritten to prevent errors. Options 2, 3, and 4 are incorrect. Having another nurse read the order will not necessarily ensure that the dosage is correct for the patient's condition. Whereas the pharmacist or a drug guide may provide the nurse with the usual dose for most patients, they do not take into consideration the patient's weight, disease condition, and other variables that influence the drug's pharmacokinetic and pharmacodynamic actions. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

3 Answer: 2 Rationale: Pharmacies maintain records of medication dispensed to individuals. If a pharmacist can conduct a medication reconciliation by reviewing the patient's drug history on each subsequent visit, serious potential drug–drug interactions may be identified. Options 1, 3, and 4 are incorrect. Insisting on acquiring a trade-name drug rather than a generic does not ensure the safety of a medication. For safety reasons, drugs are dispensed in containers that are sometimes difficult to open. Unless there is a specific reason (such as impaired hand dexterity), medications should be stored in their original safety bottles. Information found on the internet may vary in quality and may be provided by non–healthcare-related sources. When in doubt, the prescriber or pharmacist can provide the most accurate information about expected effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 3 Rationale: The nurse should always validate a questionable order when a patient or a family member verbalizes concern. Options 1, 2, and 4 are incorrect. Medications purchased by a clinical agency vary in appearance depending on the manufacturer. The nurse should withhold the medication and then confirm that it is the correct drug as ordered before administering. If a patient questions a change in medication or procedure, the nurse should verify the order and obtain validation from the prescriber. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

5 Answer: 1 Rationale: The nurse's first priority is always the patient. The nurse should first determine the patient's baseline assessment data in order to determine if any adverse effects are occurring. Options 2, 3, and 4 are incorrect. The healthcare provider should be notified of the medication error; however, it is also important to report the patient's assessment data at the same time. All healthcare agencies have reporting mechanisms for drug errors, and the nurse is responsible for completing this process after assessing the patient and notifying the provider. If the patient experiences an adverse reaction to the drug, further assessment is needed before confirming that the drug itself, rather than a patient variable (e.g., allergy), was behind the reaction before filing an adverse drug reaction report (see Chapter 5). Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

6 Answer: 3 Rationale: Returning when the patient is available ensures that the patient takes the medication and offers opportunity for the nurse to assess for effects or provide teaching related to the medication. Options 1, 2, and 4 are incorrect. A nurse must ensure that the patient takes the medication. By leaving the medication at the bedside or with visitors, the nurse will not know with certainty that the patient took the medication. When a patient refuses a medication, the nurse should document reasons for the refusal so that appropriate follow-up may be carried out. In this situation, the patient did not refuse the medication but was not available to take it at that moment. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

Chapter 7

1 Answer: 1 Rationale: Although CAM medications have been used for thousands of years, many of these substances lack adequate scientific clinical studies to verify their effectiveness. Most healthcare providers are hesitant to recommend a substance that has questionable effectiveness. Options 2, 3, and 4 are incorrect. CAM has a rich history of use over thousands of years in treating certain diseases and conditions. To imply that all alternative therapies are nothing more than fable is incorrect. There is no evidence that response to CAM therapies is related to the placebo effect. In many cases the CAM therapy may be less expensive than prescription medications. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

2 Answer: 3 Rationale: It is best to advise the patient to take small amounts of a new supplement to determine any initial intolerance. Options 1, 2, and 4 are incorrect. Doubling dosages can be extremely dangerous and is seldom, if ever, advisable. There is no indication that fluid intake should be reduced with echinacea. Allergic reactions are possible with natural supplements. Patients should be taught to read the label carefully and avoid any supplement that contains any known allergy-provoking substances. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 1 Rationale: Older adults with hepatic disease are at higher risk of developing serious drug reactions when taking dietary supplements. Options 2, 3, and 4 are incorrect. Patients with cardiac irregularities, pneumonia, or acne may require traditional medications and should be encouraged to consult their healthcare provider. If the patient prefers to use CAM, this can also be discussed with the provider at the time of the healthcare visit. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1, 2, 3, 5 Rationale: Dietary supplements can be found in almost every supermarket, pharmacy, and health food store. Due to aggressive marketing, herbal supplements are also extremely popular. Most dietary supplements are less expensive than prescribed medications and are therefore more appealing to individuals for whom cost is a critical issue. Older patients may also seek therapeutic alternatives for chronic health conditions. Option 4 is incorrect. Natural substances are not necessarily safer than synthetic products and do not undergo the same rigorous testing as synthetic products. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

5 Answer: 1 Rationale: The USP verified dietary supplement mark is awarded to dietary supplements that pass verification processes. The mark represents that USP has tested the supplement to verify that the label accurately reflects the product in the bottle and that the supplement does not contain harmful levels of contaminants. Options 2, 3, and 4 are incorrect. A DEA number is assigned to a healthcare provider and allows him or her to write prescriptions for controlled substances such as a narcotic. The FDA does not control herbal supplements and this code does not exist. U.S. Customs is not responsible for ensuring that herbal supplements are pure. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

6 Answer: 4 Rationale: Changes in liver or kidney function in the older adult may lead to changes in metabolism or excretion for herbal as well as synthetic medications. Options 1, 2, and 3 are incorrect. Older adults are no more likely to have difficulty taking herbal medications or to spend more money on these products than the younger adult population. These difficulties are patient specific at any age. Due to aggressive marketing campaigns by the herbal and dietary supplement industry, all age groups are as likely to hold unrealistic expectations for herbal products. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 8

1 Answer: 2 Rationale: It is recommended that all drugs be avoided as much as possible during pregnancy due to the potential effect on the fetus or infant. Options 1, 3, and 4 are incorrect. Drugs that are available OTC may also be hazardous and may affect the unborn fetus and nursing infant. Drugs used for treating medical conditions such as asthma, hypertension, diabetes, and epilepsy should be continued throughout pregnancy after review by the healthcare provider for the safety of both mother and infant. There must be close monitoring during this time. In such cases the benefits may outweigh the risks. The woman should consult with her healthcare provider regarding any drugs taken during pregnancy and lactation. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 4 Rationale: Drugs in category X are clearly contraindicated because they pose serious risk to the fetus. Options 1, 2, and 3 are incorrect. Category A drugs are safe for the pregnant woman because they demonstrate no risk of injury to the unborn fetus. Category B consists of drugs that may be given to the mother during pregnancy. Drugs in category C represent those whereby there is insufficient evidence that the drug is either safe or dangerous to the fetus, and these drugs will be evaluated by the provider to determine if the benefit outweighs the risk. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 1 Rationale: Although multiple factors affect the transfer of drugs across the placenta, highly lipid soluble drugs will cross the placental barrier more easily than water-soluble drugs. Options 2, 3, and 4 are incorrect. Small molecules such as alcohol easily cross the placental barrier, whereas larger molecules are slower to cross. When drugs are highly protein bound, they are too large to cross the placental membrane. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 1 Rationale: Weeks 1–2 of the first trimester are known as the preimplantation phase. Before implantation, the developing embryo has not yet established a blood supply with the mother. This is sometimes called the "all-or-none" period because exposure to a teratogen either causes death of the embryo or has no effect. Drugs are less likely to cause congenital malformations during this period because the baby's organ systems have not yet begun to form. Options 2, 3, and 4 are incorrect because the embryonic period is 3 to 8 weeks postconception. During the embryonic period there is rapid development of internal structures and maximum sensitivity to teratogens. Teratogenic drugs taken during this phase can lead to structural malformation and spontaneous abortion. The specific abnormality depends on which organ is forming at the time of exposure. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

5 Answer: 1, 3, 4, and 5 Rationale: OTC drugs are generally safe when taken as directed but any drug taken by the mother should be discussed with the healthcare provider first. Lowering the dose will not alter the safety profile of an unsafe OTC drug. Medications are found in breast milk and may be ingested by the infant. The provider will review any prescription medications the mother is taking and will plan for alternatives if any are unsafe during breastfeeding. The form of the medication does not affect the passage of the drug into the breast milk. Option 2 is incorrect. It is true that the higher the dose, the more likely it is that the drug will enter the breast milk and the patient has understood that part

of the teaching. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

6 Answer: 3 Rationale: Increased levels of progesterone cause a decrease in gastric tone and intestinal motility, resulting in delayed gastric emptying. This leads to extended time for drug absorption. Options 1, 2, and 4 are incorrect. Medications may take a longer time to be absorbed and distributed, thus delaying their onset and prolonging their duration of action. Due to the changes in body fluid volume associated with pregnancy, there is greater hemodilution, not hemoconcentration, of drugs. Of all pharmacokinetic factors, drug metabolism is least affected by pregnancy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 9

1 Answer: 1, 3 Rationale: In young children, delayed gastric emptying causes oral medications to remain in the stomach longer, resulting in slowed absorption and an increased risk for adverse drug reactions. Between ages 3 and 5, the liver's metabolic rate reaches adult levels. Before age 5, extra caution and dosage adjustments may be required, particularly for drugs that are metabolized primarily in the liver. Options 2, 4, and 5 are incorrect. Before 6 months of age, there are very small amounts of plasma proteins, and drugs that are normally protein bound remain as free drugs, increasing drug distribution and increasing the risk for adverse effects. Drug excretion through the kidneys increases with age, and standard pediatric doses may be used between 3 and 5 months of age. Cautious monitoring should be continued even after this age, especially with drugs known to be nephrotoxic. The blood–brain barrier is not well developed at birth and drugs can easily penetrate the CNS, causing heightened effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 1 Rationale: The poison control center will have an exact plan of action for this child. Options 2, 3, and 4 are incorrect. Whenever poisoning is suspected, the poison control center and the 911 EMS system should be called immediately. Treatment should begin as soon as possible. Waiting to observe the child for symptoms or driving the child to the hospital delays appropriate treatment significantly. Syrup of ipecac is not to be used, especially in cases where a caustic substance is suspected, because it may increase damage or lead to aspiration. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 1 Rationale: IM injections in infants are absorbed slowly due to low blood flow to skeletal muscles. Options 2, 3, and 4 are incorrect because children experience delayed absorption and distribution of IM drugs, and IM medications may be absorbed slowly and erratically in children. Children have very weak muscle contractions that contribute to this delayed absorption and distribution. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 3 Rationale: At 3 years of age the child begins seeking control and independence. Giving the patient a choice of liquid with which to combine the medicine will give the child a feeling of control and independence and at the same time encourage cooperation. Options 1, 2, and 4 are incorrect. At age 3 years the child does not yet associate medicine with getting better. Threatening patients to get them to take medicine is never appropriate in any situation. Three-year-olds do not imitate actions unless they want to, and saying that a roommate took the medicine may not result in the child doing the same. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 3 Rationale: Drugs with extensive protein binding compete for binding sites, resulting in increased absorption and high potential for drug interactions. Options 1, 2, and 4 are incorrect. Low-potency drugs, drugs with a wide therapeutic index, and drugs applied to the skin are at low risk for drug interactions. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1 Rationale: Children and their parents are most likely to adhere if their medication regimen is simple and inexpensive. Options 2, 3, and 4 are incorrect. Patients are less likely to adhere to the regimen if the medications are costly, they have to be taken over an extended period of time, or they have to be taken at varying times during the day. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

Chapter 10

1 Answer: 1, 2 Rationale: Increased gastric pH is a common physiologic condition of aging that can affect absorption by increasing the time it takes for oral medications to dissolve. Decreased blood flow to the GI tract decreases the amount of absorption as well as distribution. Options 3, 4, and 5 are incorrect. GI motility slows in the older adult and increased body surface area does not directly impact the area of absorption of oral drugs. The older adult may have decreased cardiac output, but this will not affect the absorption of a drug. Cognitive Level: Understanding; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 2 Rationale: A patient who is functioning independently in all ADLs should be encouraged to take full responsibility for self-administering medications. Options 1, 3, and 4 are incorrect. Teaching the daughter to administer the insulin may become an option if the patient does not want to or cannot self-administer the drug, but that is not noted at this time. There is no reason for recommending a home health aide if the patient is competent in self-administering. Since the provider's original order was to treat the patient's condition with insulin, there may be a reason that an oral antidiabetic medication is not appropriate for this patient or not appropriate at this time. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 2 Rationale: In the older adult, renal blood flow decreases and excretion of drugs also decreases, requiring dosage or frequency adjustments for many drugs. Options 1, 3, and 4 are incorrect. Total body fat increases rather than decreases, which may increase storage of fat-soluble drugs. Liver function declines and the amount of plasma proteins decreases. There is a decrease in total body water, and water-soluble drug concentration may increase. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1, 2, 3 Rationale: Excessive prescribing, multiple drug therapy, and increased drug sensitivity are all reasons for adverse effects in older adults. As an individual ages, renal function decreases, leading to alterations in pharmacokinetics and pharmacodynamics. Coupled with multiple-drug therapy and increased sensitivity, it is not unusual for adverse effects to develop. Options 4 and 5 are incorrect. Body mass decreases as age increases. Exercise engagement does not influence the frequency of adverse effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

5 Answer: 2 Rationale: Thirty-one percent of older adult patients report that they did not take their medication because they did not have it on hand when it was time to take it. Options 1, 3, and 4 are incorrect. These are other reasons cited for nonadherence, but they are not the most frequently cited answer. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

6 Answer: 1 Rationale: Older adults may comply with prescribed drug regimens because of confidence in the ability of their provider. Making the statement "It doesn't matter if the medication works as long as the doctor prescribed it" indicates that the patient is not aware of how to monitor the drug's effectiveness or for its adverse effects, and more teaching is required. Options 2, 3, and 4 are positive responses by the patient that indicate that teaching has been effective toward increasing the potential for adherence. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

Chapter 11

1 Answer: 2 Rationale: The statement reflects an attempt to understand the patient holistically. The nurse understands that multiple contributing factors may contribute to illness and involving the patient helps elicit possible factors. Options 1, 3, and 4 are incorrect. Tylenol should not be recommended initially because it may not address the possible causative factors related to the headaches. Monitoring the patient's pupil response to light, although eventually appropriate, should not be performed initially. An ophthalmology referral may be inevitable; however, making such a referral should be done after ruling out other possible sources of the headaches. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 3 Rationale: Factors associated with a drug's expense and the patient's ability to purchase or access needed medication are considered psychosocial variables that may influence adherence to drug therapy. Options 1, 2, and 4 are incorrect. Unpleasant taste or medications that are difficult to swallow may hinder patient adherence; however, the problem is physiologic rather than psychosocial. Liver damage (hepatotoxicity) is also a physiologic factor. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

3 Answer: 2 Rationale: Cultural beliefs refer to the cumulative ideas of knowledge, experiences, values, attitudes, meanings, and roles acquired by a group of people. A preference for traditional healers, such as a Shaman, reflects these beliefs. Options 1, 3, and 4 are incorrect. Ethnicity is a population of human beings whose members identify with each other either on the basis of common genealogy or ancestry. Genetic polymorphisms are changes in enzyme structure and DNA function that occur within a specific subset of the population. A health-related bias is a prejudice or a sense of preference for one particular point of view and is not specifically culturally related. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

4 Answer: 1 Rationale: Patients who are known as slow acetylators have reduced hepatic metabolism and reduced clearance by the kidney. These patients have a greater potential for drug toxicity. Options 2, 3, and 4 are incorrect. Acetylation is a metabolic process that does not influence absorption. The route or form of administration is not associated with acetylation, and protein intake does not affect the rate of acetylation. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1, 2, 3, 4 Rationale: All of these factors—fat-to-muscle ratio, cerebral blood flow, limited drug research on women, and health beliefs—may be considered gender factors that influence pharmacotherapy. Option 5 is incorrect. Dietary considerations are a potential ethnic or cultural consideration. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 4 Rationale: Drug response is unique to each individual. The nurse should observe the responses and exercise caution with all medications. Options 1, 2, and 3 are incorrect. Patient self-report may not be a reliable method, and the patient may not have taken a particular drug before. Learning more about genetic effects on pharmacotherapy is important, but each patient response is unique. Other patients' responses to a drug will not help predict the response in another patient and there are many genetic variations, even within racial groups. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 13

1 Answer: 1 Rationale: Muscarinic agonists may cause reflex tachycardia, which is precipitated by a drop in the patient's blood pressure. When this occurs, the baroreceptors recognize the decline in pressure and alert the medulla to increase the heart rate as a compensatory mechanism. Options 2, 3, and 4 are incorrect. Although the heart rate increases, muscarinic agonists do not directly affect the sinoatrial node. Hypertension is not a problem with this drug therapy; however, hypotension may occur. Muscarinic drugs stimulate bronchial smooth muscles; however, this does not impact the heart rate. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Pyridostigmine is used primarily for myasthenia gravis, a neurologic disorder characterized by muscle weakness and ptosis. A decrease in these symptoms is an expected therapeutic outcome for this drug. Options 1, 2, and 4 are incorrect because the symptoms listed are not usual problems faced by the patient with MG and would therefore be inappropriate outcome statements. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 4 Rationale: Bethanechol works on the muscles needed for urination by increasing ureteral peristalsis and promoting urinary bladder elimination. Options 1, 2, and 3 are incorrect. Bethanechol does not cause changes to urinary structures, nor does it increase urine production or renal blood flow. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1, 2, 3, 5 Rationale: Common adverse effects of bethanechol include abdominal discomfort, sweating, flushed skin, and blurred vision. Option 4 is incorrect because bethanechol increases GI peristalsis and promotes bowel evacuation. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 3 Rationale: Because of the potential for bronchoconstriction, patients with COPD should be treated cautiously with cholinergic agonists. Options 1, 2, and 4 are incorrect. Neostigmine is used to reduce postoperative abdominal distention. Urinary retention may also be relieved with the administration of neostigmine. Neostigmine may be used to reverse the effects of nondepolarizing muscle relaxants. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 4 Rationale: Symptoms of a cholinergic crisis include tachycardia, hyperglycemia, and muscle weakness progressing to paralysis, which may require intubation and mechanical ventilation if profound. Options 1, 2, and 3 are incorrect. Nausea, vomiting, miosis, drooling, and involuntary muscle twitching are common adverse effects and may be treated with atropine. Atropine is also the antidote for cholinergic crisis. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 14

1 Answer: 2 Rationale: Anticholinergic drugs such as tolterodine can cause constipation by slowing GI motility. Therefore,

increases in dietary fiber and water intake will help avoid constipation. Options 1, 3, and 4 are incorrect. Daily exercise helps in avoiding muscle atrophy and anticholinergic drugs are not related to muscle atrophy. Consuming foods high in iron to increase red blood cell production is not related to the effects of anticholinergic drugs. Anticholinergic drugs cause tachycardia, not bradycardia. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 1, 2, 3, 4 Rationale: These drugs cause mydriasis and paralysis of the ciliary muscle, which is useful in ophthalmic examinations. These drugs are therapeutic in correcting cardiac rhythm abnormalities such as bradycardia. Muscarinic antagonists, most notably ipratropium and tiotropium, are useful in treating asthma due to their ability to dilate the bronchi. These drugs are used to reverse the symptoms of overdose of organophosphate insecticides or ingestion of poison mushrooms. Option 5 is incorrect. Urinary retention is an adverse effect of these drugs. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 2 Rationale: Atropine causes urinary retention to worsen in patients with BPH. Options 1, 3, and 4 are incorrect because these are not contraindications for using atropine. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1 Rationale: Muscarinic drugs affect the intraocular pressure by causing mydriasis and paralysis of the ciliary muscle. Options 2, 3, and 4 are incorrect because the drug does not promote infections, cause miosis, or affect the retina. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

5 Answer: 3 Rationale: Cholinergic antagonists typically cause dry eyes and the patient should be encouraged to use lubricating eyedrops. Options 1, 2, and 4 are incorrect. These statements suggest that the patient has understood the teaching. Patients receiving anticholinergic antagonists frequently report extreme dry mouth discomfort and increased fluid intake may ease this symptom. Many anticholinergic antagonists may cause drowsiness initially. Women receiving anticholinergic therapy should be advised to avoid breastfeeding until the medication is discontinued. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

6 Answer: 1 Rationale: The therapeutic effect of succinylcholine is to paralyze skeletal muscles. However, this drug does not produce anesthesia or a loss of consciousness. Options 2, 3, and 4 are incorrect. Succinylcholine produces no change in the patient's sensorium (consciousness) and the patient can still experience pain. The effect of succinylcholine is total muscle paralysis, not muscle relaxation. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 15

1 Answer: 1 Rationale: Phenylephrine causes vasoconstriction, reducing the swelling in the nasal passages. Options 2, 3, and 4 are incorrect. The drug does not destroy organisms or coat nasal passages. Whereas some drugs may be swallowed via the nasopharynx, localized action is predominant, and excessive drug use and swallowing may result in adverse effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 1, 2, 4 Rationale: Adrenergic agonist nasal sprays should not be shared among individuals due to the risk of spreading infection. Individuals should be taught the dangers of using adrenergic nasal sprays for longer than 3 days. These medications can cause increased blood pressure, increased heart rate, and insomnia. Habitual use of nasal adrenergic drugs can also cause rebound congestion as well as necrosis of the nasal mucosa due to the severe vasoconstriction caused by the drug. Due to the CNS stimulation, nasal adrenergic drugs are not indicated in children and infants. Options 3 and 5 are incorrect. The drug causes CNS stimulation rather than depression. People with diabetes must use caution when using adrenergic drugs and must monitor their blood glucose levels more frequently for hyperglycemia. They are also at higher risk for adverse cardiac effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 4 Rationale: Epinephrine is used during anaphylaxis to prevent hypotension and bronchoconstriction. Options 1, 2, and 3 are incorrect because the administration of epinephrine for anaphylaxis does not prevent the formation of histamine or antibodies in response to an invading antigen nor does it affect white blood cell function. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1 Rationale: When $beta_2$-adrenergic agonists such as albuterol are taken too close to bedtime, the patient may experience insomnia. Options 2, 3, and 4 are incorrect because all adrenergic agonists act as stimulators, and urticaria and tinnitus are not adverse effects associated with this drug therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 2 Rationale: At high dosage, dopamine stimulates $alpha_1$-adrenergic receptors, causing vasodilation and increased blood pressure. Options 1, 3, and 4 are incorrect. Dopamine does not affect the reflexes responsible for pupillary response or the patient's gag reflex, and it does not directly affect the patient's level of consciousness. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1, 4 Rationale: The nurse should consult with the prescriber when adrenergic drugs are prescribed for individuals with hyperthyroid disease or dysrhythmias. The medication will further increase the already overactive metabolic system in hyperthyroidism and may increase the risk for dysrhythmias due to the cardiac stimulation caused by these medications. Options 2, 3, and 5 are incorrect. These are therapeutic indications for the administration of adrenergic agonists. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 16

1 Answer: 1 Rationale: With beta-adrenergic blockers such as propranolol, the most important action is to monitor the patient for adverse effects associated with the cardiovascular system such as changes in pulse and blood pressure. Options 2, 3, and 4 are incorrect. Elevation of the head of the bed is not specifically required for this drug regimen. Inderal can be taken anytime regardless of meals, and its therapeutic action is not contingent on serum K^+ levels. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 4 Rationale: Beta-adrenergic antagonists may cause hypoglycemic episodes in patients with diabetes. The patient should be instructed to monitor blood glucose levels frequently initially and to notify the prescriber of a decrease. Options 1, 2, and 3 are incorrect. Insulin dosages are never arbitrarily increased without checking with a healthcare provider. Patients with diabetes should remain on their normal diabetic diets even though they may be taking antihypertensive medications. Elevation of the extremities is not relevant to a patient with diabetes taking beta-adrenergic blocker drugs. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 1 Rationale: Initial doses of drugs that cause a "first-dose phenomenon" should be very low and administered at

bedtime. The decline in blood pressure due to prazosin is often marked when beginning pharmacotherapy and when increasing the dose. This "first-dose phenomenon" can lead to syncope due to reduced blood flow to the brain. Options 2, 3, and 4 are incorrect. Doses of antihypertensive medications should never be doubled but should be gradually increased to avoid hypotension, and the best time to give prazosin in the initial phases of therapy is at bedtime. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1 Rationale: The nurse should suspect that the patient is describing orthostatic hypotension induced by the medication. Most patients find it helpful to move slowly from a recumbent position to avoid dizziness and syncope. Options 2, 3, and 4 are incorrect. Although drinking a full glass of water with the medication is a health promotion activity that the nurse might suggest, this action does not eliminate orthostatic hypotension. Sleeping positions do not influence the presence of orthostatic hypotension. The patient should never abruptly stop taking antihypertensive medication. Such action could result in hypertensive crisis, stroke, or heart attack. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: One adverse effect of alpha$_1$-adrenergic antagonists is tachycardia. Patients experiencing tachycardia should not receive alpha$_1$-adrenergic antagonists. Options 1, 2, and 3 are incorrect. Alpha$_1$-adrenergic antagonists are often prescribed for BPH because they relax muscles in the prostate. A pheochromocytoma is a benign tumor of the adrenal medulla that secretes catecholamines. Alpha$_1$-adrenergic antagonists help to reduce the HTN associated with these tumors. Alpha$_1$-adrenergic antagonists diminish the vasospasms associated with Raynaud's disease. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 2, 3, 4 Rationale: Beta-adrenergic blockers can have dramatic metabolic effects that produce an increase in serum triglycerides and hypoglycemia. Additionally, these drugs can affect the sexual function of men by decreasing libido. Options 1 and 5 are incorrect. Anorexia and thrombocytopenia are not adverse effects associated with beta-adrenergic antagonists. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 18

1 Answer: 3 Rationale: Ataxia, weakness, restlessness, dizziness, and other motor problems can occur with lorazepam. Options 1, 2, and 4 are incorrect. These are not adverse effects associated with lorazepam. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 4 Rationale: Sleeping for 7 h is the desired effect of temazepam. Options 1, 2, and 3 are incorrect. The client should experience periods of sleep lasting longer than 3 h and should obtain a full night's sleep. The client will be taking temazepam to assist with insomnia, not to treat anxiety related to everyday stress or to help control panic attacks. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 3 Rationale: This medication must be gradually reduced, not abruptly terminated. Abrupt termination may cause withdrawal symptoms (nausea, vomiting, abdominal cramps, diaphoresis, confusion, tremors, seizures). Options 1, 2, and 4 are incorrect. These are appropriate statements, and indicate that the client understands the teaching. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

4 Answer: 2 Rationale: Panic disorder is not an appropriate use for phenobarbital. Options 1, 3, and 4 are incorrect. Treatment of status epilepticus, use prior to diagnostic testing, and use prior to receiving general anesthesia are all appropriate for phenobarbital. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 3 Rationale: Client safety is the major concern with sedative–hypnotics, so prevention of falls is the highest priority. Options 1, 2, and 4 are incorrect. The client may experience urinary incontinence, activity intolerance, or poor nutritional intake related to drug therapy or other reasons. Safety, however, is the priority concern. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1 Rationale: Smoking enhances the metabolism of benzodiazepines, so the medication is broken down and removed from the body more quickly if the client is a smoker. Therefore, a smoker may require a larger dose of a benzodiazepine to get the same effect as that of a nonsmoker. Options 2, 3, and 4 are incorrect. A smaller or half dose, or a single extra dose, may not adequately help relieve the client's symptoms. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 19

1 Answer: 1 Rationale: Imipramine should not be used by patients with seizure disorders because it lowers the seizure threshold. Options 2, 3, and 4 are incorrect. Imipramine is a drug that is effective in treating depression, and is one of only two drugs approved for enuresis (bedwetting) in children. Like other TCAs, imipramine has a number of off-label indications. These include the adjuvant treatment of cancer or neuropathic pain. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Full therapeutic effects of fluoxetine may take up to 1 month. Options 1, 2, and 4 are incorrect. Normal water and sodium intake do not affect fluoxetine. The patient cannot take an MAOI or other CNS depressant concurrently. The use of other drugs or CNS depressants such as alcohol could increase the risk of adverse effects or increased depression. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 1, 2 Rationale: Persistent GI upset and confusion are signs of elevated lithium levels between 1.5 and 2.0, which signify early toxicity. Options 3, 4, and 5 are incorrect. Polyuria is an adverse effect that may occur in early therapy, but is not associated with early toxicity. Convulsions may occur at serum levels above 2.5, but not in early stages of toxicity. Ataxia is also not a sign of early lithium toxicity. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1 Rationale: The patient taking lithium must be conscious of maintaining normal sodium intake. Because lithium is a salt, if sodium intake is low the body will replace the sodium with lithium, leading to lithium toxicity. Options 2, 3, and 4 are incorrect. The patient taking lithium must have regular blood studies and toxicity is a very real concern; hence the necessity for routine blood studies. Women should refrain from breastfeeding while taking lithium. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 3 Rationale: An atypical antidepressant such as venlafaxine may take up to 3 weeks or longer to reach full therapeutic effect, so the patient must continue taking the medication as ordered so that therapeutic drug levels can be reached and maintained. Options 1, 2, and 4 are incorrect. It is not within a nurse's scope of practice to suggest changes in medication routine without consulting the prescriber, and these comments are not helpful to maintaining a therapeutic nurse–patient relationship. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

6 Answer: 2, 3 Rationale: Fluoxetine causes weight loss in some patients while others experience weight gain or fluctuations in weight. A healthy diet and adequate exercise will help maintain normal weight while on this drug. While rare, an increased risk of suicide has been noted in patients up to age 24, and the patient should be carefully monitored, especially during the early initiation of therapy. Options 1, 4, and 5 are incorrect. Fluoxetine may cause insomnia but not sedation. Abrupt withdrawal of fluoxetine may lead to withdrawal symptoms. If the drug needs to be discontinued, gradually tapering the dose is recommended. Fluoxetine is not known to cause excessive thirst. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 20

1 Answer: 4 Rationale: Antipsychotic medications treat the symptoms associated with mental illness but do not cure these disorders. Without the medication, the symptoms will return. Options 1, 2, and 3 are incorrect. These are not symptoms associated with abrupt withdrawal of an antipsychotic medication. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2 Rationale: Grapefruit and grapefruit juice are known to interact with drugs and may increase drug levels of aripiprazole to potentially toxic concentrations. Options 1, 3, and 4 are incorrect. Social withdrawal is a symptom of the disease, and slowed activity may occur as a result of the medication. Tardive dyskinesia is not commonly noted with aripiprazole. SSRIs such as fluoxetine inhibit CYP2D6, which can cause reduced metabolism of aripiprazole, raising serum levels, and potentially causing toxicity. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 1 Rationale: Benztropine is classified as an autonomic nervous system drug and an anticholinergic. It suppresses tremor and rigidity by decreasing the excess cholinergic effect associated with dopamine deficiency. Options 2, 3, and 4 are incorrect. Diazepam and lorazepam are antianxiety medications that will not improve the patient's symptoms. Haloperidol is an antipsychotic medication that may cause these symptoms. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 2, 4 Rationale: EPS occur frequently, especially at the beginning of therapy with haloperidol. An individual with Parkinson's disease, seizure disorders, alcoholism, or severe mental depression should not take haloperidol because they are all disorders that affect the CNS. Dementia, seizures, depression, and severe CNS depression are known to occur with the use of haloperidol in these patients. Options 1, 3, and 5 are incorrect. Haloperidol and antacids may be given simultaneously; there are no known interactions between these two medications. Haloperidol must be taken as ordered, on a regular schedule. Taking the drug prn will not reduce symptoms of psychosis because it takes several weeks of regular administration before therapeutic levels are reached. Sustained release medications should never be crushed. If the patient cannot take the medication, another form should be used. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: The patient taking risperidone or any antipsychotic medication should refrain from consuming alcohol. Concurrent use of alcohol with antipsychotic medications will increase CNS depression. Because there is an increased risk of hyperglycemia or diabetes in patients taking risperidone, alcohol should also be avoided because it may affect blood sugar levels. Options 1, 2, and 3 are incorrect. Weight gain may occur, and obtaining a weekly weight will help the patient track any gain. Increasing fluids and fiber may help to limit GI adverse effects. Hypotension is related to adverse reactions the patient may experience and must be monitored and reported if it occurs. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1 Rationale: Fever, tachycardia, stupor, and incontinence are symptoms of neuroleptic malignant syndrome (NMS), a potentially fatal adverse effect of antipsychotics that must be diagnosed and treated immediately. Options 2, 3, and 4 are possible adverse reactions, but are not life threatening, and therefore do not need to be reported with the same urgency as symptoms of NMS. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 21

1 Answer: 2 Rationale: Benztropine, a cholinergic antagonist, is frequently used as combination therapy with other antiparkinson drugs to decrease tremors. Options 1, 3, and 4 are incorrect. Amantadine acts to increase dopamine's release, but only as long as dopamine is available. Haloperidol is a phenothiazine antipsychotic that may lead to pseudo-Parkinson's disease in many people. Donepezil prolongs the time between diagnosis and the institutionalization of the patient with Alzheimer's disease and is not used for Parkinson's disease. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Being independent with ADLs shows an improvement in physical abilities. Options 1, 2, and 4 are incorrect. Drowsiness is a common adverse effect of antiparkinson medications. Anorexia or loss of appetite is a common adverse effect, not an expected therapeutic effect. Itchy skin is not directly related to PD symptoms or to the medications used. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

3 Answer: 3 Rationale: It is important that the caregivers understand that there is no cure for AD, but that the medication may delay the worsening of symptoms. Options 1, 2, and 4 are incorrect. The medication should be given continuously and not only when the symptoms are present. The patient may become constipated but does not require emergency treatment. The drug may cause bradycardia or atrial fibrillation and the pulse rate should be checked weekly, but it is not necessary to take the patient's vital signs before each dose of medication. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

4 Answer: 1, 2, 5 Rationale: Alzheimer's patients and their families may struggle with complex medication routines, and it is difficult to remember to take a medication multiple times a day. Donepezil has not been associated with hepatotoxicity. It requires once per day dosing, usually at bedtime. While it does not cure AD, donepezil may lengthen the time between when the patient is diagnosed and memory care in a skilled facility is needed. Options 3 and 4 are incorrect. There is a risk of GI bleeding, especially in patients with a history of peptic ulcers or chronic NSAID use. Potentially life-threatening cardiac dysrhythmias, including atrial fibrillation and sinus bradycardia, are possible adverse effects associated with donepezil. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

5 Answer: 1 Rationale: Rivastigmine has no significant drug interactions. This is thought to be true because there is no interaction with enzymes in the liver that metabolize drugs. Options 2, 3, and 4 are incorrect because they do not apply to rivastigmine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 1, 2, 4 Rationale: Flulike symptoms with general malaise, body aches, fever, and headache are common. Insomnia

and rashes may also occur and may be treated symptomatically after conferral with the provider. Options 3 and 5 are incorrect. Depression should never be ignored and should be reported immediately. Significant pain with darkening or blackening of the skin at the injection site indicates that tissue necrosis may be occurring and requires prompt treatment. Cognitive Level: Analyzing; Client Need: Psychosocial Integrity; Nursing Process: Evaluation

Chapter 22

1 Answer: 3 Rationale: GI effects such as nausea, anorexia, and abdominal pain are common with ethosuximide. Because the patient is still growing, improper nutrition may affect normal growth. Monitoring height and weight weekly will assist in tracking normal growth. Options 1, 2, and 4 are incorrect. Physical activity will not affect the drug's metabolism and activity is normal and needed for healthy growth and development. Ethosuximide is not known to cause bone loss or dehydration. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

2 Answer: 4 Rationale: Oxcarbazepine is excreted by the kidneys, and renal function laboratory studies will be monitored to detect adverse renal effects. Because hyponatremia may develop during treatment, serum sodium levels should also be monitored. Options 1, 2, and 3 are incorrect. Oxcarbazepine does not affect CBC, albumin or serum glucose levels, sedimentation rate, or platelets. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 4 Rationale: Sedation and an increased risk of falls are associated with carbamazepine. Options 1, 2, and 3 are incorrect. Carbamazepine is used off-label to treat dementia with aggressiveness and agitation. The drug is not associated with insomnia and has not been demonstrated to increase the risk of stroke. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: Slurred speech, diplopia, sedation, and dyspnea are symptoms of gabapentin overdose. Options 1, 3, and 4 are incorrect. Seizure activity is likely to recur if the drug is stopped abruptly. Neither grapefruit juice nor smoking is known to affect drug level. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: High doses of phenytoin can cause nystagmus, confusion, ataxia, coma, and seizures and the dosage should be reduced. Options 2, 3, and 4 are incorrect. Increasing or maintaining the same dose will continue or exacerbate the symptoms of toxicity. The drug should not be discontinued abruptly because seizure activity may occur. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 3 Rationale: Carbamazepine is associated with an increased risk of SJS and toxic epidermal necrosis in genetically susceptible individuals. Sunburning and a reddish-purple rash, especially associated with blisters, are possible symptoms of severe dermatologic reactions and should be evaluated immediately. Options 1, 2, and 4 are incorrect. Blurred vision, leg cramping, and lethargy are all possible side effects of carbamazepine but tolerance to these effects usually develops over time. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 23

1 Answer: 1, 4, 5 Rationale: Cyclobenzaprine may cause tachycardia, and any palpitations or rapid heart rate should be reported. Drowsiness may also occur, and driving or other hazardous activities should be avoided until the effects of the drug are known. Swelling of the face or tongue may occur and must be reported immediately to the provider. Options 2 and 3 are incorrect. Patients with severe muscle spasms are encouraged to rest affected muscle groups until acute spasms subside. Cyclobenzaprine may cause dry mouth, and alcohol-based mouth rinses may exacerbate the condition. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 3 Rationale: Abruptly discontinuing baclofen may result in fever, seizures, rebound spasticity, and hallucinations. Options 1, 2, and 4 are incorrect. Baclofen may cause weakness, and like other muscle relaxants and antispasmodics, may cause constipation. Being cautious with activities and increasing fluid and fiber intake will help to limit the adverse effects caused by baclofen. It may take several months before the full effects of baclofen are reached. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 2 Rationale: Capsaicin should be applied to the site of pain with a gloved hand to prevent irritation of the skin on the hands and to avoid introducing the capsaicin to the eyes or other parts of the body not under treatment. Options 1, 3, and 4 are incorrect. Capsaicin should only be applied to the site of pain, not proximal or distal to the pain. If capsaicin begins to irritate and cause redness and inflammation, it should be discontinued. Capsaicin should not be applied with a bare hand. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: Dysphagia, blurred vision, and ptosis are all symptoms of possible botulism toxicity and should be reported immediately. Options 1, 3, and 4 are incorrect. Fever, aches, and chills are not anticipated adverse effects of this drug, and while they should be evaluated, they do not require immediate reporting. Moderate levels of muscle weakness may occur after the drug is administered, and strengthening exercises may be needed on the affected side. Continuous muscle spasms and pain should not occur because the drug blocks muscle contraction. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 4 Rationale: Physostigmine may be administered to reverse serious anticholinergic adverse effects. Options 1, 2, and 3 are incorrect. Naloxone is often used to decrease the effects of opioids on the CNS but is not the preferred drug in the treatment of CNS depression with cyclobenzaprine. Meperidine is a CNS depressant and should not be administered with cyclobenzaprine. Diazepam is a skeletal muscle relaxant and should not be administered with cyclobenzaprine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 2, 3, 5 Rationale: Dantrolene may cause hepatotoxicity with the greatest risk occurring in women over age 35. Estrogen taken concurrently with dantrolene may increase this risk. The drug may cause xerostomia, and sucking on hard candy or ice chips or sipping water may relieve the dryness. Options 1 and 4 are incorrect. Fluids and fiber may also help diarrhea, but dantrolene may cause diarrhea, not constipation. Dantrolene may cause photosensitivity, so patients taking the drug should avoid direct exposure to the sun. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 24

1 Answer: 4 Rationale: ADHD drugs are Schedule II through IV drugs that require tight controls. Because they can be abused, they should be kept under lock and tightly monitored with only the minimal number of doses kept at the school as per school policy. Options 1, 2, and 3 are incorrect. Keeping the drug in a lunch bag may lead to the child forgetting to take it or to other children

taking the drug. Because it is a highly regulated drug, additional prescriptions or dosages are not allowed under the schedule because they could result in the misuse of the drug by people other than the student for whom it is prescribed. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 2 Rationale: Atomoxetine should decrease hyperactivity. Options 1, 3, and 4 are incorrect. Atomoxetine should increase attention, not decrease it. Mydriasis and elevated liver enzymes are adverse effects associated with atomoxetine; they are not therapeutic effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

3 Answer: 1 Rationale: Chlorpromazine is the preferred drug to assist in counteracting amphetamine overdosage. It has strong alpha-adrenergic blocking actions that treat the effects of amphetamine. Options 2, 3, and 4 are incorrect. Phenytoin is an antiepileptic drug, propofol is a nonbarbiturate sedative–hypnotic, and dexamethasone is a corticosteroid. None of these drugs would counteract the effects of an amphetamine overdose. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 3 Rationale: Atomoxetine has been linked to suicidal ideations and an increased risk of suicide. These symptoms should be reported immediately to the family or caregiver for assessment and treatment by the healthcare provider. Options 1, 2, and 4 are incorrect. The need for drug withdrawal will be determined by the provider after assessing the patient. The drug may take up to 4 weeks to achieve maximum therapeutic effects, but this patient is experiencing an adverse effect linked to the drug. Caffeine will not counteract depressive effects and may increase the risk of CNS adverse effects. Cognitive Level: Analyzing; Client Need: Psychosocial Integrity; Nursing Process: Evaluation

5 Answer: 2 Rationale: Palpitations, dysrhythmias, and facial tingling are all symptoms of a caffeine overdose. Options 1, 3, and 4 are incorrect. Zolpidem and gabapentin are associated with CNS depressant-type effects such as drowsiness, dizziness, and bradycardia. Some herbal teas may contain stimulant properties, but many have calming effects and are not as likely as caffeine to cause these symptoms. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 3 Rationale: Taking the medication before late afternoon ensures that peak drug activity will occur during waking hours. Options 1, 2, and 4 are incorrect. Drinking wine with dinner should not have a noticeable effect on sleep unless taken directly before bedtime when the metabolism of the alcohol may actually diminish sleep as the blood glucose rises and falls. Chocolate contains caffeine, and also sugar, which may cause additional wakefulness. Decaffeinated coffee will limit the intake of the additional stimulant of caffeine but will not significantly improve the patient's sleep if the methylphenidate is taken later in the afternoon or evening. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 25

1 Answer: 1, 3, 4, 5 Rationale: Common adverse effects of opioids include respiratory depression, urinary retention, constipation, and nausea. Option 2 is incorrect. Hypotension, not hypertension, is an adverse effect of opioids. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 4 Rationale: Opioids decrease peristalsis, and bowel surgery may produce a temporary cessation of peristalsis (paralytic ileus). Both lead to constipation. Once sufficient bowel function has returned for the patient to start eating, constipation is still likely and needs to be prevented by increased dietary fiber and fluids as well as taking a stool softener. Options 1, 2, and 3 are incorrect. Respiratory depression and urinary retention are not likely after several days with decreasing opioid use. Addiction is not a concern in the treatment of acute pain in this scenario. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 3 Rationale: Chest pain is a serious adverse effect of sumatriptan and needs to be differentiated from angina, which can also be caused by the drug. Options 1, 2, and 4 are incorrect. The patient should not use the drug again until being evaluated by the provider and should report the chest pain immediately. Reclining in a quiet room with cold packs is a nondrug treatment for migraines, but reporting the chest pain is most important at this time. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: The patient is describing neuropathic pain, which is most likely to respond to the adjuvant analgesic gabapentin, an antiseizure drug used for neuropathic pain. Options 1, 3, and 4 are incorrect. Nonopioids such as ibuprofen, or opioids such as methadone, are less effective at relieving pain that is of neurologic origin. Naloxone is an opioid antagonist and will not relieve the patient's pain. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

5 Answer: 2 Rationale: Ergot alkaloids such as dihydroergotamine (Migranal) are one of the two drug classes for aborting migraines. Options 1, 3, and 4 are incorrect. Morphine is an opioid agonist and is not effective in aborting migraines. Propranolol is a beta blocker and is used to prevent migraines. Ibuprofen is a nonopioid analgesic that is used to treat mild to moderate pain. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 4 Rationale: Older adult patients are at highest risk for hypotension, respiratory depression, and increased incidence of adverse CNS effects such as confusion. Options 1, 2, and 3 are incorrect. Most 23-year-old patients can tolerate opioids without adverse effects. Individuals who have experienced a traumatic injury may receive narcotic analgesia. However, caution should be taken if the individual has also experienced any type of head injury. Opioids are often used with individuals who have had an MI. No adverse effects such as hypotension or respiratory depression are usually present if the dose is appropriate for the size of the patient. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 26

1 Answer: 2 Rationale: In stage 2 the patient becomes excitable with hyperactivity and irregular heart and respiratory rates. Options 1, 3, and 4 are incorrect. In stage 1, the patient loses general sensation but remains awake. In stage 3, the patient's skeletal muscles become relaxed, and delirium stabilizes. In stage 4, the patient has paralysis of the medulla with possible adverse effects on respiratory and cardiac function. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1 Rationale: Patients who have an allergy to eggs or soy products may have an allergic reaction to the propofol emulsion, which contains these products. Options 2, 3, and 4 are incorrect. Patients with allergies to iodine, kidney disease, or Addison's disease may be administered propofol cautiously. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 4 Rationale: Anxiety, excitement, and combativeness are signs that the dose of nitrous oxide is high and the patient

is exhibiting signs of the second stage of anesthesia. Lowering the dose may reduce these symptoms. Options 1, 2, and 3 are incorrect. The dose of nitrous oxide would be lowered, not increased. Propofol would cause additional CNS depression and is not advised. Succinylcholine is a neuromuscular blocking drug that will increase the risk of significant respiratory adverse effects due to its muscle-paralyzing actions. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 3 Rationale: Ketamine produces dissociation anesthesia, which is a feeling of being separated from the environment. Options 1, 2, and 4 are incorrect because anxiety and dry mouth are not significant adverse effects of ketamine. Ketamine may cause decreased energy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Epinephrine is administered with lidocaine to increase the duration of the anesthetic action at the site by causing vasoconstriction, keeping the anesthetic localized. Options 2, 3, and 4 are incorrect because epinephrine will cause vasoconstriction, not vasodilation at the site; may increase blood pressure if the drug enters the systemic circulation; and neither lidocaine nor epinephrine has any antibacterial properties. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 2, 3, 4 Rationale: Alfentanil is a parenteral opioid that promotes general anesthesia. Sufentanil is also a parenteral opioid. Remifentanil is an opioid that is used to induce and maintain general anesthesia. Options 1 and 5 are incorrect. Nitrous oxide is not an opioid and it is administered by inhalation. Succinylcholine is a neuromuscular blocking drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 27

1 Answer: 1 Rationale: Addiction is not a problem for the majority of patients who receive narcotic analgesia in the postoperative period. The nurse should administer the dose to treat the pain. Options 2, 3, and 4 are incorrect. Reviewing the patient's past medical history is an important assessment that should guide nursing practice, but a patient's past tendencies toward substance abuse are not appropriate criteria to consider in the nurse's decision to treat the pain with analgesia. Pain is best treated in the early stage. If a nurse waits to treat pain until it becomes intolerable, the patient may require a higher dose of the analgesia. There is no evidence that patients request medication when it is not needed. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Patients with a substance use disorder tend to revert back to drug-seeking behavior when they return to the company of other substance abusers. Options 1, 2, and 4 are incorrect. A good support system can be extremely beneficial when an individual is attempting to withdraw from physiologically and psychologically addictive substances. Patients with substance use disorder may experience the desire to use drugs long after the drug has physiologically cleared the body. Generally speaking, individuals who share a common experience will be perceived as being most helpful to an individual undergoing the same or similar experience. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

3 Answer: 1, 4, 5 Rationale: Varenicline (Chantix) doses are increased over an 8-day period and maintained for 12 to 24 weeks, reducing withdrawal symptoms and craving for smoking. Serious dermatologic reactions have been noted, and any unusual skin reactions or angioedema should be reported to the provider immediately and the drug stopped. Varenicline carries a black box warning for serious neuropsychiatric events, and any changes in behavior, depression, hostility, or thoughts of suicide should be immediately reported. Options 2 and 3 are incorrect. Varenicline (Chantix) activates nicotinic acetylcholine receptors in the brain and blocks nicotine from reaching the receptors. It does not prevent nicotine's harmful effects on body systems from occurring. It has several adverse effects, including serious dermatologic and neuropsychiatric effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 2 Rationale: Sedatives cause a profound suppression of the respiratory system through direct action with the CNS. Patients who have experienced an overdose of sedatives are at high risk for respiratory arrest. Options 1, 3, and 4 are incorrect. Sedatives do not typically cause any type of stimulation. Long-term effects of overdose will most likely manifest through liver and kidney dysfunction, but the immediate need is to determine the current status of the patient. Level of consciousness is one of the assessments to be made with a patient receiving sedatives, but the nurse would expect a decrease in consciousness with an overdose of sedatives. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 4 Rationale: Typical symptoms of heroin withdrawal include chills, dilated pupils, diarrhea, runny nose, muscle spasms, goose bumps, abdominal pain, sweating, and agitation. Options 1, 2, and 3 are incorrect. Heroin is an opiate that depresses the CNS, and the patient may exhibit hyperactive behavior during withdrawal. Dermatologic effects are not common during heroin withdrawal. Paranoia, delusions, or hallucinations are typical effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1 Rationale: Disulfiram is a drug used in the rehabilitation of alcoholism. When patients are taking this drug, even small amounts of alcohol, such as that found in mouthwash and many OTC medications, can produce flushing, throbbing in the head and neck, respiratory difficulty, nausea, vomiting, sweating, thirst, chest pain, blurred vision, and confusion. Options 2, 3, and 4 are incorrect. There is no reason for a patient to avoid dairy products or foods high in iron. Disulfiram should not directly impact the patient's driving or level of alertness. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 29

1 Answer: 1 Rationale: Rhabdomyolysis is a serious adverse effect of the statins. Early signs include unexplained fatigue or muscle weakness, pain in joints or muscles, and an increase in CK level. Options 2, 3, and 4 are incorrect. The weakness, fatigue, and pain that the patient is experiencing are not symptoms of renal failure or hepatic insufficiency. In rheumatoid arthritis, pain is often present but tends to be greatest in the mornings and associated with red, hot, swollen joints. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2 Rationale: One of the most serious adverse effects of cholestyramine is obstruction of the GI tract. Options 1, 3, and 4 are incorrect. Cholestyramine does not cause orange urine, sore throat, or fever, nor does it affect capillary refill. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 1 Rationale: Although there are few contraindications to the use of bile acid sequestrants such as colestipol, they should be used cautiously in patients with GI disorders such as peptic ulcer disease. Options 2, 3, and 4 are incorrect. MI is not a contraindication for the use of bile acid sequestrants. Bile acid sequestrants do not affect serum sodium levels, and patients allergic to foods high in tyramine may be prescribed bile acid sequestrants. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2, 3 Rationale: Intense flushing and hot flashes occur in almost every patient who is taking niacin. Tingling of the extremities may also occur. Options 1, 4, and 5 are incorrect. Neither fever and chills nor dry mucous membranes are associated adverse effects of niacin therapy. Niacin may cause an *increase* in fasting blood glucose, especially in people with diabetes. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 4 Rationale: Grapefruit juice inhibits the metabolism of statins such as lovastatin, allowing them to reach high serum levels. Options 1, 2, and 3 are incorrect. Most patients with lipid disorders are asymptomatic. A patient should be instructed that maintenance of optimal body weight will help reduce unhealthy lipid levels. Because cholesterol biosynthesis in the liver is higher at night, statins are usually best taken in the evening. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

6 Answer: 1, 4, 5 Rationale: Fibric acid drugs (fibrates) such as gemfibrozil may cause or worsen gallbladder disease and may enhance the hypoglycemic effects of antidiabetes drugs. Because it is excreted through the kidneys, it may be used cautiously in patients with CKD, but the order should be validated with the provider before giving if the patient has a history of CKD. Options 2 and 3 are incorrect. Angina and hypertension may indicate the existence of atherosclerosis and arteriosclerosis, both of which are indications for a lipid-lowering drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 30

1 Answer: 1 Rationale: A major complication associated with the administration of CCBs such as nifedipine is HF. Daily weighing will alert the patient to signs of fluid retention, which may indicate cardiac dysfunction. A weight gain of 1 kg (2 lb) or more in 24 hours indicates possible fluid retention and may signal impending HF. Options 2, 3, and 4 are incorrect. Nifedipine does not affect the immune system, and there is no reason to avoid crowds. The intake of oral or dietary calcium and CCBs has not been shown to be problematic. HTN is asymptomatic, and patients should be instructed to take the medication even when feeling healthy. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 4 Rationale: Felodipine may cause hypotension with associated reflex tachycardia. Options 1, 2, and 3 are incorrect. Rash and chills, increased urine output, and weight loss are not adverse effects of CCBs. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 4 Rationale: An adverse effect of verapamil is HF, which will be reflected in the patient's intake and output ratio and weight gain of more than 1 kg (2 lb) per 24 hours. Options 1, 2, and 3 are incorrect. Verapamil does not affect coagulation or thrombocytes. Verapamil is usually given during hours that the patient is awake; however, it can be administered at any time. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: Grapefruit juice will enhance the absorption of nifedipine. Options 1, 3, and 4 are incorrect. Nifedipine should not be taken with antacids since this will affect the absorption rate of the drug. Patients should never double the dose of nifedipine because life-threatening hypotension could result. Nifedipine does not affect the efficacy of birth control pills. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

5 Answer: 1, 2, 3, 4 Rationale: Diltiazem reduces the patient's blood pressure, which may result in syncope or dizziness. Until the effects of the medication are known, the patient should avoid driving or other activities requiring mental alertness. One of the adverse effects associated with diltiazem and CCBs is constipation, which can be reduced by increasing fluid and dietary fiber intake. Patients should be taught to report a weight gain of 1 kg (2 lb) per day or 2 kg (5 lb) per week. Diltiazem may cause orthostatic hypotension. To ensure safety, patients should be instructed to rise slowly from sitting or lying positions. Option 5 is incorrect. Sudden discontinuation could cause the patient to experience hypertensive crisis. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 3 Rationale: Nifedipine is a negative inotropic drug and symptoms of pulmonary edema call for discontinuation of the drug. The nurse should also monitor more closely for HF and pulmonary edema if the patient has a medical history of pulmonary edema. Options 1, 2, and 4 are incorrect. An appendectomy does not warrant monitoring the patient any more than usual. Patients receiving renal dialysis should be closely monitored during therapy with nifedipine due to a reduction in renal function. However, these patients are not as high risk as a patient with pulmonary edema. Psychotropic drugs are not known to interact negatively with this drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 31

1 Answer: 4 Rationale: Lisinopril does not affect serum calcium levels and, thus, would not cause an elevated blood pressure. Options 1, 2, and 3 are incorrect. Common adverse effects for lisinopril are cough, headache, dizziness, orthostatic hypotension, and rash. These symptoms should be reported to the prescriber. Salt substitutes usually contain potassium chloride and should be avoided to reduce the risk of hyperkalemia. Patients on this medication should be instructed to stay on regular doses of blood pressure medication. If a dose is missed, take it as soon as possible but not too close to the next dose. Never take a double dose. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

2 Answer: 1 Rationale: Lisinopril should be stored in a dry place at room temperature, because heat and moisture may cause drug breakdown. Options 2, 3, and 4 are incorrect. Heat and moisture do not enhance the strength of the drug, crystallize the medication, or convert the medication to toxic metabolites. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

3 Answer: 3 Rationale: ACE inhibitors such as enalapril also prevent the breakdown of bradykinin. Accumulation of bradykinin in certain tissues such as the lungs can cause adverse effects, as manifested by a nonproductive cough, and may require an antihistamine for treatment. Options 1, 2, and 4 are incorrect. Dry mucous membranes are not adverse effects related to ACE inhibitors. The expected outcome associated with ACE inhibitors is a decline in blood pressure, and the nurse should expect both systolic and diastolic pressures to be reduced. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: The most common adverse effects of losartan are headache, dizziness, nasal congestion, fatigue, and insomnia. Options 1, 3, and 4 are incorrect. Irritability, tremors, sleepiness, slurred speech, pruritus, and rash are not common adverse effects associated with losartan. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Patients with severe dehydration may experience hypovolemia and are at high risk of life-threatening hypotension. Options 2, 3, and 4 are incorrect. Irbesartan may be prescribed for the prevention of diabetic nephropathy,

HTN, and as an off-label use for heart failure. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 3 Rationale: Patients receiving benazepril should avoid driving or engaging in other potentially hazardous activities until the effects of the drug are known. Benazepril may cause adverse effects that impair thinking and reaction time. Options 1, 2, and 4 are incorrect. The patient or family should be taught methods of home blood pressure measurement and maintenance of a blood pressure log while taking benazepril. OTC medications for colds, sinus, fever, asthma, or appetite control should be avoided because they may increase blood pressure. The consumption of alcohol while taking benazepril can lower blood pressure, which will lead to dizziness and fainting. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

Chapter 32

1 Answer: 2 Rationale: As a diuretic, furosemide may dramatically reduce the patient's circulating blood volume, thus producing episodes of orthostatic hypotension. Patients may minimize this effect by rising slowly from sitting or lying positions. Options 1, 3, and 4 are incorrect. Cabbage, cauliflower, and kale are high in vitamin K, but furosemide does not require restricted consumption of these foods. Monitoring pulse rate during administration of furosemide for reflex tachycardia secondary to hypotension is advised, but it is not required that it be taken before the dose or for 1 full minute. Due to the potential for significant diuresis, fluids should not be restricted unless ordered by the healthcare provider. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 2 Rationale: Loop diuretics such as bumetanide cause a significant loss of potassium. Hypokalemia is often the most predominant electrolyte imbalance. Options 1, 3, and 4 are incorrect. Hypernatremia is unlikely with the administration of bumetanide because it promotes sodium loss. Hyperkalemia is inconsistent with the administration of bumetanide due to the increase in potassium excretion. If elevated potassium levels are present in these patients, other etiologies should be investigated. Bumetanide does not cause hypocalcemia but may cause hypercalciuria with an increased risk of calcium-based kidney stones. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 3 Rationale: Muscle cramps and weakness may indicate hypokalemia and should be reported to the healthcare provider. Options 1, 2, and 4 are incorrect. Many patients taking diuretic therapy are instructed to monitor the intake of both sodium and water to maintain adequate but not excessive amounts. Patients should ingest foods high in potassium, not vitamin K. Thiazide diuretics and antihypertensive drugs are not known to cause sleepiness when taken together. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1 Rationale: Spironolactone is a potassium-sparing diuretic and may cause hyperkalemia. Options 2, 3, and 4 are incorrect. This drug does not have a direct effect on magnesium and does not cause hypokalemia. It does not have calcium-binding effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 4 Rationale: In the early stages of the administration of mannitol, fluid is drawn into extracellular spaces and vascular compartments. Pulmonary and peripheral edema may occur, and increased intracranial pressure may also occur along with an early change in level of consciousness. Options 1, 2, and 3 are incorrect. Keeping a urinal or bedpan nearby; monitoring electrolytes, including potassium; and recording I&O and daily weight are important nursing interventions but are not the main nursing priority in the early administration of mannitol. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1 Rationale: Patients receiving acetazolamide are at risk for metabolic acidosis due to excess bicarbonate loss. Options 2, 3, and 4 are incorrect. Metabolic alkalosis is characterized by a deficit of bicarbonate and is not an adverse effect of acetazolamide (Diamox). Acetazolamide does not cause respiratory acidosis. Respiratory alkalosis is also not an expected adverse effect of acetazolamide. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 33

1 Answer: 1 Rationale: The serum pH is a measure of alkalinity or acidity in the blood. The administration of bicarbonate neutralizes acidic conditions and causes the patient's serum to become more alkaline. Options 2, 3, and 4 are incorrect. Changes in the pH can affect the ability of RBCs to release oxygen, but administration of sodium bicarbonate will not influence the number of circulating RBCs. The liver does not metabolize sodium bicarbonate; it is naturally occurring in the body and does not metabolize. Liver function tests are not indicators of the drug's effectiveness. Although sodium bicarbonate excretion occurs in the kidneys, the blood urea nitrogen level will not reflect the effectiveness of this drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2 Rationale: Liquid preparations are very irritating to the gastric mucosa and should always be diluted with juice or water. Options 1, 3, and 4 are incorrect. Salt substitutes are high in potassium and should be avoided by patients on potassium supplementation. Symptoms such as weakness or fatigue may be the first indicators of potassium imbalances. The GI secretions are rich in potassium. Episodes of persistent vomiting may lead to hypokalemia and should be reported to the healthcare provider. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 4 Rationale: Dextran 40 interferes with coagulation and reduces blood viscosity. Bleeding, potentially severe, is associated with these effects. Options 1, 2, and 3 are incorrect. Dextran solutions are used to correct low circulating blood volume states. This solution does not cause dehydration. Dextran increases the circulating volume and thereby increases urine output, which is a therapeutic effect of the solution. Dextran is used for shock (hypovolemia); it does not cause shock. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 2 Rationale: This solution is often used to dilute (reconstitute) powdered forms of drugs that are intended to be given parenterally. Options 1, 3, and 4 are incorrect. This solution can cause hyperglycemia in the patient with diabetes due to the dextrose content. D_5W is considered a crystalloid solution. One liter of this solution supplies only 170 calories, which is not enough to supply the metabolic nutritional needs of adult patients. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: Magnesium sulfate toxicity may cause significant neuromuscular depression as noted by changes in level of consciousness and diminished deep tendon reflexes. Options 1, 2, and 3 are incorrect. Pupillary constriction to bright light is a normal physiologic response. The nurse should notify the prescriber when the patient develops chest congestion and coughing, but they are not directly associated with magnesium sulfate toxicity. Elevated blood pressure is common in preeclampsia but it is not associated with magnesium toxicity. Cognitive

Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 3, 4 Rationale: Normal serum albumin is a product derived from blood. Although rare, transfusion reactions can still occur with normal serum albumin. Albumin causes intercellular and interstitial fluid to move into the intravascular compartment. This movement of fluid will cause increases in the patient's blood pressure and heart rate. The nurse should monitor the patient for fluid overload with this solution. As the circulating fluid volume is corrected, the patient's urinary output will increase. Options 2 and 5 are incorrect. Patients receiving normal serum albumin typically do not have any dietary restrictions while receiving this solution. Serum albumin is not administered for potassium imbalances. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

Chapter 34

1 Answer: 1 Rationale: Hot baths and showers, prolonged standing in one position, and strenuous exercise may enhance orthostatic hypotension. Options 2, 3, and 4 are incorrect. Methyldopa does not discolor the urine. Bloating and weight gain are not typical adverse effects of methyldopa, and methyldopa can be taken without food. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 4 Rationale: Orthostatic hypotension is a common adverse effect of vasodilators such as hydralazine. Options 1, 2, and 3 are incorrect. Hydralazine does not typically cause atelectasis. Crystalluria is not an adverse effect of hydralazine and it does not cause photosensitivity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 2, 3, 4, 5 Rationale: Adverse effects of ACE inhibitors such as enalapril (Vasotec) include persistent cough and orthostatic hypotension. Hyperkalemia may occur and can be a major concern for those patients with CKD and in patients who are taking potassium-sparing diuretics. Though rare, the most serious adverse effect of ACE inhibitors is the development of angioedema. Option 1 is incorrect. Hypotension with reflex *tachycardia* is a possibility depending on how low or how fast the blood pressure decreases. Cognitive Level: Analyzing. Nursing Process: Evaluation. Client Need: Physiological Integrity

4 Answer: 4 Rationale: The nurse will titrate (adjust) the rate of infusion based on the patient's blood pressure. Options 1, 2, and 3 are incorrect. Listening for bowel sounds in the patient with hypertensive crisis is not a nursing priority. Urine specific gravity and glucose levels may be obtained but are not associated with hypertensive crisis or the administration of this drug. Observing skin pressure points is a nursing intervention that does not directly relate to hypertensive crisis or nitroprusside therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 2, 3, 4 Rationale: New guidelines in the JNC-8 report recommend ACEIs or ARBs, CCBs, and thiazide diuretics as primary treatment options for most patients. Options 1 and 5 are incorrect. Beta blockers may still be used for some patients but are no longer recommended for primary treatment of HTN. Direct-acting vasodilators are used to treat hypertensive crisis and for patients who have not responded adequately to other antihypertensive drugs. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 1, 2, 4 Rationale: Thiocyanate poisoning may develop more quickly in patients with CKD. Renal function and creatinine levels should be evaluated before starting the drug. Signs of thiocyanate poisoning include hypotension, lethargy, unconsciousness, and faint heart sounds. Options 3 and 5 are incorrect. Past alcohol use will not determine whether thiocyanate poisoning develops or influences its symptoms. While flushing of the skin may occur with nitroprusside administration, skin color and turgor are not reliable indicators of thiocyanate poisoning. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 35

1 Answer: 3 Rationale: Patients should be taught to remove the old ointment before applying the next dose. Options 1, 2, and 4 are incorrect. Nitroglycerin should be kept at room temperature, not in the refrigerator. Patients should take the medication before chest pain becomes severe. Nitroglycerin can be applied to any skin surface. However, absorption is decreased when applied to hairy areas, soles of feet, and palms. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 4 Rationale: A decline in blood pressure is an expected adverse effect. The nurse should always assess the blood pressure prior to and 5 minutes after administering nitroglycerin. Options 1, 2, and 3 are incorrect. Photosensitivity, vomiting, and diarrhea are not expected adverse effects. Nitroglycerin will cause a decline in blood pressure, not an increase. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 4 Rationale: Skin irritation due to the nitroglycerin ointment can occur if the same site is used repeatedly. Options 1, 2, and 3 are incorrect. Patients should be instructed to rotate the site of application when using nitroglycerin ointment. Repeated use of the same application site may actually decrease absorption. Rebound phenomenon is not an expected occurrence with nitroglycerin. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 3 Rationale: Patients may experience lightheadedness or dizziness as a result of the hypotensive effects of isosorbide. Options 1, 2, and 4 are incorrect. Because the oral form of isosorbide has a slower onset than sublingual forms, a flushing sensation and headache are not usually experienced as they are with sublingual nitroglycerin. Tremors and anxiety are not associated adverse effects with this drug. Isosorbide does not usually cause sleepiness or lethargy, and if these occur they should be evaluated. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Atenolol increases blood flow to the myocardium, thereby increasing oxygen supply by reducing the heart rate and decreasing the contractility. Options 2, 3, and 4 are incorrect. Atenolol is a beta-adrenergic blocker, which decreases heart rate. This drug does not affect the sodium channels. Although this drug reduces blood pressure, the mechanism of action is not by blocking the alpha$_2$ receptors. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 3 Rationale: Verapamil decreases blood pressure and heart rate. The administration of this drug may cause significant bradycardia and hypotension in some patients. Options 2, 4, and 5 are incorrect. Verapamil may be used to treat fast heart rates and HTN in addition to angina. Tinnitus and hearing loss are not adverse effects associated with verapamil. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 36

1 Answer: 2 Rationale: ACE inhibitors such as enalapril lower peripheral resistance through the inhibition of angiotensin II

formation, and reduce blood volume through inhibition of aldosterone secretion. This reduces arterial blood pressure, decreasing afterload and increasing cardiac output. Options 1, 3, and 4 are incorrect. Enalapril is not a positive inotropic drug and does not strengthen the force of myocardial contraction. It does not slow heart rate (negative chronotropic and dromotropic effects) and it does not have diuretic effects. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2 Rationale: The patient will be taught to take the pulse daily and to contact the prescriber if the pulse rate is less than 60 or greater than 100 beats/min. Options 1, 3, and 4 are incorrect. The medication should be taken at the same time each day, but preferably after the patient has been active for a period of time (midmorning). Typically, the pulse rate will be lower in the morning before the patient rises. Digoxin should be withheld if the pulse rate is below 60 beats/min. A high-fiber diet may decrease the absorption of digoxin, and the drug should not be taken along with meals high in fiber. Furthermore, foods high in calcium may create hypercalcemia, which will potentiate the possibility of digoxin toxicity. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 1 Rationale: Milrinone is a positive inotropic drug and is given to increase the force of the contraction of the heart, which improves cardiac output. Options 2, 3, and 4 are incorrect. Inotropic effects increase the volume of the cardiac output rather than decrease it and do not relax the myocardial muscle. Milrinone may cause cardiac dysrhythmias as an adverse effect. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 4 Rationale: Hydralazine with isosorbide may cause hypotension with reflex tachycardia, resulting in dizziness and rapid heart rate. Options 1, 2, and 3 are incorrect. Hydralazine with isosorbide does not cause confusion, agitation, bleeding, tingling, or cramping of the extremities. If these occur, other causes should be investigated. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Beta-adrenergic blockers such as carvedilol must be started at 1/10 to 1/20 of a usual dose and gradually increased to a target dosage. Options 2, 3, and 4 are incorrect. Because lower dosages are required, a higher loading dose will not be given, and beta-adrenergic blockers are often combined with ACE inhibitors, although dosage will not be directly related to the ACE inhibitor. While caution is required if beta-adrenergic blockers are used to treat HF, they are an important drug group used to treat heart failure. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 2, 4 Rationale: Beta-adrenergic blockers require gradual increases in dosage amount approximately every 2 weeks to a target dosage. Significant improvement may not be noticed in early therapy and the patient may feel worse during initiation of therapy. Overall, however, the therapy has been proven to reduce the number of HF-related hospitalizations and mortalities. Options 3 and 5 are incorrect. Beta-adrenergic blocker therapy may require alterations in dosage for other cardiac drugs but not all drugs will be affected. Lifestyle changes may be advisable in HF but are not necessarily directly related to beta-adrenergic blocker use. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

Chapter 37

1 Answer: 4 Rationale: Procainamide should be avoided in patients with severe HF since this drug can worsen the condition. Options 1, 2, and 3 are incorrect. Ventricular tachycardia, paroxysmal atrial tachycardia, and atrial fibrillation are indications for the use of procainamide. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Early signs of lidocaine toxicity include CNS effects such as paresthesias, drowsiness, confusion, anxiety, or tremors. Options 1, 2, and 4 are incorrect. Decreased platelet levels are not related to the administration of lidocaine. Unless the patient experiences hypotension, there is no need to routinely keep the patient supine. Although coughing and deep breathing are effective nursing strategies to maintain pulmonary function, they are not pertinent for the administration of IV lidocaine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3 Rationale: The therapeutic goal of verapamil is to stabilize the dysrhythmia by slowing the conduction. While the atrial dysrhythmia may continue, the rate should return to a normal range (e.g., 60–100 beats/min in an adult). Options 1, 2, and 4 are incorrect. Verapamil may cause hypotension, but as an adverse rather than a therapeutic effect. It should not cause an increase in potassium levels or a reduction in urine output. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 4 Rationale: Adenosine has an extremely short half-life and must be administered by rapid IV push, over 1 to 2 seconds. Options 1, 2, and 3 are incorrect. Adenosine is not given by IV infusion or slowly. While potassium is an important electrolyte to monitor in patients with dysrhythmias, adenosine does not cause hypo- or hyperkalemia. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 3 Rationale: Beta blockers such as propranolol are negative inotropic drugs and reduce myocardial contractility. In patients with existing HF, this may result in less cardiac output and worsening of symptoms. Options 1, 2, and 4 are incorrect. Propranolol does not cause sodium retention and its adverse effects include hypotension rather than HTN. It may cause bronchoconstriction because it is a nonselective beta-adrenergic antagonist (blocker), but this effect does not worsen HF. It warrants caution or is contraindicated in patients with COPD and other respiratory conditions. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 3 Rationale: An adverse effect associated with amiodarone is photosensitivity. The patient should be instructed to avoid direct sunlight, wear protective clothing, and use adequate sunscreen lotions of SPF 15 or higher. Options 1, 2, and 4 are incorrect. Amiodarone is not known to cause immunosuppression or to interact with oral contraceptives. Increased bleeding tendencies are not an adverse effect of amiodarone. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 38

1 Answer: 1 Rationale: An activated partial thromboplastin time (aPTT) is the appropriate laboratory value to monitor with heparin infusions. When the patient is receiving this drug, the results should be 1.5 to 2 times that patient's baseline, or 60 to 80 seconds. Options 2, 3, and 4 are incorrect. A PT or INR is used to monitor the effectiveness of warfarin. Platelets are not affected by anticoagulants and are therefore not used in the monitoring of these drugs. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1, 2, 3 Rationale: The patient should be taught proper injection technique, including the need to inject the heparin into the deep subcutaneous fat layer. A soft toothbrush should be used for oral hygiene. Puncture wounds or cuts will require longer than normal pressure held at the site to stop

bleeding—15 minutes or longer. Options 4 and 5 are incorrect. Dental flossing should be avoided while the patient is receiving anticoagulants. The flossing can cause gum irritation and excessive bleeding. Aspirin has antiplatelet effects and concurrent use may increase the risk of bleeding or hemorrhage. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

3 Answer: 3 Rationale: Many drugs such as aspirin and ibuprofen have strong anticoagulant effects. When the patient on warfarin takes these drugs, the increased risk of bleeding can be hazardous. Options 1, 2, and 4 are incorrect. Drugs such as aspirin and ibuprofen do not neutralize the effect of an anticoagulant. Anticoagulants do not influence the half-life of any drugs. The pain associated with arthritis is not worsened by the combination of these drugs. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: Because of the risk of hemorrhage, dysrhythmias, and hypotension, the patient should remain supine during and for up to 8 hours post–drug infusion. Options 1, 3, and 4 are incorrect. The patient will remain in the hospital for a minimum of 24 hours or longer post-procedure for monitoring per agency protocol. The risk of bleeding remains elevated for 2 to 4 days postinfusion. Oral anticoagulants such as warfarin or antiplatelet drugs will be ordered after the infusion; increasing vitamin K in the diet or by supplement may increase the risk of clotting. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1 Rationale: Clopidogrel is an antiplatelet drug used to prevent blood clots from forming inside arteries by inhibiting platelet aggregation. Options 2, 3, and 4 are incorrect. Heparin is an anticoagulant that blocks the formation of blood clots by activating antithrombin III. Warfarin is a vitamin K antagonist used to prevent the blood from clotting. The drug alteplase is a tissue plasminogen activator that dissolves fibrin clots. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 3, 4, 5 Rationale: Ginger, garlic, and green tea may all increase the risk of bleeding. Dabigatran may be used for DVT and is monitored by aPTT, similar to heparin. The drug is contraindicated in patients with gastritis because of the increased risk of bleeding. Option 2 is incorrect. Vitamin B_{12} does not enhance the response of dabigatran. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

Chapter 39

1 Answer: 2 Rationale: The patient who receives epoetin alfa has anemia. This reduction in RBCs produces cellular oxygen deficiency, which causes severe fatigue and weakness. Patients receiving this drug should be taught to take scheduled rest periods to avoid overexertion. Options 1, 3, and 4 are incorrect. Avoiding fresh fruits and vegetables or uncooked meat would be instructions more appropriate for an individual with neutropenia. Limiting exposure to direct sunlight and using sunscreen would be appropriate instructions for a patient who is receiving a drug that causes photosensitivity, but epoetin alfa is not associated with this adverse effect. Patients with anemia are not necessarily thrombocytopenic and do not routinely need to avoid activities that may cause injury. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

2 Answer: 2 Rationale: Darbepoetin should not be given to patients with uncontrolled HTN because hematopoietic growth factors can increase blood pressure. Options 1, 3, and 4 are incorrect. Patients with HIV may receive hematopoietic growth factors such as epoetin alfa to correct anemia caused by their HIV drug therapy. Patients with chronic kidney disease often also have anemia because they are unable to secrete sufficient endogenous erythropoietin. Hematopoietic growth factors are often prescribed for these patients. Chemotherapy also causes anemia and patients may require hematopoietic growth factors if the anemia is severe. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3 Rationale: Neupogen increases WBC counts. The nurse would monitor for effectiveness by examining this laboratory value. Options 1, 2, and 4 are incorrect. Epoetin alfa is the drug that increases RBC count. Oprelvekin may be given to increase platelet levels. Reticulocytes are immature RBCs and MCV is a measure of the volume of RBCs. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 4 Rationale: Oprelvekin does not affect iron levels and there would be no reason to instruct the patient to increase dietary intake of it. Options 1, 2, and 3 are incorrect. Oprelvekin is used to stimulate the production of platelets in patients who are at risk for severe thrombocytopenia. Oprelvekin may cause severe fluid retention that may lead to pulmonary edema, pericardial effusion, and ascites. Patients should monitor weight gain and report significant increases to the healthcare provider. Visual impairment, including blurred vision, papilledema, and optic neuropathy, may occur with oprelvekin, and vision changes should be reported. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Patients who regularly consume large amounts of alcohol often have a nutritional deficit of vitamin B_{12}, which can manifest as abnormal neurologic symptoms. Options 2, 3, and 4 are incorrect. Alcohol interferes with folate metabolism in the liver, but lack of folate does not cause destruction of vitamin B_{12}. Pernicious anemia is caused by a lack of intrinsic factor, a substance needed to absorb vitamin B_{12} from the GI tract, which may lead to the anemia, not neutropenia. Vitamin B_{12} is a water-soluble vitamin and is not stored in the body. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 2, 3 Rationale: Ferrous preparations bind to many substances including food and other drugs. To ensure complete absorption of the drug, iron supplements should be taken 1 hour before or 2 hours after eating. Liquid iron preparations are often given to children. Such preparations should be given with a straw to prevent contact with the teeth, which can produce staining. After swallowing, the patient should be instructed to brush the teeth or thoroughly rinse the mouth to prevent staining. The patient should be informed that iron preparations can cause dark tarry-like or green-tinged stools and may cause constipation. When patients take iron preparations, increased fiber and water intake are measures to take to decrease constipation. Options 4 and 5 are incorrect. Vitamin C increases the absorption of iron preparations, not vitamin E. Caffeinated beverages inhibit the absorption of this drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

Chapter 41

1 Answer: 2 Rationale: Acetaminophen overdose is treated with PO or IV acetylcysteine. For maximum effectiveness, the antidote should be administered within 8 hours of acetaminophen ingestion. Options 1, 3, and 4 are incorrect. The administration of 1000 mL/h of normal saline IV would place the patient at risk for fluid volume overload. The patient will not require cardioversion to treat acetaminophen poisoning. The patient's hepatic enzymes will be assessed; however, these enzymes only provide information as to the extent of liver damage. They do not treat acute acetaminophen overdose; they merely monitor for the effectiveness of

the treatment and any effects of the overdose itself. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 3 Rationale: Acetaminophen is the preferred drug for reduction of fever in the event the patient has a hypersensitivity to aspirin. Options 1, 2, and 4 are incorrect. A patient who has hypersensitivity to aspirin should not be administered ibuprofen or celecoxib due to the risk of hypersensitivity with the NSAIDs. Ketorolac is not administered for reduction of fever; it is administered for pain control. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 1 Rationale: Ketorolac is administered parenterally for pain. Options 2, 3, and 4 are incorrect. Ketoprofen, ibuprofen, and celecoxib are all administered PO. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 4 Rationale: Ibuprofen should be discontinued 7 to 14 days before surgery to reduce the risk of bleeding. Options 1, 2, and 3 are incorrect. Ibuprofen should not be continued until surgery and the patient should continue her anti-inflammatory medication until 7 to 14 days before surgery to maintain its antiarthritis effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1 Rationale: Acetaminophen is metabolized in the liver. The patient with cirrhosis of the liver has impaired liver function and should not receive acetaminophen for pain or fever reduction. Options 2, 3, and 4 are incorrect. A patient who has COPD, breast cancer, or who is taking warfarin can be administered acetaminophen for fever and analgesia. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 2, 3, 4 Rationale: A patient who is experiencing toxic effects from aspirin may experience tinnitus, hyperventilation, GI bleeding, or decreased urine output related to renal impairment. Option 5 is incorrect. A patient with salicylate toxicity does not tend to experience peripheral neuropathy. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 42

1 Answer: 1 Rationale: Interferon alpha-2b causes flulike symptoms in up to 50% of patients receiving the drug. Options 2, 3, and 4 are incorrect. While depression with suicidal thoughts has been reported, it is not a common effect. Edema, hypotension, tachycardia, fluid volume overload, hypertension, and renal insufficiency are not adverse effects commonly associated with this drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 2 Rationale: The patient's high fever (39.4°C [103°F]) and chills are indicative of an infectious process. The use of two immunosuppressant drugs (i.e., basiliximab and cyclosporine) increases the risk of infection related to the additional immunosuppressant effects. Options 1, 3, and 4 are incorrect. Basiliximab (Simulect) has fewer significant adverse effects than other MABs; however, GI effects (nausea, vomiting, abdominal pain) are common and anaphylaxis has been reported. Capillary leak syndrome is a condition in which fluid and protein leak out of tiny blood vessels and flow into surrounding tissue. This complication is not associated with basiliximab administration. Graft-versus-host disease is a type of transplant rejection, and androgen insensitivity is a genetically linked syndrome. Both are unrelated to the drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 2 Rationale: Cyclosporine is toxic to bone marrow although less so than other immunosuppressants. A decrease in WBCs to below 4000/mm^3 should be reported to the provider. Options 1, 3, and 4 are incorrect. Cyclosporine does not cause an elevation in RBCs. The provider should be notified if platelet counts drop below 75,000/mm^3, but a count of 100,000/mm^3 is within acceptable limits. A creatinine level of less than 1 mg/100 mL is within normal limits. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

4 Answer: 3 Rationale: Azathioprine should be used with extreme caution in patients with a previous history of varicella zoster (chickenpox, shingles) because the immunosuppression may cause the virus to reactivate and cause a serious infection. Options 1, 2, and 4 are incorrect. Benign prostatic hyperplasia and cataracts are not contraindications for the drug. Azathioprine may be used as a treatment for severe RA. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 4 Rationale: Tacrolimus is a potent immunosuppressant and patients should decrease their risk for infection by taking precautions such as avoiding raw fruits and vegetables that may harbor pathogens on the skin or inside, and by eating only fully cooked meats after the heat of cooking has destroyed pathogens. Options 1, 2, and 3 are incorrect. Aspirin may increase GI irritation, placing the patient at risk for GI infections gaining entry through the inflamed mucosa. Physical activity is important to overall health, but this drug has no direct connection with weight gain. Tacrolimus is not known to have significant cardiac effects, although HTN is a possible adverse effect and the blood pressure should be monitored. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

6 Answer: 3 Rationale: Aldesleukin causes capillary leak syndrome, which causes fluid to exit the capillary beds and vasculature, decreasing the circulating blood volume. As many as 70% of patients will develop hypotension. With the drop in blood pressure, organs may not perfuse adequately, and urine output will assess the adequacy of renal blood flow. Options 1, 2, and 4 are incorrect. Altered skin condition, rashes, increased pancreatic enzymes such as amylase and lipase, and alterations in vision and hearing are not symptoms of capillary leak syndrome. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

Chapter 43

1 Answer: 2 Rationale: A parent's preconceived ideas or reservations about accepting vaccinations will be most influential on whether the infant receives the scheduled injections. This also presents an excellent teaching opportunity for the nurse to answer questions, allay any fears the mother may have, and teach postvaccination care. Options 1, 3, and 4 are incorrect. An allergy history will be taken, but unless the infant has demonstrated an allergy to the components in the vaccine, allergies to other medications will not necessarily increase the risk of reaction, nor will the parents' allergies increase the risk. Nurses working with pediatric patients should be knowledgeable about the recommended schedule and, when in doubt, verify the necessary immunizations needed. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 3 Rationale: The MMR vaccination is an attenuated (live) virus and there is a slight risk that the virus could be transmitted to the child's father because he is immunocompromised from the chemotherapy. The nurse would check with the provider about delaying the vaccine until the father is finished with the chemotherapy. Options 1, 2, and 4 are incorrect. The nurse would teach the mother the signs of reaction and when to report them, and the family can safely go out of town if healthcare is available at their destination. Although additional teaching may be required to allay the mother's fears of reaction, the mother's reaction to

MMR will not necessarily result in a reaction in the child. As long as the brother's immune system is healthy, he should not have any adverse effects from his sister's MMR vaccination because of his cold. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3, 4 Rationale: This child would need to receive rabies immunoglobulin to provide passive immunity to the potential exposure. A series of five rabies vaccines will be started over a 28-day period unless it is confirmed that the dog did not have rabies. If the dog is shown not to have rabies, the series can be stopped. Options 1, 2, and 5 are incorrect. Tetanus and DTaP would not be required as long as the child was current on her vaccination schedule. Rabies is a viral disease and the use of rabies toxoid would be ineffective. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 4 Rationale: Acetaminophen (Tylenol) or ibuprofen (Advil) is an appropriate analgesic to treat the soreness that occurs post–tetanus toxoid vaccination. Options 1, 2, and 3 are incorrect. There is no requirement to keep the arm still; in fact, motion may help disperse the medication and help it to absorb. There is no need to restrict fluids or to avoid crowds with a toxoid vaccination. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

5 Answer: 3 Rationale: Known hypersensitivity to yeast is an absolute contraindication for hepatitis B vaccine. Options 1, 2, and 4 are incorrect. Smoking and HTN are not contraindications for the vaccine and present an opportunity for health teaching. Hepatitis B is available only by injection and the nurse would explore methods to help the patient be less fearful of the injection prior to administration. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 1 Rationale: Hypersensitivity reactions are likely to occur within the first 20 minutes of administration. The nurse should closely monitor the patient's vital signs during the initial period. Options 2, 3, and 4 are incorrect. RhoGAM does not cause thrombocytopenia or anemia or increase liver enzymes. There is no need for a low-saturated-fat, low-cholesterol diet after receiving Rho immune globulin, and RhoGAM does not cause a cough. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 44

1 Answer: 1 Rationale: A quick-acting inhaled beta agonist such as albuterol is used to abort bronchospasm. Options 2, 3, and 4 are incorrect. Beclomethasone, ipratropium, and montelukast are drugs used to prevent and control bronchospastic attacks and will not cause bronchodilation quickly enough to abort an attack. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Corticosteroids can decrease the beneficial oral flora that will allow for an overgrowth of fungal infections such as *Candida*. Rinsing the mouth removes any corticosteroid drug deposited there and prevents it from being swallowed, decreasing the likelihood of systemic absorption. Options 1, 2, and 4 are incorrect. Inhaled corticosteroids such as beclomethasone do not cause tachycardia, nervousness, or tremors, and caffeine does not need to be avoided while the drug is being used. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 1 Rationale: Bronchodilators such as albuterol may have an adverse effect on heart rate elevation and palpitations related to dosage. Options 2, 3, and 4 are incorrect. Bronchodilators do not decrease the immune response or increase alertness. While some bronchodilators have been known to cause unexpected problems and paradoxical bronchospasm, this is uncommon. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1, 2 Rationale: Because corticosteroids such as beclomethasone decrease the immune response, the risk for infections is increased. Corticosteroids also increase blood glucose, thus increasing the possibility of hyperglycemia. Options 3, 4, and 5 are incorrect. Corticosteroids do not cause urinary retention, do not increase the likelihood of tachycardia, and do not cause photophobia. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 1 Rationale: Beta agonists may be given to children younger than age 5 to manage asthma. They are available in formulations suitable for nebulizer treatments. Options 2, 3, and 4 are incorrect. Beta antagonists, corticosteroids, and leukotriene modifiers will not cause the rapid bronchodilation required in an acute asthma attack. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 3 Rationale: Some patients have difficulty mastering the coordination between inhalation and activation of the medication. In these instances, a spacer will hold the medication cloud so that this is not a concern. The spacer has additional advantages because it results in more effective delivery of the drug to the site of action and less drug deposition in the mouth and oropharynx. Options 1, 2, and 4 are incorrect. Additional practice may help in the long term, but it is not the priority for an immediate solution to the problem and may only serve to frustrate the patient further. The healthcare provider would not need to be contacted because the patient has difficulty learning, provided that a solution is readily available. Substitution of an oral form of the drug is not within the nursing scope of practice. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

Chapter 45

1 Answer: 2, 4 Rationale: Before using intranasal preparations, the nose should be cleared by blowing to ensure the drug reaches the mucosa. Oxymetazoline should not be used for more than 3 to 5 days to prevent rebound congestion. Options 1, 3, and 5 are incorrect. The medication is inhaled so a full glass of water after the drug is not needed, although any liquid that drips into the oral pharynx should be spit out. As a sympathomimetic, drowsiness is not an expected side effect of this drug. Inhaled sympathomimetic drugs such as oxymetazoline work quickly, but inhaled corticosteroids may take up 3 weeks to become fully effective. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 4 Rationale: Pseudoephedrine is a sympathomimetic and is used only for nasal decongestion. Options 1, 2, and 3 are incorrect. Both dextromethorphan and diphenhydramine are effective for some coughs associated with allergic rhinitis and the common cold. Mucolytics are found in some OTC cough preparations used in colds but are best used to treat chronic productive coughs. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: Because diphenhydramine may cause dizziness and drowsiness, an increased risk of falls is possible, particularly in the older adult. Cognitive Level: Applying; Client Need: Safe and Effective Care Environment; Nursing Process: Implementation

4 Answer: 4 Rationale: Second-generation (nonsedating) antihistamines such as fexofenadine have been associated with dysrhythmias in the sensitive individual. Options 1, 2, and 3 are incorrect. A history of osteoporosis, peptic ulcer disease, or psoriasis is not a contraindication for the drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 3 Rationale: The phenylephrine should be used first to decrease intranasal swelling. After waiting 5 minutes to allow the phenylephrine to work, the fluticasone will reach deeper into the nasal passages for better effects. Options 1, 2, and 4 are incorrect. Fluticasone is used to prevent nasal congestion due to allergic rhinitis and should be used consistently. Instilling fluticasone first may not reach deeper nasal passages if congestion is present. Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: 4 Rationale: The syrup base of an antitussive cough syrup such as dextromethorphan will help to soothe throat irritation, and the patient should avoid drinking fluids immediately following drug administration. Increasing overall fluid intake throughout the day will help moisten irritated mucous membranes as well as loosen secretions for better effects from the expectorant, guaifenesin. Options 1, 2, and 3 are incorrect. The patient does not have to remain supine after administration, and taking the drug with food will not enhance the effects. Avoiding fluid intake will not prevent cough and may cause additional respiratory tract dryness. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 47

1 Answer: 3 Rationale: Ampicillin may decrease the effectiveness of oral contraceptives, and the patient should be instructed to use a barrier method to avoid unwanted pregnancies while on the antibiotic and until the next cycle of oral contraceptives is started. Options 1, 2, and 4 are incorrect. The combination of ampicillin and oral contraceptives will not increase the risk of adverse effects related to the antibiotic. Oral contraceptive effectiveness may be reduced during ampicillin therapy, and ampicillin will not create serious toxicity related to the use of oral contraceptives. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 3 Rationale: Ototoxicity is associated with serum concentrations of vancomycin above 60 to 80 mcg/mL and manifests with tinnitus, dizziness, or balance and coordination effects. Options 1, 2, and 4 are incorrect. Redness of the ears, itching of the ears, and ocular pain are not symptoms related to ototoxicity caused by vancomycin. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 2 Rationale: A vaginal yeast infection with discharge may be a symptom of a superinfection. Superinfection is a possible adverse effect associated with all antibiotics and particularly with fungal and viral infections. Options 1, 3, and 4 are incorrect. A hypersensitivity reaction is not usually manifested by vaginal discharge. The symptoms associated with PMC are significant GI effects. Vaginal discharge is not a symptom of antibiotic toxicity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 4 Rationale: Watery diarrhea containing mucus, blood, or pus is symptomatic of CDAD and must be monitored closely for progressing to PMC; both are adverse effects related to antibiotic use. Options 1, 2, and 3 are incorrect. These symptoms are not related to peptic ulcers, malabsorption, or hypersensitivity reactions. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Shortness of breath, mouth and tongue swelling, and generalized itching are signs of hypersensitivity reaction. Options 2, 3, and 4 are incorrect. Blood dyscrasias include such problems as thrombocytopenia and neutropenia, and the drug does not cause these symptoms. Beta lactamase is a substance secreted by some bacteria that renders the antibiotic ineffective. Drug toxicity may result from an excessive level of the medication or adverse effects on body organ systems related to age or other changes. Hypersensitivity, however, is associated with antigen and antibody reactions. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 1 Rationale: Ampicillin should be taken on an empty stomach to ensure adequate absorption. Options 2, 3, and 4 are incorrect. A black and furry tongue is the symptom of an oral superinfection and should be reported. The patient should be taught to take the full prescription even if the symptoms subside. Patients should never take two doses because this will place them at risk for toxicity. Cognitive Level: Analyzing; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

Chapter 48

1 Answer: 4 Rationale: Tetracycline potentially causes photosensitivity. Options 1, 2, and 3 are incorrect. Calcium products should not be taken at the same time as tetracycline but taken 1 hour before or 2 hours after the dose. Brushing will not remove teeth staining caused by the drug. The staining of teeth due to medication can be removed only by a dental specialist. Ototoxicity is not associated with tetracycline use, and any tinnitus or dizziness may be related to other causes. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 1 Rationale: Longer duration of action is one of the benefits of azithromycin therapy. Options 2, 3, and 4 are incorrect. There is no evidence that azithromycin causes any more nausea than other antibiotics. Azithromycin is not affected by gastric contents and can be taken any time. Azithromycin is not affected by calcium-based foods. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 1 Rationale: Weight gain may be an early sign associated with renal damage secondary to amikacin toxicity. Options 2, 3, and 4 are incorrect. Adverse effects of amikacin are not manifested by visual disturbances, mental depression, or urinary frequency. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 1 Rationale: Drug-induced nephrotoxicity would cause an elevated serum creatinine level and should be reported to the healthcare provider. Options 2, 3, and 4 are incorrect. BUN level is more commonly associated with hepatic toxicity but would be elevated and not decreased if nephrotoxicity is present. Nephrotoxicity is not typically indicated via the WBC levels or changes in serum iron levels. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: Rationale: Tetracycline antibiotics should not be taken concurrently with dairy products, iron-containing preparations (e.g., multivitamins), or antacids. If these products are to be consumed, they should be taken 1 hour before or 2 hours after the tetracycline. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: 1, 2, 4, 5 Rationale: Aminoglycosides are renal, oto-, and neurotoxic. They may also cause neuromuscular blockade. Increases in serum creatinine may indicate nephrotoxicity. Urine output should also be monitored. Dizziness, vertigo, or tinnitus may be signs of ototoxicity. Muscle weakness may indicate neuromuscular blockade and may last for several days. Option 3 is incorrect. Gentamicin is not metabolized, and changes in liver function tests would not be drug related. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

Chapter 49

1 Answer: 2 Rationale: Because pathogens grow rapidly and are constantly proliferating, all antibiotic therapies should be

taken around the clock. Taking the drug as evenly spaced apart during the day as possible will help ensure a steady serum drug level to fight the bacteria. Options 1, 3, and 4 are incorrect. Ciprofloxacin is not known to cause problems with patients' sleep patterns. Superinfections occur when an antibiotic eradicates normal flora and an opportunistic organism invades. This is a problem associated with antibiotic therapy in general and is not caused by not adhering to the prescribed schedule. Allergic reactions are very common with antibiotic therapy, but they do not result from failing to adhere to the medication schedule. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3, 4, 5 Rationale: Itching, even without the presence of a rash, may indicate histamine release from a drug allergy. Swelling of the face, lips, or tongue, known as angioedema, is also a symptom of allergy. Nervousness or anxiety may indicate an adrenergic response secondary to an allergic reaction and, while they may have other causes, should be investigated further to rule out a developing allergic reaction. Options 1 and 2 are incorrect. Common adverse effects of ofloxacin are headache, nausea, and vomiting. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 1, 2 Rationale: Ciprofloxacin is excreted renally and increasing fluid intake will help to prevent drug accumulation in the kidneys. Dairy products and antacids taken concurrently may inhibit absorption of the ciprofloxacin. Options 3, 4, and 5 are incorrect. Vitamin C does not need to be avoided while on ciprofloxacin; however, products containing iron or zinc should be avoided. An antihistamine does not need to be taken concurrently and may mask the symptoms of adverse effects such as allergy. Excessive caffeine intake may increase the chance of nervousness or anxiety and should be avoided. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1 Rationale: Fluoroquinolones such as levofloxacin have been associated with tendonitis and tendon rupture, especially in patients over age 65. Any unusual joint or tendon pain or difficulty moving or walking should be reported to the provider. Options 2, 3, and 4 are incorrect. Many multivitamins may contain iron and zinc, and concurrent administration with levofloxacin will impair the antibiotic's absorption. Fluoroquinolones do not impair vitamin D absorption and may cause dermatologic toxicities such as photosensitivity and photoallergy. Sunscreen and protective clothing should be used if sun exposure is anticipated. Fluoroquinolones may be nephrotoxic and *increased* fluid intake is advised. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: Fluoroquinolones such as ciprofloxacin may cause profound muscle weakness in patients with myasthenia gravis. Options 1, 2, and 3 are incorrect. Anxiety and nervousness do not require cautious use and are not contraindications to ciprofloxacin. While the incidence of tendonitis and tendon rupture is higher in the adult over age 65, the drug is not contraindicated in this population. However, more frequent monitoring may be needed. Cross-allergy to penicillins is not known for the fluoroquinolones and a history of penicillin allergy is not a contraindication to ciprofloxacin. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 1 Rationale: Polymyxin B is a topical antibiotic used to promote wound healing. Options 2, 3, and 4 are incorrect. Skin and mucous membranes cannot be made sterile. Polymyxin B will cause cell death of the invading pathogenic bacteria but will not completely sterilize the skin. Polymyxin B does not prevent allergic reaction, nor does it provide pain relief to wounds. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

Chapter 50

1 Answer: 3 Rationale: Crystalluria is the excretion of crystals in the urine. To prevent this adverse effect, patients are instructed to consume approximately 2 to 3 L of fluid per day. This action will flush the crystals from the renal system. Options 1, 2, and 4 are incorrect. Limiting foods high in calcium will not prevent crystalluria. Positional changes are not related to the adverse effects of crystalluria. Alcohol should be avoided when taking most medications. However, the effects attributed to alcohol consumption do not include crystalluria. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 1 Rationale: Nitrofurantoin is prescribed most commonly for the prophylaxis of recurrent UTIs. Options 2, 3, and 4 are incorrect. Furadantin has no analgesic effect. The excretion of urine is not affected by this drug, and the drug is not used for pyelonephritis. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

3 Answer: 2, 4, 5 Rationale: Trimethoprim-sulfamethoxazole (TMP-SMZ) is a sulfonamide and would be contraindicated in a patient with a previous history of allergy. The drug is pregnancy category C (D in the third trimester), and the use of the drug may result in kernicterus in the newborn. For people with diabetes who are taking oral sulfonylureas, an increased risk of hypoglycemia is possible when TMP-SMZ is used; hence, blood sugars must be monitored closely. Options 1 and 3 are incorrect. The occurrence of migraine headaches is not affected by TMP-SMZ. Urinating before or after sexual intercourse will not affect the use of TMP-SMZ. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

4 Answer: 3 Rationale: Nausea and vomiting are the most common adverse effects of oral sulfonamide therapy but should not occur with topical use. If they occur, the patient should be evaluated for possible systemic effects and for the proper self-administration of the topical drug. This statement indicates that the patient has understood the teaching and when to report potential adverse effects. Options 1, 2, and 4 are incorrect. The drug should be applied topically only to affected areas. Stinging and burning are common effects of the topical application of this drug. Excess potassium consumption should be avoided with the oral forms of sulfonamides but is not necessary with the topical drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Nitrofurantoin is associated with pulmonary toxicities such as interstitial pneumonitis and pulmonary fibrosis. The drug should be used with extreme caution or not at all in the patient with preexisting pulmonary disease. Options 2, 3, and 4 are incorrect. Diabetes, rheumatoid arthritis, or angina and hypertension are not contraindications for the drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 3 Rationale: TMP-SMZ causes dermatologic toxicities including SJS. Unusual, blistering-type rashes with purplish-red discoloration should be immediately reported to the provider. Options 1, 2, and 4 are incorrect. Fungal superinfections may be wet or dry and are reddened, possibly denuded areas. Viral eruptions are most often vesicular rashes. Nonadherence with drug therapy would not result in a rash. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 51

1 Answer: 2 Rationale: For some antituberculosis drugs such as isoniazid (INH), peripheral neuropathy is problematic. This is due to a decrease in the activity of pyridoxine on the nervous

tissue. Supplemental vitamin B_6 is often prescribed to prevent this adverse effect. Options 1, 3, and 4 are incorrect. Isoniazid does not cause an increase in nerve ending sensitivity, nor does it accelerate the excretion of neurotransmitters. Isoniazid does not affect ascorbic acid levels. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2, 3, 4, 5 Rationale: Once the diagnosis of pulmonary TB is verified, sputum specimens are routinely collected to determine the effectiveness of the drug therapy. Ethambutol (Myambutol) may cause hepatotoxicity and decreases renal excretion of uric acid. Hepatic function tests and uric acid levels will be monitored before beginning the drug and routinely thereafter. It may also cause optic neuritis and vision acuity, and color vision sense will be tested before starting the drug and periodically while the drug is used. Option 1 is incorrect. Coagulation studies are not affected by ethambutol. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: To ensure that the patient is not experiencing adverse effects related to the acetylation process, both hepatic function and serum drug level will be monitored frequently. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 4 Rationale: Treatment of MAC infections in patients who are HIV positive is prolonged and relapse rates are as high as 20%. Options 1, 2, and 3 are incorrect. MAC is not considered a contagious infection. Treatment is prolonged and is indicated when CD4 counts drop below 50 cells/mL. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1 Rationale: The nurse should observe for any reddish-brown discoloration of skin, cornea, conjunctiva, and body fluids. This adverse effect occurs in 75% to 90% of patients within a few weeks of treatment. Even after discontinuation of therapy, skin discoloration may take months or years to fade. Options 2, 3, and 4 are incorrect. The drug does not cause constipation, chills, dehydration, hypoglycemia, impaired memory, impotence, memory loss, nervousness, or pruritus. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 3 Rationale: Isoniazid may increase glucose levels and more frequent monitoring is required. Options 1, 2, and 4 are incorrect. Isoniazid does not cause a decrease or rapid rises and falls of glucose levels. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 52

1 Answer: 2, 3, 4 Rationale: When administered too rapidly, amphotericin B may cause hypotension, hypokalemia, and shock. Options 1 and 5 are incorrect. Amphotericin is not known to cause laryngeal spasms or hypoglycemia. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1 Rationale: Patients who take fluconazole (Diflucan) may experience nausea, vomiting, and diarrhea. Nutritional intake is especially important to maintain optimal health in a patient with AIDS. Keeping a food diary will assist the provider in determining overall calorie and fluid intake. Antinausea medication may be helpful if nausea or vomiting is severe. Options 2, 3, and 4 are incorrect. Loss of muscle mass is not related to fluconazole therapy. The decision to wear a high-filtration mask is not related to fluconazole, and patients on this drug do not need to avoid fat-based soaps. Allowing adequate air circulation to body areas will help prevent surface fungal infections but is not required as part of fluconazole therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 1, 2 Rationale: Unless otherwise directed by the provider, small amounts of water after a feeding will rinse the mouth of milk proteins and sugars that can provide an ideal medium for *Candida* to grow. The suspension should be applied to all surfaces of the mouth and tongue, by syringe or applicator, and the infant should swallow the remainder to treat possible GI *Candida*. Options 3, 4, and 5 are incorrect. Nystatin suspension does not require chilling before administration. The suspension should not be added to formula or given before feedings; it should be administered after feedings so that it can be retained in the mouth to treat the area of infection. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 4 Rationale: Nails grow very slowly and lengthy treatment may be required to adequately treat the infection. Options 1, 2, and 3 are incorrect. The infection will be evaluated during the treatment period but it will take many months to adequately treat the infection. Purchasing more pills at one time does not necessarily reduce the cost of the prescription. Toxic doses are never administered, even to shorten treatment cycles. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 3 Rationale: Amphotericin B can cause a number of serious adverse effects including fever, chills, and headache. Pretreatment with corticosteroids, antihistamines, and antipyretics may reduce the severity of these distressing adverse effects. Options 1, 2, and 4 are incorrect. Pretreatment does not enhance the effectiveness of this antifungal drug. The by-products of amphotericin are not affected by the pretreatment of the patient, and pretreatment does not affect the half-life of the drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 3 Rationale: Depending on which oral antidiabetes medication is used (e.g., glyburide), fluconazole (Diflucan) may decrease blood sugar levels, and an adjustment in antidiabetes treatments may be required. Options 1, 2, and 4 are incorrect. Fluconazole (Diflucan) has an effect when given concurrently with some antidiabetes drugs (e.g., glyburide) and may cause hypoglycemia. It does not antagonize the effect of antidiabetes medications and does not cause an increase in blood sugar level. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 53

1 Answer: 1 Rationale: Atovaquone-proguanil (Malarone) therapy begins 1 or 2 days before entering a malaria-endemic area and continues during the stay and for 7 days after return. Options 2, 3, and 4 are incorrect. Three days is not a sufficient amount of time to ensure that the patient has adequate protection against malaria infection. If the patient develops symptoms of malaria, prophylaxis is no longer indicated, but the drug may be continued as part of the treatment regimen. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

2 Answer: 1, 4 Rationale: Hydroxychloroquine has anti-inflammatory effects and is used in the treatment of systemic lupus erythematosus, rheumatoid arthritis, and other inflammatory diseases. Options 2, 3, and 5 are incorrect. Hydroxychloroquine is not used to treat roundworm, leishmaniasis, or urinary tract infections. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 3 Rationale: Many patients report experiencing an unpleasant metallic taste that can be caused by metronidazole. Options 1, 2, and 4 are incorrect. Flatus and intestinal bloating are not characteristic adverse effects of metronidazole. Metronidazole does not cause bad breath (halitosis) and if it occurs, other causes

should be considered. Alopecia (hair loss) is not associated with metronidazole. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 2 Rationale: The use of pyrimethamine is associated with megaloblastic anemia, leukopenia, thrombocytopenia, and pancytopenia as possible adverse effects. Unusual bleeding or fatigue, sores that do not heal, or low-grade fevers may indicate that blood cell counts are low and should be assessed by the healthcare provider. Options 1, 3, and 4 are incorrect. Pyrimethamine is associated with nausea, vomiting, and abdominal cramping as adverse effects, and increasing fiber-rich foods will not affect these. Increasing fluid intake is important with most anti-infective drugs but 3 L per day is not required for this drug. Adverse eye effects are not associated with pyrimethamine and sulfadiazine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: To reduce the risk of reinfection, bed linens and undergarments should be washed thoroughly after treatment is given. Options 1, 2, and 3 are incorrect. Mebendazole is usually given as a single dose but may be repeated for up to 3 days. Family members are also at risk and should be evaluated or treated empirically. Although consuming citrus products may increase the risk of GI adverse effects, citrus and dairy do not need to be eliminated from the diet. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: 1 Rationale: An acute onset of any CNS abnormality may indicate metronidazole toxicity. If ataxia and confusion suddenly develop after the initiation of metronidazole, the nurse should discontinue the medication and contact the healthcare provider. Options 2, 3, and 4 are incorrect. Adverse effects to metronidazole are rare; however, nausea and diarrhea can occur. Anorexia and dryness of the mouth are common adverse effects. However, these adverse effects will usually disappear as the therapy continues. Weight gain and irritability are not typical adverse effects associated with metronidazole. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 54

1 Answer: 1 Rationale: Acyclovir is associated with nephrotoxicity, especially when given IV. The drug should be administered IV slowly, over a minimum of 1 hour, and increased fluid intake encouraged throughout the day to prevent adverse renal effects. Options 2, 3, and 4 are incorrect. Acyclovir is not associated with an increased risk of fungal infections or eye discomfort. Itching and skin irritation may occur with topical use but if it occurs with IV drug administration, drug allergy should be questioned and the administration stopped until evaluated. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 3 Rationale: Zepatier may be used in combination with ribavirin. Options 1, 2, and 4 are incorrect. Zepatier is a fixed-dose PO combination of elbasvir and is not a topical or IV drug. Zepatier is used for a 12- to 16-week course of therapy, not 12 to 16 months. The drug is well tolerated with the most common adverse effects being fatigue, headache, and nausea. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 2, 3, 5 Rationale: Amantadine is associated with nephrotoxicity; possible severe CNS effects including seizures, psychosis, and suicidal ideation; and peripheral edema and heart failure. Options 1 and 4 are incorrect. Amantadine is not known to interfere or affect the white blood cell or platelet count. Potassium and sodium levels are not affected by amantadine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

4 Answer: 4 Rationale: Zanamivir must be started within 48 hours after the onset of symptoms to be effective. Options 1, 2, and 3 are incorrect. Waiting to take the drug longer than 48 hours will not shorten the infection period. It should not be saved because any future infection should be evaluated at that time to ascertain it is the flu and that it will respond to the zanamivir. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 2 Rationale: Tenofovir is known to cause lactic acidosis. Symptoms such as anxiety, fatigue, nausea, vomiting, palpitations, lethargy, rapid breathing and heart rate, weakness, chest pain or tightening, hypotension, or shortness of breath should be immediately reported to the provider. Options 1, 3, and 4 are incorrect. Tenofovir is not associated with systemic yeast infections, heart failure, or ventricular dysrhythmias. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 4 Rationale: Ribavirin is associated with an increased risk of hemolytic anemia. Increased fatigue, dizziness, headache, abdominal pain, pallor, and chest pain are associated with this anemia. Options 1, 2, and 3 are incorrect. Neurologic, respiratory, or dermatologic adverse effects may occur but are not as severe as the hemolytic anemia associated with this drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 55

1 Answer: 2 Rationale: This is a false statement. No vaccine currently exists to provide immunity to HIV infection, although testing is ongoing. Options 1, 3, and 4 are incorrect. The patient should be informed that therapy for HIV will require lifelong treatment because there is no cure. Since treatment is often complex and lifelong, the patient should be taught how to adjust the daily schedule so as to not interfere with ADLs. With recent advances in pharmacotherapy for HIV, many individuals are able to live symptom-free lives. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

2 Answer: 2, 3, 5 Rationale: Hyperglycemia, pancreatitis, and hepatic failure are adverse effects associated with lopinavir with ritonavir. Options 1 and 4 are incorrect. CKD and bone marrow suppression are not adverse effects associated with lopinavir with ritonavir. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 4 Rationale: Lactic acidosis is known to occur with all NRTIs, although the risk with emtricitabine is less than that of some drugs. It is one of the preferred drugs for initial HIV therapy. Options 1, 2, and 3 are incorrect. Ventricular cardiac dysrhythmias, pulmonary fibrosis, and necrotic bowel syndrome are not associated with emtricitabine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 3 Rationale: Nausea, vomiting, diarrhea, abdominal pain, and headache are common with protease inhibitor regimens. Options 1, 2, and 4 are incorrect. Fatigue, generalized weakness, and myalgia are common adverse effects for NRTIs and NtRTIs; headache, diarrhea, nausea, fatigue, and insomnia are common with integrase inhibitors; and respiratory tract infections, cough, pyrexia, rash, and dizziness are common with miscellaneous antiretrovirals. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

5 Answer: 1, 2, 3 Rationale: Patients receiving antiretroviral therapy are immunocompromised and should avoid sources of infection such as crowds and individuals who have infections. The patient should be instructed to notify the healthcare provider

at the first sign of a rash. Several antiretroviral medications may cause SJS, a dermatologic adverse effect that can be fatal. Current research has shown that ART, especially when started early in HIV infection, significantly reduces viral load, reducing the chance of transmission. Transmission, however, is still possible and infection control measures should still be practiced. Options 4 and 5 are incorrect. Total discontinuation of medication is not recommended because viral load increases when drug therapy is discontinued. Some herbal supplements, such as St. John's wort, interfere with antiretroviral therapy. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

6 Answer: 2, 3 Rationale: Drug therapy for women with HIV infection is begun as soon as possible once pregnancy is confirmed to decrease viral load and the potential to transmit the infection to the infant. Drug therapy is also started as soon as possible in infants born to mothers with HIV infection. Options 1, 4, and 5 are incorrect. Waiting to confirm the viral load in an infant born to a mother with HIV infection delays necessary treatment and may allow the viral load to increase. Treatment of the infant whose mother was not taking antiretroviral drugs during pregnancy should be given over 6 weeks. Currently, the CDC does not recommend breastfeeding because the virus is present in breast milk and many antiretroviral drugs also are found in breast milk. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

Chapter 56

1 Answer: 3 Rationale: Stage I suggests that the tumor is relatively small in size, has not invaded the surrounding tissue, and has not been detected in surrounding lymph nodes; thus it has been detected at an early stage. Options 1, 2, and 4 are incorrect. Stage I is the earliest staging and has the best prognosis. Cell differentiation refers to grading of cancer cells, not staging of cancer cells. Stage I suggests that the tumor is small and has not begun to invade surrounding tissue. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 4, 5 Rationale: Patients and family members should avoid receiving live virus vaccination or exposure to chickenpox. Varicella (chickenpox) vaccination is usually given to children between the ages of 12 and 18 months and the patient should not care for her granddaughter if immunization with live virus vaccines is planned. The patient should also avoid crowds, especially in enclosed areas, to minimize the risk of infection. Options 1, 2, and 3 are incorrect. Attending a support group, maintaining normal activities when possible, and eating small, frequent meals with sufficient protein are routine care measures during chemotherapy. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 1 Rationale: The use of multiple drugs affects different stages of the cancer cell's lifecycle and attacks the various clones within the tumor via several mechanisms of action, thus increasing the percentage of cell kill. Combination chemotherapy also allows lower dosages of each individual drug, thus reducing toxicity and slowing the development of resistance. Options 2, 3, and 4 are incorrect. Staging describes the process of determining the extent of cancer in the body and where the cancer is located. Antineoplastic drugs may kill only a small portion of the tumor, leaving some clones unaffected and able to repopulate the tumor with resistant cells. Combination chemotherapy also allows lower dosages of each individual drug, thus reducing toxicity and slowing the development of resistance. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 3 Rationale: Mucositis is the painful inflammation and ulceration of the mucous membranes lining the digestive tract, an adverse effect of chemotherapy and radiation treatment for cancer. Patients experiencing this adverse effect should be instructed to eat a bland diet with low roughage and to use a soft toothbrush or plain water rinses for oral care if the mucositis is severe. Options 1, 2, and 4 are incorrect. Most OTC mouthwashes contain a significant amount of alcohol, which will further inflame the oral tissue and should be avoided. Citrus foods and beverages should be avoided because their acidic nature would cause pain. Mucositis can last for the duration of the chemotherapy treatment and should be treated rather than ignored. This condition will prevent intake of adequate nutrition to build new cells. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1 Rationale: Myelosuppression is the most common dose-limiting adverse effect of chemotherapy and the one that most often causes discontinuation or delays of chemotherapy. Options 2, 3, and 4 are incorrect. Although alopecia may be distressing for the patient, its presence does not determine when the next round of chemotherapy can be administered. Mucositis is not a reason that subsequent rounds of chemotherapy should be delayed. Cachexia is the physical wasting with loss of weight and muscle mass caused by disease. Although it is undesirable, it is not the most common reason for delaying chemotherapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 4 Rationale: Many antineoplastics are classified as vesicant drugs that can cause serious tissue injury if they leak into the surrounding tissue from an artery or vein during an infusion or injection. The nurse should closely monitor the infusion site for swelling and pain. Options 1, 2, and 3 are incorrect. Vesicants do not always cause nausea. It would be inappropriate for the nurse to monitor the patient's intake of calcium-rich foods because this is not related to receiving a chemotherapy drug classified as a vesicant. Respiratory status is not related to the administration of a vesicant-type chemotherapy drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 57

1 Answer: 2 Rationale: The nadir indicates that myelosuppression has occurred and is indicated by decreased blood cell counts. WBC and ANC are sensitive indicators of the nadir. Options 1, 3, and 4 are incorrect. BUN, creatinine, ionized calcium, and serum albumin are not indicators of the nadir and myelosuppression. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1, 3, 4 Rationale: The main dose-limiting toxicity to occur with vincristine is neurotoxicity. Numbness of the hands and feet, constipation related to decreased peristalsis, and diminished reflexes are all signs of neurotoxicity. Options 2 and 5 are incorrect. Cardiac and pulmonary toxicities are not associated with vincristine. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 4 Rationale: Tamoxifen is associated with an increased risk of endometrial cancer and monitoring will be necessary to detect early changes that may indicate that this adverse effect has occurred. Options 1, 2, and 3 are incorrect. Paralytic ileus and pulmonary fibrosis are not associated with tamoxifen. Alopecia is a common adverse effect of many chemotherapy drugs but will not require long-term monitoring. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 3 Rationale: As with many chemotherapy drugs, doxorubicin is associated with mucositis. Daily mouth rinses will be prescribed to decrease the risk of opportunistic infections from yeast and mouth bacteria. Options 1, 2, and 4 are incorrect.

Performing active or assisted ROM is an important intervention associated with drugs that cause neurotoxicities. Controlling pain is associated with chemotherapy that may cause pain as an adverse effect. Maintaining bed rest is not related to the use of chemotherapy but may be required for other reasons. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 1 Rationale: NSAIDs may cause severe and fatal myelosuppression when taken concurrently with methotrexate. Options 2, 3, and 4 are incorrect. Antihistamines, laxatives, and cough suppressants may be used with methotrexate. However, the provider should be consulted if they are needed because symptoms associated with these drugs may indicate a more serious condition that requires additional treatment. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 3 Rationale: Filgrastim increases neutrophil production and decreases the duration of neutropenia with associated infection risk. Options 1, 2, and 4 are incorrect. Filgrastim does not boost the action of carboplatin, prevent the formation of additional cancers, or prevent bone loss. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 59

1 Answer: 2 Rationale: Magnesium compounds, especially in higher doses, often cause diarrhea. Options 1, 3, and 4 are incorrect. Aluminum compounds and calcium compounds may cause constipation. Sodium compounds may cause flatulence. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1, 2, 4, 5 Rationale: Symptoms of GERD include dysphagia, dyspepsia, nausea, belching, heartburn, and chest pain. Option 3 is incorrect. The nurse would not expect a decrease in the patient's appetite due to this medication. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 3 Rationale: The proton pump is activated by food intake. Thus, administering it about 20 to 30 minutes before the first major meal of the day allows peak serum levels to coincide with when the maximum levels of pumps are activated, allowing maximum efficiency of the PPI. Options 1, 2, and 4 are incorrect. The proton pumps are less active at night, in the fasting state, or between meals. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

4 Answer: 2 Rationale: Blood dyscrasias have been reported, especially neutropenia and thrombocytopenia, with long-term use. Periodic blood counts should be performed. Options 1, 3, and 4 are incorrect. Ranitidine does not cause photophobia and skin irritations. Dyspnea and productive cough are not expected adverse effects for this medication. Ranitidine is not known to cause these symptoms. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

5 Answer: 1, 2, 4 Rationale: First-line therapy for *H. pylori* includes a combination of a PPI such as omeprazole; antibiotics such as metronidazole, clarithromycin, or amoxicillin; and bismuth subsalicylate. Options 3 and 5 are incorrect. Sucralfate stimulates mucus, bicarbonate, and prostaglandin secretion, and acts locally to produce a thick protective barrier that coats and binds to the ulcer, protecting it against further erosion from acid and pepsin to promote healing. It is not used as a first-line drug in *H. pylori* infections. Fluconazole is an antifungal drug and is not used to treat a bacterial infection such as *H. pylori.* Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 3 Rationale: Antibiotics have no role in the treatment of GERD although certain antibiotics are used in treating PUD to eradicate the *H. pylori* organism. Options 1, 2, and 4 are incorrect. H_2-receptor antagonists and PPIs are used routinely to relieve symptoms of GERD. OTC antacids provide intermittent relief for mild cases. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 60

1 Answer: 3 Rationale: Diphenoxylate with atropine is given for diarrhea. The patient should report a decrease in the number of loose, watery stools after administration. Options 1, 2, and 4 are incorrect. Although diphenoxylate with atropine may decrease abdominal cramping and gas as a result of slowed peristalsis, it is not the main therapeutic effect desired from this drug. Slowing peristalsis may cause a decrease in bowel sounds rather than an increase. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 2 Rationale: One adverse effect of sulfasalazine is blood dyscrasias, which may include anemia, leukopenia, and thrombocytopenia. Fever, an increase in bruising, and sore throat are all possible symptoms of these decreased cell counts. Options 1, 3, and 4 are incorrect. Stevens–Johnson syndrome results in inflammation of the skin and mucous membranes and includes a sunburn-like appearance, blisters, and possible exfoliation of the dermis. Idiosyncratic reactions are aberrant reactions that cannot be explained by the known pharmacologic action of the drug and occur only in a small percentage of the population. This patient's symptoms are well documented as adverse effects. Hypersensitivity responses are due to stimulation of the immune system and are invoked by an antigen or antibody response. The symptoms presented do not reflect hypersensitivity to the drug. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 4 Rationale: Ondansetron is known to prolong the QT interval and may cause cardiac dysrhythmias. Options 1, 2, and 3 are incorrect. An allergy to soy or soy products, chronic constipation, or glaucoma does not present contraindications to the drugs. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 1 Rationale: The enzymes in pancrelipase come from pork. If the patient is allergic to or has religious restrictions on pork, the drug is contraindicated. Options 2, 3, and 4 are incorrect. Pancrelipase is not contraindicated for individuals with HTN or coronary artery disease. Pancrelipase is not an iodine-based drug. There is no expected cross sensitivity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 4 Rationale: Because magnesium hydroxide will stimulate peristalsis, it is important for the nurse to assess for bowel sounds before giving the drug. If blockage or an ileus is suspected, the drug should be held and the provider notified. Options 1, 2, and 3 are incorrect. Blood pressure is an important vital sign to monitor postoperatively, but the magnesium hydroxide should not have direct effects. The dosage of the opioid drug and the patient's ability to ambulate to the bathroom will not impact the drug's use or action. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 1, 3 Rationale: The nurse should explore possible causes for the diarrhea with the mother before making a recommendation because if diarrhea is caused by infections, slowing motility may allow the infection to increase. Salicylates, including bismuth subsalicylate, are contraindicated in children under the age of 19 because of an increased risk for Reye's syndrome. Options 2, 4, and 5 are incorrect. Activity level and weight are important growth and development parameters to assess but are

unrelated to the drug's use. The school schedule would not have a direct impact on which drug is recommended. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 61

1 Answer: 2 Rationale: Oral contraceptives may increase the levels of vitamin A. Options 1, 3, and 4 are incorrect. Vitamins D and E are also fat-soluble vitamins and may be taken along with vitamin A. Mineral oil may decrease the fat-soluble vitamins, including vitamin A. Antibiotics are not known to have an effect on the levels of vitamin A. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: Vitamin C may cause a false-negative result in occult blood if taken within 48 to 72 hours of testing. Cognitive Level: Remembering; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 4 Rationale: Pyridoxine (vitamin B_6) may reverse or antagonize the effects of antiparkinsonism drugs. Options 1, 2, and 3 are incorrect. INH, oral contraceptives, and hydralazine (Apresoline) may increase the need for pyridoxine. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

4 Answer: 1 Rationale: Zinc is found in protein foods such as beans, lentils, nuts, meats, and dairy. Options 2, 3, and 4 are incorrect. Vegetables such as leafy greens, carrots, and squash; cruciferous vegetables such as broccoli, cauliflower, and Brussels sprouts; and citrus fruits are not high in zinc. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 1, 3 Rationale: Vitamin K is routinely given to newborn infants to prevent bleeding postdelivery. Vitamin K decreases the anticoagulant effects of the drug warfarin. Options 2, 4, and 5 are incorrect. Vitamin K is not indicated for visual disturbances or in the treatment of hypothyroidism or chronic acne. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 3 Rationale: Muscle cramping and spasms may be early signs of hypocalcemia. Options 1, 2, and 4 are incorrect. Night blindness is a sign of possible vitamin A deficiency. Anemia may indicate an iron deficiency. Bleeding abnormalities may signal a deficiency in vitamin K. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 62

1 Answer: 3 Rationale: A patient receiving enteral feedings can be at risk for dehydration caused by an inadequate intake of free water (water without solutes). It is important to irrigate the tube with water as ordered, or per protocol (before and after an intermittent feeding or medication, or every 4 to 6 hours for continuous feedings), and to include additional free water throughout the day unless contraindicated. Options 1, 2, and 4 are incorrect. Daily weights are important to track fluid balance, but they do not maintain fluid balance. The NG tube should be irrigated more than just once a day. While assessment of the skin around a PEG tube site is important, it will not indicate the patient's fluid balance. This patient is receiving the feeding via an NG tube, which is passed through the nose. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 1, 3, 5 Rationale: In addition to the base solution, TPN contains electrolytes (sodium, potassium, chloride), trace minerals, and multivitamins. Options 2 and 4 are incorrect. If diuretics are needed because of an underlying medical condition, they should be administered separately and not added to the TPN solution. Regular insulin may be added to the bag, but not NPH insulin. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 4 Rationale: 10% dextrose in water contains the highest concentration of glucose and should be hung until the new TPN bag is available. The solution selected should minimize the risk of hypoglycemia. Options 1, 2, and 3 are incorrect. They will not be effective in preventing hypoglycemia. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: The patient's temperature should be monitored for signs of infection and subsequent sepsis, which are complications of TPN therapy. The weight is monitored to assess the nutritional effectiveness of the TPN and to detect signs of fluid overload. Options 1, 3, and 4 are incorrect. Blood pressure and pulse are important assessments but do not relate specifically to the effects of TPN. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 4 Rationale: The nurse should not hang the lipids if separation of the emulsion or fat globules is visible in the solution. The solution should be returned to the pharmacy. Options 1, 2, and 3 are incorrect. Rolling or shaking the container or running the container under warm water will not correct the separation and may increase the risk of harm if the solution is used after separation has occurred. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 2 Rationale: Refrigerating unused enteral feeding solutions and limiting the length of time the solution is not refrigerated will prevent the growth of pathogens. Options 3, 4, and 5 are incorrect. Feeding bags and tubes are used for a limited length of time, typically 24 to 72 hours depending on the setting and patient condition. Washing out the bag and tubing will not prevent or reduce the growth of harmful pathogens, and using plain water to irrigate the feeding tube is an accepted technique but will not help prevent infection. Sterile technique is not needed when working with enteral feedings because the solution enters the GI tract. Clean technique is adequate except in severely immunocompromised patients. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 63

1 Answer: 1 Rationale: It is recommended that if a 5% weight loss is not achieved after 12 weeks of therapy with lorcaserin, the drug be discontinued and other options considered. Options 2, 3, and 4 are incorrect. It is not known whether long-term adverse effects arise after the time lorcaserin is taken or whether the risk continues after the drug is discontinued. Monthly visits to a cardiologist may be cost prohibitive and will not necessarily determine conclusively that a cardiovascular risk from the drug is present. Because healthcare is an individual's choice based on personal preference, insurance coverage, and other factors, the drug company would not be the best source for a follow-up program. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 4 Rationale: Phentermine is a pregnancy category X drug and should not be used if the patient is pregnant or there is a possibility of pregnancy. Options 1, 2, and 3 are incorrect. Phentermine is used for short-term treatment of obesity and the presence of extreme obesity may be an indication for the drug. The drug is used cautiously in patients with diabetes and HTN, but neither is an absolute contraindication for the drug. Careful monitoring will be required if either of these conditions exist. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 4 Rationale: Typically, orlistat is taken just prior to meals containing fats so that the drug can inhibit lipase and thus

the absorption of lipids in the meal. Options 1, 2, and 3 are incorrect. Orlistat is taken throughout the day with each meal. It does not decrease appetite; it interferes with the absorption of fat in the diet. Although exercise is a part of the treatment plan for obesity, orlistat does not have to be administered before exercise. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 4 Rationale: Intake of the proper amount and type of vitamins and nutrients is important in a healthy weight loss program. Because orlistat interferes with lipid absorption, the patient should be taught to supplement the diet with a product that contains all the essential fat-soluble vitamins. The supplement should be taken at least 2 hours before or after the orlistat. Options 1, 2, and 3 are incorrect. While increasing fluid intake may assist in a weight loss program, diet soda may contain sodium, citric acid, or other ingredients not necessary to a balanced diet. Orlistat does not cause photosensitivity, and additional sunscreen is not needed. Orlistat does not cause orthostatic hypotension, and no dizziness should be noted when rising from a lying or sitting position. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 1 Rationale: Flatus and oily stools are adverse effects that are often troubling to the patient. The nurse should inform the patient that these often occur when taking orlistat. Options 2, 3, and 4 are incorrect. Heartburn and dyspepsia (indigestion), constipation, and nausea and vomiting are not common adverse effects associated with orlistat. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 1, 2, 3 Rationale: Body weight, body mass index (BMI), and waist circumference are all indicators used to assess levels of obesity. Options 4 and 5 are incorrect. A treadmill test assesses physical fitness, not necessarily obesity. Buoyancy analysis is not a test used to determine the degree of obesity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

Chapter 65

1 Answer: 2 Rationale: GH cannot be given PO; it can be administered only subcutaneously by injections. Options 1, 3, and 4 are incorrect. A lack of GH is not associated with mental retardation. Children whose epiphyseal plates have closed are not candidates for GH therapy; therefore, most adolescents would see minimal gain in height. Periodic testing for blood hormone levels is required during therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 1, 2, 3 Rationale: GH increases the length and width of long bones; promotes organ, muscle, and connective tissue growth; and increases the synthesis of proteins. Options 4 and 5 are incorrect. GH may cause an increase in serum glucose levels, not a decrease. It may improve and decrease fat deposits around the abdomen and improve lipid levels. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 3 Rationale: Patients on desmopressin need to obtain a daily weight and should monitor for the presence of any peripheral edema. Options 1, 2, and 4 are incorrect. Desmopressin must be given in regular doses for continued therapeutic effects. Increasing the dosage may cause an increased risk of vasoconstriction and other adverse effects. Leg cramping when walking may indicate adverse peripheral vascular effects and should be assessed by the provider. Taking NSAIDs concurrently may increase the antidiuretic effect, leading to adverse effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Planning

4 Answer: 1 Rationale: Octreotide prolongs intestinal transit time and stimulates reabsorption of fluids and electrolytes from the GI tract. These effects would have the therapeutic action of decreasing diarrhea related to the cancer or treatment. Options 2, 3, and 4 are incorrect. Octreotide will not slow cancer growth or metastasis or improve lean body mass or fat deposits. Hypo- and hyperglycemia are possible adverse effects of octreotide, not therapeutic effects. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 4 Rationale: Concurrent administration of octreotide with PO antidiabetic drugs or insulin can produce hypoglycemia. Glucose levels would have to be monitored closely and insulin dose adjustments made. Options 1, 2, and 3 are incorrect. Glaucoma, COPD, or alcoholism would not be contraindications for this drug. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 1 Rationale: A patient with diabetes insipidus (DI) who is responding to therapy with desmopressin would have decreasing signs of dehydration. Options 2, 3, and 4 are incorrect. DI is characterized by large volumes of urine output with a very low urine specific gravity accompanied by signs of dehydration, including reports of thirst and an increased pulse rate. The patient responding to desmopressin therapy would see a lowered pulse rate related to an increase in circulating volume secondary to the decrease in urine output. Desmopressin therapy would also cause the urine specific gravity to increase, not decrease. Blood glucose levels are not affected by desmopressin. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 66

1 Answer: 2 Rationale: Insulin peaks are the times of maximum insulin utilization with the greatest risk of hypoglycemia. Options 1, 3, and 4 are incorrect. Insulin schedules for the patient are developed by the provider and the patient should not self-select a schedule for insulin use. Because the risk for hypoglycemia is highest at peak serum insulin levels, exercise or additional insulin may increase the risk further. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 2, 3, 5 Rationale: The blood glucose level should be checked prior to administering any type of insulin. Because lispro is a rapid-acting insulin, the nurse should ensure that a meal is available and that the patient will be able to eat shortly after receiving a dose. If signs of hypoglycemia are present, the insulin dose should be held and the patient treated for hypoglycemia. The provider should be notified. Options 1 and 4 are incorrect. Urine testing for glucose and ketones does not give exact information, and patients vary on the degree to which glucose and ketones will "spill" into the urine. While a check of the pulse or blood pressure may be included in routine vital signs or to further assess symptoms of hypoglycemia, they do not provide information directly pertinent to the administration of insulin. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3 Rationale: A serious adverse effect of metformin is the risk of developing lactic acidosis. CKD, excess alcohol use, and IV contrast agents increase the risk for lactic acidosis and are contraindications to the use of metformin. Options 1, 2, and 4 are incorrect. Hypoglycemia, GI distress, and weight loss are common adverse effects of most oral antidiabetic drugs and are not specific to metformin. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 2 Rationale: It can take several weeks for rosiglitazone to provide full therapeutic effects, so the appropriate response would be to give it more time to reach effectiveness.

Options 1, 3, and 4 are incorrect. It is not within a nurse's scope of practice to prescribe additional drugs or change the dosage. The healthcare provider should be consulted about any change to the patient's drug regimen. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 4 Rationale: Glucagon injections can be repeated if one dose is not effective. Hypoglycemia is a medical emergency, and because this woman has not fully recovered, medical attention is needed. Options 1, 2, and 3 are incorrect. The patient is still experiencing symptoms of hypoglycemia, and continued treatment is indicated. Because she is still groggy and disoriented, it would not be safe to give this patient anything by mouth. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 4 Rationale: Insulin glargine has no definite peak, so the risk of a hypoglycemic reaction is minimal. Options 1, 2, and 3 are incorrect. Insulin glargine must be given by subcutaneous injection, it cannot be given by IM injection, and blood glucose monitoring is required for all patients taking any insulin. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 67

1 Answer: 4 Rationale: The administration of too much levothyroxine may cause hyperthyroidism, characterized by nervousness, palpitations, weight loss, diarrhea, and muscle tremors. Before altering the dosage, thyroid function studies will be performed to verify this condition. Options 1, 2, and 3 are incorrect. Nervousness, palpitations, and tremors are not symptoms of hypothyroidism or normal thyroid states. While these symptoms may occur with diabetes and hyperglycemia, other symptoms would dominate and would be noted before these symptoms occurred. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 3, 4, 5 Rationale: A euthyroid (normal) state is indicated by a return to normal performance of ADLs without fatigue, normalizing cholesterol levels, and vital signs within normal limits with a pulse rate between 60 and 100 beats/min. Options 1 and 2 are incorrect. Constipation and weight gain are symptoms of hypothyroidism. Decreased blinking and exophthalmos are symptoms of hyperthyroidism. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 1 Rationale: Sore throat, low-grade fever, and chills are symptoms of a possible infection. Because propylthiouracil may cause agranulocytosis, these symptoms should be reported to the provider. Options 2, 3, and 4 are incorrect. Increased appetite and caloric intake signal a return to a more euthyroid state. Tinnitus, altered taste, thickened saliva, insomnia, nightmares, and night sweats are not effects usually associated with propylthiouracil and if they occur, other causes should be investigated. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 3 Rationale: A heart rate of 110 beats/min would cause the nurse to hold the scheduled dose of levothyroxine, because it could indicate too high a level of thyroid hormone. Options 1, 2, and 4 are incorrect. A low level of thyroid hormone could cause weight gain or decreased blood pressure. These are symptoms of hypothyroidism and would not cause the nurse to hold the medication. An elevated temperature without other signs of hyperthyroidism would not warrant withholding the medication. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 2 Rationale: The high levels of iodine found in potassium iodide solution will inhibit the synthesis and release of thyroid hormone. The effectiveness decreases over time so it is only used short term before more definitive treatment can be accomplished. Options 1, 3, and 4 are incorrect. Iodine deficiency is rare and does not cause symptoms of hyperthyroidism, the indication for the patient's potassium iodide solution. High-dose iodine is not always used prior to thyroid surgery and the thyroidectomy is not related to a loss of iodine. High doses of iodine will not prevent diabetes. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 3 Rationale: To closely approximate the body's own hormone levels, levothyroxine should be taken in the morning, ideally at the same time each day. Options 1, 2, and 4 are incorrect. Taking levothyroxine along with food or meals containing high fiber may affect the absorption of the drug. Foods such as strawberries, spinach, and kale may inhibit thyroid secretion, reducing the effectiveness of the levothyroxine. If diarrhea occurs, the provider should be notified to determine the need to alter the dose. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 68

1 Answer: 1, 3, 5 Rationale: Edema, eye pain or vision changes, and abdominal pain are symptoms of possible adverse effects from the methylprednisolone. Options 2 and 4 are incorrect. Tinnitus is not an adverse effect commonly associated with methylprednisolone and if it occurs, other causes should be investigated. Dizziness upon standing indicates possible *hypo*tension. *Hyper*tension is a possible adverse effect from methylprednisolone. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 1 Rationale: An irregular heart rate and rhythm is a symptom of hypokalemia. Hydrocortisone given concurrently with diuretics such as thiazides, which cause loss of potassium, increases the risk of hypokalemia. Options 2, 3, and 4 are incorrect. While these are common adverse effects of hydrocortisone, they do not require immediate attention. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 1, 2 Rationale: Weight-bearing exercise 3 to 4 times weekly and increased dietary intake of calcium and vitamin D may help to prevent bone loss and osteoporosis. Options 3, 4, and 5 are incorrect. Remaining sedentary is not advisable and may increase the risk of osteoporosis and other adverse effects such as thrombophlebitis. Increased fluid intake and avoidance of alcohol are advised, but carbonated sodas should also be avoided because they have been linked to an increased risk of osteoporosis. While a bisphosphonate may be needed if bone density studies indicate the development of osteoporosis, it is not necessarily required at this time. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 4 Rationale: The patient should obtain a daily weight, ideally at the same time each day, to assess for excessive fluid retention. Fludrocortisone is a mineralocorticoid and may cause fluid retention, edema, and HTN. Options 1, 2, and 3 are incorrect. Abdominal pain and changes to the stool color may indicate GI bleeding, which is an adverse effect associated with glucocorticoids. Increased lipid levels and mood changes are also associated with glucocorticoids. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 3 Rationale: The patient is experiencing symptoms of acute adrenal insufficiency related to the inability to take the prescribed drug for several days and will require immediate IV administration of hydrocortisone. Options 1, 2, and 4 are incorrect. Fludrocortisone is a mineralocorticoid and is not indicated in this emergency situation. Ketoconazole and mitotane have antiadrenal effects and would worsen the situation. Cognitive Level:

Analyzing; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: 4 Rationale: Patients receiving replacement therapy for chronic adrenal insufficiency should carry PO and parenteral forms of the drugs they are prescribed in case of emergencies where the drugs may not be readily available. Options 1, 2, and 3 are incorrect. Checking BP, avoiding crowds and infections, and monitoring for visual changes are appropriate interventions when hyperphysiologic doses are given to treat disease and other conditions. Patients on replacement therapy for adrenal insufficiency receive physiologic doses to maintain normal levels of the hormones in their body and should not experience adverse effects unless the dosage is inappropriate. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

Chapter 69

1 Answer: 2, 3, 4 Rationale: A history of thromboembolic conditions, breast cancer, or hyperlipidemia may be contraindications for the use of HRT for this patient and will require further assessment by the healthcare provider before prescribing conjugated estrogen. Options 1 and 5 are incorrect. Because conjugated estrogen is metabolized through the CYP450 pathways and the drug may have hepatic effects, women with diabetes may need to more closely monitor their blood glucose to ensure that their diabetes medications are effective, but this is not considered a contraindication to the drug. A past history of cesarean birth is also not a contraindication. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 3 Rationale: Regular contractions increasing in occurrence indicate that the oxytocin is exerting a therapeutic effect. Options 1, 2, and 4 are incorrect. Control of postpartum hemorrhage is a therapeutic effect of oxytocin but would not be considered a therapeutic effect during labor. Sustained contractions are an adverse effect of oxytocin and immediate intervention is needed to prevent serious injury to the mother or baby should they occur. Oxytocin stimulates the milk letdown reflex in nursing, but this would not be considered a therapeutic effect during labor. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 4 Rationale: Clomiphene is given over six ovulatory-menstrual cycles in increasing doses with HCG added as needed. If no pregnancy has occurred after six cycles, other treatment options will be considered. Options 1, 2, and 3 are incorrect. The drug will not be continued for 1 year if pregnancy has not occurred, and the dosage may be increased after each cycle. Clomiphene is a category X drug and should be stopped if pregnancy occurs. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 3 Rationale: Medroxyprogesterone is known to decrease bone density over time. The patient should be taught to report any bone, joint, or musculoskeletal pain and to report any difficulty or pain with movement or ambulation. Options 1, 2, and 4 are incorrect. Insomnia or sleep difficulty and mouth, eye, or vaginal dryness are not related adverse effects. The drug may cause breakthrough spotting between menstrual cycles, but this is a common effect and does not require evaluation unless the bleeding is heavy or continuous. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Implementation

5 Answer: 2 Rationale: The standard treatment with clomiphene is to begin with a low dose for 5 days beginning on the fifth day of the menstrual cycle. Options 1, 3, and 4 are incorrect. Starting therapy on the first day of the menstrual cycle would not be as effective in stimulating ovulation because this usually occurs closer to midcycle. Because women experience menstrual periods of varying length, starting the drug on the "last day" would vary, and the drug might be started sooner or later than the recommended fifth day of the menstrual cycle. Many women do not know when ovulation occurs to be able to take it based on an ovulatory cycle and there is likelihood that this patient is not experiencing ovulation. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: 4 Rationale: Sedation, intense thirst, flushing of the skin, confusion, and muscle weakness are early symptoms of magnesium toxicity and should be immediately reported to the provider. Options 1, 2, and 3 are incorrect. The drug decreases deep tendon reflexes and CNS stimulation, and hyperactivity or seizure activity would not be expected. Chest congestion and cough are not associated with the drug and other causes should be explored. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 70

1 Answer: 3, 4 Rationale: Smokers have a significantly increased risk of serious thromboembolic events when taking OCs. Mood disorders, including depression, may worsen in patients taking OCs, and additional monitoring may be advised. Options 1, 2, and 5 are incorrect. Obesity is a risk factor for both treatment failure and thromboembolic events; however, this patient is considered overweight and is not in the high-risk category. Patients with asthma are not high risk, and a healthy 42-year-old woman with no significant health history is not considered high risk. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Assessment

2 Answer: 1 Rationale: If two consecutive days are missed, the patient should take two pills on the day it is discovered, two pills the following day, then resume the normal one pill per day routine. A second method of contraception should be used for 7 days after resuming the pills. Options 2, 3, and 4 are incorrect. Taking only one pill, skipping additional doses, or stopping the drug will not allow continued contraception. If the patient is concerned about pregnancy due to the missed pills, a pregnancy test may be conducted. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

3 Answer: 4 Rationale: Levonorgestrel–estradiol is taken for 84 days followed by a lower dose of estrogen included in the pill package for 7 days. Options 1, 2, and 3 are incorrect. Taking levonorgestrel–estradiol for 3 weeks, year-round, or for 2 months would be incorrect administration cycles. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

4 Answer: 3 Rationale: The patient takes misoprostol 24 to 48 hours after taking the mifepristone. Options 1, 2, and 4 are incorrect. Only one dose of mifepristone is taken. The misoprostol is taken within 24 to 48 hours after the mifepristone dose. Bleeding is a common effect of both drugs and is not an indication of when or whether to take the misoprostol. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 2 Rationale: Patients should be informed that spermicidal agents have relatively low levels of efficacy when used alone and should therefore be used only in conjunction with barrier methods such as condoms and diaphragms. Options 1, 3, and 4 are incorrect. Spermicides such as nonoxynol-9 are not extremely effective in preventing pregnancy, do not cause or protect against HIV or PID, and do not prevent ectopic pregnancies. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: 5, 1, 4, 3, 2 The correct ranking from most effective to least effective with *typical* use of the method is

1. Depo-Provera: 94% effective
2. Oral contraceptives: 91% effective
3. Transdermal (Ortho-Evra): 91% effective
4. Calendar rhythm: 76% effective
5. Spermicides: 72% effective

Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Assessment

Chapter 71

1 Answer: 2 Rationale: Primary hypogonadism results in patients with normal pituitary function and testes that are either diseased or unresponsive to FSH and LH. A primary goal of therapy would be an increased sperm count with an increase in male masculinization. Options 1, 3, and 4 are incorrect. Testosterone should not affect RBC count. Administering testosterone to the patient will not increase FSH or LH levels. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

2 Answer: 1 Rationale: The use of nitrates is contraindicated with sildenafil because dangerous hypotension may result. Options 2, 3, and 4 are incorrect. A history of diabetes would not be of concern and may be an indication for treatment if ED occurs. An allergy to penicillin products is not a contraindication for use of sildenafil. There are no expected adverse reactions with sildenafil and the use of antiulcer medication. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 2, 3, 5 Rationale: Women and children should avoid skin contact with areas where testosterone gels or creams have been applied to avoid drug absorption. Testosterones may trigger sodium and water retention and a weight gain of 2 kg (5 lb) or more per week should be reported to the provider. They may also increase blood lipid levels. Therefore, the patient should follow a low-fat diet and have periodic blood lipid level assessments. Options 1 and 4 are incorrect. Testosterone gel should be applied to the upper arms, shoulders, or abdomen and never to the scrotum, perineal area, or on broken or irritated skin. Showering or swimming should be avoided for several hours after application to allow drug absorption, but a wait of 12 to 14 hours is excessive. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2 Rationale: For sildenafil to be effective, the ED must be physiologic in nature. It is not effective if the dysfunction has solely psychologic origins and therefore does not always cause an erection. Options 1, 3, and 4 are incorrect. Sildenafil simply enhances, rather than causes, an erection. Prolonged use does not result in less intense feelings over time. Use of sildenafil by men will not have effects on female sexual function. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 1, 2, 4 Rationale: Finasteride promotes shrinkage of enlarged prostates and subsequently helps restore urinary function. Women should avoid handling crushed medication because it may be absorbed through the skin and have teratogenic effects. Maximum benefit may take 6 to 12 months to be achieved. Options 3 and 5 are incorrect. Finasteride does not affect vision. Dizziness is a possible adverse effect but significant dizziness or orthostatic hypotension should not occur and should be reported to the healthcare provider. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

6 Answer: 4 Rationale: Full effects of finasteride are realized within 6 to 12 months of therapy. Because the symptoms of dysuria have suddenly increased, the patient should be assessed for possible prostate cancer. Options 1, 2, and 3 are incorrect. Continuing to take the drug after full therapeutic results should have been realized is not appropriate, given the sudden increase in symptoms. Decreasing fluid irritants such as caffeine and alcohol may help overall but will not cause the sudden symptoms. A low-dose diuretic may not be appropriate in this situation and may worsen the dysuria. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 72

1 Answer: 3 Rationale: Alendronate may cause severe GI adverse effects. To decrease this risk, particularly for esophageal irritation, and to promote the absorption of the medication, alendronate should be taken with a full glass of water after rising in the morning. The patient should not eat or drink anything or lie down for 30 minutes after administration. Options 1, 2, and 4 are incorrect. The medication should be taken before breakfast, not before lunch or at bedtime. The patient should not lie down after taking alendronate for at least 30 minutes, preferably longer. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Evaluation

2 Answer: 1 Rationale: Headache, dizziness, and blurred vision are all early symptoms of toxicity to methotrexate. Options 2, 3, and 4 are incorrect. Hematuria, hiccoughs, jaundice, ascites, and edema formation are not associated with the use of methotrexate. While stomatitis may occur, constipation would be unrelated to methotrexate. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

3 Answer: 2 Rationale: Colchicine prevents the migration of neutrophils (WBCs) into the area of inflammation caused by uric acid crystals, reducing further inflammation and relieving the symptoms of gout and gouty arthritis. Options 1, 3, and 4 are incorrect. Colchicine does not increase uric acid deposits in the synovial spaces of the joints, prevent accumulation of uric acid crystals in the joints, or increase renal excretion of uric acid crystals. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 1 Rationale: The patient with osteomalacia has low serum calcium and low phosphate levels. An indicator that replacement therapy is achieving therapeutic benefits would be increasing serum calcium and phosphate levels. Options 2, 3, and 4 are incorrect. Increasing or decreasing actions of the serum calcium and phosphate levels are incorrectly stated. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

5 Answer: 1 Rationale: Vitamin D toxicity may occur in the patient receiving calcitriol. Symptoms to assess include muscle weakness, fatigue, nausea, vomiting, and changes in the color or amount of urine. Options 2, 3, and 4 are incorrect. Diarrhea, abdominal pain, stomatitis, joint stiffness, photosensitivity, and tinnitus are not symptoms that would be associated with the effects of vitamin D therapy. Bone pain and fever are symptoms of vitamin D deficiency. Cognitive Level: Analyzing; Client Need: Physiological Integrity; Nursing Process: Evaluation

6 Answer: 1, 3, 4 Rationale: DMARDs modify immune and inflammatory responses but may increase the risk of infections and malignancies, and reactivate latent TB. Injection-site reactions such as pain, swelling, and bruising are common adverse effects. Options 2 and 5 are incorrect. Adalimumab has not been associated with an increased risk of osteoporosis and is given subcutaneously, every other week. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

Chapter 73

1 Answer: 4 Rationale: Lice and nits can live in areas of the body other than the hair on the patient's head. Options 1, 2, and 3 are incorrect. Permethrin should not be applied after body lotions and should not be used on eyelashes or eyebrows. Lice can survive for up to 24 to 48 hours on inanimate objects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

2 Answer: 1 Rationale: Patients taking topical corticosteroids for the treatment of atopic dermatitis may experience burning and stinging of the skin in the affected area. Options 2, 3, and 4 are incorrect. Localized pruritus and hives, a loss of hair in the application area, or a worsening of acne vulgaris are not symptoms that would be related specifically to the effects of therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

3 Answer: 1, 2, 3 Rationale: Benzoyl peroxide suppresses sebum production and has antimicrobial action against the bacteria that cause acne. It also has a keratolytic effect, drying and encouraging more rapid cell turnover in the outer layer of the epidermis. Options 4 and 5 are incorrect. Microdermal abrasion is not a primary mechanism of action of the drug and benzoyl peroxide does not have sunscreen activity. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Evaluation

4 Answer: 3 Rationale: Tretinoin may cause dryness, irritation, and erythema. Mild soaps, gentle cleansing, warm but not hot water, and gentle drying should be used during tretinoin therapy. Options 1, 2, and 4 are incorrect. Antiacne soaps often contain compounds that dry and desquamate the skin and may cause further irritation. Sunscreens with an SPF of 15 and coverings should be used while on tretinoin to avoid sunburn. Alternating tretinoin with benzoyl peroxide may cause excessive dryness and irritation and increase the risk of adverse effects. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 3 Rationale: A small test area should be used if benzocaine has not been used before to assess for allergy. If no symptoms are noted within 30 to 60 minutes, it may be used on a wider area. Options 1, 2, and 4 are incorrect. Benzocaine should not be used on partial-thickness burns because of the risk of open blistered areas. The solution should not be warmed to avoid further heat and damage to the area of the burn. The burn should not be covered with plastic wrap to avoid heat trapping, potentially increasing the damage. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

6 Answer: A patient who has been prescribed isotretinoin must comply with the iPledge Program because of the risk of teratogenic effects. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

Chapter 74

1 Answer: 4 Rationale: Timolol is a beta-adrenergic blocker. To prevent swallowing and systemic absorption, pressure is to be applied to the inner canthus of the eye for 1 minute after instilling the drop. Options 1, 2, and 3 are incorrect. No other eyedrops or ointments should be used when taking timolol or other drops for glaucoma without the approval of the provider. Eye solutions for allergies may contain adrenergic drugs that may worsen glaucoma. Timolol is not contraindicated during seasonal allergies. It is not known to worsen seasonal allergies although it may cause bronchoconstriction in the sensitive individual or if swallowed and systemic effects occur. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

2 Answer: 1, 2, 4 Rationale: Latanoprost (Xalatan) may cause thickening and darkening of the eyelashes and upper eyelid and may cause darkening of the iris, especially noticeable in patients with light eye colors. Options 3 and 5 are incorrect. Latanoprost will not cause lightening of the iris or darkening of the sclera or a permanent bluish tint to the conjunctiva. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: Pilocarpine causes miosis, which stretches the trabecular meshwork, allowing greater outflow of aqueous humor and decreasing the IOP. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 2, 3, 1, 4 Rationale: The ear should be pulled gently upward and back and the drop instilled, allowing it to flow down the side of the canal. Dropping the solution directly on the tympanic membrane may cause dizziness or nausea. The area in front of the ear (the tragus) should be gently massaged. The patient should remain in a side-lying position or with the treated ear uppermost for 5 minutes to allow complete absorption of the solution. If needed, a dry cotton ball may be placed in the outer ear area to prevent leakage of solution. Cognitive Level: Applying; Client Need: Health Promotion and Maintenance; Nursing Process: Implementation

5 Answer: 4 Rationale: Increasing pain, particularly around the ear area, may indicate worsening infection or mastoiditis and should be immediately reported. Options 1, 2, and 3 are incorrect. Mild itching and irritation may occur, but severe itching or swelling should be reported. Gradually decreasing pain is a therapeutic effect as the infection clears. Dizziness may occur if the eardrop is instilled directly onto the tympanic membrane. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Planning

6 Answer: Phenylephrine causes mydriasis, allowing better visualization of the area of the lens during cataract surgery. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

Chapter 75

1 Answer: 1 Rationale: No antidote or specific treatment exists for radiation poisoning. Supportive therapy for the associated symptoms is the only treatment available. Options 2, 3, and 4 are incorrect. Ultraviolet light does not affect individuals who experience radiation poisoning. An individual with radiation toxicity is incapable of contaminating other individuals. No antiradiation medications exist. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

2 Answer: 1 Rationale: The preferred drug for *Y. pestis* exposure is doxycycline. Options 2, 3, and 4 are incorrect. Trivalent botulinum antitoxin is one of the two available treatments for botulism. The other antitoxin for botulism is heptavalent botulinum antitoxin. Ribavirin is an antiviral drug that may be used to treat serious virus infections. Atropine sulfate is a cholinergic antagonist used for organophosphate poisoning and other health problems. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

3 Answer: 3 Rationale: Time is a critical factor in acute poisonings. The emergency should be called into 911 and the rescue squad should transport the child to the nearest healthcare facility immediately. Options 1, 2, and 4 are incorrect. Instructions for poisoning may have changed since the packaging was printed. Based on the information provided in the question, the nurse does not know what chemicals the child has ingested. Forced vomiting is contraindicated for most poisonings. Waiting for the child to develop seizures or shortness of breath is too late since the development of these symptoms most likely represents a toxic level of the poison. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Implementation

4 Answer: 3 Rationale: Patients with decreased sensorium are at high risk for pulmonary aspiration. Activated charcoal should be given to these patients only if the airway is maintained with an endotracheal tube. Options 1, 2, and 4 are incorrect. Activated charcoal is not absorbed in the GI tract and therefore would not be contraindicated in patients with liver pathology. Activated charcoal is eliminated in the feces and therefore would not be contraindicated in patients with CKD. Anxiety and nervousness are not reasons to withhold the administration of activated charcoal. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

5 Answer: 1 Rationale: Chelating drugs capture the toxic metal through a bonding process. The kidneys remove both the chelator and the metal bound to it from the body. Options 2, 3, and 4 are incorrect. A chelator binds heavy metals but does not deactivate any chemical reactions. Chelation therapy is not involved in metabolism. Glomerular filtration is not affected by chelation therapy. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

6 Answer: 2 Rationale: Edetate calcium disodium may produce renal damage that may be reduced by ensuring adequate diuresis before therapy begins. Options 1, 3, and 4 are incorrect. Bowel function is not a critical parameter to consider prior to giving this drug. Edetate calcium disodium administration is not based on visual acuity. Skin integrity is not a critical parameter to consider prior to giving edetate calcium disodium. Cognitive Level: Applying; Client Need: Physiological Integrity; Nursing Process: Assessment

Appendix B
ISMP List of *High-Alert* Medications in Acute Care Settings

High-alert medications are drugs that bear a heightened risk of causing significant patient harm when they are used in error. Although mistakes may or may not be more common with these drugs, the consequences of an error are clearly more devastating to patients. We hope you will use this list to determine which medications require special safeguards to reduce the risk of errors. This may include strategies such as standardizing the ordering, storage, preparation, and administration of these products; improving access to information about these drugs; limiting access to high-alert medications; using auxiliary labels and automated alerts; and employing redundancies such as automated or independent double-checks when necessary. (Note: Manual independent double-checks are not always the optimal error-reduction strategy and may not be practical for all of the medications on the list.)

Classes/Categories of Medications
adrenergic agonists, IV (e.g., **EPINEPH**rine, phenylephrine, norepinephrine)
adrenergic antagonists, IV (e.g., propranolol, metoprolol, labetalol)
anesthetic agents, general, inhaled and IV (e.g., propofol, ketamine)
antiarrhythmics, IV (e.g., lidocaine, amiodarone)
antithrombotic agents, including: • anticoagulants (e.g., warfarin, low molecular weight heparin, IV unfractionated heparin) • Factor Xa inhibitors (e.g., fondaparinux, apixaban, rivaroxaban) • direct thrombin inhibitors (e.g., argatroban, bivalirudin, dabigatran etexilate) • thrombolytics (e.g., alteplase, reteplase, tenecteplase) • glycoprotein IIb/IIIa inhibitors (e.g., eptifibatide)
cardioplegic solutions
chemotherapeutic agents, parenteral and oral
dextrose, hypertonic, 20% or greater
dialysis solutions, peritoneal and hemodialysis
epidural or intrathecal medications
hypoglycemics, oral
inotropic medications, IV (e.g., digoxin, milrinone)
insulin, subcutaneous and IV
liposomal forms of drugs (e.g., liposomal amphotericin B) and conventional counterparts (e.g., amphotericin B desoxycholate)
moderate sedation agents, IV (e.g., dexmedetomidine, midazolam)
moderate sedation agents, oral, for children (e.g., chloral hydrate)
narcotics/opioids • IV • transdermal • oral (including liquid concentrates, immediate and sustained-release formulations)
neuromuscular blocking agents (e.g., succinylcholine, rocuronium, vecuronium)
parenteral nutrition preparations
radiocontrast agents, IV
sterile water for injection, inhalation, and irrigation (excluding pour bottles) in containers of 100 mL or more
sodium chloride for injection, hypertonic, greater than 0.9% concentration

Specific Medications
EPINEPHrine, subcutaneous
epoprostenol (Flolan), IV
insulin U-500 (special emphasis)*
magnesium sulfate injection
methotrexate, oral, non-oncologic use
opium tincture
oxytocin, IV
nitroprusside sodium for injection
potassium chloride for injection concentrate
potassium phosphates injection
promethazine, IV
vasopressin, IV or intraosseous

*All forms of insulin, subcutaneous and IV, are considered a class of high-alert medications. Insulin U-500 has been singled out for special emphasis to bring attention to the need for distinct strategies to prevent the types of errors that occur with this concentrated form of insulin.

Background

Based on error reports submitted to the ISMP National Medication Errors Reporting Program, reports of harmful errors in the literature, studies that identify the drugs most often involved in harmful errors, and input from practitioners and safety experts, ISMP created and periodically updates a list of potential high-alert medications. During May and June 2014, practitioners responded to an ISMP survey designed to identify which medications were most frequently considered high-alert drugs by individuals and organizations. Further, to assure relevance and completeness, the clinical staff at ISMP, members of the ISMP advisory board, and safety experts throughout the US were asked to review the potential list. This list of drugs and drug categories reflects the collective thinking of all who provided input.

© **ISMP 2014.** Used with permission from the Institute for Safe Medication Practices. Visit www.ismp.org for more medication safety information, or to report medication errors or near misses to the ISMP Medication Errors Reporting Program (MERP).

Glossary

A

Abortifacients drugs used to induce abortion

Absence seizures seizures with a loss or reduction of normal activity, including staring and transient loss of responsiveness

Absorption the process by which drug molecules move from their site of administration to the blood; movement of nutrients and other substances from the alimentary canal to the circulation

Accessory organs of digestion include the salivary glands, liver, gallbladder, and pancreas

Acetylation a general biochemical process that adds a two-carbon chain to a drug molecule, which usually renders the drug less effective

Acetylcholine (ACh) primary neurotransmitter of the autonomic nervous system

Acetylcholinesterase (AChE) enzyme that resides in the synaptic cleft and catalyzes the destruction of ACh

Acetylcholinesterase (AChE) inhibitors indirect-acting cholinergic agonists that are nonselective and affect all ACh synapses

Acidosis condition of having too much acid in the blood; plasma pH below 7.35

Acne vulgaris disorder of the hair follicles and sebaceous glands characterized by small inflamed bumps that appear on the surface of the skin

Acquired immunodeficiency syndrome (AIDS) infection caused by the human immunodeficiency virus (HIV)

Acquired resistance ability of an organism to become unresponsive over time to the effects of an anti-infective

Acromegaly excessive growth hormone disorder in which bones become deformed

Activated partial thromboplastin time (aPTT) laboratory test used to measure blood coagulation

Active immunity resistance resulting from a previous exposure to an antigen

Acute dystonia occurs during early pharmacotherapy with antipsychotics and involves severe muscle spasms, particularly of the back, neck, tongue, and face

Acute gouty arthritis condition in which uric acid crystals accumulate in the joints of the big toes, ankles, wrists, fingers, knees, or elbows, resulting in extremely painful and red, inflamed tissue

Acute retroviral syndrome symptoms during the initial phase of HIV infection

Adaptive defenses defenses that are specific to certain threats; the immune response

Addiction the continued use of a substance despite serious health and social consequences

Addison's disease hyposecretion of glucocorticoids and mineralocorticoids by the adrenal cortex

Additive effect type of drug interaction in which two drugs combine to produce a summation response

Adherence taking medications in the manner prescribed by the healthcare provider, or in the case of OTC drugs, following the instructions on the label or as provided by the prescriber

Adhesins chemicals produced by *H. pylori* that allow the organism to penetrate the GI mucosa and cause inflammation

Adipocytes fat cells

Adjuvant analgesics drugs that have indications other than pain but are used to enhance analgesia

Adjuvant chemotherapy administration of antineoplastic drugs *after* surgery or radiation therapy

Adrenal atrophy condition in which the adrenal cortex shrinks and stops secreting endogenous corticosteroids due to lack of stimulation by adrenocorticotropic hormone (ACTH)

Adrenal crisis condition that occurs when corticosteroid medication is abruptly withdrawn

Adrenergic receptors at the ends of postganglionic sympathetic neurons

Adrenergic agonists drugs that activate adrenergic receptors in the sympathetic nervous system; also known as sympathomimetics

Adrenergic antagonists drugs that block norepinephrine from reaching its receptors

Adrenocortical insufficiency lack of adequate corticosteroid secretion by the adrenal cortex

Adrenocorticotropic hormone (ACTH) hormone secreted by the anterior pituitary that stimulates the release of glucocorticoids by the adrenal cortex

Adverse drug effect an undesirable and potentially harmful action caused by the administration of medication

Aerobic pertaining to an oxygen environment

Aerosol suspension of minute liquid droplets or fine solid particles in a gas

Affinity the ability of some tissues to attract, accumulate, and store drugs in high concentrations relative to other tissues

Afterload pressure in the aorta that must be overcome for blood to be ejected from the left ventricle

Agonist drug that activates a receptor and produces the same type of response as the endogenous substance

Agoraphobia an extreme avoidance of closed places where a panic attack might occur such as airplanes, public meetings, or elevators

Akathisia inability to rest or relax; constantly moving

Alimentary canal a long, continuous, hollow tube that extends from the mouth to the anus; the GI tract

Alkalosis plasma pH above 7.45

Alkylating agents agents that kill cancer cells by altering the shape of the DNA double helix and preventing the DNA from duplicating during cell division

Allergic rhinitis inflammation of the nasal mucosa due to exposure to allergens

Alopecia hair loss

Alpha-adrenergic antagonists drugs that block alpha-adrenergic receptors in the sympathetic nervous system

Alzheimer's disease (AD) neurodegenerative disease that involves a chronic progressive loss of cognitive function

Amide local anesthetic that has the same mechanism of action as esters but has less effect on myocardial contraction and lower allergic reaction

Amygdala located in the temporal lobe, it is essential for the ability to feel certain emotions and to perceive them in other people

Anabolic effects testosterone hormone's ability to accelerate the growth of red blood cells, muscle, bone, and neural tissues

Anabolic steroids testosterone-like substances with hormonal activity that are commonly abused by athletes

Anaerobic pertaining to an environment without oxygen

Analgesics drugs used to relieve pain

Anaphylaxis life-threatening allergic response that may cause cardiovascular shock and death

Androgens steroid sex hormones that promote the appearance of masculine characteristics

Anemia decreased oxygen-carrying capacity of the blood

Angina pectoris acute chest pain caused by myocardial ischemia

Angioedema rapid swelling of the throat, face, larynx, and tongue that can lead to airway obstruction and death

Angiogenesis the formation of new blood vessels

Angiotensin I a precursor to the formation of angiotensin II that is produced when angiotensinogen is split by the enzyme renin

Angiotensin II vasopressor substance released in response to falling blood pressure that causes vasoconstriction and release of aldosterone

Angiotensin-converting enzyme (ACE) inhibitor enzyme that blocks the formation of angiotensin II, decreasing blood pressure

Angiotensinogen protein synthesized by the liver that is continuously circulating in the bloodstream

Anorexiants drugs used to suppress appetite

Anovulatory cycles menstrual cycles without ovulation

Antacids inorganic compounds containing aluminum, magnesium, sodium, or calcium that neutralize gastric acid and inactivate pepsin

Antagonist drug that blocks the response of another drug

Antagonistic effect type of drug interaction in which adding a second drug results in a diminished pharmacologic response

Anterior pituitary gland (adenohypophysis) consists of glandular tissue that manufactures and secretes hormones that control major body functions and systems

Anterograde amnesia type of short-term memory loss where the user cannot remember events that occurred while under the influence of a drug

Anthrax an acute infectious disease that results from exposure to the spore-forming bacterium *Bacillus anthracis*

Antibiotic natural substance produced by a microorganism that can kill other microorganisms

Antibodies proteins produced by the body in response to an antigen; used interchangeably with the term *immunoglobulin*

Anticholinergic syndrome symptoms such as dry mouth, blurred vision, photophobia, visual changes, difficulty swallowing, agitation, and hallucinations, caused by an overdose of anticholinergic substances

Anticoagulants natural substances that inhibit the formation of blood clots

Antidepressants drugs used to enhance, elevate, or stabilize mood

Antidiuretic hormone (ADH) hormone released by the posterior pituitary gland when blood pressure falls or when the osmotic pressure of the blood increases; most important means by which the body maintains fluid homeostasis

Antigens microbes and foreign substances that elicit an immune response

Anti-infective general term for any medication that is effective against pathogens

Antipyretics medications used to reduce body temperature

Antiretroviral therapy (ART) therapy designed to reduce the replication of HIV as much as possible, as measured by a reduction in plasma HIV RNA to its lowest possible (or undetectable) level; formerly called highly active antiretroviral therapy (HAART)

Antiretrovirals drugs that are effective against retroviruses

Antithrombin III (AT-III) protein that prevents abnormal clotting by inhibiting thrombin and other clotting factors

Antitussives medications that control cough

Anxiety state of apprehension, tension, or uneasiness that stems from the anticipation of danger, the source of which is largely unknown or unrecognized

Anxiolytic drugs that relieve anxiety

Apoprotein protein component of a lipoprotein

Appetite a psychologic response that drives food intake based on associations and memory

Aqueous humor fluid that fills the anterior and posterior chambers of the eye

Asthma chronic inflammatory disease of the lungs characterized by airway obstruction

Atherosclerosis condition characterized by the presence of plaque within the walls of arteries

Atonic seizures very short-lasting seizures during which the patient may stumble and fall for no apparent reason

Atrial natriuretic peptide (ANP) hormone secreted by specialized cells in the right atrium when large increases in blood volume produce excessive stretch on the atrial wall

Atrial reflex causes the heart rate and CO to increase until the backlog of venous blood (or IV fluid) is distributed throughout the body

Attention-deficit/hyperactivity disorder (ADHD) disorder typically diagnosed in childhood characterized by hyperactivity as well as attention, organization, and behavior control issues

Attenuated organisms that have been rendered less able to cause disease through the application of heat or chemicals from which effective vaccines can be developed

Atypical antidepressants diverse class of drugs that act by mechanisms other than those of the selective serotonin reuptake inhibitors, tricyclic antidepressants, and monoamine oxidase inhibitors

Atypical mycobacterial infections (AMIs) nontuberculosis opportunistic diseases caused by mycobacteria

Auras sensory warnings such as flashing lights, visual blind spots, and arm or leg tingling that precede a migraine

Automaticity ability of certain myocardial cells to spontaneously generate an action potential without an outside signal from the nervous system

Automatisms repetitive arm movements, leg movements, head rolling, chewing, lip smacking, or swallowing that occur in complex partial seizures

Autonomic nervous system (ANS) portion of the peripheral nervous system that provides for the involuntary control of vital functions of the cardiovascular, digestive, respiratory, and genitourinary systems

Autonomic tone the background level of autonomic activity that occurs even in the absence of stimuli

Azole term for the major class of drugs used to treat mycoses

Azoospermia complete absence of sperm in an ejaculate

B

β-glucan an essential component that shapes and strengthens the cell walls of fungi

B cell lymphocyte responsible for humoral immunity

Bactericidal drug that kills bacteria

Bacteriostatic drug that inhibits the growth of bacteria

Bacteriuria uropathogens

Balanced anesthesia use of multiple medications to produce general anesthesia, provide sedation, rapid induction of unconsciousness, muscle relaxation, and analgesia

Baroreceptors receptors in the aorta and carotid artery that sense changes in blood pressure

Barrett's esophagus precancerous condition of the esophagus

Basal nuclei area of the brain responsible for starting and stopping synchronized motor activity such as leg and arm motions during walking; also called basal ganglia

Beers criteria list of drugs compiled by the American Geriatrics Society that have produced a high incidence of adverse effects in older adults

Belladonna natural source of alkaloids with anticholinergic activity acquired from the deadly nightshade plant, *Atropa belladonna*, which grows throughout the world

Benign prostatic hyperplasia (BPH) nonmalignant abnormal enlargement of the prostate gland

Best Pharmaceuticals for Children Act authorizes the FDA to contract for the testing of already approved pediatric drugs, or when the pharmaceutical company declines the option of exclusivity

Beta-adrenergic antagonists drugs that block beta-adrenergic receptors; may be nonselective or selective; also called beta blockers

Beta-lactam ring portion of the chemical structure of penicillin and some other antibiotics that is responsible for their antibacterial activity

Beta-lactamase any of several enzymes produced by bacteria that are able to render certain antibiotics ineffective

Bioavailability the rate and extent to which the active ingredient is absorbed from a drug product and becomes available at the site of drug action to produce its effect

Biologic response modifiers natural cytokines that boost specific functions of the immune system

Biosimilar drug drug that has comparable effectiveness and safety to an FDA-approved biologic product

Bioterrorism intentional release of an infectious agent for the purpose of causing harm to a large number of people

Bipolar disorder syndrome characterized by extreme and opposite moods, such as euphoria and depression

Bisphosphonates class of drugs for treating osteoporosis that inhibit bone resorption by suppressing osteoclast activity

Black box warning in some drug inserts, a requirement by the FDA that warns prescribers that the drug carries a risk for serious or fatal adverse effects

Blood–brain barrier network of capillaries in the CNS that inhibits many chemicals and drugs from gaining access to the brain

Body mass index (BMI) measurement of obesity determined by dividing body weight (in kilograms) by the square of height (in meters)

Body surface area (BSA) method method of calculating pediatric dosages using an estimate of the child's BSA

Body weight method method of calculating pediatric dosages that requires a calculation of the number of milligrams of drug, based on the child's weight in kilograms (mg/kg)

Bone deposition opposite of bone resorption; bone building

Bone resorption process of bone demineralization or the breaking down of bone into mineral components

Boosters follow-up doses of vaccines that are required to provide prolonged protection

Botanical plant extract used to treat or prevent illness

Botulism condition caused by *Clostridium botulinum*, an organism that secretes a potent toxin that paralyzes the muscles after an individual is poisoned

Bradydysrhythmias disorders characterized by a heart rate less than 60 beats/min

Bradykinesia difficulty initiating movement and controlling fine muscle movements

Bradykinin chemical released by cells during inflammation that produces pain and side effects similar to those of histamine

Broad-spectrum antibiotic an anti-infective that is effective against a wide variety of different microbial species

Bronchospasm sudden contraction of the smooth muscle of the airways that causes acute dyspnea

Buffers chemicals that help maintain normal body pH by neutralizing strong acids or bases

C

Cachexia general wasting of muscle and other tissue

Calcineurin intracellular messenger enzyme that is activated when a T cell encounters an antigen

Calcitonin hormone secreted by the thyroid gland that decreases plasma levels of calcium by inhibiting resorption of calcium from bone and increasing excretion of calcium by the kidneys

Calcitriol the active form of vitamin D

Calcium channel type of voltage-gated channel in cardiac muscle and smooth muscles

Cancer malignant disease characterized by abnormal, uncontrolled cell division

Capillary leak syndrome a serious condition in which plasma proteins and other substances leave the blood and enter the interstitial spaces because of porous capillaries

Capsid protein coat that surrounds a virus

Carbonic anhydrase enzyme that forms carbonic acid by combining carbon dioxide and water

Carcinogens agents that cause cancer

Cardiac output (CO) amount of blood pumped by a ventricle per minute

Cardiac remodeling change in the size, shape, and structure of the myocardial cells (myocytes) that occurs over time in heart failure

Cardiotonic drugs drugs that increase the force of cardiac contraction; also called inotropic drugs

Cardioversion electrical shock of the heart that under ideal conditions will allow the return to a normal heart rhythm; also called defibrillation

Cataplexy sudden loss of muscle strength manifested as slurred speech, sagging of the jaw, head nodding, or even complete collapse of the body

Catecholamines class of endogenous hormones involved in neurotransmission that include epinephrine (adrenalin), norepinephrine, and dopamine

Catechol-O-methyltransferase (COMT) enzyme that destroys catecholamines such as norepinephrine in kidney and liver cells

Cathartic substance that causes accelerated, stronger, and more complete bowel emptying

CD4 receptor protein that accepts HIV and allows entry of the virus into the T_4 lymphocyte

Cell-kill hypothesis theoretical model that predicts the ability of antineoplastic drugs to eliminate cancer cells

Central nervous system (CNS) stimulants drugs that raise the general alertness level of the brain

Cerumenolytics agents used to loosen and remove impacted cerumen from the ear canal

Chelation therapy use of drugs to detoxify poisonous metals such as mercury, arsenic, and lead by converting them to a chemically inert form that can be easily excreted

Chemical names standard nomenclature for drugs assigned by the International Union of Pure and Applied Chemistry (IUPAC)

Chemoreceptor trigger zone (CTZ) location in the cerebral cortex that sends sensory signals to the vomiting center

Chemoreceptors sensory receptors in the aorta and carotid artery that recognize levels of oxygen, pH, or carbon dioxide in the blood

Chemotherapy pharmacotherapy of cancer

Chief cells cells located in the mucosa of the stomach that secrete pepsinogen, an inactive form of the enzyme pepsin that chemically breaks down proteins

Chloasma darkened pigmentation found on the forehead, temples, cheeks, and upper lips

Cholecalciferol inactive form of vitamin D

Cholestatic hepatitis type of liver inflammation caused by obstruction of the bile ducts

Cholinergic relating to neurons that release acetylcholine (ACh)

Cholinergic agonists drugs and chemicals that increase the action of acetylcholine (ACh) at a cholinergic receptor; also called parasympathomimetics

Cholinergic crisis caused by an overdosage with acetylcholinesterase (AChE) inhibitors or poisoning with organophosphate insecticides or toxic nerve gases; characterized by intense signs of parasympathetic stimulation such as miosis, nausea, vomiting, urinary incontinence, increased exocrine secretions, abdominal cramping, and diarrhea

Cholinesterase inhibitors the most widely prescribed drug class for treating Alzheimer's disease

Chronic bronchitis recurrent disease of the lungs characterized by excess mucus production, inflammation, and coughing

Chronic kidney disease condition characterized by a gradual loss of kidney function, usually over a period of months or years; also called renal failure

Chronic obstructive pulmonary disease (COPD) progressive pulmonary disorder characterized by chronic obstructive airflow

Chyme partly digested food that is passed from the stomach to the small intestine

Cinchonism syndrome with symptoms such as tinnitus, headache, diarrhea, blurred vision, hearing loss, and dysrhythmias, caused by high doses of quinidine

Circadian rhythm cyclic basis by which body temperature, blood pressure, hormone levels, and respiration all fluctuate throughout the 24-hour day

Climacteric the period of endocrine, somatic, and psychologic changes occurring in the transition to menopause

Clinical phase trials the second stage of drug testing in a clinical investigation; involves the testing of a new drug in selected patients

Closed-angle glaucoma acute glaucoma that is caused by obstruction of drainage of aqueous humor through the canal of Schlemm

Club drug a diverse group of abused substances taken by people at dance clubs, all-night parties, and raves

Coagulation formation of an insoluble clot

Colloids proteins, starches, or other large molecules that remain in the blood for a long time because they are too large to easily cross the capillary membranes

Colony-stimulating factors (CSFs) hormones that activate existing white blood cells to fight an infection and stimulate the growth and differentiation of one or more types of leukocytes

Combination drugs drug products with more than one active generic ingredient

Comedolytics drugs that prevent and break up the formation of clogged pores

Comedones types of acne lesions that develop just beneath the surface of the skin (whitehead) or as a result of a plugged oil gland (blackhead)

Complement system a cluster of 20 plasma proteins that combine in a specific sequence and order when an infection occurs

Complementary and alternative medicine (CAM) diverse set of therapies and healing systems that are considered to be outside of mainstream healthcare

Complex partial seizures seizures that originate from a single focus, usually in the temporal lobe of the brain, and involve sensory, motor, or autonomic symptoms with some degree of altered or impaired consciousness

COMT inhibitors drugs that prevent the destruction of catechol-O-methyltransferase (COMT) in peripheral tissues, thus increasing the amount of levodopa available to enter the brain

Conjugation the direct transfer of small pieces of DNA from one bacterium to another

Constipation infrequent passage of abnormally hard and dry stools

Contraception the use of devices, drugs, or surgery to prevent pregnancy

Contractility the strength with which the myocardial fibers contract

Controlled substances in the United States, drugs whose use is restricted by the Comprehensive Drug Abuse Prevention and Control Act

Convulsions involuntary violent spasms of the face, neck, arms, and legs

Coronary artery disease (CAD) a narrowing or occlusion of one or more coronary arteries

Corpora cavernosa tissue in the penis that fills with blood during an erection

Corpus luteum endocrine tissue formed from a ruptured follicle that remains in the ovary after ovulation and secretes progesterone

Cretinism condition marked by profound mental retardation and impaired growth that results from untreated congenital hypothyroidism

Cross-tolerance situation in which tolerance to one drug makes the patient tolerant to another drug

Crystalloids IV solutions that contain electrolytes and other agents in concentrations that mimic the body's extracellular fluid

Crystalluria crystals that form in the urine and potentially obstruct the kidneys or ureters

Culture set of beliefs, values, religious rituals, language, customs, and behavioral expectations that provide meaning for an individual or group

Culture and sensitivity (C&S) testing a laboratory test used to identify bacteria and the most effective antibiotic

Curare the first neuromuscular blocker, which was initially extracted from several different plant species native to the rain forests of South America

Cushing's syndrome condition of high levels of corticosteroids in the body over a prolonged period of time

Cyclooxygenase (COX) key enzyme in the synthesis of prostaglandin that is blocked by aspirin and other NSAIDs

Cycloplegics drugs that relax or temporarily paralyze ciliary muscles and cause blurred vision

Cystitis bladder infection

Cysts protective capsules formed by some protozoa that allow the organisms to survive in harsh environments in a dormant state for prolonged time periods

Cytokine release syndrome an acute inflammatory response that occurs 30 to 60 minutes following the initial IV administration of muromonab due to massive cytokine release

Cytokines proteins produced by T cells, such as interleukins, leukotrienes, interferon, and tumor necrosis factor, that guide the immune response

D

Deep vein thrombosis (DVT) thrombosis that occurs in the legs

Defecation elimination of indigestible substances from the body

Defibrillation electrical shock of the heart that under ideal conditions will allow the return to a normal heart rhythm; also called cardioversion

Delirium tremens a syndrome of intense agitation, confusion, terrifying hallucinations, uncontrollable tremors, panic attacks, and paranoia caused by alcohol withdrawal

Delusions false ideas and beliefs not founded in reality

Dementia degenerative disorder characterized by progressive memory loss, confusion, and the inability to think or communicate effectively

Dependence a powerful physiologic or psychologic need for a substance

Depolarization loss of membrane potential in a cell

Depression characterized by a sad or despondent mood that becomes out of proportion to actual life events

Dermatitis superficial inflammatory disorders of the skin characterized by redness, pain, and pruritus

Dermatomycosis fungal infections of the skin and hair

Diabetes insipidus (DI) disorder marked by production of large volumes of urine, usually accompanied by increased thirst

Diabetes mellitus metabolic disorder characterized by an imbalance between insulin availability and insulin need

Diabetic ketoacidosis (DKA) acute condition that occurs primarily in patients with type 1 diabetes characterized by hyperglycemia, metabolic acidosis, and osmotic diuresis

Diarrhea increase in the frequency and fluidity of bowel movements

Dietary Supplement and Nonprescription Drug Consumer Protection Act law that requires companies that market herbal and dietary supplements to include their address and phone number on the product labels so consumers can report adverse events

Dietary Supplement Health and Education Act of 1994 (DSHEA) primary law in the United States regulating herbal and dietary supplements

Dietary supplements products available over the counter that are intended to add to or supplement the nutritional value of the diet

Diffusion the movement of a chemical from an area of higher concentration to an area of lower concentration

Digestion the mechanical and chemical breakdown of food into a form that may be absorbed into the systemic circulation

Digestive system body system consisting of the alimentary canal and the accessory organs

Digitalization procedure in which the dose of digoxin is gradually increased until tissues become saturated with the drug, and the symptoms of heart failure diminish

Dihydropyridines the largest class of calcium channel blockers that bind reversibly to closed-type (inactivated) calcium channels to make them unresponsive to depolarization

Directly observed therapy (DOT) requires that a healthcare provider directly observe the patient swallowing the pills, whether it is in the hospital, office, or home care setting

Disease-modifying antirheumatic drugs (DMARDs) drugs that slow or modify the progression of rheumatoid arthritis

Dissociative anesthesia a trance-like feeling of being separated from the environment produced by an anesthetic agent

Distribution the transport of drugs throughout the body after they are absorbed

Diuretic substance that increases the rate of urine flow

Diuretic resistance phenomenon in some patients who become less responsive as therapy continues with loop diuretics

DNA gyrase (topoisomerase II) in bacterial DNA replication, the enzyme that relaxes the supercoil

DNA helicase in bacterial DNA replication, the enzyme that unwinds the two DNA strands after the supercoil is relaxed

DNA polymerase in bacterial DNA replication, the enzyme that adds the precursor bases to replicate the original DNA and form new DNA strands

Dopamine chemical precursor in the synthesis of norepinephrine; classified as a catecholamine

Dopamine system stabilizers (DSSs) partial agonists that reduce the hyperactivity of dopamine in certain regions of the brain (to produce therapeutic effects), while at the same time restoring normal dopamine activity in other regions (to lower the incidence of adverse effects)

Dopamine type 2 (D_2) receptors receptors for dopamine in the basal nuclei of the brain that are associated with schizophrenia and antipsychotic drugs

Dose–response relationship the way a patient responds to varying doses of a drug

Down-regulation the process by which cells make fewer receptors on their surface

Drug any substance that is taken to prevent, cure, or reduce symptoms of a medical condition

Drug allergies a hyperresponse of body defenses to a particular drug that may result in a diverse range of patient symptoms

Drug interaction occurs when a medication interacts with another substance such as another drug, a dietary supplement, an herbal product, or food that is taken concurrently with the medication, and the drug's actions are affected

Drug misuse improper use of drugs, including overuse, underuse, or, in some cases, erratic use

Drug–protein complex formed when a drug that binds reversibly to a plasma protein, particularly albumin, makes the drug unavailable for distribution to its site of action

Dry powder inhaler (DPI) device used to convert a solid drug to a fine powder for the purpose of inhalation

Dwarfism a growth hormone deficiency disorder in children associated with normal birth length followed by a slowing of the growth rate

Dysfunctional uterine bleeding hemorrhage that occurs on a noncyclic basis or in abnormal amounts

Dyslipidemia a general term that refers to abnormal amounts of lipids in the body

Dysrhythmias disorders of cardiac rhythm characterized by an abnormal heart rate or irregular contractions

Dystonia chronic neurologic disorder that is characterized by involuntary muscle contraction that forces body parts into abnormal painful movements or postures

E

Eclampsia pregnancy-induced hypertensive disorder

Ectopic foci regions of the heart outside the normal cardiac conduction pathway that may send impulses across the myocardium

Ectopic pregnancy the development of the fetus elsewhere rather than in the uterus

Eczema chronic, inflammatory skin disorder

Efficacy the maximal response that can be produced from a particular drug

Electrocardiogram (ECG) graphic recording of the wave of electrical conduction across the myocardium

Electroconvulsive therapy (ECT) treatment used for serious and life-threatening mood disorders in patients who are unresponsive to pharmacotherapy and psychotherapy

Electrolyte charged substance in the blood such as sodium, potassium, calcium, chloride, and phosphate

Elemental (monomeric) formulas enteral products that are usually lactose free and contain only a small percentage of calories from fat

Emergency contraception (EC) the prevention of implantation following unprotected intercourse or contraceptive failure

Emergency preparedness the ability to respond quickly and effectively to an unexpected event that may impact human health

Emetogenic potential usually applied to antineoplastic drugs; degree to which an agent is likely to trigger the vomiting center in the medulla, resulting in nausea and vomiting

Emphysema lung disease characterized by loss of bronchiolar elasticity and destruction of alveolar walls

Endocrine system body system that consists of various glands that secrete hormones

Endometriosis presence of endometrial tissue in nonuterine locations such as the pelvis and ovaries; a common cause of infertility

Endorphins a group of neurotransmitters that function as endogenous opioids or natural pain modifiers in the CNS

Endotoxins harmful nonproteins that are part of the normal cell wall of gram-negative bacteria

Enteral nutrition (EN) nutritional support used for patients with functioning GI tracts but who are unable to orally ingest adequate amounts of nutrients to meet their metabolic needs

Enteral route administration of drugs orally or through nasogastric or gastrostomy tubes

Enteric-coated tablets that have a hard, waxy coating designed to dissolve in the alkaline environment of the small intestine

Enteric nervous system (ENS) network of neurons in the submucosa of the alimentary canal that has sensory and motor functions that regulate the GI tract

Enteroendocrine cells cells that secrete hormones that modify the digestive processes

Enterohepatic recirculation recycling of drugs and other substances by the circulation of bile through the intestine and liver

Enzyme induction process by which a drug increases the activity of the hepatic microsomal enzymes

Epilepsy disruption of the activity of clusters of neurons in the brain that is characterized by two or more seizures

Erectile dysfunction (ED) consistent inability to either attain an erection or to sustain an erection long enough to achieve satisfactory sexual intercourse

Ergosterol lipid substance in fungal cell membranes

Erythema redness associated with skin irritation

Erythrocytic stage phase in malaria during which infected red blood cells rupture, releasing more merozoites and causing acute symptoms

Erythropoietin hormone secreted by the kidney that stimulates the body's production of erythrocytes (red blood cells)

Esters local anesthetics that act by decreasing the amount of sodium that enters the neuron

Estrogen general term that refers to three different steroid hormones: estradiol, estrone, and estriol

Ethnicity groups of people with biologic and genetic similarities

Euphoria an intense sense of happiness and well-being

Exclusivity after approval of a drug application by the U.S. Food and Drug Administration, a period of time when competing companies are not allowed to market generic versions of a drug

Excoriation scratches that break the skin surface and fill with blood or serous fluid to form crusty scales

Excretion the process of removing substances from the body

Exophthalmos an outward bulging of the eyes

Exotoxins proteins released by bacteria into surrounding tissues that have the ability to inactivate or kill host cells

Expectorants drugs used to increase bronchial secretions

Extended release tablets or capsules designed to dissolve very slowly, resulting in a longer duration of action for the medication; also called long-acting or sustained release

Extracellular fluid (ECF) compartment of body fluid lying outside cells, which includes plasma and interstitial fluid

Extrapyramidal symptoms (EPS) symptoms of acute dystonia, akathisia, parkinsonism, and tardive dyskinesia often caused by antipsychotic drugs

Extrapyramidal system part of the CNS that controls locomotion, complex muscular movements, and posture

Extrinsic pathway activated in response to injury when blood leaks out of a vessel and enters tissue spaces; the pathway takes several seconds to complete

F

Fasting plasma glucose (FPG) test a primary blood test for diagnosing diabetes

Fat-soluble vitamins group of vitamins stored in the liver and fatty tissue that includes A, D, E, and K

FDA Adverse Event Reporting System (FAERS) a voluntary program that encourages healthcare providers and consumers to report suspected adverse effects directly to the FDA or the product manufacturer

Febrile seizures tonic–clonic motor activity lasting 1 to 2 minutes with rapid return of consciousness that occurs in conjunction with fever

Ferritin one of two protein complexes that maintain iron stores inside cells (hemosiderin is the other)

Fetal–placental barrier special anatomic barrier that inhibits many chemicals and drugs from entering the fetus

Fibrin an insoluble protein formed from fibrinogen by the action of thrombin in the blood clotting process

Fibrinogen blood protein that is converted to fibrin by the action of thrombin in the blood coagulation process

Fibrinolysis physiologic process that limits clot formation and removes existing clots

Fight-or-flight response characteristic set of actions produced when the sympathetic nervous system is activated that prepares the body for heightened activity and for an immediate response to a threat

Filtrate fluid in the nephron that is filtered into the Bowman's capsule

First-dose phenomenon serious orthostatic hypotension that occurs with the initial doses of alpha$_1$-adrenergic blockers

First-pass effect mechanism whereby drugs are absorbed, enter into the hepatic portal circulation, and are inactivated by the liver before they reach the general circulation

Folate see Folic acid

Folic acid B vitamin that is essential for normal DNA and RNA synthesis; also called folate

Food and Drug Administration (FDA) Modernization Act act that gave financial incentives to pharmaceutical companies

to conduct pediatric research in pharmacology; in exchange for providing pediatric labeling, the legislation gives drug companies the ability to exclusively market the drug for an additional 6 months with no competition

Formulary list of drug and drug recipes commonly used by pharmacists

Frequency distribution curve a graphic representation of the actual number of patients responding to a particular drug action at different doses

Fungi kingdom of organisms that includes mushrooms, yeasts, and molds

G

Gamma aminobutyric acid (GABA) neurotransmitter in the CNS

Ganglia collection of neuron cell bodies located outside the CNS

Ganglionic blockers drugs that inhibit transmission at the ganglia in the sympathetic and parasympathetic nervous systems

Gastroesophageal reflux disease (GERD) regurgitation of acidic stomach contents into the esophagus

Gate control theory proposes a gating mechanism for the transmission of pain in the spinal cord

General anesthesia medical procedure that produces unconsciousness and loss of sensation throughout the entire body

Generalized anxiety disorder (GAD) difficult-to-control, excessive anxiety that lasts for 6 months or longer

Generalized seizures seizures that travel throughout the entire brain

Generic name name assigned to a drug by the U.S. Adopted Name Council

Genetic polymorphism changes in enzyme structure and function due to mutation of the encoding gene

Gestational diabetes condition resulting from glucose intolerance with an onset, or first recognition, during pregnancy

Gigantism unusual tallness

Glaucoma condition that is characterized by optic neuropathy with gradual loss of peripheral vision and usually accompanied by increased intraocular pressure

Glomerular filtration rate (GFR) the volume of water filtered through the Bowman's capsules per minute

Glomerulus a specialized capillary in the Bowman's capsule of the kidney that filters the blood during urine formation

Glucocorticoids class of hormones secreted by the adrenal cortex that prepare the body for long-term stress; also called corticosteroids

Gluconeogenesis the production of new glucose from noncarbohydrate molecules

Glutamate amino acid that is the most common neurotransmitter in the CNS

Glycogenolysis the process of glycogen breaking down

Glycoprotein IIb/IIIa receptor found on the surface of platelets

Goiter refers to an increase in the size of the thyroid gland

Gonadocorticoids sex hormones secreted by the adrenal cortex

Gout form of acute arthritis caused by an accumulation of uric acid (urate) crystals in the joints and other body tissues

Grading process that examines potential cancer cells under a microscope and compares their appearance to normal parent cells

Gram-negative bacteria that do not retain a violet stain because they have thin cell walls

Gram-positive bacteria that contain a thick cell wall composed of peptidoglycan and retain the violet color after staining

Graves' disease syndrome caused by hypersecretion of thyroid hormone

Gray baby syndrome serious condition seen most often in premature or newborn infants that occurs when the baby's liver is unable to metabolize or excrete chloramphenicol

Growth fraction the ratio of the number of replicating cells to resting cells in a tissue or tumor

Growth hormone (GH) hormone that is produced and secreted by the anterior pituitary gland; also called somatotropin or somatropin

H

H^+, K^+-ATPase enzyme secreting hydrochloride acid in the stomach

H_1 receptors histamine receptors that, when activated, produce allergy symptoms

H_2-receptor antagonists drugs that suppress gastric acid by blocking histamine receptors in the stomach

Hallucinations seeing, hearing, or feeling things that are not there

Hallucinogens chemicals that have the ability to produce an altered, dreamlike state of consciousness

Hashimoto's thyroiditis an autoimmune disorder that is the most common cause of hypothyroidism

Healthcare-associated infections (HAIs) infections acquired in a healthcare setting that are often resistant to common antibiotics

Healthcare failure mode and effect analysis (HFMEA) a tool that helps healthcare agencies identify processes where medication errors may occur related to prescription, dispensing, and administration

Heart failure (HF) inability of the heart to pump enough blood to meet the body's metabolic needs

Helminths various species of multicell parasitic worms

Hemagglutinin an enzyme that facilitates the attachment of the virus to host cells

Hematopoiesis production and maturation of blood cells that occurs in red bone marrow; also called hemopoiesis

Hematopoietic growth factors drugs that promote the formation of specific blood cells and enhance the ability of the immune system to reduce some of the myelosuppression caused by antineoplastic medications

Hemoglobin A1C test (A1C) a laboratory test used in diabetic management; also called glycosylated hemoglobin

Hemophilia series of coagulation disorders caused by genetic insufficiencies

Hemopoiesis production and maturation of blood cells that occurs in red bone marrow; also called hematopoiesis

Hemosiderin one of two protein complexes that maintain iron stores inside cells (ferritin is the other)

Hemostasis the slowing or stopping of blood flow

Hepatic microsomal enzyme system as it relates to pharmacotherapy, liver enzymes that metabolize drugs as well as nutrients and other endogenous substances; sometimes called the CYP450 system

Hepatic portal system a network of venous vessels that collects blood draining from the stomach, small intestine, and most of the large intestine

Hepatitis inflammation of the liver

Herb plant with a soft stem that is used for healing or as a seasoning

High-alert medications drugs that have a high risk of causing significant harm to the patient when used in error

High-density lipoprotein (HDL) lipid-carrying particle in the blood that transports excess cholesterol away from body tissues or back to the liver for metabolism

Histamine chemical released by mast cells in response to foreign agents or injury that initiates the inflammatory response within seconds

HMG-CoA reductase primary regulatory enzyme for the biosynthesis of cholesterol

Hormone replacement therapy (HRT) supplies physiologic doses of estrogen, sometimes combined with progestin, to treat unpleasant symptoms of menopause and to prevent long-term consequences of estrogen loss

Hormones chemicals secreted by endocrine glands that act as chemical messengers to maintain homeostasis

Host flora microorganisms that normally inhabit the human body

Human immunodeficiency virus (HIV) the causative agent for AIDS

Hyperaldosteronism excessive secretion of aldosterone

Hypercholesterolemia high levels of cholesterol in the blood

Hyperemesis gravidarum condition of continual vomiting during pregnancy

Hyperkalemia serum potassium level above 5 mEq/L

Hyperlipidemia elevated levels of lipids in the blood

Hypernatremia high sodium level in the blood

Hyperosmolar hyperglycemic state (HHS) acute complication seen in individuals with type 2 diabetes that is characterized by extreme hyperglycemia, hyperosmolarity with dehydration, the absence of ketoacidosis, and CNS dysfunction

Hypertension (HTN) consistent elevation of systemic arterial blood pressure

Hypertensive emergency (HTN-E) a diastolic pressure of greater than 120 mmHg, with evidence of target-organ system damage; also called hypertensive crisis

Hypertensive urgency severe hypertension, but with no evidence of target-organ damage

Hypertrichosis the elongation, thickening, and increased pigmentation of body hair

Hypertriglyceridemia refers to an increase in triglyceride levels

Hyperuricemia serum uric acid level 7 mg/dL or higher

Hypervitaminosis intake of toxic levels of vitamins

Hypnagogic hallucinations vivid, fearful illusions that may be experienced at the onset of sleep or on awakening

Hypoaldosteronism lack of adequate aldosterone secretion

Hypogonadism lack of sufficient testosterone by the testes

Hypokalemia serum potassium level below 3.5 mEq/L

Hypomania characterized by the same symptoms as bipolar disorder, but they are less severe and do not cause impaired functioning

Hyponatremia low sodium level in the blood

I

Idiosyncratic response unpredictable and unexplained drug reaction

Immunity ability to resist injury and infections

Immunization process of disease prevention in which the body produces its own antibodies in response to initial exposure to antigens

Immunomodulator general term referring to any drug or therapy that affects body defenses

Immunostimulants drugs that increase the ability of the immune system to fight infection and disease

Immunosuppressants drugs that diminish the ability of the immune system to fight infection and disease

Impotence inability to obtain or sustain an erection; also called erectile dysfunction

Incretins hormones released by the mucosa of the small intestine in response to meals

Incubation period following the first exposure to an antigen, the time needed for the body to process the antigen and mount an effective response

Indications the medical conditions for which a drug is approved

Infantile spasm usually occurs in the first year of life and is characterized by a sudden bending forward, body stiffening, or arching of the torso; also called West syndrome

Infertility inability to become pregnant after at least 1 year of frequent, unprotected intercourse

Inflammation nonspecific body defense that occurs in response to an injury or antigen

Inflammatory bowel disease (IBD) disease characterized by the presence of ulcers in the distal portion of the small intestine (Crohn's disease) or mucosal erosions in the large intestine (ulcerative colitis)

Influenza a viral infection characterized by acute symptoms that include sore throat, sneezing, coughing, fever, and chills; also called flu

Ingestion the process of taking food into the body by mouth

Innate body defenses those that are present even before an infection occurs and which provide the first line of protection from pathogens

Inoculation the placement of a foreign substance on or in an individual for the purpose of disease prevention using "live" virus particles obtained from an infected patient

Inotropic drugs drugs that increase the force of contraction of the heart; also called cardiotonic drugs

Insomnia inability to fall asleep or stay asleep

Insulin pancreatic hormone that acts to decrease blood glucose levels

Insulin resistance occurs in type 2 diabetes mellitus; cells become unresponsive to insulin due to a defect in insulin receptor function

Insulin-like growth factor (IGF) a family of peptides that promote cartilage and bone growth

Integrase an enzyme unique to HIV that incorporates the viral DNA into the host's chromosomes

Interferons (IFNs) type of cytokine secreted by T cells in response to antigens to protect uninfected cells

Interleukins (ILs) class of cytokines synthesized by lymphocytes, monocytes, macrophages, and certain other cells in response to antigen exposure

Intermittent claudication (IC) pain or cramping in the lower legs that worsens with walking or exercise

Intracellular fluid (ICF) compartment contains water that is inside cells

Intracellular parasites infectious microbes that live inside host cells

Intrinsic activity the ability of a drug to bind to a receptor and produce a strong action

Intrinsic factor chemical substance secreted by stomach cells that is essential for the absorption of vitamin B_{12}

Intrinsic pathway coagulation pathway activated in response to injury; it takes several minutes to complete

Intrinsic sympathomimetic activity (ISA) low level of beta-agonist activity possessed by certain beta-adrenergic blockers

Invasiveness the ability of a pathogen to grow extremely rapidly and cause direct damage to surrounding tissues by virtue of sheer numbers

Investigational New Drug (IND) application to the FDA that contains all the animal and cell testing data

Iodism toxicity to Lugol's iodine solution therapy

Ion trapping phenomenon in which alkalinizing drugs are used to aid in the renal excretion of toxic substances

Irritable bowel syndrome (IBS) disease of the lower GI tract, characterized by abdominal pain, bloating, gas, cramping, and alternating diarrhea and constipation

Irritative voiding symptoms cluster of complaints that accompanies cystitis

Isozymes multiple, similar forms of an enzyme that perform slightly different metabolic functions

J

Juxtaglomerular (JG) cells specialized smooth muscle cells found in the afferent arteriole that sense blood pressure and release renin

K

Kappa receptors one of two major receptors in the CNS where opioids act

Keratolytic action that promotes shedding of the outer layer of the epidermis

L

Laxatives drugs that promote defecation

Lennox-Gastaut syndrome mixed seizure that has characteristics of tonic–clonic, atonic, and atypical absence seizures

Leprosy a chronic infection caused by *Mycobacterium leprae*

Leptin hormone that regulates hunger and weight balance

Leucovorin rescue therapy drug therapy administered following chemotherapy with toxic folic acid analogs such as methotrexate to rescue normal cells

Leukotrienes chemical mediators of inflammation stored and released by mast cells

Leydig cells the primary cells in the testes that are responsible for androgen secretion

Libido interest in sexual activity

Limbic system area in the brain responsible for emotional expression, learning, and memory

Lipodystrophy a disorder in which fat is redistributed in specific areas in the body

Lipoproteins substances that carry lipids in the bloodstream that are composed of fat bound to carrier proteins

Loading dose relatively large dose of a drug given at the beginning of treatment to rapidly obtain a therapeutic response

Local anesthesia loss of sensation to a limited part of the body without loss of consciousness

Locus coeruleus located within the brainstem, monitors internal and external signals and is the principal site for norepinephrine synthesis in the brain

Long-acting reversible contraceptives (LARCs) provide contraception for periods lasting from weeks to years

Low-density lipoprotein (LDL) lipoprotein that carries the highest amount of cholesterol

Lymph nodes the principal lymphoid organs in the body

Lymphatic system consists of a network of cells, vessels, and tissues that provide immune surveillance

M

Macrominerals inorganic compound needed by the body in amounts of 100 mg or more daily

Macula densa specialized cells in the distal convoluted tubule of the nephron that sense the flow rate and osmolality in the filtrate and send a message to the juxtaglomerular cells to release more renin

Maintenance dose amount of drug that keeps the plasma drug concentration in the therapeutic range

Major depressive disorder a depressed mood lasting for a minimum of 2 weeks that is present for most of the day, every day, or almost every day

Malaria disease characterized by severe fever and chills caused by the protozoan *Plasmodium*

Malignant hyperthermia rare but potentially fatal condition that is an adverse effect of some general anesthetics; characterized by a rapid onset of extremely high fever with muscle rigidity

Mania condition characterized by an inflated self-esteem, decreased need for sleep or food, distractibility, increased activity, excessive pursuit of pleasurable activities, increased talkativeness, delusions, paranoia, hallucinations, and bizarre behavior

Margin of safety (MOS) the amount of drug that is lethal to 1% of animals (LD_1) divided by the amount of drug that produces a therapeutic effect in 99% of the animals (ED_{99})

Mast cell stabilizers drugs that inhibit the release of inflammatory mediators from mast cells

Mastoiditis inflammation of the mastoid sinus

Median effective dose (ED_{50}) the dose of a drug required to produce a specific therapeutic response in 50% of a group of patients

Median lethal dose (LD_{50}) the dose of a drug that will kill 50% of a group of animals

Median toxicity dose (TD_{50}) the dose of a drug that will produce a given toxicity in 50% of a group of patients

Medication administration record (MAR) legal documentation of all pharmacotherapies received by a patient

Medication error any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the healthcare provider, patient, or consumer

Medication error index categorization of medication errors according to the degree of harm an error can cause

Medication reconciliation the process of comparing a patient's medications with newly ordered medications to address duplications, omissions, and interactions, and the need to continue current medications

Menopause progressive decrease in estrogen secretion by the ovaries resulting in the permanent cessation of menses

Merozoites transformation of sporozoites carried by the blood to the liver inside the human host where they multiply into millions of progeny

Metabolic bone disease (MBD) refers to a cluster of disorders that have in common defects in the structure of bone

Metabolic syndrome a group of abnormalities that tend to occur together that places the patient at increased risk for developing diabetes and vascular complications

Metabolism the process used by the body to chemically change a drug molecule; also called biotransformation

Metastasis travel of cancer cells from their original site to a distant site

Metered-dose inhaler (MDI) device used to deliver a precise amount of medicine to the respiratory system

Methylxanthines chemical class for theophylline and caffeine and theobromine

Microbial antagonism condition of various host flora in competition with each other for physical space and nutrients that helps protect the host from being overrun by pathogenic organisms

Microminerals inorganic compounds needed by the body in amounts of 20 mg or less daily

Migraine severe headache preceded by auras and that may include nausea and vomiting

Milk-alkali syndrome syndrome caused by the administration of calcium carbonate antacids with milk or food containing vitamin D; symptoms include headache, urinary frequency, anorexia, nausea, and fatigue

Mineralocorticoids hormones secreted by the adrenal glands that affect the secretion of sodium and water

Minerals essential substances that constitute about 4% of an individual's body weight and serve many diverse functions

Minimum alveolar concentration describes the potency of inhalation anesthetics

Minimum effective concentration amount of drug required to produce a therapeutic effect

Miosis constriction of the pupil

Mitochondrial toxicity specific type of adverse effects resulting from a drug's toxic actions on mitochondria

Modular formulas enteral feedings that contain nutrients that are designed to meet a specific nutrient deficiency or disease state

Monitored anesthesia care (MAC) use of sedatives, analgesics, and other low-dose drugs that allow patients to remain responsive and breathe without assistance

Monoamine oxidase (MAO) enzyme that destroys catecholamines such as norepinephrine in the nerve terminal

Monoamine oxidase inhibitor (MAOI) drug inhibiting monoamine oxidase, an enzyme that slows the destruction of norepinephrine, dopamine, and serotonin

Monoclonal antibody (MAB) antibody produced by a single B cell that targets a single type of cell or receptor

Mood disorder change in emotion that impairs the patient's ability to effectively deal with normal activities of daily living (ADLs)

Mood stabilizers drugs for bipolar disorder that can moderate extreme shifts in emotions and relieve symptoms of mania and depression during acute episodes

Motor end plate cholinergic synapse on skeletal muscle that allows for communication between the nervous system and skeletal muscle

Mu receptors one of two types of opioid receptors in the CNS

Mucolytics drugs used to remove mucus by loosening thick bronchial secretions

Mucositis inflammation of the epithelial lining of the digestive tract

Muscarinic type of cholinergic receptor found at postganglionic nerve endings in the parasympathetic nervous system that, when activated, results in stimulation

Muscarinic agonist drug that is selective for muscarinic receptors

Muscarinic antagonist drug that blocks receptors at cholinergic synapses in the parasympathetic nervous system and at a few target organs in the sympathetic nervous system

Muscle rigidity stiffness occurring in Parkinson's disease that causes difficulty bending over and moving limbs, changes in facial expression, or a lack of facial expression

Muscle spasms involuntary contractions of muscles that cause sudden, intense pain, which slowly diminishes after a few minutes

Muscle spasticity condition caused by damage to the CNS in which certain muscle groups remain in a continuous state of contraction

Mutations errors made by bacteria while duplicating their genetic code

Myasthenia gravis (MG) muscular disorder caused by a destruction of nicotinic synapses on skeletal muscles and

characterized by extreme fatigue, double vision, speech impairment, and difficulty chewing or swallowing

Myasthenic crisis extreme muscular weakness and symptoms similar to those of cholinergic crisis; caused by abrupt discontinuation of medication for myasthenia gravis

***Mycobacterium avium* complex (MAC)** infection that usually arises as a secondary infection due to the immunosuppression caused by HIV infection or AIDS

Mycolic acid a complex lipid that covers the cell surfaces of the genus *Mycobacterium* to protect them and make them resistant to many disinfectants

Mycoses diseases caused by fungi

Mydriasis pupil dilation

Mydriatics drugs that cause pupil dilation

Myocardial infarctions (MIs) blood clots blocking a portion of a coronary artery that cause necrosis of cardiac muscle

Myocardial ischemia condition in which the heart is receiving an insufficient amount of oxygen to meet its metabolic needs

Myocardium the muscular layer of the heart, responsible for its physical pumping action

Myoclonic seizures seizures characterized by brief, sudden contractions of major muscle groups

Myxedema mucous type of edema caused by accumulation of hydrophilic substances in connective tissues

Myxedema coma a life-threatening end-stage condition of hypothyroidism

N

Nadir lowest values of erythrocyte, leukocyte, and platelet counts caused by chemotherapy

Narcolepsy sleep disorder that is characterized by severe daytime sleepiness and inability to stay awake

Narcotic natural or synthetic drug related to morphine; may be used as a broader legal term referring to hallucinogens, CNS stimulants, marijuana, and other illegal drugs

Narrow-spectrum antibiotic an anti-infective that is effective against only one or a small number of organisms

Natriuresis sodium excretion in the urine

Natriuretic peptides substances secreted in response to increased pressure in the heart

Nausea unpleasant feeling of the need to vomit accompanied by weakness, diaphoresis, dizziness, and hyperproduction of saliva

Nebulizer machine that delivers medication as a fine mist for the purpose of inhalation; also called small-volume nebulizer

Negative chronotropic effect the property of slowing the speed of electrical conduction across the myocardium

Negative feedback controls secretion and release of hormones by signaling the endocrine system once homeostasis is restored

Negative inotropic effect the reduction in the force of myocardial contraction

Negative symptoms in schizophrenia, symptoms associated with a loss of normal functioning, including a lack of interest, motivation, responsiveness, or pleasure in daily activities

Neoadjuvant chemotherapy the administration of antineoplastic drugs before surgery or radiation therapy with the goal of shrinking a large tumor to a more manageable size

Neoplasm swelling, abnormal enlargement or mass; same as *tumor*

Nephrons structural and functional units of the kidney

Neuraminidase an enzyme that assists the virus in exiting the host cell

Neurodegenerative diseases degenerative diseases of the CNS that include a diverse set of disorders differing in their causes and outcomes

Neuroeffector junction specialized synapse where the postganglionic neuron terminates on smooth muscle, cardiac muscle, or a gland

Neurofibrillary tangles bundles of nerve fibers found in the brain of patients with Alzheimer's disease on autopsy

Neurolept analgesia type of general anesthesia that combines fentanyl with droperidol to produce a state in which patients are conscious though insensitive to pain and unconnected with surroundings

Neuroleptic malignant syndrome (NMS) potentially fatal condition caused by certain antipsychotic medications characterized by high fever, sweating, fluctuating blood pressure, tachycardia, and muscle rigidity

Neuromuscular blockers drugs that inhibit transmission at the neuromuscular junctions on skeletal muscles in the somatic nervous system

Neuron the primary functional cell in all portions of the nervous system; its purpose is to communicate messages through conduction of an action potential

Neuropathic pain pain caused by injury or irritation to nerve tissue described as burning, shooting, or numbing pain

Neurotransmitters chemicals utilized in the communication of a message from one cell to another, or synaptic transmission

New Drug Application (NDA) application submitted to the FDA that signals that a pharmaceutical company is ready to sell a new drug

New molecular entities medications that are truly unique and structurally different from existing drugs

Nicotinic agonist drug that selectively activates nicotinic receptors

Nicotinic antagonist drug that blocks receptors at cholinergic synapses in the ganglia or in the somatic nervous system at the neuromuscular junction

Nicotinic receptor receptor for acetylcholine in the ganglia of both the sympathetic and parasympathetic nervous systems

Nitric oxide in vascular smooth muscle, an important cell-signaling molecule and a potent vasodilator that causes relaxation of both arterial and venous smooth muscle

Nits eggs of the louse parasite

Nociceptor pain pain produced by injury to body tissue

Nociceptors sensory nerve receptors located throughout the body that initiate pain transmission when stimulated

Nondepolarizing neuromuscular blockers (NDNBs) class of nicotinic antagonists that bind to ACh receptors at motor end plates in skeletal muscle and prevent ACh from reaching its receptors

Nonopioid analgesics analgesics that have a peripheral site of action, have no dependence potential, and provide the baseline pharmacotherapy for pain management; include NSAIDs, acetaminophen, and a few centrally acting medications

Non–rapid eye movement (NREM) sleep phase of sleep during which respirations slow, heart rate and blood pressure decrease, oxygen consumption by muscles decreases, and urine formation decreases

Norepinephrine (NE) primary neurotransmitter in the sympathetic and autonomic nervous systems

O

Obsessive-compulsive disorder (OCD) recurrent, intrusive thoughts or repetitive behaviors that interfere with normal activities or relationships

Oligospermia presence of less than 20 million sperm per milliliter of ejaculate

Oncology nurse nurse who has received special training to care for patients with cancer and to administer chemotherapy

On–off syndrome occurs when a patient with Parkinson's disease alternates between symptom-free periods (on) and times when the drugs stop working and symptoms abruptly reappear (off)

Onychomycosis the invasion of the nail plate by a fungus; also called tinea unguium

Open-angle glaucoma common form of glaucoma caused by the partial obstruction of the outflow of aqueous humor through the canal of Schlemm

Opiates natural substances obtained from opium, such as morphine and codeine

Opioid class of drugs that includes natural substances obtained from the seeds of the poppy plant such as opium, morphine, and codeine, and synthetic drugs such as meperidine, oxycodone, fentanyl, methadone, and heroin

Opium a milky substance extracted from the unripe seeds of the poppy plant that contains over 20 different chemicals having pharmacologic activity

Oral glucose tolerance test (OGTT) a primary blood test for diagnosing diabetes

Orphan product a drug or biologic for treating rare diseases that affect fewer than 200,000 people in the United States

Orthostatic hypotension fall in blood pressure that occurs when changing position from recumbent to upright

Osmolality number of dissolved particles, or solutes, in 1 kg (1 L) of water

Osmosis process by which water moves from areas of low solute concentration (low osmolality) to areas of high solute concentration (high osmolality)

Osmotic pressure creates a force that moves substances between body compartments or across a membrane

Osteoarthritis (OA) progressive, degenerative joint disease caused by the breakdown of articular cartilage

Osteomalacia rickets in children; caused by vitamin D deficiency and characterized by softening of the bones without alteration of basic bone structure

Osteoporosis metabolic bone disease characterized by bone demineralization, decreased bone density, and subsequent fractures

Otitis externa an inflammation of the outer ear; commonly called swimmer's ear

Otitis interna infection of the inner ear; also called labyrinthitis

Otitis media inflammation of the middle ear

Ototoxicity drug-induced hearing impairment

Ovarian hyperstimulation syndrome (OHS) serious complication of certain fertility drugs characterized by rapid, massive enlargement of the ovaries accompanied by physical symptoms

Ovulation release of an oocyte (egg) by the ovary

Ovulatory dysfunction the presence of abnormal, irregular, or absent ovulation

Oxytocics drugs that stimulate uterine contractions and promote the induction of labor

P

Paget's disease chronic progressive condition characterized by accelerated remodeling of the bone, producing enlarged and softened bones; also called osteitis deformans

Palliation form of cancer chemotherapy intended to alleviate symptoms rather than cure the disease

Pancreatitis inflammation of the pancreas

Panic disorder anxiety disorder characterized by intense feelings of immediate apprehension, fearfulness, terror, or impending doom, accompanied by increased autonomic nervous system activity

Para-aminobenzoic acid (PABA) precursor molecule used by bacteria to make their own folic acid

Parasympathetic nervous system portion of the autonomic nervous system that is activated during nonstressful conditions and produces a set of symptoms known as the rest-and-digest response

Parenteral nutrition the administration of high-calorie nutrients via a central vein, such as the subclavian vein

Parietal cells cells in the stomach mucosa that secrete hydrochloric acid

Parkinsonism having tremor, loss of fine motor skills, muscle rigidity, stooped posture, and a shuffling gait

Parkinson's disease (PD) degenerative disorder of the nervous system characterized by tremor, muscle rigidity, hypokinesia, masklike face, and a slow, shuffling gait

Paroxysmal supraventricular tachycardia (PSVT) occurs when episodes of atrial tachycardia alternate with periods of normal rhythm; also called paroxysmal atrial tachycardia (PAT)

Partial agonist medication that produces a weaker, or less efficacious, response than an agonist

Partial fatty-acid oxidation inhibitors a class of drugs used in the treatment of coronary artery disease

Partial (focal) seizures seizures that start on one side of the brain and travel a short distance before stopping

Partial parenteral nutrition a parenteral solution that lacks an essential element, usually fats or lipids

Passive immunity immune defense that lasts 2 to 3 weeks; obtained by administering antibodies

Patent medicines in early America before drug regulation, products that contained an easily identified trade name that claimed to cure just about any symptom or disease

Pathogenicity ability of an organism to cause disease in humans

Pathogens microbes that are capable of causing disease

Patient safety event an event, incident, or condition that could have resulted or did result in harm to a patient

Pediatric Research Equity Act of 2003 (PREA) act that authorizes the FDA to require research of pediatric uses for new drugs

Pediculicides drugs that kill lice

Pegylation process that attaches polyethylene glycol to a drug molecule to extend its duration of activity

Penicillinase enzyme present in certain bacteria that is able to make penicillin ineffective

Penicillin-binding proteins (PBPs) enzymes used by bacteria to build bacterial cell walls that are targets for penicillins and related antibiotics

Pepsin digestive enzyme that breaks down proteins from food

Peptic ulcer erosion of the mucosa in the stomach or small intestine

Peptidoglycan substance containing sugars bound to peptides that is only found in bacteria

Peripheral parenteral nutrition (PPN) delivery system used when a central venous line cannot be accessed or when it is not appropriate for the patient

Peripheral resistance amount of friction encountered by blood in the arteries

Peripherally inserted central catheter (PICC) line a central catheter that is threaded into the vena cava for administration of chemotherapy

Peristalsis contractions of layers of smooth muscle

Pernicious anemia type of anemia usually caused by a deficiency of vitamin B_{12}

Phagocytes cells that engulf and destroy pathogens and other foreign substances

Pharmacodynamics study of the mechanisms of drug action and how the body responds to drugs

Pharmacogenetics the study of genetic variations that alter patients' responses to medications; branch of pharmacology that examines the role of genetics in drug response

Pharmacokinetic enhancers two drugs, ritonavir and cobicistat, that are given concurrently with antiretrovirals primarily for the purpose of inhibiting liver enzymes that would inactivate the antiretroviral; also called boosters

Pharmacokinetics study of drug movement throughout the body

Pharmacologic classification method of organizing drugs on the basis of their mechanisms of action

Pharmacology the study of medicines, ranging from how drugs are administered, to where they travel in the body, to the actual responses they produce

Pharmacopoeia a medical reference summarizing standards of drug purity, strength, and directions for synthesis

Pharmacotherapy the application of drugs for the purpose of disease prevention and treatment of suffering; also called pharmacotherapeutics

Pheochromocytoma a tumor, usually benign, arising from the adrenal medulla that is characterized by excessive secretion of catecholamines

Phobia fearful feeling attached to situations or objects such as snakes, spiders, crowds, or heights

Phosphodiesterase III enzyme in cardiac and smooth muscle; inhibition increases cardiac output due to an increase in myocardial contractility and a decrease in left ventricular afterload

Phospholipids type of lipid that contains two fatty acids, a phosphate group, and a chemical backbone of glycerol

Phototherapy therapy used for the treatment of seasonal affective disorder that consists of artificial lighting approximately 5 to 20 times brighter than normal indoor lighting

Physical dependence condition of experiencing unpleasant withdrawal symptoms when a substance is discontinued after repeated use

Pill rolling common behavior in Parkinson's disease, in which patients rub the thumb and forefinger together in a circular motion, resembling the motion of rolling a tablet between two fingers

Placebo in drug testing, an inert substance that serves as a control "nontreatment" group used to compare the effectiveness of the new drug

Placenta organ that allows for nutrition and gas exchange between a mother and her fetus

Plaque fibrous, fatty material that builds up in the walls of arteries

Plaques psoriatic lesions characterized by red, raised patches of skin covered with flaky, thick, silver scales

Plasma cells cells derived from B lymphocytes that secrete antibodies

Plasma half-life ($t_{1/2}$) the length of time required for the plasma concentration of a drug to decrease by one half after administration

Plasminogen inactive protein that is present in fibrin clot formation; precursor of plasmin

Pluripotent stem cells (hemocytoblasts) cells that are capable of maturing (differentiating) into any blood cell type

Pneumonic plague life-threatening infectious lung disease that occurs after breathing *Yersinia pestis*, a bacterium found on rodents and their fleas that is responsible for the bubonic plague

Polarized describes a cell that has negative membrane potential

Polyclonal antibodies contain a wide mixture of different antibodies that attack the T cells or T-cell receptors

Polycystic ovary syndrome a condition in which the ovaries are filled with follicular cysts and the patient has elevated levels of androgens and estrogen

Polydipsia excessive thirst

Polyherbacy use of multiple herbal and other supplements

Polymeric formulas solutions that contain various mixtures of proteins, lipids, and carbohydrates in high-molecular-weight form and are considered the most common enteral preparation

Polyphagia excessive appetite

Polypharmacy taking multiple drugs concurrently

Polyuria excessive urine production

Positive symptoms in schizophrenia, symptoms associated with an excess of distortion of normal function, including hallucinations, delusions, disorganized thought or speech patterns, and movement disorders

Postantibiotic effect antimicrobial activity that continues for a time after discontinuation of a drug

Posterior pituitary gland (neurohypophysis) consists of nervous tissue and is an extension of the hypothalamus that secretes antidiuretic hormone and oxytocin

Postherpetic neuralgia a serious form of the shingles in which the pain lasts for years

Postictal state period immediately following a seizure

Postmarketing surveillance stage 4 of the drug approval process during which testing is done to survey for harmful drug effects in a large population

Postpartum depression major depression experienced by new mothers following delivery that is related to hormonal shifts and situational stresses that occur during that period

Post-traumatic stress disorder (PTSD) type of anxiety that develops in response to reexperiencing a previous life event that was psychologically traumatic

Potency the strength of a drug at a specified concentration or dose

Potentially inappropriate medications (PIMs) medications that comprise the Beers criteria that are of special concern for older adults

Preclinical research first stage of drug development that involves extensive laboratory testing by the pharmaceutical company on human and microbial cells

Prediabetes condition in which serum glucose levels are elevated but are not high enough to be diagnosed as diabetes

Preeclampsia occurs during pregnancy when blood pressure increases to 140/90 mmHg or higher on two separate occasions, and 300 mg of protein is found in the urine over a 24-hour period

Pregnancy categories five classifications developed by the FDA that rate medication risks during pregnancy

Preload degree of stretch of the cardiac muscle fibers just before they contract

Preterm labor the initiation of labor prior to week 37 of gestation

Primary hypertension hypertension having no identifiable cause

Procoagulants natural substances that promote the formation of blood clots

Prodrugs drugs that become more active after they are metabolized

Prodysrhythmics conditions that promote the formation of cardiac rhythm abnormalities

Progesterone a natural progestin secreted by the corpus luteum

Progestins synthetic hormones that have actions identical to natural endogenous progesterone

Prostaglandin E_2 hormone that stimulates the secretion of mucus and bicarbonate, promotes repair of damaged gastric mucosal cells, and increases blood flow to the mucosa to help maintain optimal mucosal conditions

Prostaglandins local hormones that have diverse functions depending on the location

Prostatitis bacterial infection of the prostate gland

Protease viral enzyme that is responsible for the final assembly of the HIV virions

Prothrombin blood clotting factor that is converted to the enzyme thrombin

Prothrombin time (PT) laboratory test used to measure blood coagulation

Proton pump inhibitors (PPIs) drugs that inhibit the enzyme H^+, K^+-ATPase

Prototype drug well-understood model drug to which other drugs in a pharmacologic class are compared

Protozoan single-celled organism that inhabits water, soil, and animal hosts

Provirus stage of a virus in which the viral DNA integrates into the host chromosome

Pruritus itching associated with dry, scaly skin or a parasite infection

Pseudocholinesterase enzyme that rapidly destroys certain drugs in the plasma

Pseudomembranous colitis (PMC) caused by *Clostridium difficile*, a rare though potentially severe disorder resulting from therapy with tetracyclines and other classes of antibiotics

Psoralens drugs used along with phototherapy for the treatment of severe psoriasis

Psychologic dependence desire to continue using a drug despite obvious negative economic, physical, or social consequences

Psychosis general term used in medicine to describe a loss of contact with reality

Psychosocial describes an individual's psychologic development in the context of one's social environment

Pulmonary embolism condition that occurs when a venous clot dislodges, migrates to the pulmonary vessels, and blocks arterial circulation to the lungs

Pulmonary perfusion blood flow through the lung

Purified protein derivative (PPD) tuberculin skin test

Pyelonephritis an inflammation of the kidney, pelvis, and other renal cells

R

Radiation sickness occurs after exposure to ionizing radiation; symptoms include nausea, vomiting, diarrhea, weight loss, anorexia, fatigue, and suppression of the bone marrow

Rapid eye movement (REM) sleep stage of sleep characterized by diminished muscle tone, movements of the eyes, and irregular heart rate and breathing

Raynaud's disease vasospasms of vessels serving the fingers and toes that can lead to intermittent pain and cyanosis of the digits

Reabsorption movement of filtered substances from the kidney tubule back into the blood

Rebound congestion adverse effect of intranasal decongestants; prolonged use causes hypersecretion of mucus and worsening nasal congestion once the drug effects wear off

Rebound effects symptoms of lethargy and fatigue caused by withdrawal of methamphetamine and other stimulants

Rebound insomnia increased sleeplessness that occurs when long-term sedative medication is discontinued abruptly

Receptor cellular molecule to which a drug binds to produce its effects

Recommended dietary allowances (RDAs) minimum amount of vitamins and minerals needed each day to prevent disease

Refeeding syndrome metabolic complications that can occur when nutritional support, including enteral nutrition therapy, is introduced to severely malnourished patients

Reflex tachycardia temporary increase in heart rate that occurs when blood pressure falls

Refractory period time during which the myocardial cells rest and are not able to contract

Regional anesthesia similar to local anesthesia except that it encompasses a larger body area, such as an entire limb

Renin an enzyme that is synthesized, stored, and secreted by juxtaglomerular cells in the kidney

Renin-angiotensin-aldosterone system (RAAS) series of enzymatic steps by which the body raises blood pressure

Replacement therapy hormones administered to patients who are unable to secrete sufficient quantities of their own endogenous hormones

Repolarization return of a negative resting membrane potential to the cell

Rest-and-digest response signs and symptoms produced when the parasympathetic nervous system is activated; they promote relaxation and maintenance activities

Reticular activating system (RAS) responsible for sleeping and wakefulness and performs an alerting function for the cerebral cortex

Reticular formation portion of the brain affecting awareness and wakefulness

Retinoids drug class related to vitamin A used in the treatment of inflammatory skin conditions, dermatologic malignancies, and acne

Reverse cholesterol transport the process by which cholesterol is transported away from body tissues to the liver

Reverse remodeling occurs after several months of therapy with beta-adrenergic antagonists, when heart size, shape, and function return to normal

Reverse transcriptase viral enzyme that converts RNA to DNA

Rhabdomyolysis breakdown of muscle fibers usually due to muscle trauma or ischemia

Rheumatoid arthritis (RA) chronic, progressive, autoimmune disease that causes inflammation of the joints

Rhinophyma reddened, bulbous, irregular swelling of the nose

Rifamycin derivatives include rifampin, rifabutin, and rifapentine; used in combination with other antituberculosis medications

Risk management system of reducing medication errors by modifying policies and procedures within the institution

Risk–benefit ratio determination of whether the risks from a drug outweigh the potential benefits received by taking the medication

Root-cause analysis (RCA) attempts to focus attention on the causes of a medication error, rather than on the individual responsible for the error

Rosacea inflammatory skin disorder affecting mainly the face, characterized by small papules that swell, thicken, and become painful

S

Salicylates the chemical family to which aspirin belongs

Salicylism acute or chronic overdose of aspirin

Sarcolemma the muscle membrane

Sarcoplasmic reticula structures within cells that store the calcium ions that are released by depolarization

Satiety the psychologic feeling of fullness or satisfaction following a meal

Satiety center region of the hypothalamus that recognizes satiety

Scabicides drugs that kill scabies mites

Scheduled drugs drugs that are frequently abused or have a high potential for dependence are classified and regulated according to their potential for abuse

Schizoaffective disorder psychosis with symptoms of both schizophrenia and mood disorders

Schizophrenia psychosis characterized by abnormal thoughts and thought processes, withdrawal from people and the outside environment, an inability to independently perform ADLs, and a high risk of suicide

Sclerosing abnormal tissue hardening of the veins

Seasonal affective disorder a type of depression experienced during the dark winter months

Seborrhea skin condition characterized by overproduction of sebum by the oil glands

Second messenger cascade of biochemical events that initiates a drug's action by either stimulating or inhibiting a normal activity of the cell

Secondary hypertension hypertension having a specific identifiable cause

Secretion in the kidney, movement of substances from the blood into the tubule after filtration has occurred

Sedative–hypnotic drug with the ability to produce a calming effect at lower doses and sleep at higher doses

Sedatives substances that depress the CNS and cause drowsiness or sleep

Seizure symptom of epilepsy characterized by abnormal neuronal discharges within the brain

Selective estrogen receptor modulators (SERMs) drugs that produce an action similar to estrogen in body tissues; used for the treatment of osteoporosis in postmenopausal women

Semielemental (oligomeric) formulas enteral solutions that contain larger molecules than elemental products and a higher percentage of fat

Sentinel event a risk to patient safety that may result in death, permanent harm, or severe temporary harm

Serotonin a natural neurotransmitter that is found in high concentrations in the hypothalamus, limbic system, medulla, and spinal cord

Serotonin syndrome (SES) set of symptoms associated with overmedication with antidepressants that includes altered mental status, fever, hypertension, tremors, sweating, and lack of muscular coordination

Shingles herpes zoster infection caused by reactivation of the varicella-zoster virus or chickenpox

Short stature height below the fifth percentile for age and gender, or more than two standard deviations below the mean (average) for age and gender

Side effects types of drug effects that are less serious than adverse effects, are predictable, and may occur even at therapeutic doses

Silent ischemia myocardial ischemia that occurs in the absence of pain

Simple partial seizures seizures that have an onset that may begin as a small, regional focus, and subsequently progress to a generalized seizure

Sinus rhythm number of beats per minute normally generated by the SA node

Situational anxiety anxiety experienced by people faced with a temporarily stressful environment

Sjögren's syndrome chronic autoimmune disorder characterized by excessive dryness of mucous membranes

Sleep attacks sudden bouts of sleep that last 10 to 30 minutes and may occur during the daytime without warning

Sleep paralysis the temporary inability to move after waking up from sleep

Small volume nebulizer machine that delivers medication as a fine mist for the purpose of inhalation; also called nebulizer

Smallpox serious, contagious potentially fatal disease that is caused by the variola virus

Social anxiety disorder unreasonable and persistent fear of crowds or of being judged, ridiculed, or embarrassed by others; also called social phobia

Somatic nervous system nerves that provide for voluntary control of the skeletal muscles

Somatostatin hormone released by the hypothalamus, stomach, intestine, and pancreas that inhibits the effects of growth hormone and lowers acid secretion; also known as growth hormone-inhibiting hormone

Specialty supplements dietary products used to enhance or complement a specific function in the body, such as supporting joint health or immune function. These supplements form a diverse group of products obtained from plant and animal sources that include probiotics, fish oils, amino acids, and enzymes

Spermicides drugs that kill sperm

Sporozoite mature and infective form of *Plasmodium* that resides in the gut of the female *Anopheles* mosquito

Stable angina type of angina that occurs in a predictable pattern of frequency, intensity, and duration, usually relieved by rest

Staging the process of determining where a cancer is located and the extent of its invasion

Status asthmaticus emergency situation in which acute asthma attacks are unresponsive to drug treatment; may lead to respiratory failure

Status epilepticus medical emergency that occurs when a seizure continues for more than 30 minutes or when two successive seizures occur without full recovery of consciousness between seizures

Steatorrhea the passing of bulky, foul-smelling fatty stools

Steroids types of lipids consisting of a ring structure

Sterol nucleus ring structure common to all steroids

Strategic National Stockpile (SNS) national repository of antibiotics, chemical antidotes, antitoxins, antiviral drugs and other essential medical supplies for use in a major health emergency

Striatum location in the brain where dopamine encounters its receptors and produces multiple actions

Stroke volume amount of blood pumped by a ventricle in a single contraction

Substance abuse self-administration of a drug that does not conform to the medical or social norms within the patient's given culture or society

Substantia nigra location in the brain where dopamine is produced that is responsible for regulation of unconscious muscle movement

Substrate drug that is metabolized by a CYP450 enzyme

Suicide the intentional act of ending one's life

Supercoil the highly twisted arrangement of the helix in bacterial DNA

Superinfections new infections caused when an antibiotic kills the host's normal flora, making additional space and nutrients available for pathogenic organisms to grow unchecked

Supplements additional vitamins or minerals that some people take to complement their diets by providing missing nutrients

Surgical anesthesia stage 3 of anesthesia, in which most major surgery occurs

Svedberg unit a unit of measurement represented by the letter "S" that indicates the size or sedimentation rate of the bacterial 70S ribosome

Sympathetic nervous system portion of the autonomic nervous system that is activated under emergency conditions or stress and produces a set of actions called the fight-or-flight response

Sympathomimetics drugs that activate adrenergic receptors in the sympathetic nervous system

Symporter a membrane protein that transports two molecules at the same time

Synapse a junction between two neurons or a neuron and a muscle

Synaptic cleft space where neurotransmitters enter that must be crossed for the impulse to reach the postganglionic neuron or organ

Syndrome of inappropriate antidiuretic hormone (SIADH) condition characterized by marked fluid retention, elevated urine osmolality, low serum osmolality, and sodium loss in the urine

Synergistic effect type of drug interaction in which two drugs produce an effect that is much greater than would be expected from simply adding the two individual drugs' responses

T

T cells types of lymphocytes that are essential for the cell-mediated immune response

Tachydysrhythmias disorders exhibiting a heart rate greater than 100 beats/min

Tachyphylaxis the rapid development of tolerance to any action of a drug, either adverse or therapeutic effects

Tardive dyskinesia (TD) unusual tongue and face movements such as lip smacking, rapid eye blinking, and wormlike motions of the tongue that occur during pharmacotherapy with certain antipsychotics

Target cells cells affected by hormones

Targeted therapies drugs that block the growth, progression, and spread of cancer by interfering with a molecular process that is specific to the cancer cell

Telomerase an enzyme contained in certain human stem cells that can lengthen the DNA chains and allow continued replication

Telomeres regions in chromosomes that prevent the vital sequences of DNA from being destroyed each time a cell divides

Tension headache common type of head pain caused by stress and relieved by over-the-counter analgesics

Teratogen agent that causes birth defects

Tetrahydrocannabinol (THC) the active chemical in marijuana

Therapeutic classification method of organizing drugs on the basis of what condition is being treated by the drug

Therapeutic drug monitoring practice of monitoring plasma levels of drugs that have low safety profiles and using the data to predict drug action or toxicity

Therapeutic index (TI) the ratio of a drug's LD_{50} to its ED_{50}

Therapeutic range dosage that produces the desired effects of a drug

Threshold potential an action potential triggered by the membrane potential during myocardial electrical conduction

Thrombin enzyme that causes clotting by catalyzing the conversion of fibrinogen to fibrin

Thrombocytopenia coagulation disorder in which there is a deficiency of platelets

Thromboembolic disorder condition in which the body forms undesirable clots

Thrombopoietin hormone that promotes the formation of platelets in the blood

Thyroid crisis a rare, life-threatening form of thyrotoxicosis; also called thyroid storm

Thyroid storm see Thyroid crisis

Thyroid-stimulating hormone (TSH) hormone secreted by the anterior pituitary when stimulated by thyrotropin-releasing hormone

Thyroid-stimulating immunoglobulins (TSIs) stimulate the thyroid gland in Graves' disease

Thyrotoxicosis an acute condition caused by very high levels of circulating thyroid hormone

Thyrotropin-releasing hormone (TRH) hormone secreted by the hypothalamus when blood levels of thyroid hormone are low

Thyroxine (T_4) thyroid hormone that is synthesized from the amino acid tyrosine and 4 atoms of iodine

Thyroxine-binding globulin (TBG) a plasma protein produced in the liver

Tocolytics drugs used to delay preterm labor

Tolerance process of adapting to a drug over a period of time and subsequently requiring higher doses to achieve the same effect

Tonic–clonic seizures seizures characterized by intense muscle contractions and loss of consciousness

Tonicity the ability of a solution to cause a change in water movement across a membrane owing to osmotic forces

Tonometry technique that tests for glaucoma by measuring intraocular pressure

Topical route medications applied to the skin or the membranous linings of the eye, ear, nose, respiratory tract, urinary tract, vagina, and rectum

Topoisomerase IV in DNA replication, the enzyme that frees the newly formed interlocked strands, allowing them to migrate into the two daughter cells

Torsades de pointe type of ventricular tachycardia that is characterized by rates between 200 and 250 beats/min and "twisting of the points" of the QRS complex on the ECG

Total parenteral nutrition (TPN) nutrition provided through a peripheral or central vein

Toxic concentration level of drug that results in serious adverse effects

Toxoids type of vaccine that uses bacterial toxins that have been chemically modified to be incapable of causing disease

Trade name name assigned by the pharmaceutical company marketing a drug; sometimes called the proprietary, product, or brand name

Transdermal patches topical delivery method that uses patches that contain a specified amount of medication that is released over a specified time period

Transferrin protein complex that transports iron to sites in the body where it is needed

Translation basic steps in protein synthesis

Transplant rejection recognition by the immune system of a transplanted tissue as foreign and subsequent attack on the tissue

Tricyclic antidepressants (TCAs) class of drugs used in the pharmacotherapy of depression

Triglycerides types of lipids that contain three fatty acids attached to a chemical backbone of glycerol

Tri-iodothyronine (T_3) thyroid hormone that is synthesized from the amino acid tyrosine and 3 atoms of iodine

Trophozoite the active, growing stage during which a protozoan organism feeds, often at the expense of its host

Tropic hormones ability of the anterior pituitary gland hormones to regulate the secretory actions of other endocrine glands

Tubercles cavity-like lesions in the lung characteristic of infection by *Mycobacterium tuberculosis*

Tuberculosis (TB) a highly contagious infection caused by the organism *Mycobacterium tuberculosis*

Tularemia serious infectious disease found in rodents, rabbits, and hares that is caused by the organism *Francisella tularensis*

Tumor abnormal swelling, enlargement, or mass; also called neoplasm

Type 1 diabetes metabolic disorder characterized by hyperglycemia caused by a lack of secretion of insulin by the pancreas in which glucose cannot enter cells and fatty acids are used as the primary energy source

Type 2 diabetes chronic metabolic disease characterized by hyperglycemia and insulin resistance

Tyramine form of the amino acid tyrosine that is found in foods such as cheese, beer, wine, and yeast products

U

Unstable angina angina that occurs suddenly, has added intensity, and occurs during periods of rest

Up-regulation process by which cells create more receptors on their surface to capture hormone molecules

Urethritis infection of the urethra

Uricosurics drugs that increase the rate of excretion of uric acid by blocking its reabsorption in the kidney

Uropathogens harmful microorganisms that invade the urinary system

Urticaria hypersensitivity response that is characterized by hives and is often accompanied by pruritus (itching)

U.S. Food and Drug Administration (FDA) U.S. regulatory agency responsible for ensuring that drugs and medical devices are safe and effective

USP verification program mark on the label of a dietary supplement that indicates to consumers that the product has been manufactured under acceptable standards of purity, has been tested for active ingredients stated on the label, and is free of harmful contaminants

V

Vaccination process of introducing foreign proteins or inactive cells (vaccines) into the body to trigger immune activation before the patient is exposed to the real pathogen

Variant (Prinzmetal's) angina type of angina in which the decreased myocardial blood flow is caused by spasms of the coronary arteries; also called vasospastic angina

Vasomotor center cluster of neurons in the medulla that controls baseline blood pressure

Vectors organisms that harbor pathogens and spread several major protozoan infections by carrying them from one host to another

Venous return the volume of blood returning to the heart from the veins

Venous thromboembolism (VTE) occurs when blood flow through a vein is very slow (stasis)

Ventilation process of moving air into and out of the lungs

Very low-density lipoprotein (VLDL) primary carrier of triglycerides in the blood that is converted to LDL in the liver

Vesicants agents that can cause serious tissue injury if they escape from an artery or vein during an infusion or injection; many antineoplastics are vesicants

Viral load a measurement of HIV RNA levels in the blood that provides an estimate of how rapidly the virus is replicating

Virilization appearance of the male sex characteristics

Virion mature infective virus particle

Virologic failure a plasma HIV RNA level that rises above 200 copies/mL during HIV treatment

Virulence quantitative measure of an organism's pathogenicity

Viruses nonliving agents that do not contain any of the cellular organelles that are present in living organisms that are able to cause disease

Vitamins organic nutrient substances required for the health of the human body

Vomiting emesis in which the stomach contents are forced upward into the esophagus and out of the mouth

Vomiting center area in the medulla that controls the vomiting reflex

von Willebrand's disease (vWD) decrease in quantity or quality of von Willebrand factor

W

Water-soluble vitamins group of vitamins stored briefly in the body and then excreted in the urine, including the C and B-complex vitamins

Wearing-off effect appears gradually near the end of a dosing interval; symptoms become worse because the concentration of the drug has fallen below the therapeutic level

Withdrawal syndrome symptoms that result when a patient discontinues taking a substance on which he or she was dependent

X

Xanthine oxidase enzyme responsible for the formation of uric acid

Xerostomia dry mouth

Z

Zollinger-Ellison syndrome (ZES) disorder of excess acid secretion in the stomach resulting in peptic ulcer disease

Weight Gain in Children Prescribed Antipsychotic Drugs 297

Prototype Drugs

abciximab (ReoPro) 677
acarbose (Precose) 1220
acetaminophen (Tylenol) 735
acetazolamide (Diamox) 554
activated charcoal (CharcoAid) 1418
acyclovir (Zovirax) 980
adalimumab (Humira) 1350
albuterol (Proventil HFA, Ventolin HFA, VoSpire ER) 792
aldesleukin (Proleukin) 746
alendronate (Fosamax) 1340
allopurinol (Lopurin, Zyloprim) 1357
alteplase (Activase) 681
aluminum hydroxide (AlternaGEL, Others) 1095
amantadine (Symmetrel) 984
aminocaproic acid (Amicar) 684
amiodarone (Pacerone) 653
ammonium chloride 577
amphetamine and dextroamphetamine (Adderall, Adderall XR) 380
amphotericin B deoxycholate (Fungizone) 939
ampicillin 854
aripiprazole (Abilify) 297
aspirin (Acetylsalicylic Acid) 728
atenolol (Tenormin) 611
atomoxetine (Strattera) 382
atorvastatin (Lipitor) 496
atropine (Atropen) 174
azathioprine (Azasan, Imuran) 753
basiliximab (Simulect) 755
beclomethasone (Beconase AQ, Qvar) 797
benzocaine (Americaine, Anbesol, Others) 1384
benztropine (Cogentin) 314
bethanechol (Urecholine) 159
buprenorphine with naloxone (Suboxone, Zubsolv, Others) 454
caffeine 386
calcitriol (Calcijex, Rocaltrol) 1338
calcium salts 1333
carbamazepine (Carbatrol, Tegretol, Others) 346
cefazolin (Ancef, Kefzol) 858
celecoxib (Celebrex) 734
chloroquine (Aralen) 956
chlorpromazine 290
cholestyramine (Questran) 500
ciprofloxacin (Cipro) 891
clomiphene (Clomid, Serophene) 1281
clopidogrel (Plavix) 675
colchicine (Colcrys) 1356
conjugated estrogens (Cenestin, Enjuvia, Premarin) 1265
cromolyn 799
cyanocobalamin (Nascobal) 708
cyclobenzaprine (Amrix) 363
cyclophosphamide (Cytoxan) 1038
cyclosporine (Gengraf, Neoral, Sandimmune) 751
dabigatran (Pradaxa) 671
dantrolene (Dantrium, Revonto) 366
dapsone (DDS) 929
desmopressin (DDAVP, Noctiva, Stimate) 1194
dextran 40 (Gentran 40, Others) 567
dextromethorphan (Delsym, Robitussin DM, Others) 826
5% dextrose in water (D_5W) 566
diazepam (Valium) 342
digoxin (Lanoxin, Lanoxicaps) 632
dimercaprol (BAL in Oil) 1419
diphenoxylate with atropine (Lomotil) 1110
disulfiram (Antabuse) 457
donepezil (Aricept) 319
doxorubicin (Adriamycin) 1048
edetate calcium disodium (Calcium EDTA) 1419
efavirenz (Sustiva) 1006
epinephrine (Adrenalin) 190
epoetin alfa (Epogen, Procrit) 693
erythromycin (EryC, Erythrocin, Others) 875
estradiol and norethindrone (Ortho-Novum, Others) 1292
ethosuximide (Zarontin) 347
fentanyl (Sublimaze) 425
ferrous sulfate (Feosol, Feostat, Others) 705
fexofenadine (Allegra) 816
filgrastim (Granix, Neupogen, Zarxio) 697
finasteride (Proscar) 1322
fluconazole (Diflucan) 941
fludrocortisone 1257
fluoxetine (Prozac) 261
fluticasone (Flonase, Veramyst) 818
furosemide (Lasix) 546
gabapentin (Neurontin) 348
gemfibrozil (Lopid) 502
gentamicin (Garamycin, Others) 878
glucagon (GlucaGen) 1205
glyburide (DiaBeta, Glynase) 1215
haloperidol (Haldol) 291
heparin 666
hepatitis B vaccine (Engerix-B, Recombivax HB) 770
human regular insulin (Humulin R, Novolin R) 1209
hydralazine 593
hydrochlorothiazide (Microzide) 549
hydrocortisone (Cortef, Solu-Cortef, Others) 1252
ibuprofen (Advil, Motrin, Others) 731
imipenem-cilastatin (Primaxin) 860
imipramine (Tofranil) 268
interferon alfa-2b (Intron A) 743
interferon beta-1b (Betaseron, Extavia) 322
ipratropium (Atrovent) 796
isoflurane (Forane) 432
isoniazid (INH) 922
isoproterenol (Isuprel) 195
latanoprost (Xalatan) 1393
levodopa and carbidopa (Sinemet, Parcopa) 308
levothyroxine (Levothroid, Levoxyl, Others) 1233
lidocaine (Anestacon, Xylocaine, Zingo, Others) 439
lisinopril (Prinivil, Zestril) 529
lithium carbonate (Eskalith, Lithobid) 274
lopinavir with ritonavir (Kaletra) 1008
lorazepam (Ativan) 238
losartan (Cozaar) 532
magnesium sulfate ($MgSO_4$) 574
mannitol (Osmitrol) 553
mebendazole (Vermox) 968
medroxyprogesterone (Depo-Provera, Depo-SubQ-Provera, Provera) 1269
metformin (Glucophage, Glumetza, Others) 1217
methotrexate (MTX, Rheumatrex, Trexall) 1044
metoprolol (Lopressor, Toprol XL) 211
metronidazole (Flagyl) 960
midazolam (Versed) 427
mifepristone (Mifeprex) 1302
milrinone (Primacor) 635
modafinil (Provigil) 384
montelukast (Singulair) 800
morphine sulfate (Astramorph PF, Duramorph RF, Others) 402
nifedipine (Adalat CC, Procardia XL) 515
nitrofurantoin (Furadantin) and nitrofurantoin macrocrystals (Macrobid, Macrodantin) 908
nitroglycerin (Nitrostat, Nitro-Bid, Others) 609
nitroprusside sodium (Nitropress) 595
nitrous oxide 430
nonoxynol-9 1298
normal serum albumin (Albuminar, Plasbumin, Others) 565
nystatin (Nystop) 946
octreotide (Sandostatin) 1190
omeprazole (Prilosec) 1090
ondansetron (Zofran, Zuplenz) 1123
oprelvekin (Neumega) 700
orlistat (Alli, Xenical) 1168
oxytocin (Pitocin) 1274
pancrelipase (Creon, Pancreaze, Zenpep) 1126
penicillin G 852
permethrin (Acticin, Elimite, Nix) 1369
phenelzine (Nardil) 270
phenobarbital (Luminal) 246
phenylephrine (Neo-Synephrine) 193
phenytoin (Dilantin, Phenytek) 344
potassium chloride (KCl) 572
pramipexole (Mirapex) 311
prazosin (Minipress) 205
procainamide 649
procaine (Novocaine) 438
propofol (Diprivan) 428
propranolol (Inderal, InnoPran XL) 208
propylthiouracil (PTU) 1238
pseudoephedrine (Sudafed) 823
psyllium mucilloid (Metamucil, Naturacil, Others) 1107
pyridostigmine (Mestinon, Regonol) 163
pyrimethamine (Daraprim) 964
raloxifene (Evista) 1343
ranitidine (Zantac) 1093
repaglinide (Prandin) 1218
Rho(D) immune globulin (RhoGAM) 776
risperidone (Risperdal) 293
rosiglitazone (Avandia) 1219
sildenafil (Viagra) 1317
sitagliptin (Januvia) 1221
sodium bicarbonate 576
sodium chloride (NaCl) 571
somatropin (Genotropin, Humatrope, Norditropin, Others) 1188
spironolactone (Aldactone) 551
succinylcholine (Anectine, Quelicin) 178
sulfasalazine (Azulfidine) 1115
sumatriptan (Imitrex, Onzetra) 415
tamoxifen 1053
tenofovir (Vemlidy, Viread) 989
testosterone 1311
tetracycline (Sumycin, Others) 872
theophylline 802
timolol (Betimol, Timoptic, Others) 1396
tramadol (Ultram, Others) 406
tretinoin (Avita, Retin-A, Others) 1373
trimethoprim-sulfamethoxazole (Bactrim, Septra) 907
valproic acid (Depacon, Depakene, Depakote) 349
vancomycin (Vancocin) 862
varenicline (Chantix) 464
venlafaxine (Effexor) 264
verapamil (Calan, Isoptin, Verelan) 517
vincristine (Marqibo, Oncovin) 1057
warfarin (Coumadin) 669
zidovudine (Retrovir, AZT) 1004
zolpidem (Ambien, Edluar, Others) 241
