articaine (Septocaine, Zorcaine)	Infiltration: 0.5–2.5 mL (20–100 mg) Nerve block: 0.5–3.4 mL (20–136 mg) Oral surgery: 1–5.1 mL (40–204 mg)	**Topical applications:** *Erythema, dermatitis, burning* **Infiltration, nerve block, epidural applications:** *Hypersensitivity, dizziness, drowsiness, urinary retention, fecal incontinence, slowing of labor, numbness of lips or tongue, hypotension, blurred or double vision* Laryngeal edema, bradycardia, anaphylactoid reaction, respiratory arrest, seizures, rectal bleeding (dibucaine)
bupivacaine (Exparel, Marcaine, Sensorcaine)	Local infiltration, sympathetic block: 0.25% solution Epidural, caudal, or retrobulbar block: 0.25–0.75% solutions Liposomal (Exparel): 8–20 mL of 1.3% solution	
dibucaine (Nupercainal)	Topical: Apply to skin 1 ounce q24h	
lidocaine (Anestacon, Xylocaine, Zingo, others)	Infiltration: 0.5–1% solution Nerve block or epidural: 1–2% solution Caudal: 1–1.5% solution Spinal: 5% solution with dextrose Saddle block: 1.5% with dextrose Topical: 2.5–5% jelly, ointment, cream, or solution	
mepivacaine (Carbocaine, Isocaine, Polocaine)	Subcutaneous: 1–5 cartridges, each containing approximately 1.8 mL (54 mg) of a 3% solution	
prilocaine (Citanest)	Infiltration: 1–2 mL (40–80 mg) of a 4% solution for dental use	
ropivacaine (Naropin)	Surgical anesthesia: Intrathecal administration: Epidural or nerve block: 5–250 mg (0.5–1% solution) Labor pain: 20–40 mg (0.2% solution) Postoperative pain management: Epidural: 12–20 mg/h (0.2% solution) Infiltration: 2–200 mg (0.2–0.5% solution)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

26.10 Ester-type local anesthetics have been widely used for topical and spinal anesthesia.

Cocaine was the first local anesthetic to be widely used for medical procedures. Cocaine is a natural ester found in the leaves of *Erythroxylum coca*, a plant native to the Andes Mountains in Peru. Cocaine was discovered by a German chemist in 1855 and ultimately used in 1884 as a topical eye anesthetic. Although still approved by the FDA as a local anesthetic, cocaine is a Schedule II controlled substance and is rarely used because of its high potential for abuse. In 1904 a German chemist named Einhorn discovered procaine (Novocaine), which soon came into widespread use, especially in dental offices.

Esters act by decreasing the amount of sodium that enters the neuron, thereby depressing depolarization and preventing conduction of the pain impulse. Esters may be administered with epinephrine as a vasoconstrictor to limit blood loss at the surgical site and to decrease the amount of anesthetic absorbed systemically. The local anesthetic effect of an ester is rapid, occurring in 1 to 8 minutes. The duration ranges from 15 to 60 minutes.

Ester-type anesthetics are generally safe when applied as directed. All can cause serious CNS and cardiac toxicity, however, if they reach the blood in high concentrations. The first CNS symptoms may be stimulatory: anxiety, nervousness, dizziness, tremor, or seizures.

Subsequent CNS depression may cause the patient to become drowsy, experience respiratory depression, and enter a coma. High amounts can cause dysrhythmias, QT prolongation, hypotension, and cardiac arrest. Care must be taken that the drug is administered correctly to prevent serious adverse effects.

PROTOTYPE DRUG **Procaine (Novocaine)**

Classification **Therapeutic:** Local anesthetic
Pharmacologic: Ester, sodium channel blocker

Therapeutic Effects and Uses: Procaine is used for spinal, epidural, and peripheral nerve blocks through injection or infiltration. It produces local anesthesia with loss of sensation close to the injection or application site. It has a short duration of action. An off-label use is for the treatment of severe pain due to cancer, herpes, or burns. Once used widely in dentistry, it has largely been replaced by other local anesthetics.

Procaine causes vasodilation, which could potentially increase its rate of absorption from tissues and cause systemic toxicity. Some procaine solutions contain small amounts of epinephrine, which constricts arteries to keep the procaine localized and prolong the anesthetic effect. The drug is rapidly metabolized to inactive metabolites by esterase, an enzyme found in the plasma. Once it reaches the plasma, the half-life of procaine is only 40 seconds.

Mechanism of Action: Procaine decreases the influx of sodium into the neuron, which increases the threshold for depolarization and prevents the conduction of the nerve impulse.

Pharmacokinetics:

Route(s)	Subcutaneous
Absorption	Rapid
Distribution	Not distributed; highly bound to plasma proteins
Primary metabolism	Metabolized by plasma esterase
Primary excretion	Renal: 80% as metabolites
Onset of action	2–5 min
Duration of action	1 h

Adverse Effects: With therapeutic doses, adverse effects are rare. Adverse events may occur, however, if multiple doses of procaine are administered or if it is injected intravascularly. The most severe adverse effects include respiratory arrest and anaphylaxis. A patient who has experienced an allergic reaction to procaine will likely be allergic to other esters. Myocardial depression may result in atrioventricular (AV) block dysrhythmias or cardiac arrest. CNS effects are stimulatory and usually transient; nervousness, dizziness, confusion, and tremor may occur. Spinal anesthesia with procaine can cause headache, palsies, spinal nerve paralysis, and meningism (nuchal rigidity, photophobia, and headache). Cutaneous lesions can occur in a delayed time frame. The caudal or epidural administration of procaine in the obstetric patient can result in urinary incontinence, loss of perineal sensation, slowing of labor, and increased incidence of forceps delivery.

Contraindications/Precautions: Patients who have experienced hypersensitivity to any ester anesthetic or agent containing para-aminobenzoic acid (PABA) should not receive procaine. Patients with generalized septicemia, inflammation, or sepsis should not be injected with procaine. It is also contraindicated in patients with heart block, hypotension, HTN, or altered coagulation. It should be used cautiously in older and acutely ill patients. Patients who have increased abdominal pressure should be administered procaine cautiously.

Drug Interactions: Ester anesthetics such as procaine may antagonize the antimicrobial effects of sulfonamides. Risk of hypotension increases when administered with antihypertensives. Procaine is incompatible with aminophylline, chlorothiazide, magnesium sulfate, phenobarbital, phenytoin, secobarbital, and sodium bicarbonate. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: The effects of procaine overdosage are treated symptomatically. Rapid systemic absorption will affect the cardiovascular system and could require cardiopulmonary resuscitation.

Nursing Responsibilities: Key nursing implications for patients receiving procaine are included in the Nursing Practice Application for Patients Receiving Local Anesthesia.

Drugs Similar to Procaine (Novocaine)

Other local anesthetic esters include benzocaine, chloroprocaine, and tetracaine.

Benzocaine (Americaine, Anbesol, others): Approved in 1938, benzocaine is an over-the-counter (OTC) local anesthetic ester applied topically as a lotion, cream, ointment, spray, gel, or otic solution. Chemically it is almost identical to procaine, but it has a prolonged duration of anesthetic action. It provides temporary relief of pain and discomfort due to sunburn, minor wounds, pruritus, serous otitis media, swimmer's ear, otitis externa, canker sores, sore throat, hemorrhoids, and anal fissures. It can be applied to the penis as a male desensitizer to slow the onset of ejaculation. Benzocaine preparations are commonly used as an anesthetic for the passage of catheters and endoscopic tubes. Onset of anesthetic action occurs in less than a

minute, and because absorption of benzocaine is minimal, systemic effects are rare. Contact dermatitis can occur and is more common with benzocaine than with some of the other topical anesthetics. Although rare, benzocaine sprays have been associated with serious methemoglobinemia, a condition in which hemoglobin is unable to bind sufficient oxygen. This drug is pregnancy category C.

Chloroprocaine (Nesacaine): Approved in 1957, chloroprocaine is a short-acting local anesthetic ester that is used for infiltration, epidural, and caudal anesthesia. It is not effective as a topical agent. Anesthesia occurs in 6 to 12 minutes and can last up to 90 minutes if epinephrine is added to the injection. A test dose is given before epidural use to assess for intravascular or subarachnoid injection. In the event of intravascular injection, the patient would experience an epinephrine response with tachycardia, circumoral pallor, palpitations, and nervousness. Signs of subarachnoid injection include motor paralysis and extensive sensory anesthesia. Like other ester anesthetics, allergic reactions such as rash, pruritus, and anaphylaxis are possible. This drug is pregnancy category C.

Tetracaine (Pontocaine): Tetracaine is a local anesthetic ester that is used in spinal anesthesia and topically. It may be used to anesthetize the conjunctiva during eye surgery and in the nose and throat to eliminate the laryngeal and esophageal reflexes. It is administered on the skin to relieve pruritus, pain, and burning. An OTC preparation (Viractin) is available for topical treatment of pain associated with cold sores and fever blisters. Onset of action is rapid for topical use (3–10 minutes) but longer following spinal administration (15 minutes). Of the topical anesthetics, tetracaine is the most likely to cause skin sensitivity, including rash, erythema, pruritus, burning, and edema. Systemic absorption can cause significant CNS and cardiac toxicity. Tetracaine is contraindicated in patients who are hypersensitive to ester-type anesthetics, sulfites, or PABA. This drug is pregnancy category C.

26.11 Local anesthetics from the amide class have a lower incidence of adverse effects than those from the ester class.

Amide-type local anesthetics have largely replaced the administration of drugs from the ester class. The amides produce less effect on myocardial contractility, and the incidence of allergic reactions is lower. Amides and esters have the same mechanism of action: decreasing the sodium flux into the neuron, thus inhibiting the initial depolarization and conduction of the nerve impulse. Whereas the esters are inactivated by the enzyme esterase in the plasma, the amides are metabolized by hepatic CYP450 enzymes. Caution should be exercised when administering large amounts of amide anesthetics to patients with hepatic impairment.

PROTOTYPE DRUG **Lidocaine (Anestacon, Xylocaine, Zingo, Others)**

Classification **Therapeutic:** Local anesthetic
Pharmacologic: Amide, sodium channel blocker

Therapeutic Effects and Uses: Lidocaine is a local anesthetic that has a prompt onset of action of 2 to 5 minutes. It has a longer duration of action than procaine, lasting 10 to 90 minutes, depending on its route of administration. It may be administered as a surface and infiltration anesthetic agent to block the nerve. It is also used in caudal and spinal block anesthesia to relieve local discomfort of the skin and mucous membranes. Lidocaine patches are administered to relieve pain related to post-herpetic neuralgia (Lidoderm) or dental procedures (DentiPatch). Parenteral lidocaine is administered to treat life-threatening ventricular dysrhythmias (see Chapter 37). Zingo (lidocaine hydrochloride monohydrate) is a needle-free intradermal injection system. Zingo is indicated for rapid local anesthesia for procedures such as IV insertions or blood draws.

Mechanism of Action: Lidocaine blocks the conduction of action potentials by reducing the sodium permeability, thus decreasing the action potential and slowing nerve conduction.

Pharmacokinetics:

Route(s)	Subcutaneous, IM, IV, IV bolus; topical
Absorption	Topical absorption: 3% through intact skin
Distribution	Crosses the blood–brain barrier and the placenta; secreted in breast milk
Primary metabolism	Hepatic via CYP3A4 and 2D6
Primary excretion	Renal
Onset of action	IV: 45–90 sec; IM: 5–15 min; topical: 2–5 min
Duration of action	IV: 10–20 min; IM: 60–90 min; topical: 30–60 min Half-life: 1.5–2 h

Adverse Effects: When used topically, adverse reactions to lidocaine are uncommon. Mild and transient reactions at the site of application include erythema, pruritus, dermatitis, and burning. The transoral DentiPatch may cause alterations in taste, headache, and gingivitis. Should the drug be unintentionally injected intravascularly, CNS adverse effects will be those of stimulation (anxiety, tremors, shivering, and seizures) followed by depression (drowsiness, respiratory depression, and coma). Cardiovascular effects include hypotension, dysrhythmias, cardiovascular collapse, and cardiac arrest.

Black Box Warning: Significant systemic absorption may occur with topical use.

Contraindications/Precautions: Patients who have experienced a hypersensitivity reaction to amide-type local anesthetics should not be administered lidocaine. Topical lidocaine should not be applied to skin seriously damaged by trauma, burns, or eczema.

Other precautions apply to patients receiving parenteral lidocaine, although these also apply to situations in which the drug is unintentionally injected intravascularly. Patients who have been diagnosed with Stokes–Adams syndrome, untreated sinus bradycardia, or sinoatrial, AV, or intraventricular heart block should not be administered lidocaine. The medication should be used cautiously in the presence of liver or kidney disease, myasthenia gravis, and hypovolemia as well as in debilitated patients and older patients or when there is a family history of malignant hyperthermia.

Drug Interactions: Lidocaine patches can cause toxic effects with tocainide and mexiletine. Barbiturates decrease lidocaine activity. Increased pharmacologic effects of lidocaine will be noted if it is administered with cimetidine, beta blockers, or quinidine. **Herbal/Food:** After receiving transoral lidocaine, patients should not eat or drink until the effects of the anesthesia have worn off.

Pregnancy: Category B.

Treatment of Overdose: Overdose may occur if the drug is injected intravascularly. The patient is treated through symptom management.

Nursing Responsibilities: Key nursing implications for patients receiving lidocaine are included in the Nursing Practice Application for Patients Receiving Local Anesthesia.

Drugs Similar to Lidocaine (Anestacon, Xylocaine, Zingo, Others)

Other local anesthetic amides include articaine, bupivacaine, dibucaine, mepivacaine, prilocaine, and ropivacaine. The amides levobupivacaine (Chirocaine) and etidocaine (Duranest) have been removed from the U.S. market.

Articaine (Septocaine, Zorcaine): Approved in 2000, articaine is approved for administration by infiltration or by nerve block for dental procedures. It is unique because it has both an amide and an ester group. Anesthesia is rapid, occurring in 1 to 6 minutes, and lasts up to an hour. Articaine appears to diffuse through soft tissue and bone better than other local anesthetics. It is combined with epinephrine, which provides vasoconstriction and prolongs the duration of action. The adverse effects are the same as those of other amide anesthetics. This drug is pregnancy category C.

Bupivacaine (Exparel, Marcaine, Sensorcaine): Approved in 1972, bupivacaine is an amide local anesthetic that is used for infiltration anesthesia, peripheral sympathetic nerve block, and epidural block. Bupivacaine in dextrose solution is administered for spinal anesthesia. Its 3- to 9-hour duration of action is one of the longest of any local anesthetic. A liposomal form (Exparel) provides analgesia for up to 72 hours. The anesthetic is injected into the surgical area for procedures such as bunionectomy and hemorrhoidectomy. Adverse effects are similar to those of other amide anesthetics. This drug is pregnancy category C.

Dibucaine (Nupercainal): Approved in 1947, dibucaine is administered to relieve pain and itching related to hemorrhoids and other anorectal disorders. It is also administered to relieve discomfort from insect bites, sunburn, minor burns, cuts, and scratches. It is a long-acting amide anesthetic that inhibits the initiation and conduction of nerve impulses by reducing the permeability of nerve cells to sodium ions. It is available OTC. This drug is pregnancy category C.

Mepivacaine (Carbocaine, Isocaine, Polocaine): Approved in 1960, mepivacaine is an amide anesthetic used for infiltration, transtracheal anesthesia, and epidural nerve blocks in surgical and dental procedures. Onset of action is very rapid—less than a minute for the upper and lower jaws. Epidural onset is 7 to 15 minutes. This drug has an intermediate duration of action of 60 to 100 minutes for soft tissue and 115 to 150 minutes for epidural. Mepivacaine is sometimes combined with levonordefrin, a vasoconstrictor that prolongs the duration of action of the local anesthetic. The adverse effects are the same as those of other amide anesthetics. This drug is pregnancy category C.

Prilocaine (Citanest): Approved in 1965, prilocaine is used for dental anesthesia via infiltration. Onset of action is 2 minutes and its duration is 1 to 2 hours. The adverse effects are the same as those of other amide anesthetics. This drug is pregnancy category B.

Ropivacaine (Naropin): Ropivacaine is a newer local anesthetic agent approved in 1996 that is used in epidural anesthesia and postoperative pain management. It has an onset of action of 1 to 30 minutes and a duration of anesthetic action of 2 to 6 hours. It is important that disinfecting agents with heavy metal content not be used to disinfect the skin prior to the insertion of the epidural catheter because these have been associated with swelling and edema. Also, the container of ropivacaine should not be cleaned with a heavy metal disinfecting agent. Unlike most local anesthetics, the presence of epinephrine does not affect the systemic absorption of ropivacaine. Like other amide anesthetics, high serum concentrations may cause serious CNS and cardiac toxicity; care must be taken

not to inject the drug intravascularly or intrathecally. This drug is pregnancy category B.

Adjuncts to Anesthesia

26.12 Adjunctive agents are used during the perioperative phase to enhance anesthesia or to treat the potential adverse effects of the anesthetics.

Surgery is often a stressful and painful procedure for patients. In addition, anesthetics dampen vital reflexes, which can lead to aspiration pneumonia. Diminished autonomic function can have serious adverse effects on the cardiovascular and gastrointestinal (GI) systems. Adjunctive medications are those used to enhance anesthesia or to make the procedure safer and less unpleasant for patients.

Preoperative medications: The most common preoperative symptom is anxiety. Oral benzodiazepines may be given for several days prior to a major procedure to lessen anxiety. Just prior to surgery, midazolam (Versed) may be administered parenterally to sedate the patient and to cause perioperative amnesia (see Section 26.5).

Aspiration pneumonia is a potentially serious problem during a surgical procedure because the patient may lose protective airway reflexes. Histamine (H_2) receptor antagonists such as ranitidine (Zantac) or famotidine (Pepcid) can reduce the possibility of aspiration pneumonia by decreasing gastric fluid volume and reducing acidity. For aspiration prophylaxis, the H_2 receptor antagonist may be given PO the night prior to surgery and by IV infusion an hour before the procedure. A drug prototype feature for ranitidine is found in Chapter 59.

Anticholinergics such as atropine may be administered prior to surgery to reduce salivary and airway secretions. Atropine also blocks the bradycardia caused by some anesthetics. The drug is given by the IM route 45 to 60 minutes prior to anesthesia. A prototype feature for atropine is presented in Chapter 14.

Pain management: Pain reduction is an important component of preanesthesia and postanesthesia care. Opioids are used when the pain is expected to be severe, but these drugs can cause significant respiratory depression. If the pain level is moderate or mild, nonsteroidal anti-inflammatory drugs (NSAIDs) are administered because they cause fewer serious adverse reactions than the opioids. Clonidine (Catapres, Duraclon) is a centrally acting alpha$_2$-adrenergic agonist that has been used to reduce severe pain associated with surgery. When administered epidurally Duraclon allows the dosages of the anesthetic and opioids to be reduced. The primary indication of clonidine is HTN (Catapres), but it has largely been replaced by safer antihypertensives (see Chapter 34).

Neuromuscular blockers: Skeletal muscle relaxation is an important component of general anesthesia. Insertion of an endotracheal tube would be difficult and painful without muscle relaxation, and contraction or spasticity of muscles during a surgical procedure could render some operations impossible. Complete paralysis of muscle is necessary for major surgical procedures. Although some of the general anesthetics do have mild to moderate ability to relax skeletal muscles, most are incapable of causing the degree of relaxation necessary for surgery.

It is important to note that neuromuscular blockers do not enter the CNS. Although these drugs cause muscle paralysis, they do not induce unconsciousness or provide analgesia. The patient is still able to feel pain and is aware of his or her surroundings.

The nondepolarizing neuromuscular blocking agents such as atracurium (Tracrium) and cisatracurium (Nimbex) have a short duration of action and bind competitively with acetylcholine to produce skeletal muscle relaxation. The depolarizing neuromuscular blocking agents such as succinylcholine (Anectine) are ultra-short acting and possess a high affinity for the acetylcholine receptor sites.

The neuromuscular blocking agents are very dangerous; the diaphragm and intercostal muscles are paralyzed and breathing requires a mechanical ventilator. Serious cardiovascular adverse effects are possible. Details of the actions, indications, and adverse effects of the neuromuscular blockers are included in Chapter 14. A prototype feature for succinylcholine is included in that chapter.

Postoperative medications: Because many anesthetics induce severe nausea and vomiting in the postanesthesia phase, the administration of antiemetic drugs is indicated for prophylaxis in high-risk patients or for treatment. Several drugs have been used as antiemetics. Promethazine (Phenergan) is an older antiemetic that may be administered pre- or postoperatively. It has the advantage of also being a sedative; thus it can be used in the induction phase of anesthesia. Also an older medication, metoclopramide (Reglan), may be administered near the end of the surgical procedure for prophylaxis of postanesthetic nausea and vomiting. A newer and very effective antiemetic is ondansetron (Zofran, Zuplenz), a 5-HT$_3$ antagonist. Commonly used to prevent the acute nausea and vomiting caused by cancer chemotherapeutic agents, ondansetron may be injected just prior to chemotherapy or 30 minutes before the end of the surgical procedure.

CONNECTION Checkpoint 26.3

Atropine and succinylcholine are both cholinergic blockers but they produce very different effects. From what you learned in Chapter 14, explain the mechanisms for the differences in pharmacologic actions. (*Hint:* One drug affects the muscarinic receptor and the other the nicotinic receptor.) *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Local Anesthesia

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, hepatic, renal, respiratory, or neurologic disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. If the patient reports allergy to "caine" drugs, note the specific drug and reactions the patient experienced. Be alert to possible drug interactions.
- Obtain baseline vital signs and weight.
- Assess for areas of broken skin, abrasions, burns, or other wounds in the area to be treated with a local anesthetic.
- Evaluate laboratory findings appropriate to the procedure (e.g., CBC, electrolytes, hepatic or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., local or regional area numbness).
- Assess vital signs, especially blood pressure and pulse, if regional block is used. Report a blood pressure less than 90/60 mmHg, pulse above 100 beats/min, or per the parameters as ordered by the healthcare provider.
- Assess the local or regional area blocked. Expect blanching in the localized area if the local anesthetic contained epinephrine. If a regional area was blocked, periodically assess the patient's ability to move limbs distal to the block.
- Assess level of consciousness if a large regional block was given. Report any increasing drowsiness, dizziness, lightheadedness, confusion, or agitation immediately.
- Assess for and promptly report adverse effects: bradycardia or tachycardia, hypotension or HTN, or dyspnea.

Implementation

Interventions and (Rationales)	Patient-Centered Care

Ensuring therapeutic effects:
• Continue assessments as above for therapeutic effects. Assess the localized area for numbness and blanching if the local anesthetic included epinephrine. Assess the patient's ability to move limbs distal to the regional anesthetic. (Duration of anesthetic action will depend on the solution used and whether it contains epinephrine. If a large regional area is blocked [e.g., epidural], the patient may regain some motor ability before sensation returns and the return of motor activity signals decreasing levels of anesthesia. An ability to perceive pressure-type sensations may remain during anesthesia and may be alarming to the patient. Epinephrine in the anesthetic solution will constrict localized blood vessels and result in blanching of the area.)
	• Teach the patient that:
	  • The area may be numb for several hours after the procedure is completed.
	  • It is normal that a slight pressure sensation may remain during anesthesia (e.g., sensation of "tugging" during suturing) but that no pain should be felt. Have the patient alert the healthcare provider if more than slight pressure sensation or any pain is noticed during anesthesia.
	  • It is normal to regain some ability to move limbs (e.g., after epidural anesthetic), and movement may return before the ability to feel the movement.

Minimizing adverse effects: • Continue to monitor vital signs, especially blood pressure and pulse, for patients given regional anesthesia. Report blood pressure below 90/60 mmHg or per the parameters as ordered by the healthcare provider, tachycardia, bradycardia, changes in level of consciousness, dyspnea, or decrease in respiratory rate, immediately. (Adverse effects of local anesthesia are rare. Regional blocks may cause hypotension with the possibility of reflex tachycardia. Be particularly cautious with older adults who are at increased risk for hypotension due to physiologic changes related to aging or concurrent vasoactive drug use. Bradycardia, hypotension, decreased level of consciousness, decreased respiratory rate, and dyspnea may signal that the anesthesia has entered the systemic circulation and is acting as a general anesthetic.)	• Instruct the patient to report any increasing nausea, drowsiness, dizziness, lightheadedness, confusion, or anxiety immediately. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• **Diverse Patients:** Continue to monitor hepatic function and drug effects. (Because amide anesthetics such as lidocaine are metabolized through the CYP450 system, they may result in less than optimal results based on differences in enzymes.)	• Teach ethnically diverse patients to observe and report effects of local anesthetic use to ensure therapeutic results.
• Caution the patient not to eat, chew gum, or drink until mouth sensation has returned if local (dental) or oral or throat anesthesia has been used. If throat anesthesia is used, assess gag reflex before eating. (Local anesthetics are effective for up to 3 h or more. Biting injuries to oral mucous membranes may occur while tissue is numb. Aspiration of food or liquids is possible until swallowing sensation and gag reflex return.)	• Instruct the patient to refrain from eating or drinking for 1 h or more postanesthesia, or until sensation has completely returned to the oral cavity or throat.
• Ensure patient safety; monitor motor coordination and ambulation post-regional block until certain that motor movement is unaffected. **Lifespan:** Be particularly cautious with older adults who are at increased risk for falls. (Numbness or effects on motor ability post-regional anesthetic may impair movement and increase the risk of falls or injuries.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone post-epidural block, and to avoid driving or other activities requiring physical coordination (e.g., regional upper limb block) until residual effects of the drug are known.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Assess areas of abrasion, burns, or open wounds if a local anesthetic is applied to area. (Large open or denuded areas may increase the amount of drug absorption into the general circulation. Use sterile technique to apply the drug to open areas.)	• Instruct the patient to report increased redness, swelling, or drainage from open areas under treatment.
• Read all labels carefully before using parenteral solutions. (Solutions containing epinephrine must *never* be used IV or for local anesthesia in areas of decreased circulation [e.g., fingertips, toes, earlobes, tip of nose, penile tissue] due to vasoconstrictive effects.)	• Provide an explanation of desired effects of the local anesthetic and the need for postprocedure monitoring.
• Monitor pain relief in patients post-regional block (e.g., epidural). (Pain sensation will increase as the regional block wears off. Additional pain relief may be required.)	• Teach the patient to report any discomfort or pain as anesthesia wears off.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, anticipated sensations, adverse effects to observe for, and when to report them.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug as prescribed when needed. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Teach the patient to take oral medication (e.g., lidocaine viscous) by swishing and spitting if used for oral cavity, or by gargling, and do not swallow unless directed by the healthcare provider. Apply topical medication in a thin layer to the skin area as directed.

Understanding Chapter 26

Key Concepts Summary

26.1 Anesthesia is used to produce a controlled loss of sensation during a diagnostic or surgical procedure.

26.2 Balanced anesthesia uses multiple drugs to provide for the safe induction and maintenance of general anesthesia.

26.3 Intravenous anesthetics include opioids, benzodiazepines, and several miscellaneous agents.

26.4 Opioids are used as intravenous anesthetics to provide analgesia and to accomplish neurolept anesthesia.

26.5 Benzodiazepines are used in anesthesia to produce relaxation, sedation, and amnesia.

26.6 Propofol and ketamine are widely used intravenous drugs for inducing and maintaining anesthesia.

26.7 Inhalation anesthetics used to produce loss of consciousness are classified as gases or volatile liquids.

26.8 Volatile liquid general anesthetics are used to induce and maintain deep anesthesia.

26.9 Local anesthetic agents block pain transmission in peripheral nerves and are grouped in two major classes.

26.10 Ester-type local anesthetics have been widely used for topical and spinal anesthesia.

26.11 Local anesthetics from the amide class have a lower incidence of adverse effects than those from the ester class.

26.12 Adjunctive agents are used during the perioperative phase to enhance anesthesia or to treat the potential adverse effects of the anesthetics.

CASE STUDY: Making the Patient Connection

Remember the patient "Elena Moore" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Elena is a 37-year-old woman who is scheduled for a vaginal hysterectomy after a positive Pap smear returned with results suggestive of cancer. While in the holding area of the operating room suite, she states that she is fearful of general anesthesia. The preoperative nurse caring for this patient notices that she is very anxious. Upon further assessment and conversation, she states that her mother died of breast cancer when she was young.

The patient's vital signs are as follows: blood pressure, 138/88 mmHg; temperature, 36.3°C (97.4°F); pulse, 94 beats/min; and respiration, 20 breaths/min. She denies pain and states that she is concerned she will wake up during the surgery. She is to receive balanced anesthesia.

Critical Thinking Questions

1. In your own words, how would you describe balanced anesthesia to Elena?
2. How does nitrous oxide differ from IV anesthetic agents?
3. How should the nurse educate a patient regarding the use of IV propofol?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Anthony Holiday is a 28-year-old steelworker for a heating and cooling company. While on the job he cut his right hand with a piece of steel for an air-conditioning vent. He is admitted to the emergency department for sutures to the right middle finger and palm. The laceration will be anesthetized with lidocaine prior to suturing.

1. What is the action of lidocaine?
2. Why is lidocaine preferred over procaine?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The surgical nurse becomes alerted that the patient who is receiving general anesthesia has become excitable and hyperactive with irregular heart and respiratory rates. The nurse knows that the patient has entered which stage of general anesthesia?
    1. Stage 1
    2. Stage 2
    3. Stage 3
    4. Stage 4

2. The nurse should question the administration of propofol (Diprivan) for which patient? An individual with:
    1. Allergy to eggs or soy products.
    2. Allergy to iodine.
    3. Kidney disease.
    4. Addison's disease.

3. During the administration of nitrous oxide, the patient develops anxiety, excitement, and combativeness. The nurse would anticipate what change in the patient's anesthesia is needed?
    1. The nitrous oxide dose will be increased.
    2. Propofol (Diprivan) will be given along with the nitrous oxide.
    3. Succinylcholine (Anectine) will be given to the patient.
    4. The nitrous oxide dose will be decreased.

4. The nurse is providing the patient, who will be receiving ketamine (Ketalar), with preoperative instructions. Which statement, if made by the patient, indicates that teaching is successful?
    1. "The medication will decrease anxiety during surgery."
    2. "I will experience increased energy due to this drug."
    3. "I may experience a feeling of being separated from the environment."
    4. "The drug will cause me to have dry mouth after the operation."

5. The patient who is having a scalp laceration sutured will be receiving local anesthesia with lidocaine (Xylocaine) that contains epinephrine. The nurse knows that the purpose of this drug combination is to:
   1. Increase the duration of the anesthetic action.
   2. Increase vasodilation at the site of the laceration.
   3. Decrease blood pressure in individuals who are hypertensive.
   4. Ensure that infection at the wound site will not occur.
6. Identify the general anesthetic agents that are parenteral opioid agents. (Select all that apply.)
   1. Nitrous oxide
   2. Alfentanil (Alfenta)
   3. Sufentanil (Sufenta)
   4. Remifentanil (Ultiva)
   5. Succinylcholine (Anectine)

Chapter 27
Pharmacology of Substance Abuse

Chapter Outline

- Fundamental Concepts of Substance Abuse
  - Legislation of Controlled Substances
  - Addiction and Dependence
  - Tolerance
- Central Nervous System Depressants
  - Sedatives and Antianxiety Drugs
  - Opioids
  - **PROTOTYPE** *Buprenorphine with Naloxone (Suboxone, Zubsolv, Others), p. 454*
  - Alcohol (Ethanol)
  - **PROTOTYPE** *Disulfiram (Antabuse), p. 457*
- Marijuana and Related Substances
- Hallucinogens
  - LSD and Similar Hallucinogens
  - Club Drugs and Miscellaneous Hallucinogens
- Central Nervous System Stimulants
  - Amphetamines and Methylphenidate
  - Cocaine
  - Caffeine
- Nicotine
  - **PROTOTYPE** *Varenicline (Chantix), p. 464*
- Inhalants
- Anabolic Steroids

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the types of substances abused by individuals.
2. Identify the five drug schedules of controlled substances and give examples of drugs in each schedule.
3. Explain major legislation regulating controlled substances in the United States.
4. Identify factors contributing to addiction.
5. Compare and contrast physical and psychologic dependence.
6. Compare and contrast withdrawal syndromes for the different classes of abused substances.
7. Discuss the significance of drug tolerance to pharmacology.
8. Explain the major characteristics of abuse, dependence, and tolerance resulting from use of the following substances: sedatives, opioids, alcohol, marijuana, hallucinogens, club drugs, amphetamines, methylphenidate, cocaine, caffeine, nicotine, inhalants, and anabolic steroids.
9. Identify the role of the nurse in recognizing, preventing, and treating substance abuse.

Key Terms

anterograde amnesia, 452
club drug, 460
cross-tolerance, 452
delirium tremens, 456
hallucinogens, 459
physical dependence, 450
psychologic dependence, 450
rebound effects, 450
reticular formation, 461
sedatives, 452
substance abuse, 448
tachyphylaxis, 452
tetrahydrocannabinol (THC), 458
tolerance, 451
withdrawal syndrome, 450

Throughout history individuals have consumed substances to increase performance, assist with relaxation, induce spiritual visions, or simply fit in with their peer group. **Substance abuse** is the self-administration of a drug in a manner that does not conform to the norms within the individual's given culture or society. The term *substance abuse* is preferred over the term *drug abuse*, because some of these agents are not considered to be drugs by the users. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), no longer uses the terms *substance abuse* and *substance dependence*; rather it refers to *substance use disorder* (American Psychiatric Association, 2013). It defines substance use as mild, moderate, or severe depending on the number of diagnostic criteria met by an individual. According to the DSM-5, a diagnosis of substance use disorder is based on evidence of impaired control, social impairment, risky use, and pharmacologic criteria. However, because most nurses are still familiar with the term *substance abuse*, that term will continue to be used in this chapter.

This chapter introduces the types of drugs commonly abused by patients and the pharmacologic management of withdrawal syndromes.

Fundamental Concepts of Substance Abuse

27.1 A wide variety of substances may be abused by patients.

Characteristics of substance abuse vary widely from drug to drug and person to person. Diagnosis of this disorder is often difficult, even for experienced healthcare providers. Recognition of abuse is relatively easy for substances such as heroin, cocaine, or hallucinogens. However, what about legal substances such as alcohol, tobacco, or marijuana (in some states)? How many beers must one drink or cigarettes must one smoke before it is labeled as substance abuse? And with legal prescription drugs, is it considered substance abuse if a patient continues to refill prescriptions, such as oxycodone, even after symptoms have resolved? It is apparent that, with the exception of certain illegal substances, the distinction among proper use, misuse, and substance abuse is often not clear.

Certain characteristics, however, assist in the proper diagnosis of substance abuse. Nurses should be aware of these characteristics because they may be the first to recognize the following when obtaining a patient history:

- Craving for a specific substance despite an understanding that the substance is lowering the patient's quality of life (physical dependence)
- Failure to maintain normal work or home relationships because a substance is being used repeatedly
- Recognition that, over time, increased amounts of the substance are needed to produce the desired effect (tolerance)
- Repeated, unsuccessful attempts have been made to discontinue using the substance
- Recognition that behavioral changes occur when the substance is discontinued, such as agitation, drowsiness, anxiety, or pain (withdrawal syndrome)
- Increased amount of time is devoted to obtaining or using the substance, which reduces time available for work, home, or leisure activities.

Abused substances belong to a large number of diverse chemical classes. Although they have few structural similarities, most have in common the ability to affect the brain. Some illicit drugs are taken to stimulate the brain, whereas others are used to sedate the brain or dull the sensation of pain. Still other substances, such as lysergic acid diethylamide (LSD), and club drugs, such as ecstasy, are used to provide alternative psychoactive experiences such as visions or hallucinations. An important exception is the anabolic steroids, which are used for their effects on the muscular system rather than the nervous system.

Although the public associates substance abuse with illegal drugs, this is not necessarily the case. Alcohol and nicotine are the two most commonly abused substances and both are legal for adults. In addition, legal prescription drugs, such as oxycodone (OxyContin), methylphenidate (Adderall), and alprazolam (Xanax), are frequent drugs of abuse.

Several drugs that were once used therapeutically are now illegal due to their high potential for abuse. Cocaine

was once used as a local anesthetic, but today all the cocaine acquired by users is obtained illegally. LSD is now illegal although it was briefly used in psychotherapy in the 1940s and 1950s. Phencyclidine (PCP) was popular back in the early 1960s as an anesthetic but was withdrawn from the market due to patients reporting serious adverse effects while recovering from anesthesia. Many amphetamines once used for bronchodilation were discontinued in the 1980s after psychotic episodes were reported.

PharmFACT

As encouraging trends, the use of heroin, methamphetamine, and cocaine among teens has been steadily declining and alcohol use is at historically low levels. However, the daily use of marijuana among 12th graders (6%) now exceeds the daily use of tobacco (National Institute on Drug Abuse, 2016).

Legislation of Controlled Substances

27.2 Drugs with a potential for abuse are restricted by the Controlled Substances Act and are categorized into schedules.

It is not surprising that drugs and other substances with abuse potential are highly regulated. Many of these substances can cause significant harm to the user and those surrounding the user when memory or performance becomes impaired. A significant percentage of motor vehicle crashes and other injuries result from substance abuse. The government clearly has a role in protecting the public from such dangerous drugs. The Controlled Substances Act (CSA), the primary legislation establishing scheduled drugs, was discussed in Chapter 2.

Diversion from medical use is a source of some of the abused drugs. Because of this, legislation has been enacted to closely track potential drugs of abuse from manufacturer to consumer. Prescription drugs may be stolen from pharmacies, healthcare provider offices, or patients, and sold illegally, sometimes at a very high profit. In some cases, healthcare workers who have the responsibility of dispensing or administering the medications conduct the theft.

Patients contribute to the diversion by faking or exaggerating their symptoms to obtain prescriptions for pain medication or sedatives. Some patients obtain the same prescription from several healthcare providers, commonly referred to as "doctor shopping," and sell their pills to substance abusers. Because of the multitude of ways that legal drugs can be diverted to abusers, the tracking of drugs with abuse potential must be closely monitored.

In the United States, controlled substances are classified according to their potential for abuse and toxicity. This classification uses five schedules, with Schedule I drugs having the highest potential for abuse (see Chapter 2). In recent years, a few exceptions have been made to the placement of drugs in the schedules. For example, gamma hydroxybutyrate (GHB) is used illegally as a club drug as a stimulant or aphrodisiac and is classified as a Schedule I drug that has "no therapeutic use." However, this same substance is approved to treat narcolepsy as the drug Xyrem, a Schedule III drug. As another example, marijuana is a Schedule I agent, yet some states have legalized its use for specific medical indications and recreational use.

CONNECTION Checkpoint 27.1

Prior to the CSA, other attempts were made to legislate narcotics. From what you learned in Chapter 2, name the first major law in the United States that was passed in 1914 to control narcotic use and explain its major provisions. *Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.*

Addiction and Dependence

27.3 Addiction is an overwhelming compulsion to continue repeated drug use.

Addiction is an overwhelming compulsion that drives someone to repeat drug-taking behavior, despite serious health and social consequences. Why would someone continue to abuse drugs even when he or she is aware of its compelling negative consequences? The drug experience is highly personal for each user, and it is difficult to generalize reasons for continued substance abuse. In summary, the drug experience brings some degree of pleasure or satisfaction to the user. Whether it be euphoria, sedation, hallucinations, or feelings of well-being or excitement, the substance abuser finds the drug experience reinforcing and worth repeating.

Addiction depends on multiple, complex, and interacting variables. These variables focus on the following categories:

- **Agent or drug factors.** Cost, availability, dose, mode of administration (e.g., oral [PO], intravenous [IV], inhalation), speed of onset, duration of drug action, length of drug use
- **User factors.** Genetic factors (e.g., metabolic enzymes, innate tolerance), risk-taking behavior, prior experiences with drugs, pathologic state (such as severe pain) that may indicate a drug with abuse potential
- **Environmental factors.** Social and community norms, role models, peer influences, educational opportunities.

In the case of legal prescription drugs, addiction may begin with a legitimate need for pharmacotherapy. For example, narcotic analgesics may be indicated for pain relief or sedatives for a sleep disorder. These drugs may result in a favorable experience, such as pain relief or sleep, and patients will want to repeat these positive experiences. If pharmacotherapy is not carefully monitored, patients may take these drugs at high doses for prolonged periods, thus increasing the risk of addiction.

It is a common misunderstanding, even among some healthcare providers, that the therapeutic use of scheduled drugs creates large numbers of addicted patients. In fact, prescription drugs infrequently cause addiction when used according to accepted medical protocols. The risk of addiction for prescription medications is primarily a function of the dose and the length of therapy. Because of this, medications having a potential for abuse are prescribed at the lowest effective dose and for the shortest time necessary to treat the medical problem. Nurses should administer these medications as prescribed for the relief of patient symptoms without undue fear of producing dependency.

PharmFACT

In 2013, almost 25 million Americans age 12 years or older used illicit drugs in the past month. This estimate represents 9.4% of the population age 12 years or older (Substance Abuse and Mental Health Services Administration [SAMHSA], 2014).

27.4 Physical and psychologic dependence lead to continued drug-seeking behavior despite negative health and social consequences.

Whether or not a drug is addictive is related to how easily someone can stop taking the substance on a repetitive basis. Substance dependence occurs when an individual has an overwhelming craving to take a drug and cannot stop. Substance dependence is classified by two distinct categories: physical dependence and psychologic dependence.

Physical dependence occurs when the body adapts to repeated use of the substance by altering normal physiology. Essentially, the cells adapt and view the medication-altered environment as normal. These changes in physiology are reversible and when the agent is discontinued, uncomfortable symptoms known as withdrawal result (see Section 27.5). Opioids, such as morphine and heroin, may produce physical dependence relatively quickly with repeated doses, particularly when taken IV. Alcohol, central nervous system (CNS) depressants, some stimulants, and nicotine are other examples of substances that may produce physical dependence relatively easily with extended use.

It is important to understand that physical dependence is not the same as addiction. Physical dependence may occur during the normal course of therapy, such as in patients receiving high doses of narcotic analgesics during cancer treatment. A patient with cancer may be physically dependent, that is, withdrawal symptoms may occur on discontinuing the drug. However, withdrawal from a medication taken under medical supervision such as analgesics, antidepressants, or antianxiety drugs should not be considered as evidence that the patient has a substance use disorder. Addiction implies destructive, compulsive substance use. Although physical dependence does indeed occur in patients who are addicted, it is important to understand that the two terms have different meanings.

In contrast, **psychologic dependence** produces no signs of physical discomfort after the agent is discontinued. The user, however, has an intense emotional desire to continue despite obvious negative economic, physical, or social consequences. This intense craving may become worse if the patient has an unsupportive home environment or social contacts who have substance use disorders. Strong psychologic craving for a substance is responsible for relapses during substance abuse therapy and often causes a return to drug-seeking behavior. The development of psychologic dependence usually requires the use of relatively high doses for a prolonged time, such as with marijuana and antianxiety drugs. However, psychologic dependence may also develop quickly, perhaps after only one use, such as with crack cocaine. Whereas physical dependence is often overcome within a few days or weeks after discontinuing the drug, psychologic dependence may persist for months, years, or even an entire lifetime.

27.5 A withdrawal syndrome is a set of characteristic symptoms that occurs when an abused substance is discontinued.

Once a patient becomes physically dependent and the substance is abruptly discontinued, a **withdrawal syndrome** will occur. Some substances exhibit severe and prolonged withdrawal symptoms, whereas others produce barely noticeable symptoms. Because the withdrawal syndrome may be particularly acute for patients dependent on alcohol and sedatives, the process of withdrawal from these agents is best accomplished in a substance abuse treatment facility. Examples of the types of withdrawal syndromes experienced with the different abused substances are shown in Table 27.1. In a medical setting a withdrawal syndrome may be induced by a rapid dosage reduction or by the administration of an antagonist drug in patients who are physically dependent.

In general, symptoms of withdrawal are opposite to those of the drug's effects. For example, an individual may use alprazolam to *reduce* anxiety, but withdrawal may *cause* intense anxiety symptoms. People may abuse methamphetamine as a stimulant to stay awake, but during withdrawal they will experience lethargy and fatigue. Once these **rebound effects** become intense, people are driven to take additional doses of the abused substance because that will cause the withdrawal symptoms to disappear. For some patients, avoidance of withdrawal symptoms is the major motivator for continuing drug use. Thus, the cycle of continued substance abuse is perpetuated.

Prescription drugs may be used to reduce the severity of withdrawal symptoms. For example, alcohol withdrawal can be treated with a short-acting benzodiazepine such as oxazepam (Serax), and opioid withdrawal can be treated

Table 27.1 Withdrawal Symptoms and Treatment for Selected Drugs of Abuse

Drug Class	Symptoms	Treatment
Alcohol	Tremors, fatigue, anxiety, abdominal cramping, hallucinations, confusion, seizures, delirium	Benzodiazepines, antiseizure drugs; disulfiram and naltrexone after withdrawal is over
Anabolic steroids	Mood swings, fatigue, restlessness, anorexia, insomnia, reduced sex drive, depression, psychologic craving for steroids	Behavioral therapy, symptomatic treatment such as antidepressants
Barbiturates and other sedative–hypnotics	Insomnia, anxiety, weakness, abdominal cramps, tremor, anorexia, seizures, hallucinations, delirium	Similar to alcohol
Benzodiazepines	Insomnia, irritability, abdominal pain, nausea, sensitivity to light and sound, headache, fatigue, tremors	Gradual tapering of dosage over several weeks or months; for acute benzodiazepine intoxication, flumazenil (Romazicon) is administered by rapid IV infusion (15–20 sec)
Cocaine and amphetamines	Mental depression, anxiety, agitation, irritability, extreme fatigue, hunger, disturbed sleep, psychologic craving	Behavioral therapy; no specific pharmacologic treatment available
Hallucinogens	Dependent on the specific drug; may include anxiety, mental depression, insomnia, paranoid delusions, panic attacks, lethargy	Treatment usually is not necessary; symptoms resolve in about 12 h; PCP excretion is pH dependent and acidification of the urine increases the clearance rate of PCP by about 100-fold
Marijuana	Irritability, restlessness, insomnia, tremor, chills, weight loss	No treatment
Nicotine	Irritability, anxiety, restlessness, headaches, increased appetite, insomnia, inability to concentrate, decrease in heart rate and blood pressure	Nicotine replacement therapy, varenicline (Chantix) or bupropion (Zyban)
Opioids	Excessive sweating, restlessness, dilated pupils, agitation, goose bumps, tremor, violent yawning, increased heart rate and blood pressure, nausea, vomiting, abdominal cramps and pain, muscle spasms with kicking movements, weight loss	Methadone maintenance; buprenorphine therapy; clonidine reduces anxiety, agitation, cramping, and sweating; oxazepam reduces muscle spasms and insomnia; antiemetics such as ondansetron for nausea and vomiting; detoxification can be completed in 2–3 days; withdrawal may be done more rapidly using naltrexone in combination with propofol anesthetic, the antidiarrheal octreotide, and clonidine and benzodiazepines for other symptoms

with methadone. Symptoms of nicotine withdrawal may be relieved by nicotine replacement therapy in the form of patches or chewing gum. No specific pharmacologic intervention is indicated for withdrawal from CNS stimulants, hallucinogens, marijuana, or inhalants.

With chronic substance abuse, patients will often associate the drug use with their surroundings, including social contacts with other users. Users tend to revert back to drug-seeking behavior when they return to the company of other substance abusers. Counselors often encourage users to refrain from associating with past social contacts or relationships with other substance abusers to lessen the possibility for relapse. The formation of new social contacts, including association with self-help groups such as Alcoholics Anonymous, helps some patients transition to a drug-free lifestyle.

Tolerance

27.6 Tolerance occurs when the body adapts to a drug and larger doses are needed to produce a therapeutic effect.

Tolerance is a biological condition that occurs when the body adapts to a substance after repeated administration. Over time, larger doses of the drug are required to produce the same initial effect. For example, at the start of pharmacotherapy, a patient may find that 2 mg of a sedative is effective at inducing sleep. After taking the medication for several months, the patient may require 4 or perhaps 6 mg to fall asleep. Development of drug tolerance is common for drugs that affect the nervous system. Tolerance should be considered a natural consequence of continued drug use: Development of tolerance is not evidence of addiction or drug abuse. Indeed, tolerance is an expression of natural homeostasis—the body's attempt to return systems to normal.

Tolerance does not develop at the same rate for all actions of a drug. For example, patients usually develop tolerance to the nausea and vomiting produced by narcotic analgesics after only a few doses. Tolerance to the mood-altering effects of these drugs and to their ability to reduce pain develops more slowly but eventually may be complete. Tolerance to the drug's ability to constrict the pupils never develops. Patients will often endure annoying side effects of drugs, such as the sedation caused by antihistamines, if they know that tolerance to these effects will develop quickly. Thus knowing details regarding the development of tolerance helps the nurse to deliver essential patient information that may enhance adherence.

Tolerance may lead to serious consequences for those patients abusing hazardous substances. As a patient self-administers higher and higher doses to obtain a desired effect such as euphoria or sedation, the risk of overdose escalates. In some cases, the drug abuser may reach a daily dose that would be lethal for a nonaddicted individual. Tolerance fades after the patient discontinues the abused drug, often after 10 to 14 days. If the patient should return to drug-taking behavior with the same high dose, the results may be fatal.

The rapid development of tolerance after only a couple of doses, called **tachyphylaxis**, occurs with drugs such as cocaine, LSD, and amphetamines but is not unique to abused substances. For example, patients with coronary artery disease will exhibit acute tachyphylaxis to the therapeutic effects of nitroglycerin. Tachyphylaxis can occur to virtually any action of a drug, adverse effects as well as therapeutic effects. Tachyphylaxis is beneficial when it occurs to an adverse effect of a drug, such as nausea, vomiting, or dizziness.

Cross-tolerance occurs between closely related drugs. The more two drugs are similar chemically, the greater the possibility of cross-tolerance between them. This occurs frequently between drugs in the same class, such as among different barbiturates or among various opioids. It sometimes occurs between dissimilar drugs that have the same pharmacologic action. For example, patients who are physically dependent on ethanol exhibit cross-tolerance to other CNS depressant drugs such as benzodiazepines and barbiturates. Ethanol-dependent patients will require higher doses of these drugs to produce a therapeutic effect. Ethanol does not exhibit cross-tolerance to drugs in very different pharmacologic classes, such as amphetamines or LSD.

The term *resistance* is often confused with tolerance. Resistance, however, refers to microorganisms and infections and should not be used interchangeably with tolerance. For example, microorganisms may become resistant to the effects of an antibiotic; they do not become tolerant. Patients may become tolerant to the effects of pain relievers; they do not become resistant.

Central Nervous System Depressants

27.7 Central nervous system depressants, which include sedatives, opioids, and alcohol, decrease the activity of the central nervous system.

CNS depressants form a diverse group of drugs that cause patients to feel sedated or relaxed (see Chapters 18 and 25). Drugs in this group include sedatives, antianxiety drugs, opioids, and alcohol. Although the majority are legal substances, these classes of drugs are strictly controlled due to their abuse potential.

Sedatives and Antianxiety Drugs

Sedatives, also known as sedative–hypnotics and tranquilizers, are primarily prescribed for sleep disorders and certain forms of epilepsy. The two general classes of sedatives are the barbiturates and the nonbarbiturate sedative–hypnotics. The safety profiles and addictive potential of the two classes are roughly equivalent.

Physical and psychologic dependence develop when high doses of barbiturates are taken for extended periods. Doses may be 3 or more times above normal due to the development of tolerance. Abusers often combine sedatives with other substances, such as stimulants or alcohol. Addicts often alternate between amphetamines (uppers), which keep them awake for several days, and sedatives (downers), which are needed to relax and fall asleep.

Sedative users appear dull or apathetic and exhibit signs similar to alcohol intoxication such as slurred speech and motor incoordination. The medical use of barbiturates and nonbarbiturate sedative–hypnotics has declined markedly over the past two decades because safer alternatives such as the benzodiazepines are available. With the decline in therapeutic use, fewer cases of illicit barbiturate use have been reported. The use of the barbiturates in treating sleep disorders was discussed in Chapter 18, and their use in epilepsy was presented in Chapter 22.

Overdoses of sedatives are extremely dangerous because the drugs suppress the respiratory centers in the brain—very high doses are often fatal. In the 1960s to 1970s, barbiturates were the drugs most commonly used to commit suicide. The withdrawal syndrome from these drugs resembles that of alcohol and may be life threatening.

Starting in the 1970s, the benzodiazepine class of CNS depressants began to replace barbiturates because they exhibited an improved safety profile. Benzodiazepines are more accurately called antianxiety drugs instead of sedatives. They are one of the most widely prescribed classes of drugs, and a drug class commonly abused among teens and college students. Although their primary indication is anxiety, they may be used to treat seizures, sleep disorders, and muscle spasms. Benzodiazepines include alprazolam (Xanax), clonazepam (Klonopin), diazepam (Valium), temazepam (Restoril), triazolam (Halcion), and midazolam (Versed).

Flunitrazepam (Rohypnol) is an infamous benzodiazepine of abuse because it causes **anterograde amnesia**, a type of short-term memory loss in which the user cannot remember events that occur while under the influence of the drug. Effects begin 30 minutes after PO administration and last for 8 hours or longer. The abuser is conscious during this time but is unable to transfer thoughts from short-term to long-term memory. Flunitrazepam is called a "date-rape" drug because sexual predators can expose an unknowing individual to the drug and perform a physical assault with the likelihood that the victim will not remember the event. Flunitrazepam is not approved by the U.S. Food and Drug Administration (FDA) for any medical condition.

Patients on high doses of antianxiety drugs appear detached, sleepy, or disoriented. Often, patients will appear carefree and without worry. Despite their enormous popularity, however, benzodiazepines are not frequently abused in high doses. Users sometimes combine these drugs with alcohol, cocaine, or heroin to augment their drug experience. In terms of acute toxicity, benzodiazepines are safer than

barbiturates and other sedatives. Serious respiratory depression is rare and death due to overdose usually only occurs with extremely high doses. However, if combined with alcohol, cocaine, or heroin, overdose may be lethal. Withdrawal symptoms are less severe than with barbiturates.

Another popular abused CNS depressant is a substance that occurs naturally in the body called gamma-hydroxybutyric acid (GHB). The drug is approved by the FDA as sodium oxybate (Xyrem) to treat patients with narcolepsy who experience excessive daytime sleepiness or cataplexy (weak or paralyzed muscles). Although Xyrem is regulated as a Schedule III drug, its active ingredient, GHB, is classified as Schedule I. It is very unusual for the FDA to classify a drug in two schedules. Xyrem is distributed to prescribers and patients only through a single centralized pharmacy.

Once sold in health food stores as a dietary supplement to enhance athletic performance, GHB is now abused by recreational users for its ability to produce euphoria at low doses. Like flunitrazepam, GHB is called a date-rape drug because it induces retrograde amnesia in the user and has been used in sexual assaults. Most illegal GHB is obtained through home laboratories in the United States, with batches varying widely in purity and potency. The drug is usually dissolved in liquid and doses are difficult to estimate. The same enzyme that metabolizes ethanol also metabolizes GHB; concurrent use, which is common, leads to prolonged effects of GHB and an increased risk of overdose. Overdose causes severe respiratory depression, seizures, and coma. Death from GHB overdose is sometimes caused by the aspiration of vomitus, because the patient may experience coma, vomiting, and seizures simultaneously. There is no antidote for overdose with GHB.

Opioids

Opioids, also known as opiates or narcotic analgesics, are morphine-like substances prescribed for severe pain, anesthesia, persistent cough, and life-threatening diarrhea. The opioid class includes morphine, codeine, meperidine (Demerol), oxycodone (OxyContin), fentanyl (Duragesic, Sublimaze), methadone, and heroin. The therapeutic effects of the opioids are discussed in detail in Chapter 25.

PharmFACT

Among adolescents ages 12 to 17, the rates for nonmedical use of prescription drugs have been declining. For prescription pain relievers, the rates in this population declined from 3.2% in 2003 to 1.7% in 2013 (SAMHSA, 2014).

The effects of oral opioids begin within 30 minutes and may last over a day. Injecting or smoking opium produces immediate effects, including the brief, intense rush of euphoria sought by heroin addicts. Individuals experience a range of emotions, from extreme pleasure to slowed body activities and profound sedation. Other symptoms include slurred speech, constricted pupils (miosis), an increase in the pain threshold, and respiratory depression. Tolerance develops rapidly to most effects of opioids, and a patient who is addicted may eventually require 10 times the initial dose to achieve the desired effects.

Opioid dependence can occur rapidly and withdrawal produces very intense and unpleasant symptoms that start within a few hours after discontinuation of parenteral agents and within 3 to 5 days for those dependent on oral opiates. Withdrawal symptoms include dysphoria, diaphoresis, violent yawning, lacrimation, rhinorrhea, pupil dilation (mydriasis), fever, diarrhea, goose bumps, and muscle cramping and tremor. Although extremely unpleasant, withdrawal from opioids is not life threatening, compared to barbiturate or alcohol withdrawal, and the patient is not delirious. The withdrawal syndrome is self-limiting, peaking within 36 to 72 hours after discontinuation of parenteral opioids, and individual symptoms are treated as necessary. For patients dependent on low to moderate doses, withdrawal symptoms are relatively mild and resemble a case of the flu. Babies born to pregnant opioid users will experience withdrawal symptoms following birth.

Abuse-deterrent opioids: In the 1990s, pharmaceutical companies developed extended release (ER) opioids that offered around-the-clock pain control. Abusers soon discovered, however, that ER opioids such as oxycodone (OxyContin) could be crushed and snorted or dissolved and injected for an intense high. Oxycodone soon became the world's most commonly abused prescription drug, which signaled the start of a serious opioid epidemic.

The FDA (2017) responded to this public health crisis by encouraging pharmaceutical companies to reformulate ER opioids to make them less susceptible to abuse. The result has been approval of a number of opioids with abuse-deterrent (AD) properties. The properties are not intended to render the drug abuse-proof, but they make it more difficult to mishandle the drug by crushing, snorting, or dissolving it for injection. The following are examples of approved opioids with AD properties listed on the medication labels:

- **Opioids combined with an antagonist:** When mishandled, the euphoric effects of the opioid are blocked by an antagonist. These include oxycodone with naltrexone (Troxyca ER, Targiniq), oxycodone with naloxone (Oxycodone ER), and morphine with naltrexone (Embeda).
- **Resistant tablets:** These use special polymers that make the tablets difficult to crush, break, melt, or dissolve using conventional tools and methods. These medications form a viscous gel if the tablet is broken, which is difficult to inject. Medications include hydrocodone (Hysingla ER) and morphine (Arymo ER, MorphaBond).

- **Resistant beads:** Oxycodone (Xtampza ER) capsules can be opened, which is important to patients with difficulty swallowing. However, the medication is coated with fatty acid and waxes that resist dissolving or melting.

Treatment of opioid addiction: Methadone has been the conventional treatment of choice for opioid addiction. Although methadone has addictive properties of its own, it does not produce the same degree of euphoria as other opioids; it may be taken PO and its effects last 24 hours. Heroin addicts are switched to methadone during the detoxification phase of treatment to prevent unpleasant withdrawal symptoms. If the patient decides to take heroin during methadone therapy, most of the euphoric rush will be blocked because most of the opiate receptors are already occupied by methadone. During maintenance therapy, patients must report to the methadone clinic daily for their dose and to receive counseling. In some cases, patients who have remained heroin-free may be trusted with several doses for home administration. Patients sometimes remain on methadone maintenance the remainder of their lives, although most patients eventually choose to detoxify and discontinue methadone use altogether. Gradual dose reduction occurs over a period of about 6 months. Withdrawal from methadone is more prolonged than with heroin or morphine, but the symptoms are less intense.

For many healthcare providers, buprenorphine has become an important alternative to methadone therapy. Options include buprenorphine (Subutex) as monotherapy or buprenorphine combined with naloxone (Suboxone, Zubsolv). These are Schedule III drugs intended for the office management of opioid dependence. Naloxone is also used alone for the emergency treatment of severe opioid-induced respiratory depression (see Chapter 25).

PROTOTYPE DRUG Buprenorphine with Naloxone (Suboxone, Zubsolv, Others)

Classification

Therapeutic: Drug for treating opioid addiction, narcotic analgesic
Pharmacologic: Opioid agonist-antagonist

Therapeutic Effects and Uses: Approved in 2002, buprenorphine is a Schedule III narcotic analgesic that produces analgesia when given by the IM/IV (Buprenex) or transdermal (Butrans) routes for moderate to severe pain. The combination of buprenorphine with naloxone, a narcotic antagonist, is given by the sublingual (Suboxone, Zubsolv) or buccal (Bunavail) routes for the maintenance treatment of opioid dependence. When taken as directed, the combination drug reduces craving in opioid-dependent patients and prevents the unpleasant symptoms of withdrawal.

Although methadone maintenance has been the traditional preferred treatment for opioid addicts, buprenorphine with naloxone offers certain advantages. It is unlikely that the combination drug will be abused because the presence of naloxone would cause unpleasant effects identical to withdrawal symptoms. Detoxification can be more rapid and the maintenance can be conducted through office environments, rather than a daily visit to a methadone clinic.

Mechanism of Action: Buprenorphine produces its analgesic effects by occupying mu receptors in the brain and dorsal horn of the spinal cord in a manner similar to that of other opioid agonists. Because buprenorphine exhibits some opioid antagonist activity at the kappa receptor, it is considered a mixed opioid agonist-antagonist. Naloxone competes with opioid agonists for the mu and kappa receptors, thus antagonizing the effects of morphine and other opioids.

Pharmacokinetics:

Route(s)	Sublingual tablets or film; buccal film
Absorption	Variable (buprenorphine well absorbed; naloxone poorly absorbed)
Distribution	Bound to plasma protein (96% buprenorphine, 45% naloxone); crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal (30%) and feces (69%)
Onset of action	Approximately 45 min
Duration of action	8–12 h (may be as long as 72 h at high doses)

Adverse Effects: Buprenorphine with naloxone is a relatively safe drug that produces mild and transient side effects. The most frequently reported adverse events include headache, nausea, vomiting, hyperhidrosis, constipation, insomnia, pain, and peripheral edema. Abrupt discontinuation of the drug will precipitate immediate opioid withdrawal symptoms. Respiratory depression and death have occurred with high doses, although these have been with the IV route.

Buprenorphine is an opioid and thus can produce dependence when taken on a chronic basis. Although Suboxone and Zubsolv are both sublingual forms of the drug, they are not dose equivalent and care must be taken when switching between products.

Contraindications/Precautions: Buprenorphine with naloxone is contraindicated in patients with hypersensitivity to either drug. This combination may induce withdrawal in patients who have chronic physical dependence on opioids. Naloxone should be used with caution in patients with cardiovascular disease. It may precipitate seizures in patients with seizure disorders.

Drug Interactions: Caution should be used when taking buprenorphine with other narcotic analgesics and CNS depressants because additive sedation will occur. Deaths have occurred when taking very high doses of buprenorphine concomitantly with benzodiazepines. The use of buprenorphine is contraindicated with alvimopan (Entereg).

Pregnancy: Category C.

Treatment of Overdose: Buprenorphine overdose can cause coma, hypotension, and life-threatening respiratory depression, and requires immediate treatment. Additional naloxone doses are indicated to reverse the opioid intoxication.

Nursing Responsibilities: Key nursing implications for patients receiving buprenorphine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Substance Abuse Disorders.

Drugs Similar to Buprenorphine with Naloxone (Suboxone, Zubsolv, Others)

Naltrexone is an opioid antagonist that exhibits actions similar to those of naloxone. It is presented later in this chapter as a treatment for alcohol dependence.

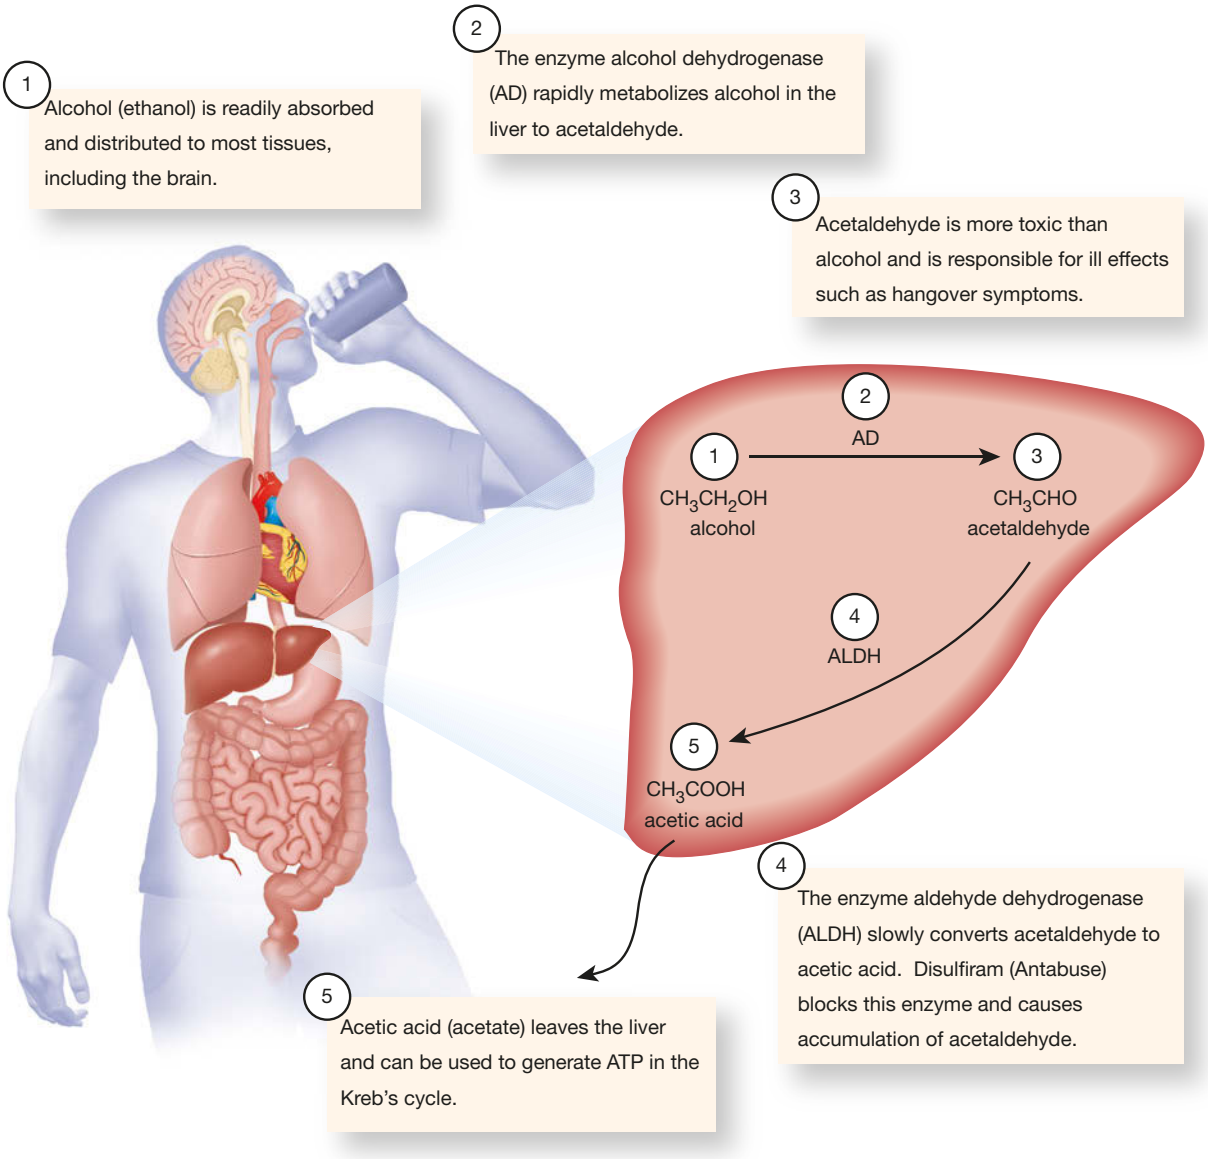
Alcohol (Ethanol)

One of the most commonly abused drugs is alcohol, the pharmacologically active agent in beer, wine, and liquor. Although there are many types of alcohol, the only one having widespread medical significance is ethanol or ethyl alcohol. Therefore, in this text, the terms *ethanol* and *alcohol* are used interchangeably. The economic, social, and health consequences of alcohol abuse are staggering. Small quantities of alcohol consumed on a daily basis, however, have been found to reduce the risk of stroke and heart attack.

Alcohol is readily absorbed across the gastrointestinal (GI) tract, primarily from the small intestine. Food slows the absorption of alcohol by prolonging gastric emptying time and diluting the alcohol, thus delaying its onset of action. Once it has entered the blood, alcohol is immediately distributed to the tissues. The drug easily crosses the blood–brain barrier so its effects on the brain are observed quickly, within 5 to 30 minutes after consumption.

Alcohol is metabolized and excreted at a constant rate, depending on the activity of two hepatic enzymes, alcohol dehydrogenase and aldehyde dehydrogenase. Metabolism is a two-step process, first yielding acetaldehyde and then acetic acid, or acetate, as shown in Pharmacotherapy Illustrated 27.1. Wide genetic variability is seen in the amounts and activity of these enzymes. For example, a significant number of Asians have a deficiency of aldehyde dehydrogenase, resulting in an accumulation of acetaldehyde and severe flushing and other uncomfortable symptoms when consuming alcohol. Patients who are alcohol dependent and those who drink alcoholic beverages regularly have higher amounts of these enzymes and thus are able to drink greater quantities of alcohol without becoming intoxicated.

The elimination of alcohol from tissues occurs at a constant rate, which is independent of the concentration of alcohol in the blood. The blood alcohol level declines at about 15 mg/h; no food or drug can speed up the rate of alcohol excretion once it has reached the blood. Eating pizza or drinking strong coffee following an alcohol binge does nothing to speed up excretion of the drug. It is a simple fact that if an individual drinks alcohol at a faster rate than it can be metabolized, intoxication will occur and will continue until the body eventually metabolizes the alcohol that has accumulated in the blood. The average rate of metabolism is one alcoholic drink per hour. Because alcohol is vaporized and excreted by the lungs, breath testing can be used to estimate the amount of alcohol in the blood, a common practice in law enforcement.



Alcohol is classified as a CNS depressant because it has the ability to slow the region of the brain controlling alertness and wakefulness. Effects of alcohol include sedation, relaxation, loss of motor coordination, reduced judgment, and decreased inhibition. Alcohol intoxication may cause partial or total amnesia, resulting in an inability to remember details that occurred during an alcohol binge. Alcohol also increases blood flow in certain areas of the skin, causing a flushed face, pink cheeks, or red nose. Like most drugs, the effects of alcohol are directly related to the amount consumed. Acute overdoses of alcohol produce vomiting, severe hypotension, respiratory failure, and coma. Death due to alcohol poisoning is not uncommon.

Chronic alcohol consumption produces both psychologic and physiologic dependence and leads directly to a large number of adverse health effects. Not surprisingly, the organ most affected by chronic alcohol abuse is the liver, which is responsible for metabolizing and detoxifying alcohol. Hepatitis occurs in up to 90% of heavy users. Alcoholism is a common cause of cirrhosis, a debilitating and often fatal failure of the liver to perform its vital functions. Liver impairment results in abnormalities in blood clotting and nutritional deficiencies and makes the patient very sensitive to the effects of medications. Chronic alcohol use also damages the brain, impairing memory and cognitive function.

Drug doses for patients with alcoholism should be decreased to avoid toxicity because such patients are more susceptible to adverse drug effects and drug interactions. Combining alcohol with nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin can promote serious GI bleeding. Combining alcohol with acetaminophen can increase the risk of fatal hepatic injury. Alcohol should never be combined with other CNS depressants, because their effects are cumulative and profound sedation or coma may result. Combining alcohol with sedatives, benzodiazepines,

Pharmacotherapy Illustrated 27.1

Metabolism of Alcohol

or opioids may be fatal. Selected drug interactions involving alcohol are shown in Table 27.2.

CONNECTION Checkpoint 27.2

Alcohol induces CYP3A and increases the formation of a toxic metabolite of acetaminophen. From what you learned in Chapter 3, what is CYP3A and what is its importance to pharmacotherapy? *Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.*

One of the major adverse effects of alcohol consumption occurs not in the patient, but in the fetus of a pregnant alcohol user. These effects, known as fetal alcohol syndrome, include birth defects and major health challenges for the child. There is no safe "dose" for alcohol consumption during pregnancy; thus use of this drug must be strictly avoided. Additional details on alcohol as a teratogen are presented in Chapter 8.

Alcohol withdrawal is severe and may be life threatening. About 5% to 10% of withdrawal cases proceed to **delirium tremens**, a syndrome of intense agitation, confusion, terrifying hallucinations, uncontrollable tremors, panic attacks, and paranoia. Without treatment, 35% of the patients with delirium tremens will die. Prevention of seizures and delirium tremens is a top priority and may be accomplished by administering a benzodiazepine such as lorazepam (Ativan) or diazepam (Valium). Hallucinations may require the administration of an antipsychotic drug such as risperidone (Risperdal).

Table 27.2 Drug–Drug Interactions with Alcohol

Class	Example Drug(s)	Interaction	Consequences
Acetaminophen	—	Increased acetaminophen metabolism to toxic metabolites	Severe, possibly fatal liver damage
Anesthetics	propofol (Diprivan), enflurane (Ethrane)	Cross-tolerance	Larger anesthetic doses needed to induce anesthesia
		Additive hepatic toxicity	Increased risk of liver damage
Antianginal medications	nitroglycerin, isosorbide dinitrate (Isordil)	Additive effects on blood pressure	Hypotension, dizziness, possible fainting
Antibiotics	furazolidone (Furoxone), griseofulvin, metronidazole (Flagyl)	Additive toxicity	Nausea, vomiting, headache, possible seizures, reduced antibiotic effectiveness
Anticoagulants	warfarin (Coumadin)	Acute consumption enhances warfarin bioavailability; chronic consumption reduces its availability	Modification of coagulation: bleeding disorders, hemorrhage
Antidepressants	amitriptyline (Elavil), paroxetine (Paxil), sertraline (Zoloft), fluoxetine (Prozac)	Additive CNS depression or sedation	Drowsiness, lethargy
Antihistamines	diphenhydramine (Benadryl, others), loratadine (Claritin), cetirizine (Zyrtec)	Additive CNS depression	Drowsiness, lethargy, dizziness
Antipsychotics	chlorpromazine (Thorazine)	Additive CNS depression	Drowsiness, lethargy
		Additive hepatotoxicity	Increased risk of liver damage
Antiseizure medications	phenytoin (Dilantin)	Chronic alcohol use may decrease phenytoin bioavailability	Increased risk of seizures
Antituberculars	isoniazid, rifampin	Decreased bioavailability	Decreased effectiveness in eliminating tuberculosis
Beta blockers	propranolol (Inderal)	Additive effects on blood pressure	Hypotension, dizziness, possible fainting
HMG-CoA reductase inhibitors (statins)	atorvastatin (Lipitor), simvastatin (Zocor)	Additive hepatotoxicity	Liver damage
NSAIDs	aspirin, ibuprofen, naproxen, others	Additive GI toxicity	Increased risk of GI bleeding
Opioids	morphine, codeine, meperidine (Demerol)	Additive CNS depression and sedation	Drowsiness, lethargy
Sedatives and antianxiety drugs	diazepam (Valium), lorazepam (Ativan), alprazolam (Xanax), phenobarbital (Luminal)	Additive CNS depression and sedation	Drowsiness, lethargy
Miscellaneous	sulfonylureas, metronidazole (Flagyl), isoniazid (INH)	Disulfiram-like reaction	Facial flushing, nausea, vomiting

Long-term therapy for alcohol dependence includes behavioral counseling and self-help groups such as Alcoholics Anonymous. Pharmacologic management of alcohol dependence includes disulfiram and naltrexone. Disulfiram (Antabuse) is given to discourage relapses.

PROTOTYPE DRUG Disulfiram (Antabuse)

Classification **Therapeutic:** Drug for treating alcohol abuse
Pharmacologic: Alcohol antagonist; acetaldehyde dehydrogenase inhibitor

Therapeutic Effects and Uses: By itself, disulfiram produces few effects. If alcohol is consumed while taking disulfiram, however, the patient becomes violently ill in a syndrome called the disulfiram–alcohol reaction. Approved in 1951, the only indication for disulfiram is the management of chronic alcohol abuse. The use of disulfiram does not cure alcohol abuse; it only prevents impulsive drinking as long as the patient chooses to take it. The protective action of disulfiram may last for 2 weeks after it is discontinued. Disulfiram should only be administered to patients who are fully informed of its effects and who are motivated to maintain sobriety.

Mechanism of Action: Disulfiram irreversibly inhibits the enzyme acetaldehyde dehydrogenase, causing toxic acetaldehyde to build up in the blood. Acetaldehyde is sometimes called the "hangover" chemical because it is responsible for causing miserable symptoms following a night of high alcohol consumption.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Lung and feces
Onset of action	12 h
Duration of action	1–2 weeks

Adverse Effects: At therapeutic doses, disulfiram produces few adverse effects, unless ingested with alcohol. At extreme doses, the drug itself can cause neurologic toxicity, psychosis, hepatotoxicity, and blood dyscrasias.

Because the disulfiram–alcohol reaction can be serious and even fatal, disulfiram therapy should not be initiated in patients at high risk for returning to alcohol abuse. Disulfiram is contraindicated in patients who are receiving metronidazole because acute psychosis may occur. All products containing alcohol must be strictly avoided, including cough syrups, mouthwashes, or liquid vitamins. Even topical products containing alcohol should be avoided because the alcohol may be absorbed across the skin. Disulfiram is also contraindicated in patients with severe heart disease and psychoses. **Black Box Warning:** Disulfiram should never be administered to a patient in a state of alcohol intoxication or without the patient's full knowledge.

Drug Interactions: Ingestion of even small amounts of alcohol will immediately result in headache, palpitations, chest pain, dyspnea, nausea, violent vomiting, and, sometimes, bizarre behaviors. Severe respiratory depression may occur. Symptoms begin within 5 to 10 minutes after alcohol consumption and may continue for several hours.

Pregnancy: Category C.

Treatment of Overdose: No specific treatment for disulfiram overdose is available.

Nursing Responsibilities: Key nursing implications for patients receiving disulfiram are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Substance Abuse Disorders.

Drugs Similar to Disulfiram (Antabuse)

Naltrexone is one of the few drugs other than disulfiram for treating alcohol dependence.

Naltrexone (ReVia, Vivitrol, others): Approved in 1984, naltrexone is an opioid antagonist that reduces the psychologic craving for alcohol. Why does a drug that blocks opiate receptors have an effect on alcohol dependence? Although the mechanism is unclear, endogenous opioids appear to be involved in "reward pathways" for alcohol. Blocking the reward pathways with naltrexone affects the psychologic experience or craving characteristic of alcohol dependence. Naltrexone does not produce a "hangover" reaction when an individual consumes alcohol, as does disulfiram. Oral naltrexone may be given once daily for several months up to a year. An intramuscular (IM) suspension of naltrexone (Vivitrol) offers the convenience of once-a-month injections. Naltrexone is also approved to treat opiate dependence. Successful use of naltrexone in alcohol or opioid rehabilitation programs is entirely dependent on patient adherence; if the patient stops taking naltrexone, the CNS effects of alcohol or opioids will return. Severe opioid withdrawal may occur if the drug is administered to a patient who has received opioids within 5 to 7 days prior to naltrexone dosing; thus the drug is contraindicated in these patients.

A fixed-dose combination of naltrexone with morphine (Embeda) is approved to treat moderate to severe pain. Morphine is used to provide analgesia, and naltrexone is included to block some of the side effects of morphine and to prevent product misuse. Naltrexone may be used off-label to treat nicotine withdrawal. Naltrexone has been awarded orphan drug status by the FDA to treat symptoms of childhood autism. Patients with serious hepatic impairment should not receive naltrexone. This drug is pregnancy category C.

Marijuana and Related Substances

27.8 Marijuana is the most frequently abused illicit substance.

Cannabinoids are natural products obtained from the hemp plant *Cannabis sativa*, which thrives in tropical climates. Cannabinoids include marijuana, hashish, and hash oil. Hashish is a solid, dried resin of the plant that is extremely potent. Hash oil is made by dissolving hashish or marijuana in a solvent such as alcohol, then allowing the liquid to evaporate to form a thick, oily concentrated form of cannabis.

Although more than 70 natural cannabinoid substances have been identified, the ingredient responsible for most of the psychoactive properties is **tetrahydrocannabinol (THC)**. Selective breeding and cultivation of *Cannabis* has produced varieties of the plant that produce much higher concentrations of THC than in previous decades. The THC content of marijuana varies from 5% to 25%; hashish from 20% to 60%; and hash oil from 30% to 80%.

Humans, as well as many other mammals, fish, and birds, produce small amounts of endogenous cannabinoids. These substances, known as endocannabinoids, are types of internal messengers that allow for intercellular communication. The exact purpose of the endocannabinoids has yet to be discovered, although they have some of the same characteristics as neurotransmitters and can modulate neuronal function. The endocannabinoids have some structural similarities to THC and bind to the same receptors, known as CB1 and CB2 receptors. Agonists and antagonists to CB1 and CB2 have been discovered, with the hope that the research may lead to new pharmacologic agents.

Marijuana, also known as grass, pot, weed, reefer, or dope, is the most commonly used illicit drug in the United States. Marijuana is usually smoked as cigarettes (joints), but it may be used in pipes, brewed as teas, or added to food. Oral absorption results in a lower serum blood level of the drug than does inhalation.

When inhaled, marijuana produces effects that occur within minutes and last 1 to 3 hours. Use of marijuana slows motor activity, decreases coordination, and causes disconnected thoughts and euphoria. The experience is nearly always pleasant and involves laughter and an increase in the subjective perception of sounds, colors, and thoughts. The subjective experience is dependent on the social surroundings during drug use. Positive, friendly, happy surroundings produce a more favorable drug experience than taking the drug alone. Time appears to pass more slowly. It increases thirst and a craving for food, particularly chocolate and other sweets. One hallmark symptom of marijuana use is red or bloodshot eyes, caused by dilation of blood vessels.

Following feelings of euphoria, the individual may become sleepy or depressed or experience paranoia. Driving is sometimes impaired, particularly when the drug is combined with alcohol. Because marijuana smoke is inhaled more deeply and held within the lungs for a longer period than cigarette smoke, marijuana smoke introduces 4 times more particulates (tar) into the lungs than does tobacco smoke. Smoking marijuana on a daily basis may increase the risk of lung cancer and other respiratory disorders. Chronic use is associated with apathy and a lack of motivation in achieving or pursuing life goals, and very high doses may cause hallucinations. THC accumulates in reproductive tissues, particularly the gonads, and has been reported to cause amenorrhea and decreased spermatogenesis.

Marijuana produces less physical dependence or tolerance than many other abused substances. At usual doses, withdrawal symptoms are mild, if they are experienced at all. After chronic abuse of high doses, patients may experience irritability, restlessness, and insomnia. Psychologic dependence occurs when the drug is taken on a chronic basis. Metabolites of THC remain in the body for months to years, allowing laboratory specialists to easily determine whether someone has taken marijuana. For 3 to 5 days after a single use, THC can be detected in the urine.

Medical marijuana is a controversial topic; many healthcare providers and politicians are reluctant to endorse a drug that impairs judgment and may harm users. THC appears to reduce the pressure in the eyeball (glaucoma). Patients receiving antineoplastic drugs have reported that THC reduces the severe nausea and vomiting associated with these drugs. The ability of THC to reduce muscle spasticity may lead to applications for patients with multiple sclerosis and other spasticity disorders. In most cases, however, current drugs for these conditions have been demonstrated to be more effective and safer. Although the medical value of the drug remains to be proven through randomized clinical studies, several states allow the medical and recreational use of marijuana, despite its being a Schedule I drug.

Hallucinogens

27.9 Hallucinogens and club drugs cause an altered state of thought and perception.

Hallucinogens are a diverse class of chemicals that have in common the ability to produce an altered, dreamlike state of consciousness. These drugs sometimes produce a profound emotional experience, allowing the user to feel enhanced interconnectedness with others and experience a higher, spiritual plane of consciousness. Sometimes called *psychedelics*, the prototype drug for this class is LSD. More recently, some drugs in this class have become closely associated with the nightclub scene and are abused by those seeking a drug-induced experience from the music, dancing, and social contact; thus the name "club drugs."

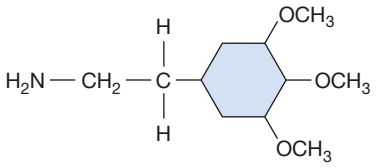
For nearly all drugs of abuse, predictable symptoms occur in every user. Effects from hallucinogens, however, are highly variable and depend on the mood and expectations of the user and the surrounding environment in which the substance is used. Two patients taking the same drug will report completely different experiences, and the same patient may report different symptoms with each use. All hallucinogens are Schedule I drugs: They have no medical use.

LSD and Similar Hallucinogens

LSD, also called acid, the beast, blotter acid, and California sunshine, is derived from a fungus that grows on rye and other grains. LSD is nearly always administered PO and can be manufactured in capsule, tablet, or liquid form. A common and inexpensive method for distributing LSD is to place drops of the drug on paper, often containing the images of cartoon characters or graphics related to the drug culture, as shown in Figure 27.1. After drying, the paper is then cut into small squares to be ingested, with each square representing a "dose." The drug is extremely potent, with doses as low as 25 mcg producing an effect.

Figure 27.1 Psychoactive substances: (left) Psilocybin is obtained from a species of mushroom; (right) LSD is often blotted on paper before ingesting.
Courtesy of Cbaloga/fotolia (left); Joe Bird/Joe Bird/Alamy Stock Photo (right).

Immediately after use, LSD is widely distributed throughout the body, including the brain. Effects begin within an hour and may last from 6 to 12 hours. Although the exact mechanism of action of the drug is unclear, it affects the central and autonomic nervous systems, increasing blood pressure, elevating body temperature, dilating pupils, causing dry mouth, and increasing the heart rate.



LSD and other hallucinogens are used for their psychoactive, rather than their physical, effects. LSD users may experience symptoms such as laughter, visions, religious revelations, or deep personal insights. Common occurrences are hallucinations and after-images being projected onto people as they move. Users also report extremely bright lights and vivid colors. Some users hear voices; others report seeing sounds and hearing colors. Many experience a profound sense of truth and deep directed thoughts. The user's sense of time is altered.

Unpleasant experiences with LSD, known as "bad trips," can be terrifying and may include acute anxiety, panic attacks, confusion, severe depression, and paranoia. Repeated use may impair memory and the ability to reason. In extreme cases, patients may develop psychoses. One common adverse effect is flashbacks, in which the user experiences the effects of the drug again, sometimes weeks, months, or years after the drug was initially taken. Flashbacks may occur without warning.

LSD is considered a recreational drug: Users rarely become dependent on the drug, and there are no withdrawal symptoms. Continuous users will experience tolerance very quickly, sometimes after only 2 to 3 days.

The following drugs are considered similar to LSD and produce equivalent psychoactive effects:

- **Psilocybin.** The primary psychoactive substance in over 100 species of psilocybin mushrooms found in Mexico and Central America (see Figure 27.1). Known as "magic mushrooms" or "shrooms," psilocybin is a prodrug that is metabolized to its active metabolite psilocin. Possession of these mushroom species is illegal. Psilocybin and psilocin are listed as Schedule I drugs. The drug is taken by eating fresh psilocybin mushrooms or by ingesting dried extracts.
- **Mescaline.** Found in the peyote cactus and several other cacti species of Mexico and Central America, as shown in Figure 27.2. The drug is usually taken in capsules consisting of dried cactus. The cactus, which grows very slowly, has become quite rare due to overharvesting. In the United States, peyote use is illegal for all but members of the Native American Church, who use the drug in religious ceremonies.
- **Dimethyltryptamine (DMT).** A natural substance found in many species of plants in Central and South America and the Caribbean Islands. Like some of the other hallucinogens, DMT was used by native cultures in their spiritual ceremonies to induce visions. The drug is usually smoked but may be snuffed (snorted through the nostrils), injected, or taken PO.

Mescaline

Club Drugs and Miscellaneous Hallucinogens

Club drug refers to substances taken by people at festivals, dance clubs, all-night parties, and raves. It is a vague term that refers to a diverse group of abused substances that includes ecstasy, GHB, methamphetamine, Rohypnol, ketamine, and other agents, usually ingested with alcohol. Not all club drugs are hallucinogens, and some of these are covered in other sections of this chapter. The following are descriptions of several major club drugs and some miscellaneous hallucinogens:

- **MDMA (3, 4-methylenedioxymethamphetamine, XTC, or ecstasy).** An amphetamine originally synthesized for research purposes that has since become popular among teens and young adults. Taken PO, its effects last 3 to 6 hours. The drug is unique because it produces both stimulant and hallucinogenic effects simultaneously. MDMA enhances emotions and awareness, increases social and extroversion behaviors, and allows the user to stay awake and physically active for long periods. Chronic users exhibit behavioral disorders such as depression, anxiety, sleeplessness, and hostility. It has a narrow therapeutic index and overdoses may be fatal.
- **MDA (3, 4-methylenedioxyamphetamine).** Called the "love drug" due to a belief that it enhances sexual desires. This drug is sometimes a component of ecstasy.
- **DOM (2, 5 dimethoxy-4-methylamphetamine).** A recreational drug popular at rave parties; also called STP,

CONNECTIONS: Using Research in Practice

Screening, Brief Intervention, and Referral to Treatment (SBIRT)

Approximately 21.5 million people age 12 or older had a substance use disorder (SUD) in 2014. This included 17 million people with an alcohol use disorder, 7.1 million with an illicit drug use disorder, and 2.6 million who had both alcohol use and illicit drug use disorders. By 2020, mental and substance use disorders will surpass all physical diseases as major causes of disability (Center for Behavioral Health Statistics and Quality, 2015).

Screening, Brief Intervention, and Referral to Treatment (SBIRT) is "an evidence-based practice used to identify, reduce, and prevent problematic use, abuse, and dependence on alcohol and illicit drugs" (SAMHSA-HRSA Center for Integrated Health Solutions, n.d.). The SBIRT model was prompted by an Institute of Medicine recommendation that called for community-based screening for health risk behaviors and specifically included substance use.

SBIRT is an approach to the delivery of early intervention and treatment to people with substance use disorders and those at risk of developing these disorders (Center for Behavioral Health Statistics and Quality, 2015).

Screening:	Assessing a patient for risky substance use behaviors by using standardized screening tools. Screening can occur in any healthcare setting.
Brief Intervention:	Engaging a patient showing risky substance use behaviors in a short conversation, providing feedback and advice.
Referral to Treatment:	Providing a referral to brief therapy or additional treatment to patients who screen in need of additional services.

For more information, visit the SAMHSA-HRSA Center for Integrated Health Solutions website.

the drug has effects similar to LSD but with a longer duration.

- **Phencyclidine (PCP, crystal, angel dust).** Produces a trancelike state without loss of consciousness that may last for days. Once available as an anesthetic, the substance was removed from the market in 1965 because patients experienced delirium and panic attacks as they recovered from anesthesia. The powdered drug is sometimes sprinkled on marijuana and smoked, or it may be snorted or taken as tablets. Typical effects include slurred speech, detachment from reality, time distortion, and a sensation of floating in space. It does not produce the same types of hallucinations seen with LSD. Phencyclidine is probably the most dangerous of the hallucinogens because high doses can cause severe and violent panic attacks, seizures, coma, and death.
- **Ketamine (K, kitkat, or special K).** Closely related to phencyclidine, ketamine has been used historically as an anesthetic but is now rarely used for that purpose. The most common source of the drug is diversion from veterinary offices. Liquid ketamine may be added to drinks, injected, or evaporated to a solid form, which is snorted or taken as pills. Effects are similar to those of phencyclidine, although they only last 35 to 40 minutes. Unconsciousness and amnesia may occur at high doses, and psychoses can be induced with continued use.
- **Dextromethorphan (DXM, robo).** A substance included in over-the-counter (OTC) cold remedies for its cough suppressant properties. Of the drugs of abuse, it is the only substance that can be readily and legally purchased by teens. Abusers will purchase extra-strength remedies and consume large quantities to achieve dissociative effects similar to those of phencyclidine and ketamine. Effects include slurred speech, dizziness, drowsiness, euphoria, and lack of motor coordination. Overdose can cause brain damage, seizures, stroke, hypothermia, and death. Because cold medicines often contain multiple drugs, abusers of dextromethorphan may experience toxicity due to overdoses of antihistamines, aspirin, or acetaminophen. Pure dextromethorphan is also available on the black market in high-dosage tablet form.

Central Nervous System Stimulants

27.10 Stimulants such as amphetamines and cocaine increase the activity of the central nervous system.

The stimulants include a diverse family of drugs with the ability to excite the CNS. Some are prescription drugs used to treat narcolepsy and attention-deficit/hyperactivity disorder (ADHD). As drugs of abuse, stimulants are taken to produce a sense of exhilaration, improve mental and physical performance, reduce appetite, or prolong wakefulness. Stimulants include the amphetamines, methylphenidate, and cocaine. Some CNS stimulants are club drugs. Caffeine is also included as a CNS stimulant although it does not have the same negative health characteristics as the other drugs in this group.

Amphetamines and Methylphenidate

Amphetamines produce their effects by increasing the activity of the endogenous neurotransmitters norepinephrine, serotonin (5-HT), and dopamine. Norepinephrine affects awareness and wakefulness by activating neurons in a part of the brain called the **reticular formation**. High doses of

amphetamines give the user a feeling of self-confidence, elevated mood, euphoria, and empowerment. Fatigue is diminished and the individual can perform at a high level of alertness for an extended time. Appetite is suppressed.

By increasing the activity of norepinephrine, many physiologic actions of amphetamines resemble those of sympathetic nervous system activation (see Chapter 15). Cardiovascular and respiratory activities are significantly affected, resulting in increased heart rate, high blood pressure, and increased breathing rate. Other symptoms include dilated pupils, sweating, and tremors. Overdoses of some stimulants lead to seizures, dysrhythmias, stroke, and cardiac arrest.

Although short-term use of amphetamines induces pleasurable feelings, long-term use causes restlessness, anxiety, defensiveness, and fits of rage, especially when the user is coming down from a prolonged drug experience. Chronic use can lead to a psychosis that closely resembles paranoid schizophrenia, although this condition usually resolves within several days after discontinuation of the drug. Tolerance to the pleasurable effects of amphetamines occurs very quickly, especially if the drugs are injected.

Amphetamines and dextroamphetamines were once widely prescribed to treat depression, weight loss, drowsiness, and congestion. Because of their ability to enhance alertness, pilots, students, and healthcare workers on long shifts have historically abused amphetamines. In the 1970s it was recognized that the adverse effects and abuse potential of amphetamines outweighed their legitimate medical uses. Current therapeutic applications of these drugs are extremely limited. Most substance abusers obtain these drugs from illegal laboratories, which can produce some of the amphetamines using readily available chemicals and make tremendous profits. Physical dependence to amphetamines is unusual and withdrawal symptoms are not life threatening. The only potentially serious symptom of amphetamine withdrawal is depression.

Dextroamphetamine (Dexedrine) may be used for short-term weight loss, when all other attempts to reduce weight have been exhausted, and to treat narcolepsy, a rare disease in which patients fall asleep unexpectedly. Methamphetamine, commonly called *ice*, is often used as a recreational drug for users who like the rush of euphoria that it gives them. It is usually administered in powder or crystal form (crystal meth) but it may also be smoked. Methamphetamine is a Schedule II drug marketed under the trade name Desoxyn, although most abusers obtain it from illegal methamphetamine laboratories. Methamphetamine can be easily synthesized from pseudoephedrine, an OTC decongestant. This has led to states placing pseudoephedrine behind the pharmacy counter and has motivated pharmaceutical manufacturers to find a replacement drug for pseudoephedrine in cold and flu remedies. A structural analog of methamphetamine, methcathinone (street name Cat), is made illegally and snorted, taken PO, or injected IV. Methcathinone is a Schedule I agent.

Methylphenidate (Ritalin) is a CNS stimulant widely prescribed for children diagnosed with ADHD because the drug exerts a calming effect in children who are inattentive or hyperactive. The drug stimulates the alertness center in the brain and the child is able to focus on complex tasks for longer periods. The therapeutic applications of methylphenidate are discussed in Chapter 24.

Methylphenidate is a Schedule II drug that has many of the same pharmacologic actions as cocaine and amphetamines. It is sometimes abused by adolescents and adults seeking euphoria, increased alertness, or appetite suppression. Tablets are crushed and snorted or dissolved in liquid and injected IV. Ritalin is sometimes mixed with heroin, a combination called a "speedball." Most Ritalin used illegally is obtained by diversion from legal prescriptions, by theft, or by patients selling or sharing their drugs.

Cocaine

Cocaine is a natural substance obtained from leaves of the coca plant, which grows in the Andes Mountains of South America. Natives in this region chew the coca leaves, or make teas of the substance. Much of the cocaine entering the United States comes from Colombia and other South American countries. It was once used as an anesthetic for eye, nose, and throat surgery but is no longer used for this purpose.

Cocaine is a Schedule II drug that produces psychoactive and physiologic actions similar to the amphetamines, although its effects can be much more rapid and intense. It is the second most commonly used illicit drug in the United States. Routes of administration include snorting, smoking, inhaling vapors, and injecting. Injection or inhalation of cocaine produces an instantaneous euphoria that lasts 10 to 20 seconds. In small doses, cocaine produces feelings of intense euphoria, a decrease in hunger and pain, illusions of physical strength, and increased sensory perception. Larger doses will increase these effects and cause rapid heartbeat, dysrhythmias, sweating, dilation of the pupils, and an elevated body temperature. The half-life of cocaine is short, 60 to 90 minutes when injected, and tolerance rapidly develops to the pleasurable aspects of the drug. Because of the short half-life, addicts may take cocaine at intervals of 10 to 45 minutes, sometimes for several consecutive days. Unfortunately, tolerance develops slowly to the cardiovascular actions of cocaine. As the abuser escalates the doses to produce a desired level of euphoria, cardiovascular damage may be progressive.

Cocaine readily crosses the placenta to produce marked effects on the fetus. Because the fetus does not have the hepatic enzymes necessary to metabolize cocaine, drug

effects are prolonged. Reports of cocaine-related changes include increased risk of miscarriage, preterm labor, low birth weight, and, possibly, birth defects. Newborns have increased irritability, feeding difficulties, and are easily startled.

The adverse effects of cocaine use are essentially the same as those for amphetamines. Metabolism by the liver forms an active metabolite that is more toxic than cocaine itself. After the feelings of euphoria diminish, the cocaine user may be left with a sense of irritability, exhaustion, insomnia, depression, and extreme distrust. Some users report the sensation that insects are crawling under the skin. Users who snort cocaine develop a runny nose, a crusty redness around the nostrils, and deterioration of the nasal cartilage. Overdose can result in dysrhythmias, seizures, stroke, or death due to respiratory arrest. Psychologic dependence often leads to intense craving for the drug.

Caffeine

Caffeine is a natural substance found in the seeds, leaves, or fruits of more than 63 plant species throughout the world. Significant amounts of caffeine are consumed in chocolate, coffee, tea, soft drinks, and ice cream. Caffeine is sometimes added to OTC pain relievers and stimulants because it has been shown to increase the effectiveness of these medications. Caffeine is rapidly distributed to almost all parts of the body after ingestion, and several hours are needed to metabolize and eliminate the drug. Caffeine has a pronounced diuretic effect.

Caffeine is considered a CNS stimulant because it produces increased mental alertness, restlessness, nervousness, irritability, and insomnia. The physical effects of caffeine include dilation of the respiratory passages, increased blood pressure, increased production of stomach acid, and changes in blood glucose levels. Repeated use of caffeine may result in physical dependence and tolerance. Withdrawal symptoms include severe headaches, fatigue, depression, and impaired performance of daily activities.

PharmFACT

In 2012, an estimated 66.9 million Americans ages 12 years and older were current users of a tobacco product. This represents 25.5% of the population in that age range (SAMHSA, 2014).

Nicotine

27.11 Nicotine is a powerful and highly addictive cardiovascular and central nervous system stimulant.

Although nicotine is sometimes considered a CNS stimulant because it enhances alertness, its actions and long-term consequences place it into a class by itself. Nicotine is unique among abused substances in that it is legal, strongly addictive, and highly carcinogenic. Furthermore, tobacco use can cause harmful effects to those in the immediate area due to secondhand smoke. Patients often do not consider tobacco use to be substance abuse. It is the most common form of chemical dependence in the United States. Tobacco use among young people has been declining: The rate of smoking among youths ages 12 to 17 in 2012 was half of the rate reported in 2002.

The most common method by which nicotine enters the body is through the inhalation of cigarette, pipe, or cigar smoke. Tobacco smoke contains several thousand chemicals, a significant number of which are carcinogens. The primary addictive drug present in cigarette smoke is nicotine, which reaches the brain in only 15 seconds, with effects that last from 30 minutes to several hours. Although nicotine has a half-life of only 2 to 3 hours, it accumulates in the body and is slowly released from the tissues, giving the patient virtually a 24-hour exposure to the drug.

Nicotine affects many body systems, including the nervous, cardiovascular, and endocrine systems. Nicotine promotes the release of epinephrine and has a direct stimulatory effect on the reticular activating system of the brain, causing symptoms that range from increased alertness and ability to focus to feelings of relaxation or lightheadedness. The psychoactive effects of smoking are generally described as pleasurable. The cardiovascular effects of nicotine include an accelerated heart rate and increased blood pressure, caused by activation of nicotinic receptors located throughout the autonomic nervous system (see Chapter 12). The cardiovascular effects of nicotine are particularly serious in smokers who are taking oral contraceptives—their risk of a fatal heart attack is 5 times greater than that of nonsmokers. Muscular tremors may occur with moderate doses of nicotine, and convulsions result from very high doses. Nicotine produces lower body weight by reducing appetite and increasing body metabolism. Chronic use leads to emphysema, heart disease, and lung cancer. There is clear evidence that tobacco use affects the reproductive system. Smokers are much more likely to be infertile, and smoking during pregnancy can cause birth defects and lower birth weight.

Both psychologic and physical dependence occur relatively quickly with nicotine. Patients tend to continue their drug use for many years, despite overwhelming medical evidence that the quality of their life will be adversely affected and their lifespan shortened. Furthermore, a large majority of smokers try to quit each year and are unsuccessful and state that they wish they had never started the habit. Only 25% of those who attempt to stop smoking remain tobacco-free 1 year later.

Figure 27.3 Nicotine replacement therapy: transdermal patch.
Courtesy of Ruth Jenkinson/Dorling Kindersley, Ltd.

Discontinuation of tobacco results in a withdrawal syndrome that includes agitation, impaired concentration, weight gain, anxiety, headache, and an extreme craving for the drug. The syndrome peaks at 24 to 48 hours after the last dose and may continue over several weeks. Symptoms vary in intensity among patients and are not related to dose or duration of use; those who are light smokers or who have smoked for a shorter length of time do not necessarily have less intense withdrawal symptoms. Approximately 90% of individuals who successfully stop smoking do so without any treatment.

Nicotine replacement therapy (NRT) is based on the assumption that the blood level of nicotine is what drives people to continue smoking. When blood nicotine levels fall, the individual begins to experience early symptoms of withdrawal, which are quickly eliminated by smoking another cigarette. Indeed, blood nicotine levels have clearly been shown to influence smoking behavior. For example, if a smoker switches to low-nicotine cigarettes, he or she will take longer and more frequent puffs. NRT delivery systems include transdermal patches (Figure 27.3), nasal sprays, and chewing gum that raise serum nicotine levels and help patients to deal with the unpleasant withdrawal symptoms. Tobacco use, however, has a strong psychologic component and simply replacing nicotine with patches or gum is ineffective for a large number of patients.

Two prescription medications are used to promote smoking cessation. Bupropion (Zyban), classified as an antidepressant, reduces cravings for nicotine and has been found to double the likelihood of becoming tobacco-free if it is taken for 3 to 6 months. Therapy generally begins 1 to 2 weeks before smoking cessation to lessen the severity of withdrawal symptoms. Bupropion is sometimes given concurrently with NRT. Common side effects include insomnia, agitation, headache, and dry mouth.

Varenicline (Chantix) is approved to manage nicotine withdrawal in patients seeking smoking cessation. Common side effects include nausea, vision changes, fainting, and unusual dreams. Both bupropion and varenicline carry a warning that advises patients of serious neuropsychiatric events such as hostility or suicidal thoughts that can occur during therapy or shortly after discontinuation of the drug.

PROTOTYPE DRUG Varenicline (Chantix)

Classification **Therapeutic:** Drug for smoking cessation
Pharmacologic: Nicotinic receptor agonist

Therapeutic Effects and Uses: Approved in 2006, the only indication for varenicline is smoking cessation treatment. Doses are gradually increased over an 8-day period and maintained for 12 to 24 weeks to reduce withdrawal symptoms and cravings for smoking. It also prevents nicotine from reaching its receptors, thus blocking some of the pleasurable sensations should the individual relapse and start smoking again.

Mechanism of Action: Varenicline activates nicotinic acetylcholine receptors in the brain and blocks nicotine from reaching the brain's receptors.

Pharmacokinetics:

Route(s)	PO
Absorption	Completely absorbed
Distribution	Bound to plasma protein (20%)
Primary metabolism	Mostly unmetabolized
Primary excretion	Renal
Onset of action	3–4 h
Duration of action	24 h

Adverse Effects: Nausea, vomiting, vivid dreams, and constipation are the most common side effects. Rare adverse events include angioedema, serious skin reactions, and myocardial infarction. Serious neuropsychiatric events can occur during therapy or shortly after discontinuation of the drug. Patients experiencing changes in behavior such as agitation, hostility, depressed mood, or thoughts of suicide should contact their healthcare provider immediately.

Contraindications/Precautions: The only contraindication is a history of serious skin reactions with varenicline.

Drug Interactions: When used in combination with NRT, varenicline causes an increased incidence of nausea, vomiting, headache, dizziness, and fatigue, which may result in a premature termination of therapy.

Pregnancy: Category C.

Treatment of Overdose: No specific treatment for varenicline overdose is available.

Nursing Responsibilities: Key nursing implications for patients receiving varenicline are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Substance Abuse Disorders.

Drugs Similar to Varenicline (Chantix)

There are no drugs similar to varenicline.

CONNECTIONS: Lifespan Considerations

Abuse of Volatile Inhalants by Children and Adolescents

Many parents are concerned that their children will smoke tobacco or marijuana or become addicted to crack or amphetamines. Few parents realize that the most commonly abused substances are readily available in their own homes. Inhaling volatile chemicals, known as *huffing*, *bagging*, or *sniffing*, is most prevalent in the 13- to 20-year-old age group. In fact, inhalants are often one of the first drugs that young adolescents use, and they are used more by younger adolescents than older ones (Center for Behavioral Health Statistics and Quality, 2015). Virtually any organic compound can be huffed, including nail polish remover, spray paint, household glue, correction fluid, propane, gasoline, and even whipped cream propellants. These agents are available in the home, in stores, and in the workplace. They are inexpensive, legal, and can be used anytime and anywhere. Children can die after a single exposure or sustain brain damage, which may be manifested as slurred or slow speech, tremor, memory loss, or personality changes. Nurses who work with pediatric patients should be aware of the widespread nature of this type of abuse and advise parents to keep a close watch on volatile substances.

Inhalants

27.12 Inhalant abuse occurs when patients breathe the fumes of vaporized substances.

Inhalants are a diverse group of substances that have in common the ability to vaporize or form a gas at room temperature. Some are already in gaseous form, whereas others are liquids that have the property of volatility—rapid evaporation when exposed to air. Sometimes the liquids are heated to increase the speed or extent of vaporization. Most drugs in this class are placed in a paper or plastic bag or soaked on a cloth and deeply inhaled. Inhaling the fumes is known as huffing.

Inhalants differ greatly in their chemical structures and include nearly any chemical that can be vaporized. Products abused as inhalants include adhesives and glues, aerosols, cleaning agents, solvents, and fuels. These products are readily available and can be purchased at hardware or office supply stores. The highest use of inhalants is found among teens and preteens, probably because these agents can be found in nearly every household (see Table 27.3). Legal anesthetics such as nitrous oxide that are sometimes abused by medical personnel are also classified as inhalantsand are discussed in Chapter 26.

The inhalation route affords almost instantaneous drug action and, because most of the inhalants are lipid soluble, the substances quickly enter the brain. The specific psychoactive effects depend on the inhalant used but generally include lightheadedness, drowsiness, exhilaration, and euphoria. Hallucinations are common. Symptoms of inhalant abuse often resemble alcohol intoxication. Because most psychoactive effects of inhalants are transient and disappear within minutes, the user may repeat the drug use multiple times over a period of several hours. Coma and death are possible with repeated exposure or high doses.

Because most inhalant abuse is sporadic, physical dependence is not observed, and it is unknown whether tolerance develops. Some of the inhalants cause hangover-like symptoms after the psychoactive effects wear off. When chronic abuse does occur, it is generally in adult men. Chronic effects can be serious and permanent, with the most obvious effects on the nervous system. Cognitive impairment, tremors, loss of coordination, hallucinations, psychosis, and dementia may be observed. Nephrotoxicity is common with certain inhalants. The breathing reflex may be diminished and patients may suffocate from placing a plastic bag over their heads.

Treatment for inhalant abuse is symptomatic. Long-term behavioral therapy may be needed to reinforce to the patient that permanent damage will result from chronic, continued abuse.

Table 27.3 Monitoring the Future Study: Trends in Prevalence of Inhalants for 8th Graders, 10th Graders, and 12th Graders; 2016 (in percent)*

Drug	Time Period	8th Graders	10th Graders	12th Graders
Inhalants	Lifetime	[7.70]	6.60	5.00
	Past Year	[3.80]	2.40	1.70
	Past Month	1.80	1.00	0.80

* Data in brackets indicate a statistically significant change from the previous year.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Substance Abuse Disorders

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, neurologic, respiratory, or hepatic disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, substance used in disorder, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a dietary history, especially noting possible vitamin deficiencies.
- Assess for the presence and level of pain.
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., hepatic function studies, complete blood count [CBC]).
- Assess the patient's commitment to treatment and the ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased use or abstinence from the substance).
- Continue periodic monitoring of hepatic function studies, CBC.
- Assess vital signs, especially blood pressure and pulse.
- Assess for and report adverse effects: headache, nausea, vomiting, insomnia, constipation, pain, skin rashes, excessive dizziness, drowsiness, confusion, agitation, thoughts of suicide, seizures.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. Substance use treatment requires commitment and continuing treatment and follow-up. (Nonpharmacologic measures such as group therapy may assist the patient in remaining substance-free. Regularly scheduled visits with the healthcare provider are opportunities to evaluate the success of treatment and possibility for relapse.)	• Teach the patient that maintaining consistency of treatment to decrease substance use and eventual abstinence is the goal of therapy.
Minimizing adverse effects: • Continue to monitor vital signs, including respiratory rate, pulse, and blood pressure as ordered in patients receiving buprenorphine and disulfiram. (Buprenorphine [Suboxone, Zubsolv] is an opioid and may cause opioid-related adverse effects in higher dosages. Disulfiram [Antabuse] may cause intense reactions when alcohol is ingested or absorbed through the skin and may cause cardiovascular effects such as dysrhythmias, chest pain, and respiratory depression.)	• Teach the patient receiving buprenorphine to maintain the dosage as prescribed and to not increase the dose. • Teach the patient receiving disulfiram that all forms of alcohol must be avoided, including skin preparations and mouth rinses that contain alcohol. A reaction may occur up to 14 days after the last dose.
• Monitor for changes in behavior, including depression, hostility, agitation, or thoughts of suicide in patients taking varenicline (Chantix). (The drug carries a black box warning for serious neuropsychiatric events.)	• Instruct the patient, family, or caregiver to report immediately any unusual changes in mood or behavior.
• Monitor for skin rashes and facial or throat edema in patients taking varenicline. (Serious dermatologic reactions including angioedema have been noted.)	• Instruct the patient, family, or caregiver to report immediately any unusual rashes, changes in skin condition, or swelling of the tongue, face, or throat.
• Additional NRT should not be used during smoking cessation therapy with varenicline (Chantix). (Additional NRT will increase the incidence of adverse drug effects and may lead to early cessation of therapy.)	• Teach the patient that other NRT, including OTC patches and gum, should not be used while taking varenicline.
• Provide referrals to supportive therapies as an adjunct to substance use treatment. (Nonpharmacologic measures such as group therapy may be beneficial during therapy and assist in maintaining a substance-free state after treatment.)	• Provide referral to supportive therapies such as Alcoholics Anonymous or Narcotics Anonymous and smoking cessation groups.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of the drug (e.g., take the drug exactly as prescribed). (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs. • Teach the patient taking buprenorphine (Suboxone, Zubsolv) to take the medication sublingually by placing the tablet under the tongue and allowing it to dissolve. Do not chew or swallow the tablet. If more than one tablet is used, place all tablets under the tongue at the same time.

Anabolic Steroids

27.13 Anabolic steroids are abused for their ability to increase muscle strength.

All of the drugs presented thus far in this chapter have in common the ability to affect the CNS and produce psychoactive effects. Many produce euphoria, some induce relaxation, and yet others enhance alertness. In most cases, the user views the drug experience as pleasurable and the drug effects are experienced soon after it is taken, sometimes within seconds. Anabolic steroids, however, are not taken for their CNS actions, and their desirable effects may be delayed for weeks or months.

Anabolic steroids are similar to testosterone, the primary male sex hormone or androgen. The term *anabolic* means "growth" or "building up." Because these substances can add to skeletal muscle mass and increase strength, they are usually abused in an attempt to enhance athletic performance. Do these drugs actually boost performance? The answer is a qualified yes. The most important aspects of athletic performance are skill, training, and confidence. If these factors are equal among performers, anabolic steroids may indeed provide an extra boost in performance, which is all important in a competitive sport such as track, downhill skiing, or swimming where a few hundredths of a second can mean the difference between first and sixth place. On the other hand, no amount of steroid is able to overcome lack of athletic skill or inadequate training. Amateur and professional sports organizations have banned the use of these drugs and athletes may be eliminated from competition if they test positive for anabolic steroids. Some abusers take anabolic steroids to enhance their appearance and self-confidence, rather than for athletic competition.

Anabolic steroids have legitimate medical uses as replacement therapy for men who secrete deficient quantities of testosterone and they are occasionally used to treat certain cancers. Doses used by abusers, however, are 10 to 100 times higher than those required for therapeutic use.

Anabolic steroids may be taken as tablets, as IM injections, or applied as ointments or as a transdermal patch. Abusers may take two or more different types of steroids concurrently, sometimes by different routes, a practice called "stacking." The drugs may be taken in a cyclic pattern called "pyramiding" in which the dose is progressively increased over 6 to 12 weeks, then slowly decreased to zero. Abusers believe that this is a safer and more effective way to obtain benefits from the drugs.

One of the ironies of steroid abuse is that the very drug that is being taken to enhance appearance and performance eventually produces serious consequences that have the opposite effect. Men may believe that anabolic steroids make them appear more masculine, but the drugs can cause infertility, impotence, testicular atrophy, and breast enlargement (gynecomastia). Women taking anabolic steroids will develop masculine characteristics, excessive growth of body hair (hirsutism), shrinking of breast size, menstrual irregularities, and deepening of the voice. The most serious adverse effects, in both men and women, include hepatic cysts, elevated cholesterol, myocardial infarction, and stroke. Personality changes include aggression, violent behavior, depression, insomnia, anorexia, and decreased libido.

Anabolic steroids are classified as Schedule II drugs due to their abuse potential. In an attempt to stem the rising abuse of these drugs, Congress passed the Anabolic Steroid Control Act of 2004 to control 26 different steroid precursors, such as androstenedione (Andro). Some companies were legally selling these precursors as dietary supplements, despite the fact that these agents are metabolized to steroids in the body and essentially carry the same risks. It is interesting to note that one of the most popular supplements, dehydroepiandrosterone (DHEA), was specifically and intentionally omitted from that list and remains legal. DHEA is a natural steroid precursor secreted by the adrenal gland that is claimed to have antiaging and performance-enhancing properties.

27.14 The nurse has a pivotal role in recognizing and treating substance abuse.

The nurse serves a key role in the prevention, diagnosis, and treatment of substance abuse. During assessment, nurses may be the first members of the healthcare team to recognize symptoms and signs of substance abuse. Patients are often reluctant to report their drug use for fear of embarrassment or being arrested. In known IV drug users, the nurse must consider the possibility of HIV infection, hepatitis, tuberculosis, and associated diagnoses. The nurse must be knowledgeable about the signs and symptoms of substance abuse and develop a keen sense of perception during the assessment process. In their role as educators, nurses distribute important information on substance abuse prevention and the proper use of prescription drugs. A trusting nurse–patient relationship is essential to helping patients deal with their dependence.

It is often difficult for a practitioner not to condemn or stigmatize a patient for his or her substance abuse. Nurses, especially those in large cities, are all too familiar with the devastating medical, economic, and social consequences of drug abuse. The nurse must be firm in disapproving substance abuse, yet compassionate in trying to help the patient receive treatment. A list of social agencies dealing with dependency should be readily available to provide to patients. Whenever possible, the nurse should attempt to involve family members and other close contacts in the treatment regimen.

Understanding Chapter 27

Key Concepts Summary

27.1 A wide variety of substances may be abused by patients.

27.2 Drugs with a potential for abuse are restricted by the Controlled Substances Act and are categorized into schedules.

27.3 Addiction is an overwhelming compulsion to continue repeated drug use.

27.4 Physical and psychologic dependence lead to continued drug-seeking behavior despite negative health and social consequences.

27.5 A withdrawal syndrome is a set of characteristic symptoms that occurs when an abused substance is discontinued.

27.6 Tolerance occurs when the body adapts to a drug and larger doses are needed to produce a therapeutic effect.

27.7 Central nervous system depressants, which include sedatives, opioids, and alcohol, decrease the activity of the central nervous system.

27.8 Marijuana is the most frequently abused illicit substance.

27.9 Hallucinogens and club drugs cause an altered state of thought and perception.

27.10 Stimulants such as amphetamines and cocaine increase the activity of the central nervous system.

27.11 Nicotine is a powerful and highly addictive cardiovascular and central nervous system stimulant.

27.12 Inhalant abuse occurs when patients breathe the fumes of vaporized substances.

27.13 Anabolic steroids are abused for their ability to increase muscle strength.

27.14 The nurse has a pivotal role in recognizing and treating substance abuse.

CASE STUDY: Making the Patient Connection

Remember the patient "Jamie Wilkins" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Jamie Wilkins has come to the counseling clinic to get information and advice about her pregnancy and drug use. She is a 19-year-old woman who has been living with her boyfriend for the past 18 months. Since she moved in, she has been a daily user of heroin.

Jamie has a long history of substance abuse. When she was 14 years old, her stepfather sexually abused her on a regular basis. To cope with the guilt and shame, she began using alcohol and marijuana. On her 16th birthday, Jamie ran away from home and never returned. Since then she has done anything and everything possible to survive, including selling herself for sex.

To support herself and her heroin addiction, Jamie has become a prostitute. She states that she usually drinks at least four to five beers before she walks the streets at night. If she cannot score enough heroin, she will smoke crack or take Valium just to "mellow out." Jamie says that her drug abuse is only to calm her nerves and get her through the night. In periods when she was not able to obtain drugs, she states she felt sick with trembling and perfuse sweating. However, she is convinced that she can stop any time she wishes.

Jamie reports that she has not had a menstrual period in 2 months and her breasts are swollen and tender. She is certain she is pregnant, although she has not been tested, and is confused about what to do. She is hopeful that her unemployed boyfriend is the father but is not totally sure. She believes that if she stops working, he will abandon her, and there will be no means to support herself or a baby.

Critical Thinking Questions

1. How would you classify Jamie's substance abuse: physical dependence or psychologic dependence, or both? Explain.

2. Create a list of abused substances reported by Jamie. What symptoms of withdrawal would you expect with each?
3. What effect will Jamie's substance abuse have on her unborn baby? Should Jamie stop using drugs while pregnant? Why or why not?
4. As the nurse, describe your approach in dealing with this patient. What is one evidence-based intervention you should consider when speaking with Jamie?
5. Addiction depends on multiple variables such as drug, user, and environmental factors. Based on the case study, describe how each variable contributes to Jamie's substance abuse.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

A neighbor reports that patient Martin Thomas was discovered wandering the halls in his apartment building in a confused state. The neighbor states that Martin called him by the wrong name even though they have known each other for several years. Martin was agitated about not being able to find the bus stop. In the emergency department, Martin appears apprehensive, diaphoretic, and trembling. His nose and cheeks are red with spider veins, and his abdomen is noticeably distended. He tells you that up until 3 days ago, he consumed alcohol daily. However, because he has no money, he cannot buy any liquor and has not been drinking.

1. Define *delirium tremens.* What is the treatment priority for this condition?
2. Discuss how food or beverages can increase the excretion rate of alcohol.
3. Describe the effects of alcohol on the central nervous system. Is alcohol a stimulant or a depressant?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient returned from major surgery 3 hours ago and requests medication for pain. In considering the best action for this patient, the nurse knows that:
    1. Prescription drugs rarely cause addiction when used according to accepted medical protocol.
    2. All drugs should be withheld until the patient's past substance abuse history is evaluated.
    3. It is best to wait until the patient can no longer tolerate the pain to avoid addiction problems.
    4. Patients often request analgesia when it is not really needed.

2. Which of the following statements made by the patient recovering from a substance use disorder would indicate high potential for relapse?
    1. "I need the help of a support system to stop using."
    2. "After I stop using, I will no longer have a desire to use drugs."
    3. "Whom I hang out with doesn't make any difference in whether or not I use drugs."
    4. "Talking with other recovering addicts will help me cope."

3. A nurse is teaching a patient who will begin varenicline (Chantix) for smoking cessation. Which of the following instructions will the nurse give the patient? (Select all that apply.)
    1. Doses will be increased over a week's period and the drug used for up to 6 months.
    2. Smoking may continue because the drug blocks the harmful effects of nicotine.
    3. The drug is not known to cause any adverse effects and has an excellent safety profile.
    4. Any unusual rashes, skin reactions, or facial edema should be reported immediately.
    5. Any unusual changes in behavior including depression, hostility, or thoughts of suicide should be reported immediately.

4. Which parameter is most critical when a nurse is assessing a patient with an overdose of sedatives?
    1. Cardiac stimulation
    2. Respiratory suppression
    3. Hepatic dysfunction
    4. Depression of consciousness

5. A 22-year-old heroin addict is exhibiting withdrawal symptoms. Which symptoms of withdrawal does the nurse expect?
   1. Somnolence, lethargy, and fatigue
   2. Dry skin, rash, and itching
   3. Paranoia, hallucinations, and delusions
   4. Chills, runny nose, and muscle spasms

6. While teaching the patient about disulfiram (Antabuse), which of the following should the nurse instruct the patient to avoid?
   1. Mouthwash, alcoholic beverages, and over-the-counter cold medications
   2. Dairy products such as milk, cream, and yogurt
   3. Foods high in iron such as green leafy vegetables
   4. Driving or operating machinery while taking this medication

Chapter 28
Review of the Cardiovascular System

Chapter Outline

- Structure and Function of the Cardiovascular System
- Functions and Properties of Blood
  - Components of Blood
  - Hemostasis
- Cardiac Structure and Function
  - Cardiac Muscle
  - Coronary Arteries
  - Cardiac Conduction System
  - Cardiac Output
- Hemodynamics and Blood Pressure
  - Hemodynamic Factors Affecting Blood Pressure
  - Neural Regulation of Blood Pressure
  - Hormonal Influences on Blood Pressure

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the major structures of the cardiovascular system.
2. Identify the components of blood and their functions.
3. Construct a flowchart diagramming the primary steps of hemostasis.
4. Describe the structure of the heart and the function of the myocardium.
5. Describe the role of the coronary arteries in supplying the myocardium with oxygen.
6. Illustrate the flow of electrical impulses through the normal heart.
7. Explain the major factors affecting cardiac output.
8. Explain the effects of cardiac output, peripheral resistance, and blood volume on hemodynamics.
9. Discuss how the vasomotor center, baroreceptors, chemoreceptors, and hormones regulate blood pressure.

Key Terms

afterload, 482
antidiuretic hormone (ADH), 485
atrial natriuretic peptide (ANP), 485
atrial reflex, 485
automaticity, 479
baroreceptors, 485
cardiac output (CO), 481
chemoreceptors, 485
coagulation, 477
contractility, 482
ectopic foci, 481
erythropoietin, 475
extrinsic pathway, 477
fibrin, 478
fibrinogen, 478
hemopoiesis, 476
hemostasis, 477
intrinsic pathway, 477
myocardium, 479
peripheral resistance, 483
preload, 482
prothrombin, 478
renin-angiotensin-aldosterone system (RAAS), 485
sinus rhythm, 479
stroke volume, 482
thrombin, 478
thrombopoietin, 476
vasomotor center, 485
venous return, 482

It is likely that the nurse will administer more cardiovascular drugs than any other class of medications. Why is this the case? First, healthcare providers have discovered the huge benefits of keeping blood pressure and blood lipid values within normal limits and how to prevent heart attacks and strokes. Second, the heart and vessels weaken over time and, as the average lifespan of the population increases, more pharmacotherapy will be needed to treat the chronic cardiovascular diseases of older adults.

A comprehensive knowledge of cardiovascular anatomy and physiology is essential to understanding cardiovascular pharmacology, which encompasses the next 11 chapters of this text. The purpose of this chapter is to offer a brief review of the components of the structure and function of the cardiovascular system that will be important to understand for pharmacotherapy. For more comprehensive treatments of these topics, the student should refer to an anatomy and physiology textbook.

Structure and Function of the Cardiovascular System

28.1 The cardiovascular system consists of the blood, heart, and blood vessels.

The three major components of the cardiovascular system are the blood, heart, and blood vessels, as shown in Figure 28.1. These three components work as an integrated whole to transport the essential oxygen, nutrients, and other substances that keep the body in homeostasis. Disruption of this flow for even brief periods can have serious, if not lethal, consequences. The functions of the cardiovascular system are diverse and include the following:

- Transport of nutrients and wastes
- Pumping of blood
- Regulation of blood pressure
- Regulation of acid–base balance
- Regulation of fluid balance
- Regulation of body temperature
- Protection against invasion by microbes.

The cardiovascular system can function only with the cooperation of other body systems. For example, the role of the autonomic nervous system in controlling heart rate and blood vessel diameter is presented in Chapter 12. The kidneys are intimately involved in assisting the cardiovascular system with fluid and acid–base balance, as discussed in Chapter 33. The respiratory system must bring oxygen to the blood and remove carbon dioxide from it. The student should view the cardiovascular system as an important part of the body's ability to maintain overall homeostasis.

Functions and Properties of Blood

28.2 Blood consists of formed elements and plasma.

Blood is a liquid connective tissue that consists of formed elements suspended in plasma. The solid, formed elements of the blood are the erythrocytes, leukocytes, and platelets. When combined, the formed elements comprise about 45% of the composition of blood.

The most numerous blood cells are erythrocytes, which comprise 99.9% of the formed elements. Carrying the iron-containing protein hemoglobin, the erythrocytes are responsible for transporting oxygen to the tissues and carbon dioxide from the tissues to the lungs. A single erythrocyte can carry as many as 1 billion molecules of oxygen. Erythrocyte homeostasis is controlled by **erythropoietin**, a hormone secreted by the kidney in response to low oxygen levels in the blood. Once secreted, erythropoietin stimulates the body's production of erythrocytes. Insufficient

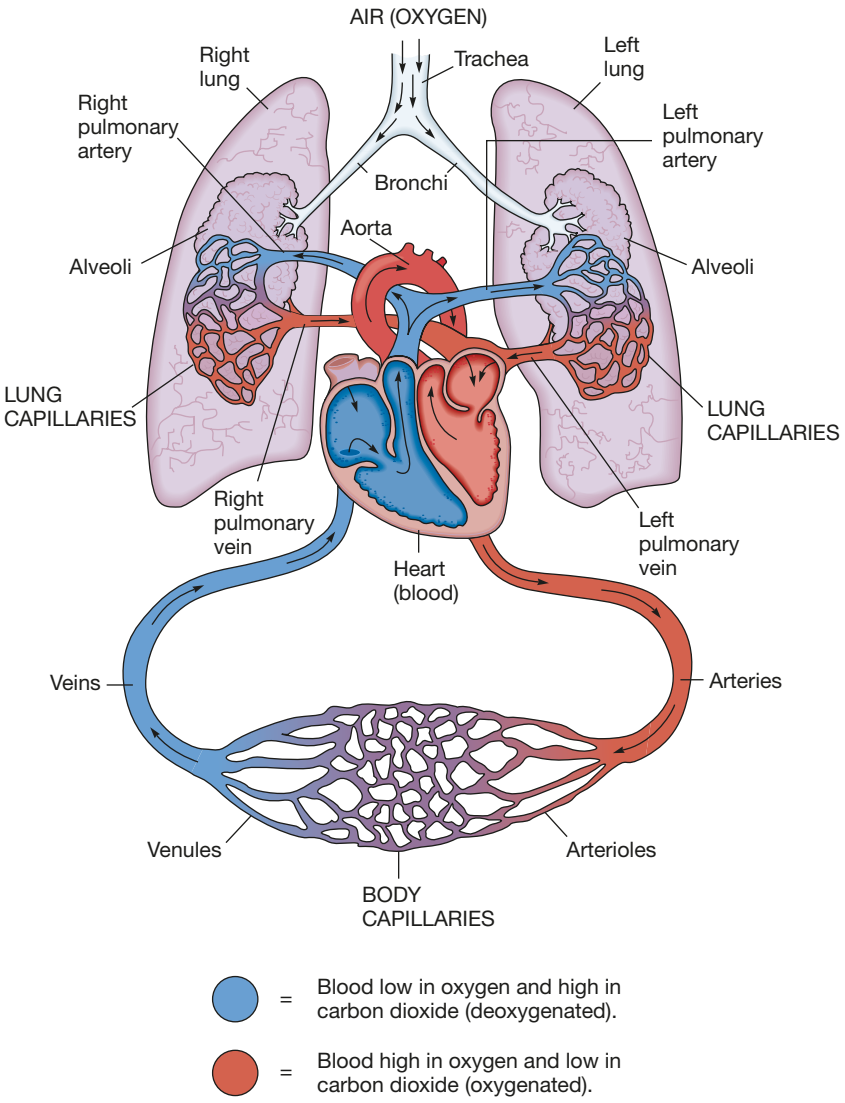

Figure 28.1 The cardiovascular system.

numbers of erythrocytes or structural defects such as sickle shapes lead to anemia, which is a common indication for pharmacotherapy (see Chapter 39).

Although small in number, leukocytes serve an essential role in the body's defense against infection. Unlike erythrocytes, which are all structurally identical, there are several types of leukocytes, each serving a different function. For example, neutrophils are the most common leukocyte and they respond to bacterial infections through phagocytosis of the microbes. The second most common leukocyte, the lymphocyte, is the key cell in the immune response that responds by secreting antibodies (B lymphocytes) or secreting cytokines (T lymphocytes) that rid the body of the microbe. A review of body defenses and the immune system is presented in Chapter 40.

The final formed elements of the blood are thrombocytes or platelets, which are actually fragments of larger cells called megakaryocytes. Platelets stick to the walls of damaged blood vessels to begin the process of blood coagulation, which prevents excessive bleeding from sites of injury. Abnormally low numbers of platelets, or thrombocytopenia, can result in serious delays in blood clotting. Platelet homeostasis is controlled by the hormone **thrombopoietin**, which promotes the formation of additional platelets. The role of platelets and thrombopoietin in blood coagulation is a major topic in Chapter 38, which discusses the pharmacotherapy of blood coagulation.

The production and maturation of blood cells, called **hemopoiesis** or hematopoiesis, occurs in red bone marrow. It is here that primitive stem cells of the blood become committed to forming erythrocytes, leukocytes, or platelets. This process occurs continuously throughout the lifespan and is subject to various homeostatic controls as well as certain drugs and physical agents. For example, ionizing radiation and a large number of drugs have the potential to adversely affect bone marrow and cause myelosuppression. Myelosuppression is a very serious adverse effect that reduces the number of erythrocytes, leukocytes, and thrombocytes, leaving patients susceptible to anemia, infection, and bleeding. Many drugs used to treat cancer and those given to reduce the possibility of transplant rejection can produce profound myelosuppression as a dose-limiting adverse effect.

Plasma is the fluid portion of blood that consists of water, proteins, electrolytes, lipoproteins, carbohydrates, and other regulatory substances. The primary proteins in plasma are albumins (54%), globulins (38%), and fibrinogen (7%). Albumin is the primary regulator of blood osmotic pressure (also called oncotic pressure), which determines the movement of fluids among the vascular, interstitial, and cellular compartments or spaces. Globulins, also known as immunoglobulins or antibodies, are important in protecting the body from foreign agents such as bacteria or viruses. Fibrinogen is a critical protein in the coagulation of blood. The liver synthesizes over 90% of the plasma proteins; therefore, patients with serious hepatic impairment will have deficiencies in coagulation and in maintaining body defenses.

Serum is a term closely related to plasma. Serum contains all the components of plasma, except clotting factors such as fibrinogen have been removed. Serum is often used for blood typing and for determining blood levels of substances such as cholesterol, glucose, and hormones.

Fluid balance in the body is achieved by maintaining the proper amount of plasma in the blood. Too little water

in plasma results in dehydration, whereas too much causes edema and hypertension (HTN). Various organs help to maintain normal fluid balance, including the kidneys, gastrointestinal (GI) tract, and skin. The pharmacotherapy of fluid and electrolyte imbalances is an important topic in pharmacology and is discussed in Chapter 33.

CONNECTION Checkpoint 28.1

From what you learned in Chapter 3, what role does plasma protein play in the distribution of drugs? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

To maintain homeostasis, the body must make 3 million erythrocytes every second. Red blood cells are so numerous that they comprise approximately one third of all cells in the body (Martini, Nath, & Bartholomew, 2015).

28.3 Hemostasis is a complex process involving multiple steps and a large number of enzymes and factors.

The process of **hemostasis** is complex, involving at least 13 different clotting factors that contribute to the slowdown and ultimate stoppage of blood flow. Hemostasis occurs in a series of sequential steps, sometimes referred to as a cascade. Hemostasis is an essential mechanism that the body uses to prevent excessive bleeding following injury. Medications can be used to modify several of these steps, either to speed up or delay the clotting process (see Chapter 38).

Injury to a blood vessel triggers the clotting process. The vessel spasms, causing constriction, which slows blood flow to the injured area. Platelets have an affinity for the damaged vessel: They become sticky and adhere to each other and to the injured area. The clumping of platelets, or aggregation, is facilitated by adenosine diphosphate (ADP), the enzyme thrombin, and thromboxane A_2. Platelet receptor sites and von Willebrand's factor make adhesion possible. The aggregated platelets disintegrate to initiate a platelet binding cascade. Blood flow is further slowed, thus allowing the process of **coagulation**, which is the formation of an insoluble clot, to occur. The basic steps of hemostasis are shown in Figure 28.2.

When collagen is exposed at the site of vessel injury, the damaged cells initiate the coagulation cascade. Coagulation itself occurs when fibrin threads create a meshwork that fortifies the blood constituents so that clots can develop. During the cascade, various plasma proteins that are circulating in an inactive state are converted to their active forms. Two separate pathways, along with numerous biochemical processes, lead to coagulation. The **intrinsic pathway** is activated in response to injury and takes several minutes to complete. The **extrinsic pathway** is activated when blood leaks out of a vessel and enters tissue spaces. The extrinsic pathway is less complex and is

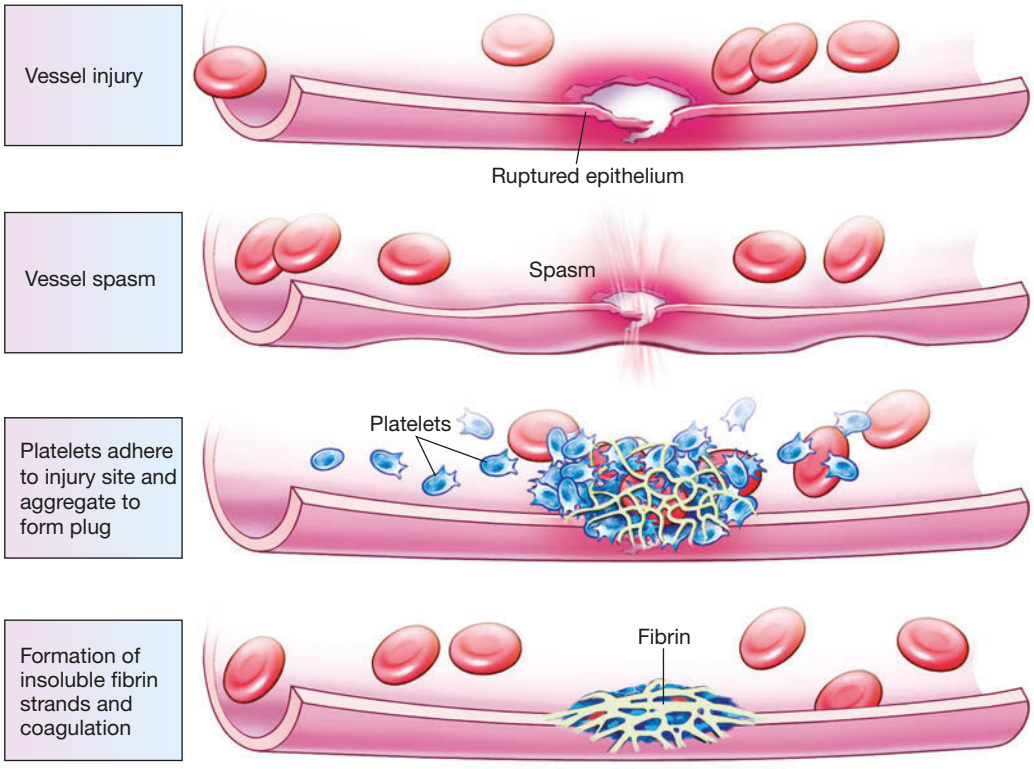

Figure 28.2 The basic steps in hemostasis.

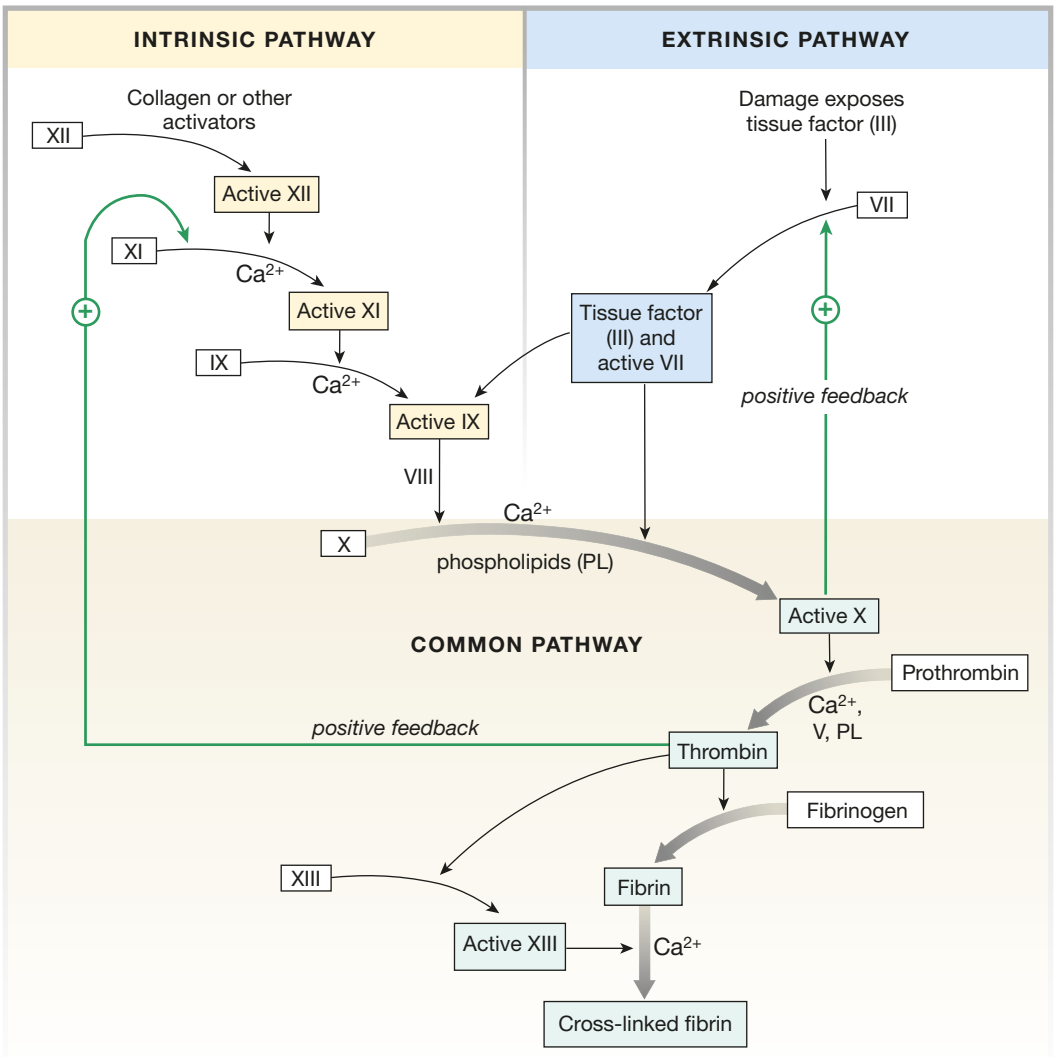

Figure 28.3 The coagulation cascade. Both the intrinsic pathway and extrinsic pathway lead to a common pathway and eventually a dense fibrin clot.

From *Human Physiology: An Integrated Approach*, 5th ed., by D. U. Silverthorn, 2010. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

completed within seconds. The two pathways share some common steps and the outcome is the same—the formation of the fibrin clot. The steps in each pathway are shown in Figure 28.3.

Near the end of the common pathway, a chemical called prothrombin activator (see Active X in Figure 28.3) is formed. The prothrombin activator converts the clotting factor **prothrombin** to an enzyme called **thrombin**. Thrombin then converts **fibrinogen**, a plasma protein, to long strands of **fibrin**. The fibrin strands provide a framework to anchor the clot. Thus two of the factors essential to clotting, thrombin and fibrin, are only formed after injury to the vessels. The fibrin strands form an insoluble web over the injured area to stop blood loss. Normal blood clotting occurs in about 6 minutes.

It is important to note that several clotting factors, including thromboplastin and fibrinogen, are proteins made by the liver that are constantly circulating through the blood in an inactive form. Vitamin K, which is made by bacteria residing in the large intestine, is required for the liver to make four of the clotting factors. Because of the crucial importance of the liver in creating these clotting factors, patients with serious hepatic impairment often have abnormal coagulation.

Cardiac Structure and Function

28.4 The heart is responsible for pumping blood throughout the circulatory system.

The heart is the hardest working organ in the body, pumping blood from before birth to the last minute of life. With the continuous workload, it is not surprising that this organ eventually weakens and that heart disease is the leading cause of death in the United States. The heart is a frequent target for pharmacotherapy.

The heart may be thought of as a thick, specialized muscle. The muscular layer, called the **myocardium**, is the thickest of the heart layers and is responsible for the physical pumping action of the heart. The thickness of the myocardium is greatest in the left ventricle because this chamber performs the greatest amount of work. Cardiac muscle contains extensive branching networks of cellular structures that connect cardiac muscle cells to each other, allowing the entire myocardium to contract as a coordinated whole.

Should myocardial cells (myocytes) die, the body is unable to replace them because cardiac muscle cells do not undergo mitosis. If a large area of cardiac muscle becomes deprived of oxygen and undergoes necrosis, the myocytes are replaced by fibrotic scar tissue and heart function becomes impaired. The different regions of the heart may not contract in a coordinated manner because conduction of the electrical potential may skip over areas of necrosis on the myocardium. This can result in heart failure or dysrhythmias, which are frequent indications for pharmacotherapy (see Chapters 36 and 37).

The heart has four chambers that receive blood prior to being pumped, as illustrated in Figure 28.4b. These chambers differ in size, depending on their function. The left ventricle is the largest and most powerful chamber, because it must hold and pump enough blood to all body tissues. During heart failure, the size of the left ventricle and the thickness of the myocardial layer in this chamber can increase in size, a condition known as left ventricular hypertrophy.

PharmFACT

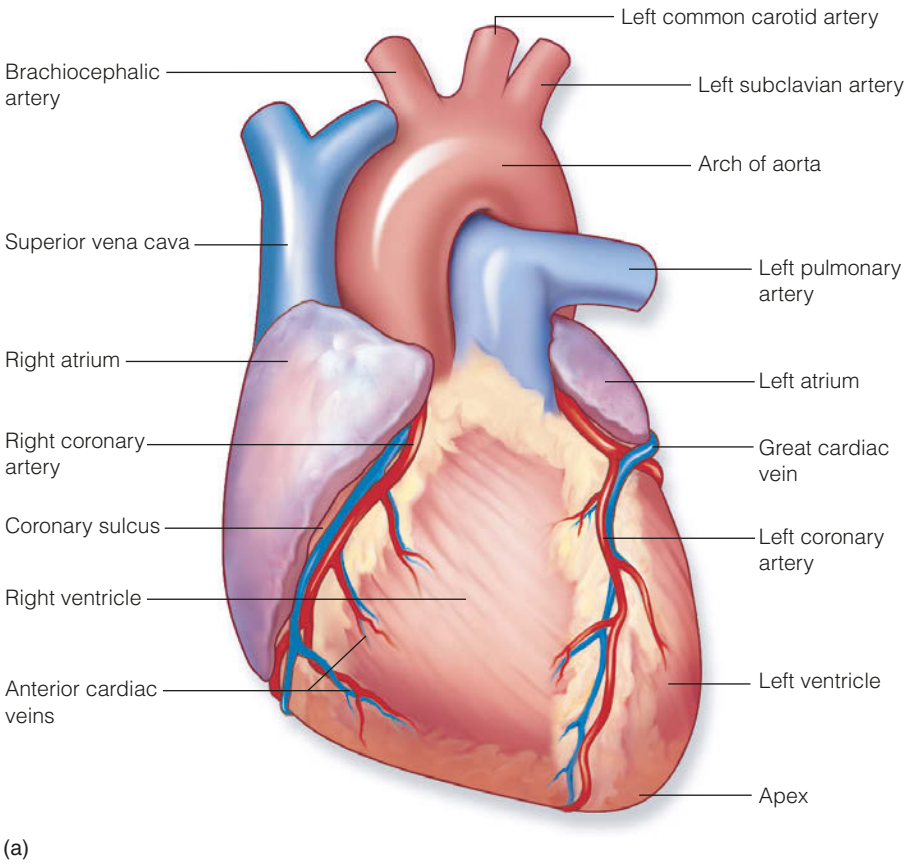
The heart pumps about 8000 liters of blood every day, which is enough to fill forty 55-gallon drums or 8800 quart-size containers (Martini, Nath, & Bartholomew, 2015).

28.5 The coronary arteries bring essential nutrients to the myocardium.

Working continuously around the clock, the heart requires a bountiful supply of oxygen and other nutrients. These are provided by the right and left coronary arteries and their branches, as shown in Figure 28.4a. The coronary arteries have the ability to rapidly adapt to the heart's needs for oxygen. For example, during exercise the heart rate and strength of contraction markedly increase, and healthy coronary arteries quickly dilate to provide oxygen to meet this increased workload on the myocardium.

The coronary arteries are subject to atherosclerosis, a buildup of fatty plaque, which narrows the lumen and restricts the blood supply reaching myocytes. If allowed to progress, the narrowing results in chest pain, a condition known as angina pectoris. The first sign of angina is pain upon exercise or exertion, since this is when the workload on the heart is increased. Continued narrowing increases the risk of a myocardial infarction.

The coronary arteries are important targets for pharmacotherapy. Chapter 29 explains how reducing lipid levels in the blood can decrease the risk of atherosclerosis of the coronary arteries (and other arteries). Chapter 35 discusses how drugs can be used to reduce angina pain and decrease the risk of mortality following a heart attack. Chapter 36 introduces drugs that reduce the cardiac workload in patients with heart failure so that the heart does not require as much oxygen from the coronary arteries.



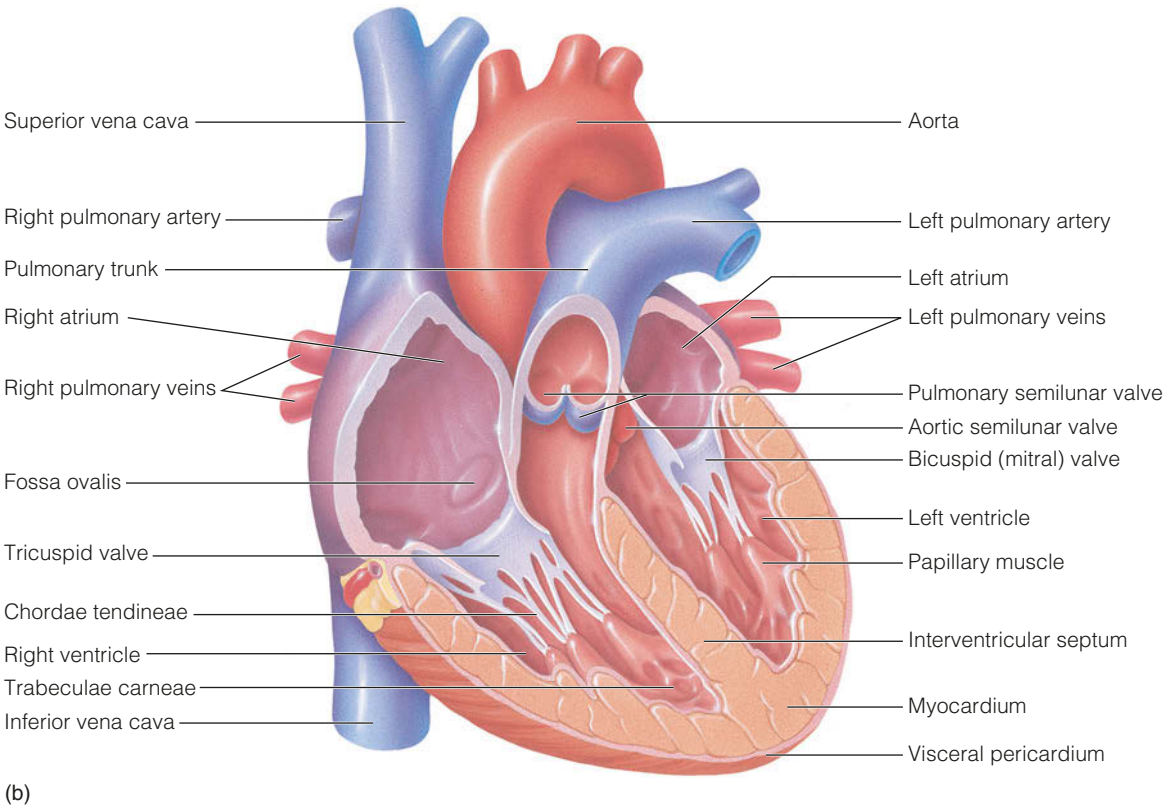
28.6 The cardiac conduction system keeps the heart beating in a synchronized manner.

For the heart to function properly, the atria must contract simultaneously, sending their blood into the ventricles. Following atrial contraction, the right and left ventricles then must contract simultaneously. Lack of synchronization of the atria and ventricles or of the right and left sides of the heart may have profound consequences. Proper timing of chamber contractions is made possible by the cardiac conduction system, a branching network of specialized cardiac muscle cells that sends a synchronized, electrical signal across the myocardium. These electrical impulses, or action potentials, carry the signal for the cardiac muscle cells to contract and must be coordinated precisely for the chambers to beat in a synchronized manner. The cardiac conduction system is illustrated in Figure 28.5.

Control of the cardiac conduction system begins in a small area of tissue in the wall of the right atrium known as the sinoatrial (SA) node or cardiac pacemaker. Cells in the SA node have the property of **automaticity**, the ability to spontaneously generate action potentials without an outside signal from the nervous system. The SA node generates a new action potential approximately 75 times per minute under resting conditions. This is referred to as the normal **sinus rhythm**. The SA node is greatly influenced by the activity of the sympathetic and parasympathetic divisions of the autonomic nervous system.

Upon leaving the SA node, the action potential travels quickly across both atria and through internodal pathways to the atrioventricular (AV) node. Myocytes in the AV node also have the property of automaticity, although less so than the SA node. Should the SA node malfunction, the AV node has the ability to spontaneously generate action potentials and continue the heart's contraction at a rate of 40 to 60 beats/min. Compared to other areas in the heart, impulse conduction through the AV node is slow. This allows the atria sufficient time to completely contract and empty their blood before the ventricles receive their signal to contract. If the ventricles should contract prematurely, the AV valves will close and the atria will be prevented from completely emptying their contents.

As the action potential leaves the AV node, it travels rapidly to the AV bundle or bundle of His. The pathway between the AV node and the bundle of His is the only



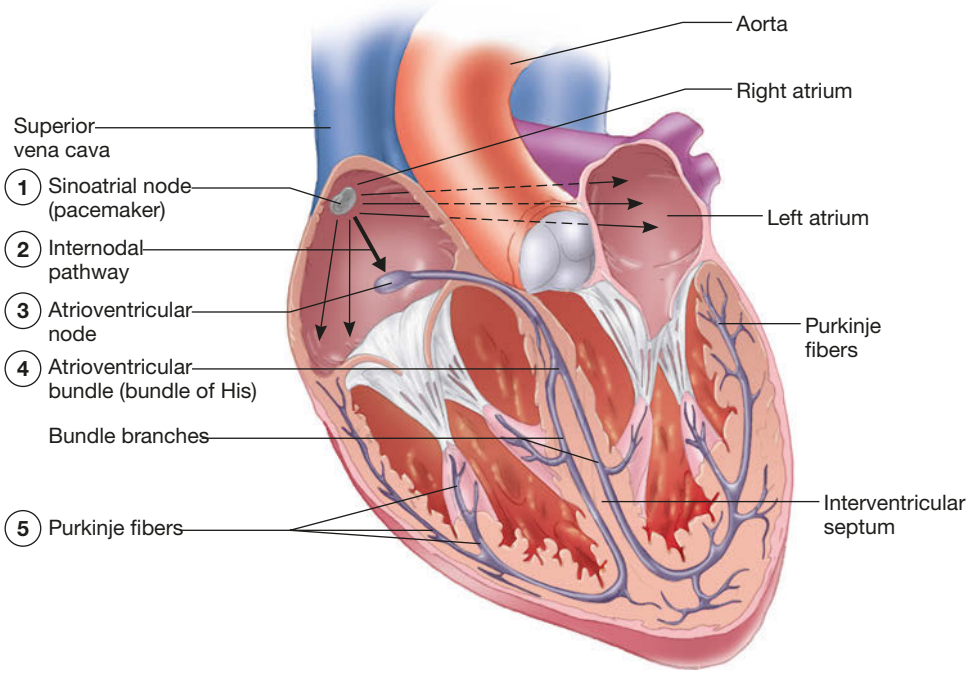


Figure 28.4 The heart: (a) coronary arteries and veins; (b) chambers and valves.

1. The sinoatrial (SA) node fires a stimulus across the walls of both left and right atria causing them to contract.
2. The stimulus arrives at the atrioventricular (AV) node.
3. The stimulus is directed to follow the AV bundle (bundle of His).
4. The stimulus now travels through the apex of the heart through the bundle branches.
5. The Purkinje fibers distribute the stimulus across both ventricles causing ventricular contraction.

Figure 28.5 The cardiac conduction system.

electrical connection between the atria and the ventricles. The impulse is conducted down the right and left bundle branches to the Purkinje fibers, which rapidly carry the action potential to all regions of the ventricles almost simultaneously. Should the SA and AV nodes become nonfunctional, cells in the AV bundle and Purkinje fibers can continue to generate myocardial contractions at a rate of about 30 beats/min.

Although action potentials normally begin at the SA node and spread across the myocardium in a coordinated manner, other regions of the heart may also initiate beats. These **ectopic foci**, or ectopic pacemakers, may send waves of depolarization across the myocardium that compete with those from the normal conduction pathway. The timing and synchronization of atrial and ventricular contractions may be affected. Although healthy hearts occasionally experience an extra beat without incident, ectopic foci in diseased hearts have the potential to cause dysrhythmias, or disorders of cardiac rhythm. The events associated with the cardiac conduction system are recorded on an electrocardiogram (ECG).

It is important to understand that the underlying purpose of the cardiac conduction system is to keep the heart beating in a regular, synchronized manner so that cardiac output can be maintained. Dysrhythmias that profoundly affect cardiac output have the potential to produce serious, if not mortal, consequences. These types of dysrhythmias require pharmacologic intervention, as discussed in Chapter 37.

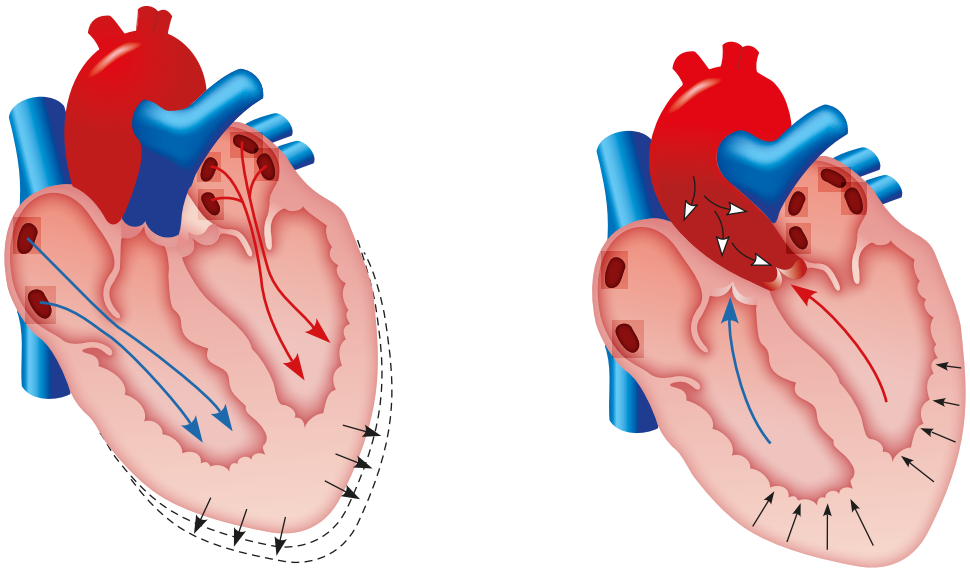
28.7 Cardiac output is determined by stroke volume and heart rate.

To understand how medications act on the heart and to predict the consequences of pharmacotherapy, it is essential to have a comprehensive knowledge of normal cardiac physiology. This includes a thorough understanding of factors that determine the amount of blood pumped by the heart and the forces acting on the chambers.

The amount of blood pumped by each ventricle per minute is the **cardiac output (CO)**. The CO is essentially a measure of how effectively the heart is performing as a

pump. The average CO is 5 L/min. CO can be calculated by multiplying stroke volume by the heart rate:

CO = stroke volume (mL/beat) × heart rate (beats/min)



Stroke volume: **Stroke volume** is the amount of blood pumped by a ventricle in a single contraction. What types of factors might cause a ventricle to eject more blood during a contraction? To understand these factors, a simple comparison to a rubber band is useful. If you stretch a small rubber band 2 inches, it will snap back with a certain force. Stretching the band 4 inches will cause it to snap back with greater force. The force of the snap will continue to increase up to a certain limit, after which the rubber band has been stretched as far as possible and has reached maximum force (or it breaks!).

Cardiac muscle fibers are analogous to rubber bands. If you fill the chambers with more blood, the fibers will have more stretch and will "snap back" with greater force. This is known as Starling's law of the heart: The strength (force) of contraction, or **contractility**, is proportional to the muscle fiber length (stretch). The contractility determines the amount of blood ejected per beat, or the stroke volume. The degree to which the ventricles are filled with blood and the myocardial fibers are stretched just prior to contraction is called **preload**. Up to a physiologic limit, drugs that increase preload and contractility will increase the CO. In addition to preload, the force of contraction can be increased by activation of $beta_1$-adrenergic receptors in the autonomic nervous system.

What causes the chambers to fill up with more blood, become stretched (more preload), and contract with greater force? Although several factors affect preload, the most important is **venous return**: the volume of blood returning to the heart from the veins. Giving a drug that constricts veins will increase venous return to the heart, as will simply increasing the total amount of blood in the vascular system (increased blood volume). Drugs or other mechanisms that constrict veins or increase blood volume will therefore increase stroke volume and CO. Conversely, drugs that dilate veins or reduce blood volume will lower CO.

Factors that increase cardiac contractility are called positive inotropic drugs. Examples of positive inotropic drugs include epinephrine, norepinephrine, thyroid hormone, and dopamine. Factors that decrease cardiac contractility are called negative inotropic drugs. Examples include quinidine and beta-adrenergic antagonists such as propranolol.

A second primary factor affecting stroke volume is afterload. In order for the left ventricle to pump blood out of the heart, it must overcome a substantial "back pressure" in the aorta. **Afterload** is the systolic pressure in the aorta that must be overcome for blood to be ejected from the left ventricle. As afterload increases, the heart pumps less blood, and stroke volume (and thus CO) decreases. The most common cause of increased afterload is an increase in systemic blood pressure, or HTN. HTN creates an increased workload on the heart, which explains why patients with chronic HTN are more likely to experience heart failure. Antihypertensive drugs create less afterload, increase stroke volume, and result in less workload for the heart. Preload and afterload are illustrated in Figure 28.6.

(a) Preload (b) Afterload

Figure 28.6 (a) Preload is the degree to which the ventricles are filled with blood and the myocardial fibers are stretched just prior to contraction. (b) Afterload is the systolic pressure in the aorta that must be overcome for blood to be ejected from the left ventricle.

Heart rate: Heart rate is the second primary factor determining CO. Heart rate is generally controlled by the autonomic nervous system, which makes the minute-by-minute adjustments demanded by the circulatory system. Both sympathetic and parasympathetic fibers are found in the SA node, and heart rate is determined by which fibers are firing at a greater rate at any given moment. Circulating hormones such as epinephrine and thyroid hormone also affect heart rate. In theory, drugs that increase heart rate will increase CO, although compensatory mechanisms may prevent this effect (see Section 28.8). In addition, a very rapid heart rate may not give the chambers sufficient time to completely fill, thus reducing CO.

CONNECTION Checkpoint 28.2

From what you learned in Chapter 12, predict what effect the following would have on heart rate: sympathomimetics, parasympathomimetics, adrenergic agonists, and anticholinergics. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hemodynamics and Blood Pressure

28.8 The primary factors responsible for blood pressure are cardiac output, peripheral resistance, and blood volume.

The homeostatic regulation of blood pressure is a key topic in pharmacology because HTN is so prevalent in the population. Regulation of blood pressure is complex with many diverse factors, both local and systemic, interacting to maintain adequate blood flow to the tissues. The three primary factors that regulate arterial blood pressure—CO, peripheral resistance, and blood volume—are shown in Figure 28.7. The following simple formula should be memorized (as well as understood) because it will help in predicting the actions and adverse effects of many classes of cardiovascular medications:

$$\text{Blood pressure} = \text{CO} \times \text{peripheral resistance}$$

CO is determined by heart rate and stroke volume as discussed in Section 28.7. From the preceding equation, it is easy to see that as CO increases, blood pressure also increases. This is important to pharmacology because medications that change the CO, stroke volume, or heart rate have the potential to influence a patient's blood pressure.

As blood speeds through the vascular system, it exerts force against the walls of the vessels. Although the lining of the blood vessel is extremely smooth, friction reduces the velocity of the blood. Further friction is encountered as the stream of fast-moving blood narrows to enter smaller vessels, divides into two channels (arteries), or encounters fatty deposits on the vessel walls (plaque). Blood flow may exhibit turbulence, a chaotic, tumbling motion that greatly increases friction. The friction that blood encounters in the arteries is called **peripheral resistance**. Arteries have smooth muscle in their walls, which controls the total peripheral resistance. For example, if the smooth muscle constricts, the inside diameter or lumen of the arteries will become smaller and create more resistance and higher blood pressure. A large number of medications affect vascular smooth muscle. Some of these drugs cause vessels to constrict, thus raising blood pressure, whereas others relax smooth muscle, thereby opening the lumen and lowering blood pressure.

An additional factor responsible for blood pressure is the total amount of blood in the vascular system, or blood volume. Although the average person maintains a relatively constant blood volume of approximately 5 L, this can be

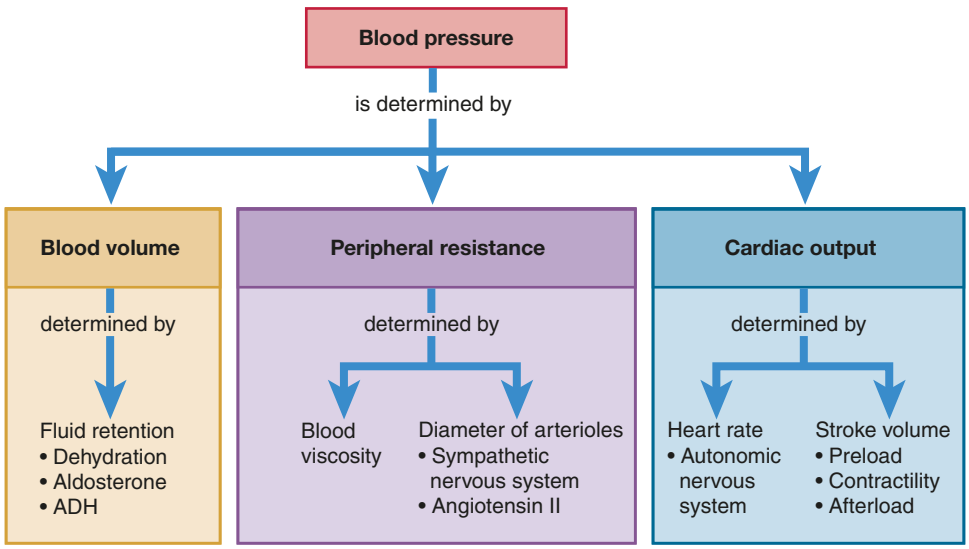


Figure 28.7 The primary factors affecting blood pressure.

changed by endogenous regulatory factors, certain disease states, and pharmacotherapy. More fluid in the vascular system increases venous pressure and venous return to the heart, thus increasing CO and arterial blood pressure. Drugs are frequently used to adjust blood volume. For example, infusion of intravenous (IV) fluids quickly increases blood volume and raises blood pressure. This is used to advantage when treating hypotension due to shock. On the other hand, diuretics cause fluid loss through urination, thus decreasing blood volume and lowering blood pressure.

PharmFACT

It is estimated that all the blood vessels in an adult stretch through about 60,000 miles of internal body landscape (Marieb & Hoehn, 2016).

28.9 Neural regulation of blood pressure includes baroreceptor and chemoreceptor reflexes.

It is critical for the body to maintain a normal range of blood pressure and for it to be able to safely and rapidly change pressure as it proceeds through daily activities such as sleep and exercise. Hypotension can cause dizziness and lack of adequate urine formation, whereas extreme HTN can cause vessels to rupture, resulting in ischemia of critical organs. Figure 28.8 illustrates how the body maintains homeostasis during periods of blood pressure change.

The central and autonomic nervous systems are intimately involved in regulating blood pressure. On a minute-to-minute basis, blood pressure is regulated by a cluster of neurons in the medulla oblongata called the

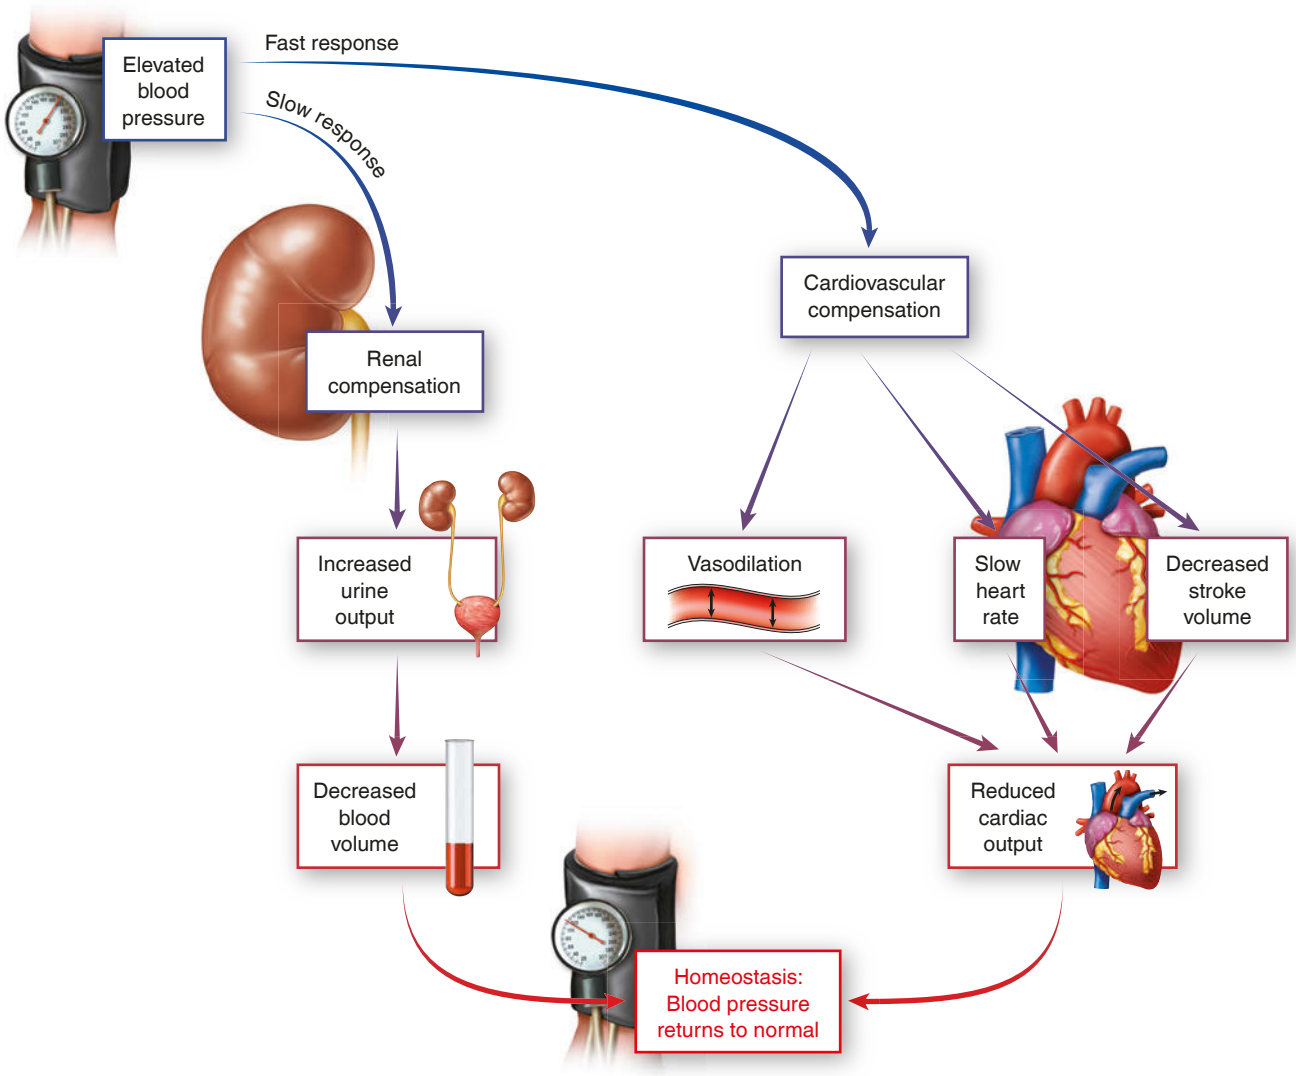

Figure 28.8 Cardiovascular and renal control of blood pressure.

vasomotor center. Sensory receptors in the aorta and the internal carotid artery provide the vasomotor center with vital information on conditions in the vascular system. **Baroreceptors** have the ability to sense pressure within large vessels, whereas **chemoreceptors** recognize levels of oxygen, carbon dioxide, and the acidity or pH in the blood. The vasomotor center reacts to information from baroreceptors and chemoreceptors by raising or lowering blood pressure accordingly. Nerve fibers travel from the vasomotor center to the arteries, where the smooth muscle is directed to either constrict (raise blood pressure) or relax (lower blood pressure). As discussed in Chapter 16, sympathetic outflow from the vasomotor center stimulates alpha$_1$-adrenergic receptors on arterioles, causing vasoconstriction. Alpha$_2$-adrenergic agonists can also decrease blood pressure by their central effects on the vasomotor center.

The baroreceptor reflex is an important mechanism used by the body for making rapid adjustments to blood pressure. If pressure in the vascular system increases, the baroreceptors in the aortic arch and carotid sinus trigger reflexes that constrict the arterioles and veins and accelerate the heart rate. Together, these actions return blood pressure to normal levels within seconds.

Drugs that raise or lower blood pressure can trigger the baroreceptor reflex. For example, antihypertensives administered by the IV route cause an immediate reduction in blood pressure that is recognized by the baroreceptors. The baroreceptors respond by attempting to return blood pressure back to the original levels. The resulting accelerated heart rate, or reflex tachycardia, may cause the patient to experience palpitations. The baroreceptors are not able to offer a continuous or sustained reduction in blood pressure. Continued administration of an antihypertensive drug will "overcome" the reflex. In addition, with aging or certain disease states such as diabetes, the baroreceptor response may be diminished.

Another example of the baroreceptor reflex occurs when baroreceptors in the right atrium are triggered. These receptors recognize excess stretching of the right atrium, such as might occur when large amounts of IV fluids are administered. The **atrial reflex** causes the heart rate and CO to increase until the backlog of venous blood (or IV fluid) is distributed throughout the body.

The chemoreceptor reflex can also significantly affect blood pressure. Sensors in the carotid sinus and near the aortic arch recognize levels of oxygen and carbon dioxide and the acidity (pH) in the blood. Triggering these chemoreceptors activates the sympathetic nervous system and causes heart rate and CO to increase. The purpose of this reflex is to circulate blood faster so that the respiratory system can remove excess carbon dioxide (which returns pH to normal levels) and add more oxygen to the blood.

CONNECTION Checkpoint 28.3

Many autonomic drugs dilate or constrict blood vessels. From what you learned in Chapter 12, which class of autonomic drugs is most commonly prescribed for HTN? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

28.10 Hormones may have profound effects on blood pressure.

Several hormones affect blood pressure, and certain classes of medications are given to either enhance or block the actions of these hormones. For example, injection of the catecholamines epinephrine or norepinephrine will immediately raise blood pressure, which is essential for patients experiencing shock.

Antidiuretic hormone (ADH) is a hormone released by the posterior pituitary gland when blood pressure falls or when the osmotic pressure of the blood increases. ADH, also known as vasopressin, is a potent peripheral vasoconstrictor that quickly increases blood pressure. The hormone also acts on the kidneys to conserve water and increase blood volume, thereby causing blood pressure to increase. The pharmacotherapy of ADH and related hormones is discussed in Chapter 65.

The **renin-angiotensin-aldosterone system (RAAS)** is particularly important in the drug therapy of HTN. As blood pressure falls, the enzyme renin is released by the kidneys. Through a two-step pathway, angiotensin II is formed, which subsequently increases CO and constricts arterioles to return blood pressure to original levels. Angiotensin II also promotes the release of aldosterone from the adrenal gland, which causes sodium and water retention. Drugs that block the RAAS are key drugs in the treatment of HTN and heart failure.

Atrial natriuretic peptide (ANP) is a hormone that is secreted by specialized cells in the right atrium when large increases in blood volume produce excessive stretch on the atrial wall. ANP has multiple effects, all of which attempt to return blood pressure to original levels. Sodium ion transport in the kidney is affected, resulting in enhanced sodium and water excretion. The release of ADH and aldosterone is suppressed by ANP. In addition, ANP reduces sympathetic outflow from the central nervous system, resulting in dilation of peripheral arteries. A summary of the various nervous and hormone factors influencing blood pressure is shown in Figure 28.9.

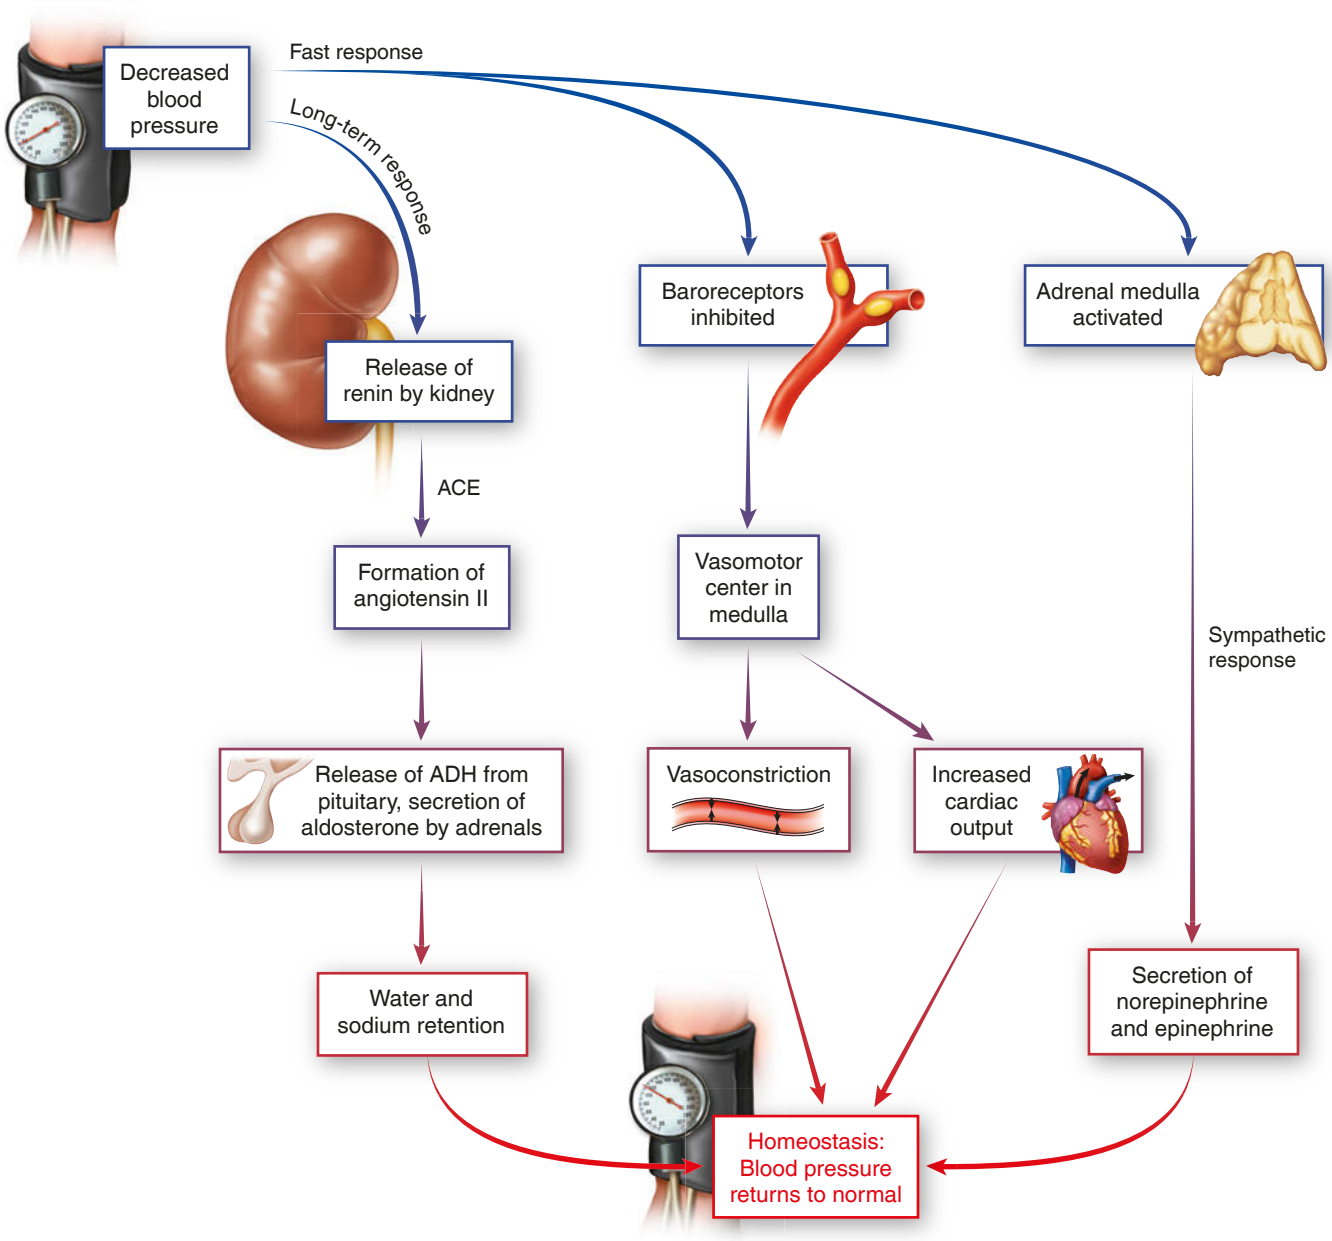

Figure 28.9 Endocrine and nervous control of blood pressure.

Understanding Chapter 28

Key Concepts Summary

28.1 The cardiovascular system consists of the blood, heart, and blood vessels.

28.2 Blood consists of formed elements and plasma.

28.3 Hemostasis is a complex process involving multiple steps and a large number of enzymes and factors.

28.4 The heart is responsible for pumping blood throughout the circulatory system.

28.5 The coronary arteries bring essential nutrients to the myocardium.

28.6 The cardiac conduction system keeps the heart beating in a synchronized manner.

28.7 Cardiac output is determined by stroke volume and heart rate.

28.8 The primary factors responsible for blood pressure are cardiac output, peripheral resistance, and blood volume.

28.9 Neural regulation of blood pressure includes baroreceptor and chemoreceptor reflexes.

28.10 Hormones may have profound effects on blood pressure.

Chapter 29
Pharmacotherapy of Hyperlipidemia

Chapter Outline

- Types of Lipids and Lipoproteins
- Measurement and Control of Serum Lipids
- Drugs for Dyslipidemias

HMG-CoA Reductase Inhibitors
PROTOTYPE *Atorvastatin (Lipitor), p. 496*
Bile Acid Sequestrants
PROTOTYPE *Cholestyramine (Questran), p. 500*
Niacin
Fibric Acid Drugs
PROTOTYPE *Gemfibrozil (Lopid), p. 502*
Miscellaneous Drugs for Dyslipidemias

Learning Outcomes

After reading this chapter, the student should be able to:

1. Summarize the link between high blood cholesterol, low-density lipoprotein levels, and atherosclerosis.
2. Explain the different types of lipids and how they are transported through the body.
3. Illustrate how lipids are transported through the blood.
4. Compare and contrast the clinical importance of the different types of lipoproteins.
5. Give examples of how cholesterol and low-density lipoprotein levels can be controlled with nonpharmacologic means.
6. Categorize antihyperlipidemic drugs based on their classification and mechanism of action.
7. Explain the nurse's role in the safe administration of drugs for lipid disorders.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients receiving pharmacotherapy for lipid disorders.

Key Terms

apoprotein, 489
atherosclerosis, 489
dyslipidemia, 491
high-density lipoprotein (HDL), 489
HMG-CoA reductase, 494
hypercholesterolemia, 491
hyperlipidemia, 491
hypertriglyceridemia, 491
lipoproteins, 489
low-density lipoprotein (LDL), 489
phospholipids, 489
reverse cholesterol transport, 491
rhabdomyolysis, 496
steroids, 489
sterol nucleus, 489
triglycerides, 489
very low-density lipoprotein (VLDL), 490

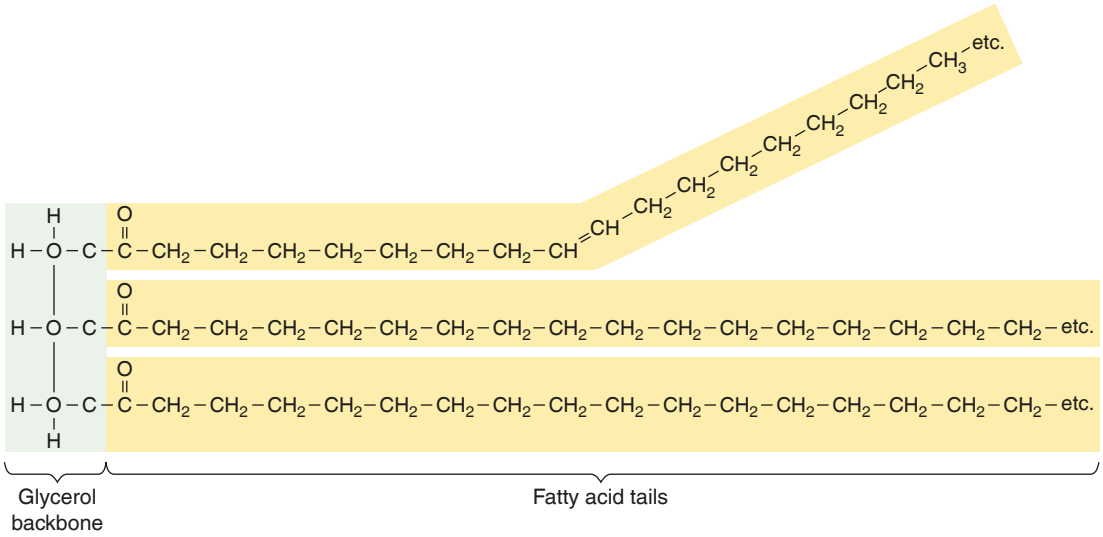
Research during the 1970s and 1980s brought about a nutritional revolution as new knowledge about lipids and their relationships to obesity and cardiovascular disease allowed people to make more intelligent lifestyle choices. Since then advances in the diagnosis of lipid disorders have helped to identify those people at greatest risk for cardiovascular disease and those most likely to benefit from pharmacologic intervention. As a result of this knowledge and from advancements in pharmacology, the incidence of death due to most cardiovascular diseases has been declining, although they remain the leading cause of death in the United States.

Types of Lipids and Lipoproteins

29.1 Lipids are classified as triglycerides, phospholipids, or sterols.

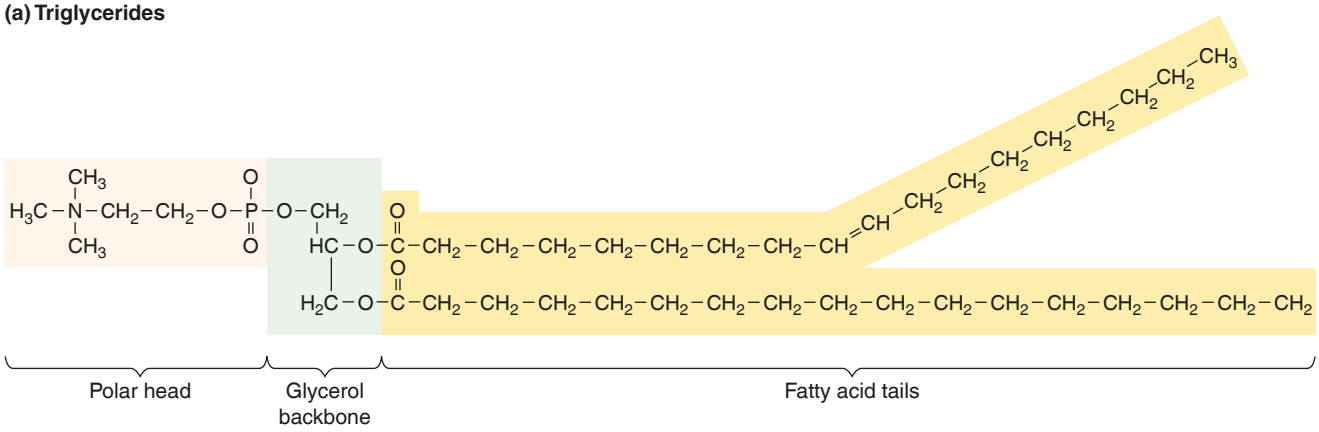
Three types of lipids are important to human physiology, as illustrated in Figure 29.1. The most common types are **triglycerides** or neutral fats, which consist of three fatty acids attached to a chemical backbone of glycerol. Triglycerides are the major storage form of fat in the body and the only type of lipid that serves as an important energy source. They account for 90% of the total lipids in the body.

A second class, the **phospholipids**, is formed when a phosphorous group replaces one of the fatty acids in a triglyceride. This type of lipid comprises the majority of the lipid bilayer that forms plasma membranes. Phospholipids also form spherical sacs called liposomes, which have been used to develop unique drug delivery systems. Once enclosed in a liposome, drugs such as amphotericin B and doxorubicin are able to overcome certain obstacles to absorption and distribution.



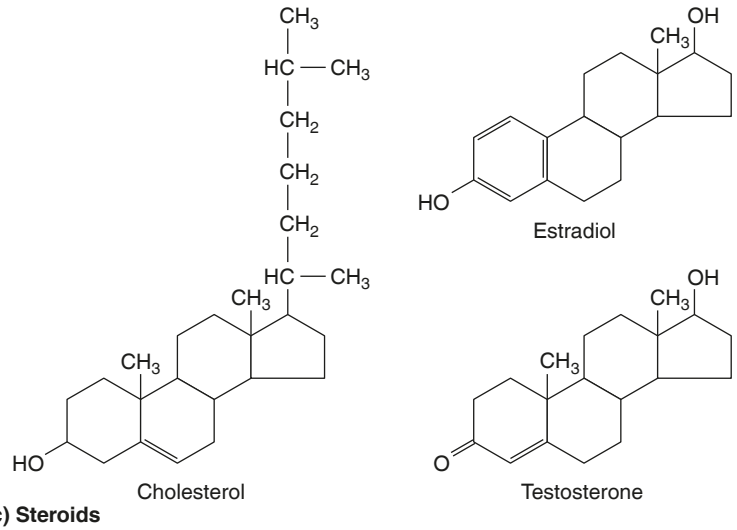
The third class of lipids, the **steroids**, is a diverse group of substances having a common **sterol nucleus** or ring structure. Cholesterol is the most widely known of the steroids, and its role in promoting **atherosclerosis** has been clearly demonstrated. Atherosclerosis is the presence of plaque—a fatty, fibrous material within the walls of the arteries. Unlike the triglycerides that provide fuel for the body, cholesterol is a vital component of plasma membranes and serves as a building block for essential biochemicals, including vitamin D, bile acids, cortisol, estrogen, and testosterone. Although clearly essential for life, the body needs only minute amounts of cholesterol because the liver is able to synthesize adequate amounts from other chemicals. It is not necessary, nor desirable, to provide excess cholesterol in the diet. The dietary sources of cholesterol are obtained solely from animal products; humans do not absorb the sterols produced by plants.

29.2 Lipoproteins are important predictors of cardiovascular disease.



Because lipid molecules are not soluble in plasma, they must be specially packaged for transport through the blood. To accomplish this, the body forms complexes called **lipoproteins**, which consist of various amounts of cholesterol, triglycerides, and phospholipids bound to carrier proteins. The protein component is called an **apoprotein** (*apo-* means "separated from" or "derived from"). There are six primary classes (and numerous subclasses) of apolipoproteins, each serving different roles in transporting lipoproteins. The six classes are named apo A, apo B, apo C, apo D, apo E, and apo H.

Lipoproteins are classified according to their composition, size, and weight or density, which come primarily from the amount of apoprotein present in the complex. Each type varies in lipid and apoprotein makeup and serves a different function in transporting lipids from the sites of synthesis and absorption to the sites of utilization. For example, **high-density lipoprotein (HDL)** contains the most apoprotein, up to 50% by weight. The highest amount of cholesterol is carried by **low-density lipoprotein (LDL)**. Figure 29.2 illustrates the three basic lipoproteins and their compositions.



To understand the pharmacotherapy of lipid disorders, it is important to know the functions of the major lipoproteins and their roles in transporting cholesterol. LDL transports cholesterol from the liver to the tissues and organs, where it is used to build plasma membranes or to

(a) Triglycerides

(b) Phospholipids

(c) Steroids

Figure 29.1 Chemical structure of lipids.

synthesize other steroids. Once in the tissues it can also be stored for later use. Storage of cholesterol in the lining of blood vessels, however, is not desirable because it contributes to plaque buildup. LDL is often called "bad" cholesterol because this lipoprotein contributes significantly to plaque deposits and coronary artery disease (CAD). Sixty to seventy percent of the cholesterol circulating in the blood is found in LDL.

Very low-density lipoprotein (VLDL) is the primary carrier of triglycerides in the blood. VLDL accounts for virtually all triglycerides being transported from the liver to storage in adipose tissue. Through a series of steps,

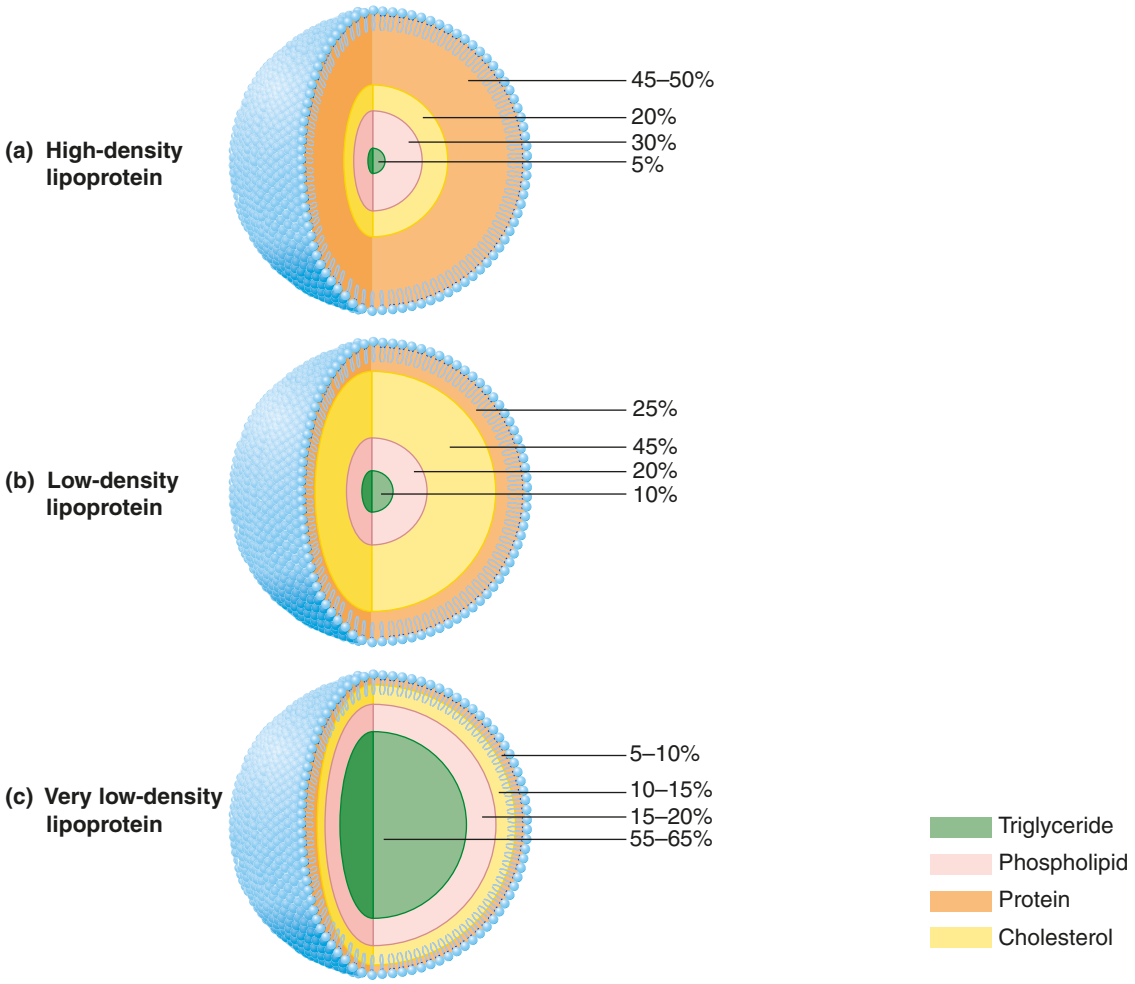


Figure 29.2 Composition of lipoproteins: (a) HDL; (b) LDL; (c) VLDL.

VLDL is reduced in size to become LDL. Lowering LDL levels in the blood has been shown to decrease the incidence of CAD.

HDL is manufactured in the liver and small intestine and assists in the transport of excess cholesterol away from the body tissues and back to the liver for metabolism in a process known as **reverse cholesterol transport**. The cholesterol component of the HDL is then broken down to unite with bile, which is subsequently excreted in the feces. Excretion via bile is the only route the body uses to remove cholesterol. Because HDL transports cholesterol for destruction and removes it from the body, it is considered "good" cholesterol. Patients with insufficient amounts of HDL are at risk for atherosclerosis, even if their total cholesterol levels are normal.

Several terms are used to describe lipid disorders. **Dyslipidemia** is a general term that refers to abnormal amounts of lipids in the body. The most common type of dyslipidemia is **hyperlipidemia** meaning elevated levels of lipids in the blood. The term *hyperlipidemia*, however, does not specify which lipid is elevated (cholesterol, triglyceride, or phospholipid). Elevated blood cholesterol, or **hypercholesterolemia**, is the type of hyperlipidemia most familiar to the public. Some patients exhibit an increase in triglyceride levels known as **hypertriglyceridemia**.

Patients with lipid disorders are asymptomatic and often do not seek medical intervention until cardiovascular disease has progressed to the point of producing chest pain or hypertension. It is estimated that almost 32% of the adult population in the United States has elevated cholesterol levels and that only half of these people are being treated for hyperlipidemia (Centers for Disease Control and Prevention, 2015). Because of the cost and the lack of symptoms for lipid disorders, nurses may face challenges persuading patients of the value of antihyperlipidemic drug therapy. The long-term benefits of drug therapy and the long-term consequences of hyperlipidemia and cardiovascular disease warrant consistent education on the importance of drug therapy and lifestyle changes.

Hyperlipidemia may be inherited or acquired. Certainly, diets high in saturated fats and lack of exercise contribute greatly to the development of hyperlipidemia and resulting cardiovascular diseases. However, genetics determines one's ability to metabolize lipids and contributes to

high lipid levels in substantial numbers of patients. Some genetic dyslipidemias can be so severe as to cause CAD and death due to myocardial infarction (MI) in patients as young as 1 or 2 years (Mose, 2016). For most patients, dyslipidemias are the result of a combination of genetic and environmental (lifestyle) factors.

Measurement and Control of Serum Lipids

29.3 Blood lipid profiles are important diagnostic tools in guiding the therapy of dyslipidemias.

Although high levels of cholesterol in the blood are associated with cardiovascular disease, it is not enough to simply measure total cholesterol in the blood. Because some cholesterol is being transported for destruction, a more accurate profile is obtained by measuring the LDL and HDL. The goal is to maximize the cholesterol carried by high-density lipoproteins (HDL-C) and minimize the cholesterol carried by low-density lipoproteins (LDL-C). This is sometimes stated as a ratio of LDL to HDL. If the ratio is greater than 5 (five times more LDL than HDL), the male patient is considered at risk for cardiovascular disease. The normal ratio in women is slightly lower at 4.5.

Scientists have further divided LDL into subclasses of lipoproteins. For example, one variety found in LDL, called *lipoprotein (a)*, has been strongly associated with plaque formation and heart disease. It is likely that further research will find other varieties with the expectation that drugs will be designed to be more selective toward the "bad" lipoproteins. Table 29.1 gives the desirable, borderline, and high laboratory values for each of the major lipids and lipoproteins. These values change periodically as additional research becomes available on the association between heart disease and lipid levels.

Establishing treatment guidelines for dyslipidemia has been challenging because the condition has no symptoms and the progression to cardiovascular disease may take decades. Until 2013, treatment guidelines focused on determining levels of LDL and HDL that could prevent the development of cardiovascular disease (CVD). Essentially, if a patient exhibited laboratory values shown to be at high risk (see Table 29.1), pharmacotherapy was initiated and continued until these values returned to the normal range.

Major revisions were made to these guidelines by the American College of Cardiology (ACC) and the American Heart Association (AHA) in 2013 (Psaty & Weiss, 2014). The 2013 ACC/AHA guidelines no longer stress specific target goals for LDL levels. The question of who should be treated for high cholesterol levels is no longer based on a laboratory number, but is now established for the following treatment categories:

1. Patients with atherosclerotic CVD
2. Patients with diabetes, ages 40 to 75 years with LDL-C levels between 70 and 189 mg/dL
3. Patients without CVD but who have LDL-C levels of 190 mg/dL or higher
4. Patients ages 40 through 75 years without CVD or diabetes but who have LDL-C levels 70 through 189 mg/dL and 7.5% or greater 10-year risk of atherosclerotic CVD.

Based on the results of hundreds of clinical trials over many years, the ACC/AHA guidelines specifically recommend statins as first-line therapy for all categories (see Section 29.5). Follow-up measures of LDL are recommended to determine adherence to the drug regimen.

The fourth category of the ACC/AHA guidelines, which bases pharmacotherapy on a 7.5% or greater risk of atherosclerotic CVD, has been controversial. The calculation of risk gives heavy emphasis to age, which suggests that most of the population over age 60 should be on statin medications. Later research suggested this guideline has been effective at preventing CVD in this population (Greenland & Lauer, 2015).

Blood lipid profiles are used to classify the different patterns of hyperlipidemias observed in clinical practice. These patterns are shown in Table 29.2. The specific type of dyslipidemia exhibited by patients is considered when planning therapy. For example, Type I requires dietary restrictions and does not respond well to pharmacotherapy. Whereas the remaining types respond to the statins, the hypertriglyceridemias may respond better to therapy with fibric acid drugs (fibrates).

Table 29.1 Standard Laboratory Lipid Profiles

Type of Lipid	Laboratory Value (mg/dL)	Standard
Total cholesterol	Less than 200	Desirable
	200–239	Borderline high risk
	240 or higher	High risk
Low-density lipoproteins (LDLs)	Less than 100	Optimal
	100–129	Near or above optimal
	130–159	Borderline high risk
	160–189	High risk
	190 or higher	Very high risk
High-density lipoproteins (HDLs)	Less than 40 (men) or 50 (women)	Low risk
	Greater than 60	Desirable
Serum triglycerides	Less than 150	Normal
	150–199	Borderline high risk
	200–499	High risk
	500 or higher	Very high risk

From "Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III), Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults," 2001, *JAMA*, *285*, 2486–2497.

Table 29.2 Types of Dyslipidemias

Name	Laboratory Findings	Features
Type I Exogenous hyperlipidemia	Triglycerides increased 3 times Chylomicrons increased	Rare condition, usually occurring in childhood
Type IIa Familial hypercholesterolemia	LDL and cholesterol increased	Common condition, may occur at any age
Type IIb Combined familial hyperlipidemia Carbohydrate-induced hypertriglyceridemia	LDL, VLDL, cholesterol, and triglycerides increased	May occur at any age but more commonly in adults
Type III Familial dysbetalipoproteinemia	Chylomicrons, VLDL, cholesterol, and triglycerides increased	Uncommon condition, occurs most frequently in middle-aged adults
Type IV Endogenous hyperlipidemia Carbohydrate-induced hypertriglyceridemia	VLDL and triglycerides increased Cholesterol normal or elevated Glucose intolerance Hyperuricemia	Most common dyslipidemia, occurs in middle-aged adults; associated with obesity, excessive alcohol intake, tobacco use, and other lifestyle factors
Type V Mixed hyperlipidemia Carbohydrate- and fat-induced hypertriglyceridemia	LDL, VLDL, cholesterol, and chylomicrons increased Triglycerides increased 3 times Glucose intolerance Hyperuricemia	Uncommon type, may begin in childhood and manifest in adults

29.4 Lipid levels can often be controlled through therapeutic lifestyle changes.

Therapeutic lifestyle changes (TLCs) should always be included in any plan for treating or preventing cardiovascular disease. Many patients with borderline high-risk laboratory values can control their dyslipidemia entirely through nonpharmacologic means.

Even in patients with high risk for whom drug therapy is indicated, using TLCs is important for reducing cholesterol levels. All drugs for hyperlipidemia have adverse effects, and implementing TLCs may allow for a reduction in drug dosages. Following are the most important lipid-reduction lifestyle interventions:

- Monitor blood lipid levels regularly, as recommended by the healthcare provider.
- Maintain weight at an optimal level.
- Implement a medically supervised exercise plan.
- Reduce dietary saturated fats and cholesterol.
- Increase soluble fiber in the diet, as found in oat bran, apples, beans, grapefruit, and broccoli.
- Eliminate tobacco use.

The single most important lifestyle factor contributing to dyslipidemia is a high amount of saturated fat in the diet. Nutritionists recommend that the intake of dietary fat be limited to less than 30% of the total caloric intake and that cholesterol intake be reduced as much as possible. It is interesting to note that restriction of dietary cholesterol alone will not result in a significant reduction in blood cholesterol levels. In fact, cutting back on cholesterol consumption may actually increase the amount of circulating cholesterol. How is this possible? The liver reacts to a low-cholesterol diet by making more cholesterol and by inhibiting its excretion whenever saturated fats are present. Saturated fats are the building blocks that the liver uses for making cholesterol. The 2013 ACC/AHA guidelines call for a reduction of saturated fat in the diet to 5% to 6% of total calories. In addition, levels of trans fatty acids from meat and dairy products should be reduced.

CONNECTIONS: Lifespan Considerations

Pediatric Dyslipidemias and Lipid-Lowering Drugs

Many people consider dyslipidemia to be a condition that occurs with advancing age. Dyslipidemias are also a concern for some pediatric patients, and multiple research studies have demonstrated that the early stages of atherosclerosis begin in childhood. With the increasing childhood obesity epidemic, there is concern that dyslipidemias, CVD, and metabolic syndrome will occur at younger and younger ages. Risk factors for dyslipidemias in children are similar to those in adults and include overweight or obesity, family history of dyslipidemias or premature CVD, hypertension, smoking or passive smoke exposure, and known genetic lipid disorders. The 2011 National Heart, Lung, and Blood Institute Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents recommended targeted screening of lipid levels for children ages 2 and older with a positive or unknown family history of dyslipidemia-related CVD or other major risk factor and universal screening in those ages 9 to 11 years and again between 17 and 21 years. Additionally, they recommended pharmacologic treatment with statins for children with LDL levels above 190 mg/dL, or above 160 mg/dL with the presence of two or more cardiovascular risk factors before age 50 (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, 2011).

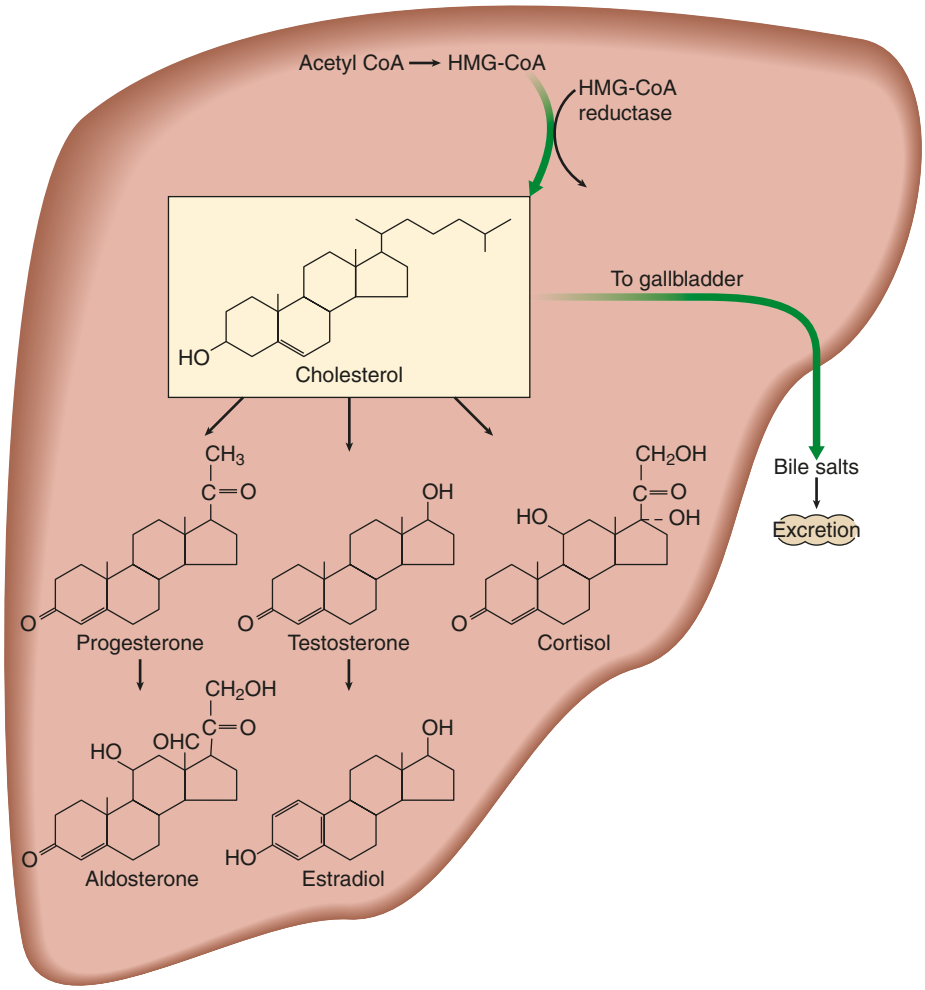

Figure 29.3 Cholesterol biosynthesis and excretion.

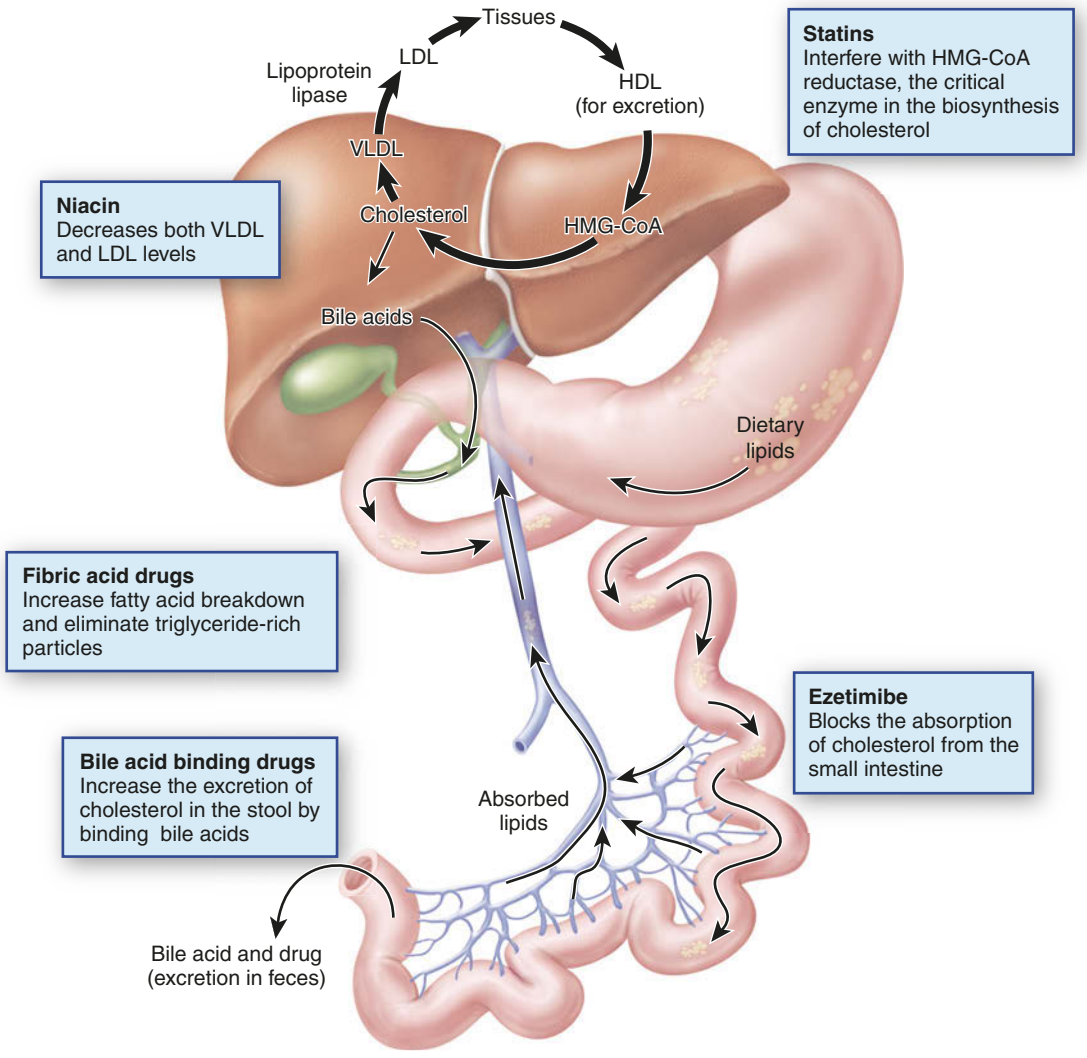
Nutritionists also recommend increased dietary intake of plant sterols as a means to reduce blood cholesterol levels. Plant sterols, also called phytosterols or stanols, are lipids used by plants to construct their cell membranes. The structure of plant sterols is very similar to that of cholesterol. When ingested, however, the plant sterols compete with cholesterol for absorption in the digestive tract. When the body absorbs the plant sterols, cholesterol is excreted from the body, less cholesterol is delivered to the liver, and serum LDL (the "bad" cholesterol) levels fall. Rich, natural sources of plant sterols include wheat, corn, rye, oats, and rice, as well as nuts and olive oil. In recent years, plant sterols have been added to commercial products such as margarines, salad dressings, certain cereals, and some fruit juices.

Drugs for Dyslipidemias



29.5 The statins are the most effective drugs for reducing blood lipid levels.

In the late 1970s substances were isolated from various species of fungi that were found to inhibit cholesterol production in human cells in the laboratory. This class of drugs, known as the statins, has revolutionized the treatment of lipid disorders. Statins can produce a dramatic reduction in LDL cholesterol levels, lower triglyceride and VLDL levels, and raise the level of "good" HDL cholesterol. High-intensity statin therapy is able to lower LDL levels by more than 50% and reduce the incidence of serious cardiovascular-related adverse events by 25% to 30%. This means that about one in every three or four heart attacks, strokes, or blood clots can be prevented with appropriate statin therapy.

Cholesterol is manufactured in the liver by a series of more than 25 metabolic steps, beginning with acetyl CoA, a two-carbon unit that is produced from the breakdown of fatty acids (Figure 29.3). Of the many enzymes involved in this complex pathway, **HMG-CoA reductase** (3-hydroxy-3-methylglutaryl coenzyme A reductase) serves as the primary regulatory enzyme for the biosynthesis of cholesterol. Under normal conditions, this enzyme is regulated through negative feedback. High levels of LDL cholesterol in the blood will shut down production of HMG-CoA reductase, thus turning off the cholesterol synthesis pathway.

Pharmacotherapy Illustrated 29.1

Mechanisms of Action of Lipid-Lowering Drugs

Pharmacotherapy Illustrated 29.1 shows some of the steps in the biosynthesis of cholesterol and the importance of HMG-CoA reductase.

The statins act by inhibiting HMG-CoA reductase, resulting in less cholesterol biosynthesis. As the liver makes less cholesterol, it responds by making more LDL receptors on the surface of liver cells. The greater number of LDL receptors on liver cells removes additional LDL from the blood. Blood levels of both LDL and cholesterol are reduced. The reduction in adverse cardiovascular events from the statins is especially high in those patients who have diabetes as a comorbid condition with hyperlipidemia. The drop in lipid levels is not permanent, however, so patients must continue these drugs for the remainder of their lives or until their hyperlipidemia can be controlled through dietary or lifestyle changes.

Statins clearly slow the progression of CVD and reduce mortality in patients with a history of cardiovascular disease. This type of therapy is called *secondary* prevention, because the patient is already at risk for increased mortality. *Primary* prevention is the administration of statins to patients with no history of CVD. The evidence for a reduction in cardiovascular adverse events with statin therapy is clear. In 2016, the U.S. Preventive Services Task Force (USPSTF) reviewed the evidence on the benefits and harms of screening for and treatment of dyslipidemia in adults 21 years and older; the benefits and harms of statin use in reducing CVD events and mortality in adults without a history of CVD; whether the benefits of statin use vary by subgroup, clinical characteristics, or dosage; and the benefits of various treatment strategies in adults 40 years and older without a history of CVD.

The latest recommendations to initiate use of low- to moderate-dose statins in adults ages 40 to 75 years *without* a history of CVD depend on an estimate of the patient's 10-year risk and the presence of major risk factors. These factors (exclusive of LDL levels) include the following.

- Cigarette smoking
- Hypertension
- Low HDL-C
- Family history of premature heart disease in a first-degree relative
- Age (men: 45 years or older; women: 55 years or older).

People who have none or one risk factor and a calculated 10-year CVD risk of less than 10% should receive low- to moderate-dose statins only when LDL-C levels reach 190 mg/dL or higher. At the other extreme, people with two or more risk factors and a 10-year CVD risk of greater than 20% should receive drug therapy at a much lower LDL-C level of 100 mg/dL. The current evidence is insufficient to assess the benefits of initiating statin use in adults 76 years and older (U.S. Preventive Services Task Force, 2016).

Currently, seven statins are available for treating various types of dyslipidemias, and these are listed in Table 29.3. Although differences among the statins exist, their actions and adverse effects are similar. Lovastatin, pravastatin, and simvastatin are natural substances derived from fungi and have a different chemical structure than the synthetic statins. There are also differences in potency among the drugs. For example, the maximum daily dose for pitavastatin is only 4 mg, whereas the dose is 80 mg for atorvastatin. The half-lives of the statins vary from 20 hours (rosuvastatin) to less than an hour (fluvastatin). Whereas pravastatin is eliminated by the renal route, the other statins are metabolized by hepatic CYP450 enzymes. In patients with renal disease, dosage adjustment is required for lovastatin, pravastatin, simvastatin, and rosuvastatin but not for fluvastatin or atorvastatin. Research evidence for cardiovascular adverse event prevention is greatest for atorvastatin and rosuvastatin. However, in clinical practice the choice of statin is often guided by the experience of the prescriber and the response of each individual patient.

All the statins are given orally (PO) and are tolerated well by most patients. Adverse effects are rarely severe enough to cause discontinuation of therapy. Minor adverse effects include headache, abdominal cramping, diarrhea, muscle or joint pain, and heartburn.

Severe myopathy and rhabdomyolysis are rare, but serious, adverse effects of the statins. **Rhabdomyolysis** is a breakdown of muscle fibers usually due to muscle trauma or ischemia. The mechanism by which statins cause this disorder is unknown. During rhabdomyolysis, the contents of muscle cells spill into the systemic circulation, causing potentially fatal acute renal failure. Macrolide antibiotics such as erythromycin, azole antifungals, fibric acid drugs, and certain immunosuppressants should be avoided during statin therapy, because these interfere with statin metabolism and increase the risk of severe myopathy. Levels of creatine kinase (CK), an enzyme released during muscle injury, should be obtained if myopathy is suspected. If CK levels become elevated during therapy, the drug should be immediately discontinued. Statins may be discontinued if muscle weakness persists even without CK elevation. Nurses should urge all patients who develop unexplained muscle or joint pain during statin therapy to immediately report this to the prescriber.

Statins are pregnancy category X drugs because teratogenic effects have been reported in laboratory animals exposed to these drugs. Statins should not be used in patients who may become pregnant, are pregnant, or who are breastfeeding.

Because cholesterol biosynthesis in the liver is higher at night, statins with short half-lives such as lovastatin should be administered in the evening. The other statins have longer half-lives and are effective regardless of the time of day they are taken.

Much research is ongoing to determine the other therapeutic effects of the drugs in the statin class. For example, statins block the vasoconstrictive effect of the A-beta protein, a significant chemical associated with Alzheimer's disease. Cholesterol and A-beta protein had very similar effects on blood vessels, both causing vasoconstriction. Preliminary research suggests that the statins may protect against dementia by inhibiting this protein, thus slowing dementia caused by blood vessel constriction. Research also suggests that the statins may have the ability to lower the incidence of colorectal cancer. The mechanism of this effect is unknown. Several attempts have been made to move low doses of certain statins to over-the-counter (OTC) status; however, the U.S. Food and Drug Administration (FDA) has not approved these applications.

PROTOTYPE DRUG **Atorvastatin (Lipitor)**

Classification **Therapeutic:** Antihyperlipidemic
Pharmacologic: HMG-CoA reductase inhibitor, statin

Therapeutic Effects and Uses: Approved in 1996, atorvastatin was initially approved to treat hypercholesterolemia. Following several years of use, it became evident that the drug also prevents adverse cardiovascular events in high-risk patients. After 2 to 4 weeks of therapy, atorvastatin lowers LDL and VLDL cholesterol as well as triglycerides. It appears to lower LDL cholesterol levels greater than most other statins—as much as 60%. Atorvastatin may also be prescribed for the treatment of familial hypercholesterolemia. All patients receiving this drug should be placed on a cholesterol-lowering diet, because this will

Table 29.3 Drugs for Dyslipidemias

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
HMG-CoA Reductase Inhibitors		
atorvastatin (Lipitor)	PO: 10–20 mg once daily (max: 80 mg/day)	*Headache, dyspepsia, abdominal cramping, myalgia, back pain, rash, pruritus* Rhabdomyolysis, severe myositis, elevated hepatic enzymes
fluvastatin (Lescol)	PO: 20 mg daily (max: 80 mg/day)	
lovastatin (Altoprev, Mevacor)	PO (immediate release): 10–80 mg once daily (max: 80 mg/day) PO (extended release): 20–60 mg/day	
pitavastatin (Livalo)	PO: 1–4 mg daily (max: 4 mg/day)	
pravastatin (Pravachol)	PO: 10–40 mg daily (max: 80 mg/day)	
rosuvastatin (Crestor)	PO: 5–40 mg daily (max: 40 mg/day)	
simvastatin (Zocor)	PO: 5–40 mg daily (max: 80 mg/day)	
Bile Acid Sequestrants		
cholestyramine (Questran)	PO: 4–8 g bid–qid (max: 32 g/day)	*Constipation, nausea, vomiting, abdominal pain, bloating, dyspepsia* Gastrointestinal (GI) tract obstruction, vitamin deficiencies due to poor absorption
colesevelam (Welchol)	PO: 1.875 g bid (max: 3.75 g/day)	
colestipol (Colestid)	PO: 5–20 g/day in divided doses (30 g/day granules or 16 g/day tablets)	
Fibric Acid Drugs		
fenofibrate (Lofibra, TriCor, others)	PO: Initial dosing 50–160 mg/day depending on trade name	*Myalgia, flulike symptoms, nausea, vomiting, increased serum transaminase and creatinine levels* Rhabdomyolysis, cholelithiasis, pancreatitis
fenofibric acid (Fibricor, Trilipix)	PO (Fibricor: regular release): 35–105 mg once daily PO (Trilipix: delayed release): 45–135 mg once daily	
gemfibrozil (Lopid)	PO: 600 mg bid (max: 1500 mg/day)	
Other Drugs for Dyslipidemia		
alirocumab (Praluent)	Subcutaneous: 75–150 mg q2wk	*Nasopharyngitis, injection-site reactions, influenza* Serious hypersensitivity reactions
evolocumab (Repatha)	Subcutaneous: 140 mg q2wk or 420 mg once monthly	*Nasopharyngitis, injection-site reactions, influenza, back pain* Serious hypersensitivity reactions
ezetimibe and simvastatin (Vytorin)	PO: 10 mg/10 mg or 10 mg/20 mg every evening (max: 10 mg/80 mg)	*Arthralgia, fatigue, abdominal pain, diarrhea* Anaphylaxis, rhabdomyolysis
ezetimibe (Zetia)	PO: 10 mg daily (max: 10 mg/day)	*Nasopharyngitis, myalgia, upper respiratory tract infection, arthralgia, diarrhea* Anaphylaxis, rhabdomyolysis
icosapent (Vascepa)	PO: 4 g/day	*Arthralgia* Hypersensitivity
lomitapide (Juxtapid)	PO: 5–60 mg once daily	*Abdominal pain, diarrhea, nausea, vomiting, dyspepsia, reduced absorption of fat-soluble vitamins and fatty acids* Fetal toxicity, hepatotoxicity
mipomersen (Kynamro)	Subcutaneous: 200 mg once weekly	*Injection-site reactions, flulike symptoms, nausea, headache, and elevations in serum transaminases*
niacin (Niaspan)	Hyperlipidemia: PO: 250 mg regular release or 500 mg extended release daily (max: 6 g/day regular release or 1–2 g/day extended release)	*Flushing, nausea, pruritus, headache, bloating, diarrhea* Dysrhythmias
omega-3-acid ethyl esters (Lovaza)	PO: 4 g/day	*Belching, dyspepsia, fishy taste* Hypersensitivity

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

enhance the drug's therapeutic effects. The primary goal in atorvastatin therapy is to reduce the risk of MI and stroke.

To decrease gastrointestinal (GI) discomfort, atorvastatin may be administered with food. It produces the same degree of LDL cholesterol reduction regardless of the time of day it is taken. Because atorvastatin is not excreted by the kidneys, no adjustment in dosage is necessary in patients with chronic kidney disease (CKD). Extensive metabolism to active metabolites gives atorvastatin a long duration of action.

Mechanism of Action: Atorvastatin acts by inhibiting HMG-CoA reductase, the primary regulatory enzyme in cholesterol biosynthesis. As the liver makes less cholesterol, it responds by making more LDL receptors, removing LDL cholesterol from the blood. Blood levels of both LDL and cholesterol are reduced.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed but only 30% reaches the circulation; food reduces absorption
Distribution	Widely distributed; crosses the placenta and is secreted in breast milk; 98% bound to plasma proteins
Primary metabolism	Hepatic; extensively metabolized to active metabolites
Primary excretion	Biliary
Onset of action	2 weeks for lipid-lowering effect; peak plasma level: 1–2 h
Duration of action	Half-life: 14 h (20–30 h for active metabolites)

Adverse Effects: Most patients tolerate atorvastatin well and only 2% or fewer discontinue the drug due to adverse effects. Common adverse effects include headache, intestinal cramping, diarrhea, and constipation. The most serious adverse effect is rhabdomyolysis. Therapy is generally discontinued in patients reporting unexplained muscle pain, weakness, fever, or fatigue due to the potential for rhabdomyolysis.

Contraindications/Precautions: Patients with hepatic impairment should be monitored carefully, because the liver extensively metabolizes atorvastatin and the drug has been associated with a small risk of liver failure. Liver enzyme tests may become elevated during therapy, although this does not necessarily indicate liver damage. Because atorvastatin is pregnancy category X, pregnancy testing should be conducted prior to treatment in women of childbearing years, and these patients should be advised to take precautions to prevent pregnancy during therapy. Atorvastatin is contraindicated during lactation because the drug is secreted in breast milk.

Drug Interactions: Because atorvastatin is a substrate for hepatic CYP3A4, it has the potential to interact with many other drugs. For example, it may increase digoxin levels by 20% as well as increase levels of norethindrone and ethinyl estradiol (oral contraceptives). Erythromycin may increase atorvastatin levels by as much as 40%. Risk of rhabdomyolysis increases with concurrent administration of atorvastatin with macrolide antibiotics, cyclosporine, and azole antifungals. The risk of myopathy increases when atorvastatin is administered concurrently with fibric acid drugs or niacin. Atorvastatin may increase serum transaminases and CK levels. **Herbal/Food:** Grapefruit juice inhibits the metabolism of statins, allowing them to reach high serum levels. Because HMG-CoA reductase inhibitors decrease the synthesis of Coenzyme Q10 (CoQ10), patients may benefit from CoQ10 supplements. Red rice yeast should not be taken with statins because it increases their toxicity.

Pregnancy: Category X.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving atorvastatin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Hyperlipidemia.

Drugs Similar to Atorvastatin (Lipitor)

Other statins include fluvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin.

Fluvastatin (Lescol): Approved in 1993, fluvastatin is a synthetic statin that has the shortest half-life of all the drugs in this class. Because the kidneys excrete less than 5% of a PO dose, dosage adjustment for patients with CKD is not necessary. Fewer drug interactions are expected with fluvastatin because it is not metabolized through the hepatic CYP450 system. It is approved for hypercholesterolemia and several other types of dyslipidemia. In 2003, the indications were expanded to include prevention of major cardiac events such as cardiac death and nonfatal MI. An extended release formulation, called Lescol-XL, is available. The drug may be administered without regard to meals. Fluvastatin is well tolerated and its adverse effects are similar to those of atorvastatin. It is contraindicated in patients with severe hepatic impairment and in patients who are pregnant. Fluvastatin is a pregnancy category X drug.

Lovastatin (Altoprev, Mevacor): Approved in 1987, lovastatin, a natural substance derived from fungi, was the first HMG-CoA reductase inhibitor marketed. Lovastatin is a prodrug with no intrinsic activity of its own, but the liver converts it to several active metabolites. This drug may achieve a 20% to 40% reduction in LDL cholesterol. Lovastatin is more effective if administered in the evening and should be taken on an empty stomach to maximize absorption. Although only 10% of this drug is excreted by the kidneys, dosage adjustment for patients with CKD is recommended. Lovastatin was originally approved for hypercholesterolemia; however, its indications have been expanded to include slowing the progression of CVD and prevention of MI and stroke. An extended

release form is available (Altoprev). Adverse effects are the same as those of other drugs in this class. It is contraindicated in patients with severe hepatic impairment and in patients who are pregnant. Lovastatin is a pregnancy category X drug.

Pitavastatin (Livalo): Approved in 2009, pitavastatin is one of the newest drugs in the statin class. It is indicated for patients with primary hyperlipidemia and mixed dyslipidemia as an adjunctive therapy to diet to reduce elevated total cholesterol, LDL, apolipoprotein B, and triglycerides, and to increase HDL. It may be administered with or without food and without regard to the time of day. It has similar effectiveness and adverse effects as other statins. Because it is only minimally metabolized by CYP450 enzymes, it may exhibit fewer drug–drug interactions than some of the other statins. However, like other drugs in this class, hepatic enzymes should be evaluated regularly and there is a small risk of myopathy. This drug is pregnancy category X and patients should be advised not to breastfeed during pitavastatin therapy.

Pravastatin (Pravachol): Like lovastatin, pravastatin is a natural substance derived from fungi. Twenty percent of the drug is excreted by the kidneys, and dosage adjustment for patients with CKD is recommended. Like fluvastatin, it is not metabolized through the hepatic CYP450 system; thus fewer drug interactions are expected. The drug may be taken without regard to meals and is slightly more effective if administered in the evening. Approved in 1991, pravastatin is approved for primary hypercholesterolemia, slowing the progression of coronary atherosclerosis and the prevention of MI and stroke. Unlabeled uses include other types of dyslipidemias. Pravigard PAC is a copackage that contains separate aspirin and pravastatin tablets in various dosage strengths. Adverse effects are the same as those of other drugs in this class. It is contraindicated in patients with hepatic impairment and in those who are pregnant. Pravastatin is a pregnancy category X drug.

Rosuvastatin (Crestor): Approved in 2003, rosuvastatin is a second-generation statin that contains a sulfur group. This drug is the most potent, has the longest half-life in its class (20 hours), and is capable of lowering LDL cholesterol by as much as 65%. Rosuvastatin is not a prodrug and it undergoes minimal hepatic metabolism. This drug may be administered with or without food and without regard to time of day. It is approved for hypercholesterolemia, hypertriglyceridemia, and for slowing the progression of coronary atherosclerosis. Adverse effects are the same as those of other drugs in this class. Rosuvastatin is a pregnancy category X drug.

Simvastatin (Zocor): Approved in 1991, simvastatin is a natural substance derived from fungi. Like lovastatin, simvastatin is an inactive prodrug that is changed to active metabolites by the liver. The drug can lower LDL cholesterol levels by as much as 47%. Although the kidneys excrete only 13% of the drug, dosage adjustment for patients with significant CKD is recommended. The drug may be taken with or without food but should be administered in the evening for maximum effectiveness. It is approved for hypercholesterolemia, hypertriglyceridemia, slowing the progression of coronary atherosclerosis, and prevention of MI and stroke. Adverse effects are the same as those of other drugs in this class. Simvastatin is contraindicated in patients with hepatic impairment and in those who are pregnant. This is a pregnancy category X drug.

CONNECTION Checkpoint 29.1

Several of the statins are prodrugs. From what you learned in Chapter 4, what type of dosage adjustment should be made if these statin prodrugs are prescribed for a patient with hepatic cirrhosis? If a dosage adjustment is not made, what types of adverse effects might you observe? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

The American Academy of Pediatrics recommends that all children undergo cholesterol screening once between the ages of 9 and 11 years and again from ages 17 to 21 years. The Centers for Disease Control and Prevention compiled and reviewed the results from the National Health and Nutrition Examination Survey for 1999–2006 and found that the prevalence of abnormal lipid levels among children ages 12 to 19 years was 20.3%. This percent varied by body mass index with 14.2% of normal weight children, 22.3% of overweight children, and 42.9% of children with obesity having had at least one abnormal lipid laboratory level (Schuman, 2013).

29.6 Bile acid sequestrants may be combined with statins to reduce LDL cholesterol levels.

Bile acids contain a high concentration of cholesterol and are secreted by the liver to emulsify fats in the small intestine. After performing their digestive function, bile acids are reabsorbed in the ileum and sent back to the liver to again become part of bile. This mechanism is known as enterohepatic circulation. In effect, the cholesterol in bile acids is recycled, with only small amounts leaving the body in the feces.

Prior to the discovery of the statins, the primary means of lowering blood cholesterol was through the use of bile acid sequestrants or resins. The bile acid sequestrants bind to bile acids, forming a large complex that cannot be reabsorbed from the small intestine. The enterohepatic circulation of cholesterol is interrupted and the bound bile acids

and cholesterol are eliminated in the feces. The liver responds to the loss of cholesterol by making more LDL receptors, which removes LDL cholesterol from the blood in a mechanism similar to that of the statins.

The bile acid resins are capable of producing a 20% drop in LDL cholesterol, which is generally less response than can be obtained from the statins. They are no longer considered first-line drugs for dyslipidemia, although they are sometimes combined with statins for patients who have contraindications or intolerance to statins.

The bile acid sequestrants tend to cause more frequent adverse effects than statins. Because they are not absorbed into the systemic circulation, adverse effects are limited to the GI tract, causing symptoms such as abdominal pain, bloating, diarrhea, steatorrhea, and constipation. In addition to binding bile acids, these agents can bind drugs such as digoxin and warfarin and increase the potential for drug–drug interactions. Bile acid sequestrants also interfere with the absorption of vitamins and minerals, and nutritional deficiencies may occur with extended use. Other medications and vitamins should be taken at least 1 hour before or 4 hours after taking a bile acid sequestrant to avoid drug interactions.

Bile acid sequestrants may cause a transient increase in triglyceride levels. This effect is particularly prominent and often sustained in patients with preexisting hypertriglyceridemia. Because of this, the bile acid sequestrants are generally not prescribed for patients with elevated triglycerides. Doses for the bile acid sequestrants are listed in Table 29.3.

PROTOTYPE DRUG **Cholestyramine (Questran)**

Classification **Therapeutic:** Antihyperlipidemic
Pharmacologic: Bile acid sequestrant

Therapeutic Effects and Uses: Approved in 1966, cholestyramine is indicated for the reduction of elevated serum cholesterol in patients with primary hypercholesterolemia (elevated LDL) who do not respond adequately to dietary modifications alone. Cholestyramine monotherapy slows the progression and increases the rate of regression of coronary atherosclerosis. A secondary indication is to relieve pruritus associated with partial biliary obstruction. It is available as a powder that is mixed with fluid before being taken once or twice daily. The drug should be mixed with 60 to 180 mL of water, noncarbonated beverages, highly liquid soups, or pulpy fruits (applesauce, crushed pineapple) to prevent esophageal irritation. The patient should swallow the medication immediately after stirring. If taken with too small a fluid volume or if not completely swallowed, the drug can swell in the throat or esophagus to cause an obstruction.

It may take 30 days or longer for cholestyramine to produce its maximum effect. To avoid interference with absorption, cholestyramine should not be taken at the same time as vitamins or other medications. An off-label indication for cholestyramine is diarrhea caused by *Clostridium difficile*, although antibiotics are the drugs of first choice.

Mechanism of Action: Cholestyramine binds to bile acids, forming an insoluble complex containing

CONNECTIONS: Complementary and Alternative Therapies

Coenzyme Q10

Description

Coenzyme Q10 (CoQ10) is a lipid-soluble vitamin-like substance found in most animal cells. It is an essential component in the cell's mitochondria for producing adenosine triphosphate (ATP) energy. Because the heart requires high levels of ATP, a sufficient level of CoQ10 is especially important to that organ.

History and Claims

The applications of CoQ10 to treating disease are relatively recent, with the agent being claimed to be an antioxidant and having benefited patients with heart failure in the mid-1960s. Subsequent reports have claimed that CoQ10 may be beneficial in angina pectoris, dysrhythmias, periodontal disease, immune disorders, neurologic disease, obesity, diabetes mellitus, and cancers.

Standardization

The dose of CoQ10 varies widely. Typical doses range from 100 to 200 mg/day.

Evidence

As with most dietary supplements, controlled research studies with CoQ10 are often lacking and give conflicting results. Supplementation with CoQ10 may be important to patients taking the HMG-CoA reductase inhibitors (statins) because these drugs significantly lower blood levels of CoQ10. Coenzyme Q10 and cholesterol share the same metabolic pathways. Inhibition of the enzyme HMG-CoA reductase by statins decreases CoQ10 levels. Many of the adverse effects of statins, including muscle weakness and rhabdomyolysis, may be due to the decrease in CoQ10 levels; supplementation with CoQ10 may improve myopathy symptoms.

Foods richest in this substance are pork, sardines, beef heart, salmon, broccoli, spinach, and nuts. Older adults appear to have an increased need for CoQ10. Although CoQ10 can be synthesized by the body, many amino acids and other substances are required for this synthesis; thus patients with nutritional deficiencies may need supplementation.

cholesterol that is excreted in the feces. Cholestyramine lowers LDL cholesterol levels by increasing LDL receptors on hepatocytes.

Pharmacokinetics:

Route(s)	PO
Absorption	Not absorbed
Distribution	Not distributed; acts locally in the alimentary canal
Primary metabolism	Not metabolized
Primary excretion	Feces
Onset of action	1–2 days
Duration of action	2–4 weeks

Adverse Effects: Cholestyramine is not absorbed or metabolized once it enters the intestine; thus it does not produce systemic adverse effects. Common GI-related adverse effects include constipation, bloating, belching, and nausea. Serious adverse effects include obstruction of the GI tract, hyperchloremic acidosis, and malabsorption syndrome. Chronic use may cause increased bleeding due to hypoprothrombinemia associated with vitamin K deficiency.

Contraindications/Precautions: Cholestyramine should be used cautiously in patients with GI disorders such as peptic ulcer disease, hemorrhoids, inflammatory bowel diseases, or chronic constipation, because bile acid sequestrants may worsen or aggravate these conditions. This drug should not be used in patients with complete biliary obstruction. Bile acid resins should be used with caution in patients with hypertriglyceridemia because they may increase serum triglyceride concentrations. They are absolutely contraindicated if serum triglycerides rise above 400 mg/dL. Although cholestyramine use is safe during pregnancy because it is not absorbed, precautions must be taken to ensure that this drug is not interfering with vitamin absorption, especially folic acid.

Drug Interactions: Cholestyramine can bind to other drugs and interfere with their absorption, causing reduced effects. This interaction has been reported for digoxin, penicillins, iron supplements, thyroid hormone, and thiazide diuretics, although it has the potential to occur with any drug administered PO. Cholestyramine may indirectly increase the effects of warfarin by binding to vitamin K, decreasing its absorption and lowering the levels of vitamin K in the body. The absorption of raloxifene can be reduced as much as 60% if coadministered with cholestyramine. To reduce the possibility of absorption interference, cholestyramine should be administered 1 hour before or 4 hours after other PO medications. **Herbal/Food:** Cholestyramine may block the absorption of iron and fat-soluble vitamins in food.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving cholestyramine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Hyperlipidemia.

Drugs Similar to Cholestyramine (Questran)

Other bile acid sequestrants include colesevelam and colestipol.

Colesevelam (Welchol): Approved in 2000, colesevelam is a bile acid-binding drug that is claimed to have more bile acid-binding capacity than the older resins. The drug has the capacity to reduce LDL cholesterol by as much as 20%. It may be administered as monotherapy or concurrently with statins to achieve greater efficacy. At least 2 weeks of therapy may be necessary before maximum therapeutic response is achieved. In 2008, colesevelam was approved as an adjunct to diet, exercise, and antidiabetic drugs to improve glycemic control in patients with type 2 diabetes. It is not approved for patients with type 1 diabetes. The most common adverse reactions with colesevelam are constipation, dyspepsia, and nausea. Colesevelam can interfere with the absorption of other medications and should be administered 4 hours after other PO drugs. Like cholestyramine, colesevelam can increase serum triglyceride levels and is contraindicated in patients with triglyceride levels greater than 500 mg/dL. The large tablets can cause dysphagia or esophageal obstruction; thus this drug should be used with caution in patients with swallowing disorders. An oral suspension, dissolved in 4 to 8 ounces of water, is available for patients who have difficulty swallowing the tablets. This drug is pregnancy category B.

Colestipol (Colestid): Approved in 1977, colestipol acts by the same mechanism as cholestyramine, has the same effectiveness in lowering LDL cholesterol, and exhibits the same adverse effects. Other drugs should be administered at least 1 hour before or 4 to 6 hours after a dose of colestipol to prevent interference with absorption. Maximum therapeutic effects may take as long as a month to appear. Because the drug can increase serum triglycerides, it should not be administered to patients with hypertriglyceridemia. Colestipol is rarely used as monotherapy. In addition to its use in treating elevated HDL cholesterol, colestipol may be used off-label to treat digoxin overdose, diarrhea, and pruritus associated with biliary obstruction. This drug is pregnancy category B.

PharmFACT

Familial hypercholesterolemia affects 1 in 200 people and is a genetic disease that predisposes people to premature CVD (Gidding, 2016).

29.7 Niacin can reduce triglycerides and LDL cholesterol levels, but adverse effects limit its usefulness.

Niacin, also called nicotinic acid, is a B-complex vitamin (B_3). Its ability to lower lipid levels, however, is unrelated to its role as a vitamin because much higher doses are needed to produce its antihyperlipidemic effects. For lowering cholesterol, the usual dose is 2 to 3 g/day. When taken as a vitamin, the dose is only 25 mg/day.

The primary action of niacin (Niaspan) is to decrease the production of VLDL, which lowers serum triglyceride levels. Because LDL is synthesized from VLDL, the patient also experiences a reduction in LDL cholesterol levels. Niacin also has the desirable effect of increasing HDL levels, although this effect does not appear to be significant in reducing mortality from cardiovascular disease. As with other lipid-lowering drugs, maximum therapeutic effects may take a month or longer to achieve.

Although effective at reducing LDL cholesterol by 20%, niacin produces more adverse effects than the statins. Intense flushing and hot flashes occur in almost every patient. Taking one aspirin tablet 30 minutes prior to niacin administration can reduce uncomfortable flushing in many patients. In addition, a variety of uncomfortable GI effects such as nausea, excess gas, and diarrhea are commonly reported. Paresthesias, such as tingling in the extremities, may also occur.

More serious adverse effects such as hepatotoxicity and gout are possible but uncommon. Patients with elevated liver enzymes or a history of liver disease should use an alternate drug to lower lipids. In patients predisposed to gout, niacin may increase uric acid levels and precipitate acute gout.

Niacin is not usually prescribed for patients with diabetes mellitus because the drug can raise fasting glucose levels. When beginning therapy, patients with diabetes should monitor their blood glucose levels more frequently until the effect of niacin is determined.

Because of the high incidence of adverse effects, niacin is most often used in low doses in combination with a bile acid sequestrant; the beneficial effects of these drugs are additive. Niacin was formerly combined with statins; however, the FDA determined that the combination did not offer any reduction in cardiovascular mortality over simply using a statin as monotherapy.

Because supplemental niacin is available without a prescription, patients should be instructed not to attempt self-medication with this drug. One form of niacin that is available OTC as a vitamin supplement, called nicotinamide, has no lipid-lowering effects. If niacin is to be used to lower cholesterol, it should be done under medical supervision.

29.8 Fibric acid drugs lower triglyceride levels but have little effect on LDL cholesterol.

Three fibric acid drugs are sometimes used for patients with high triglyceride levels: fenofibrate (Lofibra, TriCor, others), fenofibric acid (Fibricor, Trilipix), and gemfibrozil (Lopid). They are preferred drugs for treating severe hypertriglyceridemia (Types IV and V hyperlipidemia), although they have little effect on LDL cholesterol. Fibric acid drugs activate the enzyme lipoprotein lipase, which increases the breakdown and elimination of triglyceride-rich particles from the plasma. The FDA does not recommend combining a fibric acid drug with a statin because it has not been shown to have cardiovascular benefits. Doses for the fibric acid drugs are listed in Table 29.3.

The most common adverse effects of the fibrates relate to the GI system: dyspepsia, diarrhea, abdominal pain, nausea, and vomiting. Taking these medications with meals usually diminishes GI distress. Drugs in this class are generally not used in patients with hepatic impairment or gallbladder disease.

PROTOTYPE DRUG **Gemfibrozil (Lopid)**

Classification **Therapeutic:** Antihyperlipidemic
Pharmacologic: Fibric acid drug (fibrate)

Therapeutic Effects and Uses: Approved in 1981, gemfibrozil lowers serum triglycerides and LDL cholesterol. It is most effective in patients who present with hypertriglyceridemia and VLDL. Effects of gemfibrozil include up to a 50% reduction in VLDL with an increase in HDL. It is less effective than the statins at lowering LDL; thus it is not used as monotherapy. It is considered a second-line therapy that is used when statins are ineffective or not well tolerated.

Mechanism of Action: The exact mechanism of action of gemfibrozil is unknown. The drug inhibits the breakdown of stored fat, or lipolysis, in adipose tissue. By inhibiting the uptake of free fatty acids by the liver, hepatic production of triglycerides is decreased. The drug may also increase the excretion of cholesterol in the feces.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Unknown; distribution across the placenta or secretion in breast milk is unknown; 99% bound to plasma protein
Primary metabolism	Hepatic; undergoes enterohepatic recirculation
Primary excretion	Primarily renal, 6% in feces
Onset of action	1–2 h
Duration of action	Half-life: 1.5 h

Adverse Effects: The most common adverse effects of gemfibrozil are GI related, such as abdominal cramping, diarrhea, nausea, and dyspepsia. Nervous system effects include headache, dizziness, peripheral neuropathy, and diminished libido. Serious adverse effects include cholelithiasis, anemia, and eosinophilia.

Contraindications/Precautions: Gemfibrozil may worsen or cause biliary disease; thus it is contraindicated in patients with preexisting gallbladder disease or serious liver impairment. Because it is excreted by the kidneys, the drug should be used cautiously in patients with CKD

Drug Interactions: Although antihyperlipidemic drugs from different classes are sometimes combined to produce an enhanced effect, the use of gemfibrozil with statins increases the risk of myositis and rhabdomyolysis. CK levels should be regularly monitored during combined therapy and the combination immediately discontinued if myopathy is suspected. In most cases the risk of rhabdomyolysis, which may be fatal, outweighs the potential benefits of combined statin and gemfibrozil therapy.

Concurrent use of gemfibrozil with PO anticoagulants may increase the risk of bleeding because the fibrate displaces warfarin from its plasma protein binding sites. If a patient is taking warfarin, dosages should be lowered. More frequent monitoring of prothrombin time (PT) and international normalized ratio (INR) is necessary until stabilization occurs.

Gemfibrozil may enhance the hypoglycemic effects of antidiabetic drugs. Serum glucose levels must be carefully monitored because the dosage of the antidiabetic drug may require adjustment. **Herbal/Food:** No significant interactions.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving gemfibrozil are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Hyperlipidemia.

Drugs Similar to Gemfibrozil (Lopid)

Drugs similar to gemfibrozil include fenofibrate and fenofibric acid.

Fenofibrate (Lofibra, TriCor, Others) and fenofibric acid (Fibricor, Trilipix): Once absorbed, fenofibrate is quickly converted to fenofibric acid, its active metabolite. Thus the actions and adverse effects of the two drugs are the same. Fenofibrate is indicated as supplemental therapy to diet to reduce elevated LDL, total cholesterol, triglycerides, and apo B and to increase HDL in patients with primary hypercholesterolemia, hypertriglyceridemia, and mixed dyslipidemia. Approved in 1993, fenofibrate may reduce serum triglycerides by as much as 30%. One advantage of the fenofibrate formulations over gemfibrozil is that they may be taken once daily rather than twice a day. The different formulations of fenofibrate and fenofibric acid vary in strength, bioavailability, and whether the drug should be administered with a meal. These forms are not interchangeable. One of the forms, Trilipix, is approved for concurrent therapy with statins. The most frequent adverse effects are GI related, such as nausea, vomiting, dyspepsia, constipation, flatulence, and abdominal pain. Liver function tests should be performed periodically to monitor for elevated serum transaminases. Myopathy and rhabdomyolysis have been reported, and the risks for these adverse effects are increased when coadministered with a statin. Rash and photosensitivity are other adverse effects. These drugs are pregnancy category C.

CONNECTION Checkpoint 29.2

From what you learned in Chapter 10, what changes in physiology occur with aging that may require decreased starting dosages for antihyperlipidemic drugs? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Miscellaneous Drugs for Dyslipidemias

29.9 Newer strategies have been developed to treat dyslipidemias.

The large numbers of people with elevated lipid values has encouraged the pharmaceutical industry to investigate new drugs for controlling LDL cholesterol and triglycerides. The search for new and improved antilipidemics has resulted in several new drugs for this condition.

Ezetimibe (Zetia): Ezetimibe (Zetia) is the only drug in a class called the cholesterol absorption inhibitors. Cholesterol is absorbed from the intestinal lumen by cells in the

jejunum of the small intestine. Ezetimibe blocks this absorption by as much as 50%, causing less cholesterol to enter the blood. Unlike the statins, the drug does not inhibit cholesterol biosynthesis in the liver or increase the excretion of bile acid. Ezetimibe is considered a first-line drug for patients who cannot tolerate statins.

When given as monotherapy, ezetimibe produces a modest reduction in LDL of about 20%. Adding a statin to the therapeutic regimen reduces LDL by an additional 15% to 20%. The drug produces a slight drop in serum triglycerides. Ezetimibe is available as a single tablet with a once-daily dosing regimen. Vytorin is a fixed-dose combination tablet containing ezetimibe and simvastatin, and Liptruzet combines ezetimibe with atorvastatin.

Nasopharyngitis, myalgia, upper respiratory tract infection, arthralgia, and diarrhea are the most common adverse effects of ezetimibe, although these rarely require discontinuation of therapy. Because bile acid sequestrants inhibit the absorption of ezetimibe, these drugs should not be taken together. In addition, ezetimibe and statins should not be given concurrently to patients with serious hepatic impairment or with elevated serum transaminase levels. Ezetimibe is pregnancy category C.

Omega-3 fatty acids: Nutritionists have long reported the benefits of eating fish rich in omega-3 fatty acids such as tuna, salmon, and halibut. The two principal omega-3 fatty acids are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Vegetarian sources of omega-3 fatty acids include flaxseed oil, soybeans, walnuts, and pumpkin seeds.

The role of omega-3 fatty acids in preventing cardiovascular disease is well established. When taken as dietary supplements, the omega-3 fatty acids are usually marketed as fish oil. Fish oil supplementation has been shown to decrease mortality due to MI and stroke. A typical dose of omega-3 fatty acids in fish oil capsules is 180 mg of EPA and 120 mg of DHA.

Two prescription formulations of omega-3 fatty acids are available: omega-3-acid ethyl esters (Lovaza) and icosapent (Vascepa). Both drugs are approved as an adjunct to diet in the treatment of severe hypertriglyceridemia. Adverse effects are minor and include belching, fishy taste, and arthralgia. The drugs should be used with caution in patients who are allergic to seafood, especially shellfish.

Drugs for familial hypercholesterolemia: Two drugs were approved in 2013 for a very narrow indication: as an adjunct to lowering LDL in patients with homozygous familial hypercholesterolemia (HoFH). HoFH is a genetic disorder in which the body has such high levels of cholesterol and LDL that cardiovascular disease begins in childhood and results in death by the mid-30s. Many of these patients have a diminished response to therapy with statins and other antihyperlipidemics. The two new drugs, lomitapide (Juxtapid) and mipomersen (Kynamro), act by very different and unique mechanisms. Therapy is very costly and will likely limit their widespread use.

The primary protein that composes particles of LDL is apo B. When assembling the lipoprotein, lipid molecules are transported and loaded onto the apo B. Upon completion, the lipoprotein is assembled and leaves the intestine or liver as chylomicrons or VLDL, which eventually raises blood LDL levels. Lomitapide and mipomersen interfere with different aspects of this genesis of lipoprotein.

Lomitapide is classified as a microsomal triglyceride transfer protein (MTP) inhibitor. Inhibition of MTP interferes with the transfer of lipids to apo B, thus lowering plasma levels of LDL. The drug is given PO and is indicated only for HoFH. GI adverse effects such as diarrhea, nausea, vomiting, dyspepsia, and abdominal pain occur in almost all patients. Drug interactions may be serious with medications that inhibit hepatic CYP3A4, including ketoconazole, clarithromycin, lopinavir/ritonavir, or telithromycin. These drugs will markedly increase levels of lomitapide. Lomitapide is contraindicated during pregnancy (category X).

Mipomersen is classified as an inhibitor of apo B synthesis. The message for making apo B leaves the DNA as a strip of messenger RNA (mRNA). Mipomersen is a huge molecule that has mRNA complementary to apo B (called an antisense message). The antisense message binds to the apo B strip of RNA, preventing the synthesis of the apo B protein. Mipomersen is given as once-weekly subcutaneous injection. The drug is pregnancy category B.

Mipomersen and lomitapide carry identical black box warnings that the drugs can cause elevations in transaminases and may increase hepatic fat (hepatic steatosis). The drugs are contraindicated in patients with active hepatic disease, and alanine transaminases (ALT) and aspartate aminotransferase (AST) must be measured prior to and during therapy. The drugs are only available in restricted use programs that require prescribers and pharmacists to be certified through special training.

PCSK9 inhibitors: A new strategy to manage increased cholesterol levels is to inhibit PCSK9 (proprotein convertase subtilisin kexin type 9), a protein that degrades receptors for LDL-C in the liver. Binding of the drug to PCSK9 increases the number of receptors available to clear LDL-C, thus lowering the level of LDL-C in the blood. Alirocumab (Praluent) and evolocumab (Repatha), both approved in 2015, are monoclonal antibodies given by the subcutaneous route that inhibit PCSK9. They are indicated for patients with heterozygous familial hypercholesterolemia (HeFH) or HoFH who need more lowering of LDL-C than can be attained with other therapies. The two PCSK9 inhibitors are much more expensive than statins.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Hyperlipidemia

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, musculoskeletal (preexisting conditions that might result in muscle or joint pain), GI (peptic ulcer disease, hemorrhoids, inflammatory bowel disease, chronic constipation, gallbladder disease, dysphagia or esophageal strictures), and the possibility of pregnancy. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings, especially liver function studies, lipid profiles, and CK.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., lowered total cholesterol and LDL levels, increased HDL levels).
- Continue periodic monitoring of lipid profiles, liver function studies, CK, and uric acid levels.
- Assess for adverse effects: musculoskeletal discomfort, nausea, vomiting, abdominal cramping, or diarrhea. Immediately report any severe musculoskeletal pain, unexplained muscle tenderness accompanied by fever, inability to perform activities of daily living (ADLs) due to musculoskeletal weakness or pain, unexplained numbness or tingling of extremities, yellowing of the sclera or skin, severe constipation, straining with passing of stools, or tarry stools.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Follow appropriate administration guidelines. (Many of the lipid-lowering drugs have specific administration requirements. For best results, they should be taken at night when cholesterol biosynthesis is at its highest.)	• Teach the patient to take the drug following appropriate guidelines (see *Patient self-administration of drug therapy* section below).
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient and family to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation. • Encourage increased intake of foods rich in omega-3 and Coenzyme Q10: fish such as salmon and sardines, nuts, extra-virgin olive and canola oils, beef, chicken, and pork. Supplementation may be needed; instruct the patient to seek the advice of a healthcare provider before taking supplements.
Minimizing adverse effects: • Continue to monitor periodic liver function tests and CK levels. (Abnormal liver function tests or increased CK levels may indicate drug-induced adverse hepatic effects or myopathy and should be reported. **Lifespan:** Monitor the older adult frequently because age-related physiologic changes may affect the drug's metabolism or excretion. **Diverse Patients:** Because statins metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Instruct the patient on the need to return periodically for laboratory work.
• Continue to assess for drug-related symptoms, which may indicate that adverse effects are occurring. (Lipid-lowering drugs often adversely affect the liver but may also cause drug-specific adverse effects.) • Assess for the possibility of increased adverse effects when a combination of lipid-lowering drugs is used. (Lipid-lowering drugs may be combined for better effects, but this increases the risk of adverse effects.)	Teach the patient the importance of reporting signs or symptoms related to adverse drug effects as follows: • **Statins:** Report unusual or unexplained muscle tenderness, increasing muscle pain, numbness or tingling of extremities, or effects that hinder normal ADLs. **Lifespan:** The drug should not be taken during pregnancy, if pregnancy is suspected, or while breastfeeding. • **Bile acid resins:** Report severe nausea, heartburn, constipation, or straining with passing stools. Any tarry stools or yellowing of the sclera or skin should also be reported. **Lifespan:** The older adult may have an increased risk of bleeding due to drug-related changes with vitamin K synthesis. • **Niacin:** Report flank, joint, or stomach pain, or yellowing of the sclera or skin. • **Fibric acid drugs:** Report unusual bleeding or bruising, right upper quadrant pain, muscle cramping, or changes in the color of the stool. Patients with diabetes on PO medications may need a change in their dosage and should monitor their glucose more frequently in early therapy. **Lifespan:** Monitor the older adult for dizziness and assist with ambulation to prevent falls. **Diverse Patients:** Research has indicated that Hispanics and Native Americans may have a greater risk for development of gallbladder disease than other ethnic groups. • Instruct patients taking a combination of lipid-lowering drugs to be alert to symptoms related to adverse effects of *both* drugs, as above.
• If long-term therapy is used, ensure adequate intake of fat-soluble vitamins (A, D, E, K) and folic acid in the diet or consider supplementation. (Lipid-lowering drugs may cause depletion or diminished absorption of these nutrients.)	• Instruct the patient, family, or caregiver about foods high in folic acid and fat-soluble vitamins, and about the need to consult with the healthcare provider about the need for vitamin and folic acid supplementation while on long-term therapy.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., during the evening meal. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs. • The patient takes the drug following appropriate guidelines: • **Statins:** Most are taken with the evening meal; avoid grapefruit and grapefruit juice, which could inhibit the drug's metabolism, leading to toxic levels. • **Bile acid resins:** Take before meals with plenty of fluids, mixing powders or granules thoroughly with liquid. Take other medications 1 h before or 4 h after the bile acid resin is taken. • **Niacin:** Take with cold water to decrease the sensation of flushing associated with the drug. Take one adult-strength (325-mg) aspirin 30 min before the niacin dose. • **Fibric acid drugs:** Take with a meal.

Understanding Chapter 29

Key Concepts Summary

29.1 Lipids are classified as triglycerides, phospholipids, or sterols.

29.2 Lipoproteins are important predictors of cardiovascular disease.

29.3 Blood lipid profiles are important diagnostic tools in guiding the therapy of dyslipidemias.

29.4 Lipid levels can often be controlled through therapeutic lifestyle changes.

29.5 The statins are the most effective drugs for reducing blood lipid levels.

29.6 Bile acid sequestrants may be combined with statins to reduce LDL cholesterol levels.

29.7 Niacin can reduce triglycerides and LDL cholesterol levels, but adverse effects limit its usefulness.

29.8 Fibric acid drugs lower triglyceride levels but have little effect on LDL cholesterol.

29.9 Newer strategies have been developed to treat dyslipidemias.

CASE STUDY: Making the Patient Connection

Remember the patient "Belinda Cummings" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Belinda Cummings is a 39-year-old African American woman who feels fine. However, she recently had her cholesterol level checked at her church's health fair where she was told that it exceeded the normal value. As directed, she made an appointment and saw her healthcare provider for a checkup.

During the office visit, the nurse collects Belinda's social and health history. Belinda's vital signs are within normal limits, except her blood pressure is elevated (142/90 mmHg). She is also slightly overweight and has been on a low-carbohydrate diet for 1 week. Her favorite foods are potato chips and all dairy products, especially cheese. She admits to smoking less than a pack of cigarettes per day and occasionally drinks a glass of wine with dinner. Belinda is divorced and has one teenage son.

A series of laboratory tests is completed during the visit. Belinda's physical examination is normal, and there are no ECG abnormalities. The blood tests are unremarkable with the exception of the lipid profile.

	Patient Value	Normal Range
Total Cholesterol	240 mg/dL	Less than 200
Triglycerides	199 mg/dL	Less than 150
HDL Cholesterol	30 mg/dL	Greater than 60
LDL Cholesterol	184	Less than 100
Cholesterol-to-HDL Ratio	6.6	Less than 4.5

The patient is placed on a standard cholesterol-lowering diet and prescribed atorvastatin (Lipitor) 10 mg daily. Belinda is instructed to return to the office in 1 month for a follow-up visit.

Critical Thinking Questions

1. How would you respond to Belinda when she asks you, "Is high cholesterol due to heredity or what I eat?"
2. What health teaching should you provide the patient about ways to reduce high blood lipid levels?
3. Create a list of potential adverse effects that this patient should be taught to watch for related to the medication.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

David Hamilton has been taking cholestyramine (Questran) for elevated blood lipid levels for 2 years. He presents today in your clinic for a routine follow-up visit that will include a lipid profile test. He states that he has been somewhat consistent with his cholesterol-lowering diet and attempting to get "a little more" exercise. You are the nurse caring for David.

1. Outline key concepts related to health promotion activities that you would want to be sure David understands.
2. What adverse effects related to Questran should David watch for?
3. If David's triglyceride levels increase or remain consistently high, what drug group(s) might be prescribed?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient taking atorvastatin (Lipitor) reports weakness and fatigue, pain in the shoulders, and aching joints. The nurse initially assesses the patient for which condition?
   1. Rhabdomyolysis
   2. Renal failure
   3. Rheumatoid arthritis
   4. Hepatic insufficiency

2. A patient is receiving cholestyramine (Questran) for elevated low-density lipoprotein levels. Which adverse effect should the nurse include in the care plan to monitor the patient?
   1. Orange-colored urine
   2. Abdominal pain
   3. Sore throat and fever
   4. Decreased capillary refill

3. The provider orders colestipol (Colestid) in combination with atorvastatin (Lipitor) for a patient with elevated low-density lipoprotein levels. The nurse collaborates with the prescriber about which data related to the patient?
   1. Past history of peptic ulcer disease
   2. Recent myocardial infarction
   3. Laboratory value for serum sodium of 136 mEq/L
   4. Allergies to foods high in tyramine

4. Which assessment findings discovered by the nurse would be an expected adverse effect associated with niacin therapy? (Select all that apply.)
   1. Fever and chills
   2. Intense flushing and hot flashes
   3. Tingling of the fingers and toes
   4. Dry mucous membranes
   5. Hypoglycemia

5. The community health nurse visits a patient who has been prescribed lovastatin (Mevacor). Which statement, if made by the patient, indicates that further teaching is necessary concerning this drug therapy?
   1. "I should try to maintain my body weight at an optimal level."
   2. "Most patients with lipid disorders don't have any symptoms."
   3. "The best time for me to take this medication is before I go to bed."
   4. "I will take my drug with beverages that contain grapefruit juice."

6. The nurse is caring for a patient receiving gemfibrozil (Lopid) for hyperlipidemia. The nurse would validate the order with the prescriber if the patient reported a history of which of the following? (Select all that apply.)
   1. Gallbladder disease
   2. Angina
   3. Hypertension
   4. Diabetes
   5. Chronic kidney disease

"My friends all take diuretics for their hypertension, but my provider is giving me something called a 'calcium channel blocker.' Would someone please tell me what calcium has to do with high blood pressure?"
Patient "Angela Rivera"

Chapter 30
Pharmacotherapy with Calcium Channel Blockers

Chapter Outline

- Physiologic Role of Calcium Channels in Muscle Contraction
- Types of Calcium Channels
- Consequences of Calcium Channel Blockade
- Classification of Calcium Channel Blockers

  Dihydropyridines

  PROTOTYPE *Nifedipine (Adalat CC, Procardia XL), p. 515*

  Nondihydropyridines

  PROTOTYPE *Verapamil (Calan, Isoptin, Verelan), p. 517*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the role of calcium ions in the contraction of smooth and cardiac muscle.
2. Explain why the actions of the beta$_1$-adrenergic antagonists are similar to those of the calcium channel blockers.
3. Describe how calcium channel blockers interact with the L-type calcium channel.
4. Identify the physiologic effects of calcium channel blockers on arterial smooth muscle and cardiac muscle.
5. Explain the classification of calcium channel blockers.
6. Compare and contrast the actions of dihydropyridine versus nondihydropyridine calcium channel blockers.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy with calcium channel blockers.

Key Terms

calcium channel, 511
dihydropyridines, 514
negative chronotropic effect, 513
negative inotropic effect, 513
sarcolemma, 511
sarcoplasmic reticula, 511

Since the approval of the first calcium channel blocker (CCB) 30 years ago, this class of drugs has become one of the most widely prescribed in cardiovascular medicine. One reason for their widespread use is that these drugs treat two chronic diseases that affect millions of people: hypertension (HTN) and coronary artery disease (CAD). Their success is also related to their effectiveness and a favorable safety profile.

CCBs are also known as calcium channel antagonists. These drugs do not physically block calcium channels; therefore, *antagonist* is a more accurate term than *blocker*. Because both terms are used interchangeably in clinical practice, they are used as synonyms throughout this text.

Physiologic Role of Calcium Channels in Muscle Contraction

30.1 Calcium channels facilitate contraction in cardiac and smooth muscles.

Recall from muscle physiology that the signal for contraction is an action potential traveling across the muscle plasma membrane, or **sarcolemma**. The action potential causes a depolarization that opens voltage-gated channels in the sarcolemma, allowing ions to enter and leave the muscle cell. In skeletal muscle, as in nervous tissue, the primary ion channels facilitate Na^+ and K^+ movement. In cardiac and smooth muscle, a third type of voltage-gated channel, the **calcium channel**, is of particular importance to cardiovascular physiology and pharmacotherapy. Contraction of these muscle types requires the movement of calcium ions (Ca^{2+}).

Under resting conditions, the concentration of free Ca^{2+} in the cytoplasm of a muscle cell is very low. Depolarization of the sarcolemma, however, changes the amount of free Ca^{2+} in two ways. First, calcium channels in the sarcolemma open, allowing extracellular calcium to rush into the cell. Secondly, depolarization releases large amounts of calcium ions stored in cellular structures called **sarcoplasmic reticula**. This huge increase in cytoplasmic Ca^{2+} removes the inhibition of actin and myosin filaments by the proteins calmodulin (smooth muscle) or troponin C (cardiac muscle) through a cascade of complex reactions. Actin and myosin are then free to slide, and muscle contraction occurs. This process is illustrated in Figure 30.1.

Muscle contraction is terminated when the amount of free cytoplasmic Ca^{2+} is reduced, by either pumping to the outside of the cell or by returning the Ca^{2+} to storage in the sarcoplasmic reticulum.

Recall from Chapter 15 that activation of $beta_1$-adrenergic receptors in cardiac muscle increases heart rate and contractility. This is because, in myocardial cells, the signal for opening calcium channels is linked to activation of the

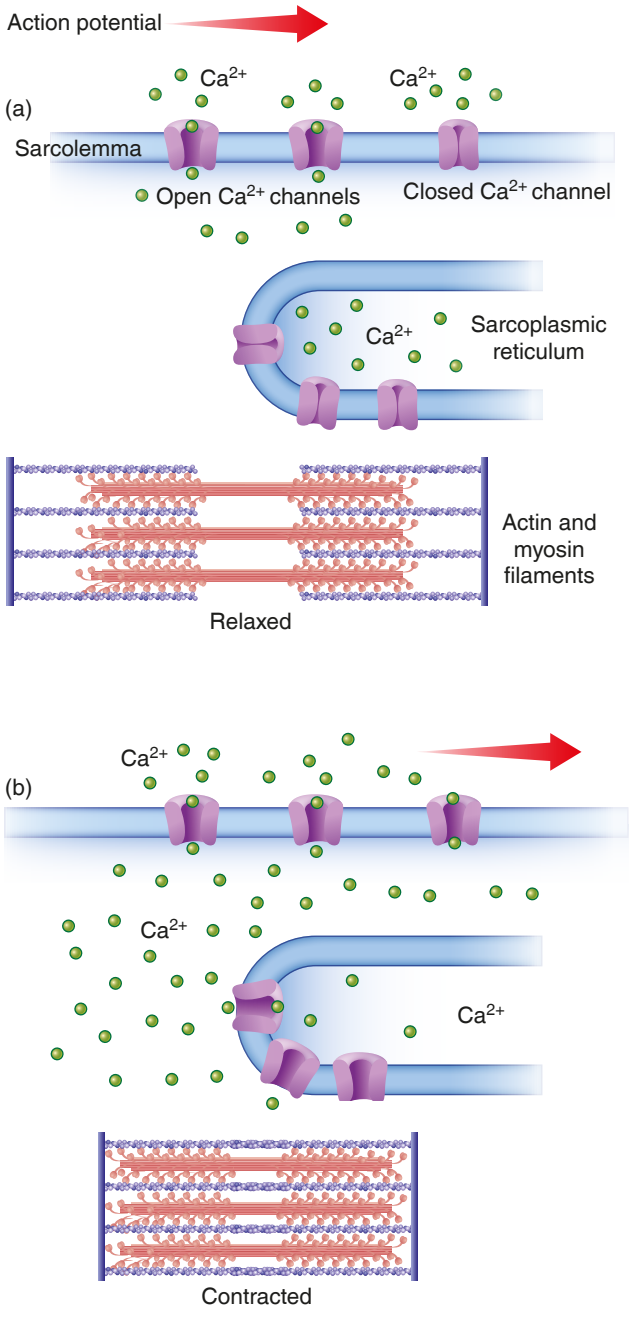

Figure 30.1 Calcium channels and muscle contraction: (a) Calcium channels open as the action potential travels along the sarcolemma. (b) Large amounts of calcium are released from storage in the sarcoplasmic reticula, causing actin and myosin filaments to slide and muscle contraction to occur.

sympathetic nervous system. In effect, calcium channels open when the sympathetic nervous system supplies the action potential, depolarizing the sarcolemma. This has important implications to pharmacology. Blocking cardiac beta$_1$ receptors with adrenergic antagonists will *prevent* the opening of calcium channels. Thus the cardiac effects of beta$_1$-adrenergic blockers, and their pharmacotherapeutic indications and adverse effects, are similar to those of CCBs.

CONNECTION Checkpoint 30.1

From what you learned in Chapters 15 and 16, what type of drug–drug interaction would you expect between a CCB and (a) a beta-adrenergic antagonist such as propranolol (Inderal) and (b) a sympathomimetic such as epinephrine? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Types of Calcium Channels

30.2 The calcium channel consists of multiple subunits and is present in many tissues.

Research has discovered different types of calcium ion channels, which are named by the letters *L*, *T*, and *N*. Differences in the structures and locations of the channels are important to drug action.

Pharmacologically, the most important calcium channels are the L type, because they are the ones that bind CCBs. L-type calcium channels are found on the sarcolemma of cardiac and smooth muscles. The channel spans across the membrane and consists of three main parts. An extracellular portion serves as a receptor to bind CCBs. A central portion serves as a pore through which calcium ions travel. An intracellular portion serves as a second messenger capable of initiating a cascade of events that signal the cell to perform specific functions.

The L-type calcium channel is regulated by voltage changes across the sarcolemma. When an action potential depolarizes the membrane, the channel opens, allowing Ca^{2+} to rush in. The L-type channels are relatively slow, which allows for a sustained flow of Ca^{2+} into the cell. When a CCB medication is present, the channel changes shape. Although the drug does not physically block the opening, the change in shape of the channel is enough to prevent Ca^{2+} from entering the muscle cell. The L-type calcium channel is illustrated in Figure 30.2.

L-type calcium channels are widespread in the cardiovascular system, and these channels bind all current CCBs. L-type calcium channels are also present in other tissues, particularly in neurons and endocrine and sensory cells. This leads to other potential uses of these drugs, a topic discussed later in this chapter.

T-type calcium channels are present in vascular smooth muscle as well as the sinoatrial (SA) node where they are involved in pacemaker functions of the heart. Like the L-type channels, they are also located in other tissues, including the central nervous system (CNS). At this time, the only medication that acts by blocking T-type channels is ethosuximide (Zarontin), which is used to treat absence seizures. Other potential indications for T-type CCBs include pain, obesity, insomnia, and anxiety.

N-type calcium channels are found throughout the nervous system. Their primary role appears to be to control neurotransmitter release at synapses. They also are involved in the transmission of pain impulses in the spinal cord. At this time ziconotide is the only approved N-type CCB. When delivered intrathecally, ziconotide blocks

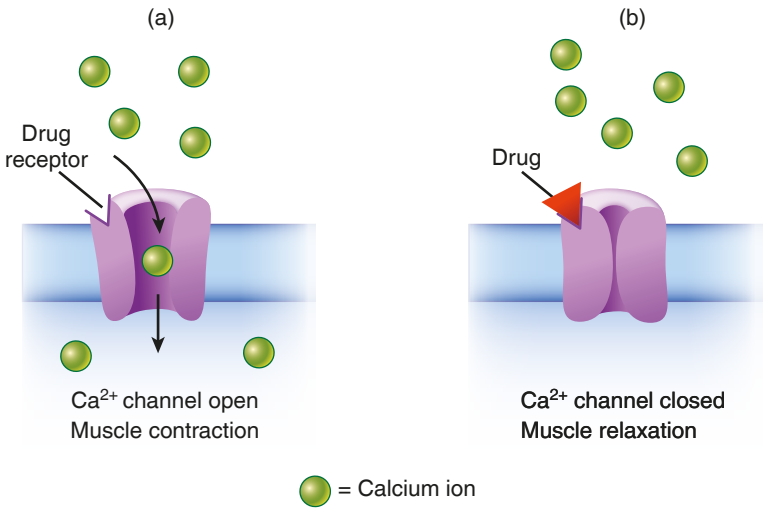

Figure 30.2 L-type calcium channel: (a) Calcium channel opens when an action potential passes across the sarcolemma. Calcium enters the cell and muscle contraction occurs. (b) Calcium channel antagonist binds to the receptor, changing its shape; channel closes and muscle relaxation occurs.

CONNECTIONS: Community-Oriented Practice

Calcium Channel Blockers and Effects on Minerals

Patients may be concerned about taking calcium supplements for osteoporosis prevention while taking CCBs. Calcium and magnesium supplements may actually help maintain a normal blood pressure or a lower high blood pressure, and as long as normal doses are taken, do not appear to affect the antihypertensive effects of CCBs. More recent research suggests that CCBs may affect the body's mineral content (Suliburska, Bogdanski, Szulinska, & Pupek-Musialik, 2014). CCBs, along with other antihypertensive drugs such as beta blockers and angiotensin-converting enzyme (ACE) inhibitors, were found to decrease serum zinc levels. Because depletion of some minerals such as zinc may have long-term effects on glucose and lipid metabolism, adequate mineral intake through diet or supplementation should be considered when a patient is taking CCBs or other antihypertensives.

N-type channels in the spinal cord to ease severe, chronic pain. Although the drug has limited applications, in the future other medications may be developed that target the neuronal N-type calcium channels to achieve pain relief.

Consequences of Calcium Channel Blockade

30.3 Blocking calcium channels has significant physiologic effects on the heart and vascular smooth muscle.

The therapeutic applications of CCBs are the result of actions of the drugs on vascular smooth muscle, cardiac muscle, and the conduction system in the heart. Some CCBs have greater actions on the heart, whereas others have more effect on arteriolar smooth muscle. None of the CCBs affects serum calcium levels.

Effects on vascular smooth muscle: The influx of calcium ions into smooth muscle cells is essential for contraction. Because the degree of contraction of arterioles controls peripheral resistance, the blockade of calcium channels has significant physiologic effects on blood pressure. All CCBs dilate peripheral arterioles, causing systemic blood pressure to decrease. Afterload is reduced, resulting in lower myocardial oxygen demand and less workload for the heart. This is particularly important for patients with angina, who will experience less chest pain due to the decrease in cardiac workload (see Chapter 35).

Another important group of vessels affected by CCBs are the coronary arteries. Dilation of the coronary arteries by the CCBs brings more blood to the myocardium, which is beneficial for patients with myocardial ischemia. Veins and cardiac preload are not affected by drugs in this class.

Effects on the myocardium: Most CCBs reduce the force of myocardial contraction. This **negative inotropic effect** occurs because these drugs reduce the inward movement of Ca^{2+} during the plateau phase of the action potential. This delayed entry of Ca^{2+} prevents the release of Ca^{2+} from its storage depots in the sarcoplasmic reticulum, resulting in fewer actin–myosin cross bridges and a diminished force of contraction.

For verapamil and diltiazem, the negative inotropic effect is clearly apparent at therapeutic doses. The remainder of the CCBs will only exhibit this effect at higher doses or in overdose situations.

Effects on cardiac conduction: In general, CCBs exhibit a **negative chronotropic effect**: the property of slowing the speed of electrical conduction across the myocardium. Under normal conditions, the SA node automatically generates an action potential because of an inward movement of Ca^{2+} through calcium channels. Blocking calcium entry causes the SA node to generate fewer action potentials, thus decreasing automaticity and slowing heart rate. Similarly, some of the CCBs block calcium channels in the atrioventricular (AV) node, reducing conduction velocity through this region of the heart and further slowing the spread of the action potential across the myocardium. Because of these actions on the cardiac conduction system, the CCBs are sometimes used to correct certain rhythm abnormalities of the heart (see Chapter 37).

Not all CCBs affect cardiac conduction to the same degree. Verapamil and diltiazem exhibit this effect at therapeutic doses, whereas the remainder of the CCBs exhibit a negative chronotropic effect only at high doses, or not at all.

CONNECTION Checkpoint 30.2

From what you learned in Chapter 28, define *afterload*. If a drug increases afterload, what effect would this likely have on cardiac output? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Classification of Calcium Channel Blockers

30.4 Calcium channel blockers are classified by their chemical structures as dihydropyridines or nondihydropyridines.

Despite the fact that all CCBs affect L-type calcium channels, there are differences in actions and adverse effects among the specific drugs. This is because the drugs interact with different subunits of the calcium channel. This gives rise to a classification of calcium channel antagonists based on their chemical structures.

The **dihydropyridines** are the largest class of CCBs. They include amlodipine (Norvasc), clevidipine (Cleviprex), felodipine (Plendil), isradipine, nicardipine (Cardene), nifedipine (Adalat CC, Procardia XL), nimodipine, and nisoldipine (Nisocor). The dihydropyridines bind reversibly to *closed-type* (inactivated) calcium channels, changing the channels' structure and making them unresponsive to depolarization. Because closed-type channels are found in greater numbers in vascular smooth muscle than in cardiac muscle, dihydropyridines are primarily used for their vasodilation effect on arterial smooth muscle.

The remaining CCBs are chemically dissimilar to the dihydropyridines and bind to different subunits of the L-type calcium channel. Although they are chemically different from each other, diltiazem (Cardizem, Dilacor, Taztia XT, Tiazac, others) and verapamil (Calan, Isoptin, Verelan) have quite similar pharmacologic properties and may be grouped together as nondihydropyridines. These drugs bind to *open-type* calcium channels, causing them to revert to their inactivated or closed state. These drugs also delay reactivation of the calcium channel, thus slowing repolarization of the muscle cell membrane. This effect is particularly noticeable in cardiac muscle, where the nondihydropyridines slow the speed of myocardial conduction. Like the dihydropyridines, the nondihydropyridines have a vasodilation effect on vascular smooth muscle. Indications for the various CCBs that have been approved by the U.S. Food and Drug Administration (FDA) are shown in Table 30.1.

30.5 The dihydropyridines are selective for vascular smooth muscle and are used to treat hypertension and angina pectoris.

All dihydropyridines have similar actions and adverse effects. All except clevidipine are well absorbed after oral (PO) administration, and most are highly protein bound, excreted by the liver, and undergo extensive first-pass metabolism. Because of this, dosage adjustments are necessary in patients with significant hepatic impairment.

Drugs in this class are highly selective for calcium channels located in vascular smooth muscle. At high doses, however, the dihydropyridines lose their selectivity and also affect calcium channels in the heart. All dihydropyridines are equivalent in effectiveness for treating HTN and angina. Some are available in extended release formulations that allow for once-daily dosing. Doses for the dihydropyridines are listed in Table 30.2.

The dihydropyridines are well tolerated in most patients. Common adverse effects include flushed skin, headache, dizziness, hypotension, peripheral edema, lightheadedness, nausea, and diarrhea, although these are usually not severe enough to discontinue therapy. The vasodilation caused by the blockade of calcium channels in vascular smooth muscle may cause reflex tachycardia. This is generally transient and clinically important only in patients with preexisting myocardial ischemia or dysrhythmias. If a CCB must be used for these patients, extended release formulations are selected because they produce a more gradual change in blood pressure with less reflex tachycardia.

Table 30.1 FDA-Approved Indications for Calcium Channel Blockers

Drug	Hypertension	Chronic Stable Angina	Vasospastic Angina	Unstable Angina	Dysrhythmias	Subarachnoid Hemorrhage
Dihydropyridines						
amlodipine (Norvasc)	X	X	X			
clevidipine (Cleviprex)	X					
felodipine (Plendil)	X					
isradipine	X					
nicardipine (Cardene)	X	X				
nicardipine (Cardene SR)	X					
nifedipine (Adalat, Procardia XL)	X	X	X			
nimodipine						X
nisoldipine (Sular)	X					
Nondihydropyridines						
diltiazem (Cardizem, Dilacor)		X	X			
diltiazem extended release (Cartia XT, Dilt-CD)	X	X	X			
diltiazem extended release (Cardizem LA, Dilacor XR, Taztia XT, Tiazac)	X	X				
diltiazem injection (Cardizem)					X	
verapamil (Calan, Verelan)	X	X	X	X	X	
verapamil injection (Isoptin)					X	

Table 30.2 Calcium Channel Blockers

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Dihydropyridines		
amlodipine (Norvasc)	PO: 5–10 mg once daily (max: 10 mg/day)	*Flushed skin, hypotension, headache, dizziness, peripheral edema, lightheadedness, nausea, diarrhea, constipation* Hepatotoxicity, MI, HF, confusion, mood changes, gingival hyperplasia
clevidipine (Cleviprex)	IV: 1–2 mg/h initial dose, gradually increased until goal blood pressure is reached (max: 16 mg/h)	
felodipine (Plendil)	PO: 2.5–10 mg once daily (max: 10 mg/day)	
isradipine	PO (controlled release): 5 mg once daily (max: 20 mg/day)	
nicardipine (Cardene, Cardene SR)	PO: 20–40 mg tid or 30–60 mg bid (Cardene SR) (max: 120 mg/day)	
nifedipine (Adalat CC, Procardia XL)	PO (extended release): 30–60 mg once daily (max: 120 mg/day)	
nimodipine	PO: 60 mg qid for 21 consecutive days	
nisoldipine (Sular)	PO (extended release): 17–34 mg once daily (max: 34 mg/day)	
Nondihydropyridines		
diltiazem (Cardizem, Dilacor, Taztia XT, others)	PO: 30 mg qid (max: 480 mg/day) Extended release: 120–240 mg once daily	
verapamil (Calan, Isoptin, Verelan)	PO: 80–160 mg tid (max: 480 mg/day) PO (Verelan, Calan SR): 120–480 mg once daily	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PROTOTYPE DRUG Nifedipine (Adalat CC, Procardia XL)

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Calcium channel blocker, dihydropyridine type

Therapeutic Effects and Uses: Approved in 1981, nifedipine is a CCB with several indications. For HTN it may be given alone or in combination with drugs from other antihypertensive classes. Its ability to dilate the coronary arteries makes it an important drug in the treatment of chronic stable or variant angina (see Chapter 35). When used as an antianginal, a beta-adrenergic blocker may be administered concurrently to prevent reflex tachycardia. Nifedipine may be used off-label to treat hypertensive emergency, persistent hiccups, or premature labor contractions, or to prevent migraines.

Nifedipine is usually prescribed as extended release tablets because this allows for once-daily dosing. At high doses, the immediate release form of nifedipine should be used with great caution because its use has been associated with an increased risk for myocardial infarction (MI).

Mechanism of Action: Nifedipine acts by selectively blocking calcium channels in vascular smooth muscle, including those in the coronary arteries, causing a decrease in the amount of intracellular calcium available for muscle contraction. This results in a fall in blood pressure and a diminished myocardial oxygen demand due to the reduced afterload. Nifedipine has no effect on myocardial conduction except at toxic doses.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed (90%)
Distribution	Widely distributed; secreted in breast milk; 92–98% bound to plasma protein
Primary metabolism	Hepatic; extensive first-pass metabolism
Primary excretion	Renal (80%) with small amounts in feces (15%)
Onset of action	30–60 min (immediate release capsules); 6 h (extended release tablet)
Duration of action	4–8 h (24 h for extended release); half-life: 2–5 h

Adverse Effects: Nifedipine is well tolerated and serious adverse effects are not common. Most adverse effects such as hypotension, dizziness, headache, and flushing are related to the vasodilation action of the drug. The most common cardiovascular-related adverse effect is peripheral edema, which occurs more frequently with nifedipine than with other CCBs. Other severe, though rare, adverse effects include hepatotoxicity, MI, heart failure (HF), severe hypotension, and confusion.

Contraindications/Precautions: The only contraindication is hypersensitivity to nifedipine or other dihydropyridines. Caution must be observed when using nifedipine in patients with bradycardia or HF because this drug has negative inotropic effects that can worsen these conditions. The immediate release form is contraindicated in patients with acute MI or cardiogenic shock. Because nifedipine causes blood pressure to fall, it should be used cautiously in patients with preexisting hypotension. Any signs of worsening pulmonary edema call for discontinuation of the drug. Patients with significant hepatic impairment are at risk for drug accumulation and toxicity. Older adults are at much

greater risk of nifedipine toxicity and experience a higher overall mortality when treated with this drug.

Drug Interactions: Nifedipine is a substrate for hepatic CYP3A4 and may interact with drugs that induce or inhibit this enzyme. When given concurrently with nifedipine, other antihypertensive drugs have additive effects on blood pressure. These additive hypotensive effects are used to advantage in the pharmacotherapy of HTN (see Chapter 34). Concurrent use of nifedipine with a beta-adrenergic blocker increases the risk of HF due to additive negative inotropic and chronotropic effects. Nifedipine may increase the serum levels of digoxin by as much as 45%, leading to bradycardia and digoxin toxicity. Alcohol potentiates the vasodilation action of nifedipine and could lead to syncope caused by a rapid drop in blood pressure. **Herbal/Food:** Grapefruit juice may enhance the absorption of nifedipine. Melatonin may reduce the effectiveness of nifedipine by increasing blood pressure and heart rate. St. John's wort can induce CYP3A4 and increase the metabolism of nifedipine and reduce the plasma level of this drug.

Pregnancy: Category C.

Treatment of Overdose: Overdosage may result in pronounced hypotension, which is treated with rapid-acting vasopressors such as dopamine or dobutamine. Calcium infusions may also be indicated.

Nursing Responsibilities: Key nursing implications for patients receiving nifedipine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Calcium Channel Blockers.

Drugs Similar to Nifedipine (Adalat CC, Procardia XL)

Other dihydropyridines include amlodipine, clevidipine, felodipine, isradipine, nicardipine, nimodipine, and nisoldipine.

Amlodipine (Norvasc): Amlodipine is indicated for the treatment of HTN, chronic stable angina, and Prinzmetal's variant angina. Approved in 1992, amlodipine has the longest half-life (35 hours) of the dihydropyridines, which allows for once-daily dosing. Like other dihydropyridines, amlodipine affects mainly arteriolar smooth muscle, including that in the coronary arteries, and has no significant effect on cardiac conduction. The drug is well tolerated, with headache, dizziness, and dose-dependent peripheral edema being frequent adverse effects. Reflex tachycardia rarely occurs because the drug has a very gradual onset. In the treatment of HTN, several weeks may be required to achieve optimal outcomes. Amlodipine is used in many fixed-dose combination products with valsartan (Exforge), valsartan and hydrochlorothiazide (Exforge HCT), atorvastatin (Caduet), aliskiren (Amturnide, Tekamlo), perindopril (Prestalia), olmesartan (Azor), olmesartan and hydrochlorothiazide (Tribenzor), benazepril (Lotrel), and telmisartan (Twynsta). This drug is pregnancy category C.

Clevidipine (Cleviprex): Approved in 2008, clevidipine is an injectable emulsion that is approved for the treatment of HTN when rapid control of blood pressure is desirable. The dose is doubled every 90 seconds until the blood pressure approaches the goal, then the infusion is slowed, with dose adjustments every 5 to 10 minutes. Blood pressure falls within minutes and must be monitored continuously during the infusion. With such rapid titration, hypotension and reflex tachycardia may occur. The most common adverse effects are nausea, vomiting, and headache. Patients with HF must be monitored carefully because clevidipine may worsen this condition. This drug is pregnancy category C.

Felodipine (Plendil): Approved in 1991, felodipine is a dihydropyridine that has greater selectivity for vascular smooth muscle than nifedipine and is approved only for the pharmacotherapy of HTN. It exerts no significant effects on the heart. Its elimination half-life of 11 to 16 hours allows for once-daily dosing. Typical adverse effects are facial flushing, headache, peripheral edema, and reflex tachycardia. Lexxel is a fixed-dose combination of felodipine with enalapril. This drug is pregnancy category C.

Isradipine: Approved in 1990, isradipine is the most potent of the dihydropyridines and is approved for the pharmacotherapy of HTN, either alone or in combination with a thiazide diuretic. Chronic stable angina is an off-label indication for the drug. The physiologic actions of isradipine are selective to arterioles, and the drug has no appreciable effect on the heart. Reflex tachycardia is usually not significant. A sustained release form is available for once-daily dosing. Optimal response may require 2 to 4 weeks of therapy. Headache, facial flushing, and dizziness are the most common adverse effects. This drug is pregnancy category C.

Nicardipine (Cardene, Cardene SR): Approved in 1988, nicardipine is indicated for the pharmacotherapy of chronic stable angina and HTN. Beta-adrenergic blockers or sublingual nitrates may be administered concurrently to reduce the possibility of reflex tachycardia in patients with angina pectoris. A sustained release form (Cardene SR) allows for once-daily dosing, and an intravenous (IV) form (Cardene IV) is available for initiation of therapy in patients with severe HTN. An off-label use of nicardipine is for migraines. The actions, contraindications, and adverse effects are similar to those of nifedipine. Peripheral edema, dizziness, headache, and facial flushing are the most common adverse effects. This drug is pregnancy category C.

Nimodipine: Approved in 1988, nimodipine is an oral CCB with one very specific indication: to reduce the incidence and severity of ischemic deficits in patients with subarachnoid hemorrhage from ruptured intracranial berry aneurysms. The drug prevents vasospasm of the injured vessel and reduces the severity of the resulting

neurologic deficit. Nimodipine appears to have a greater smooth muscle relaxation effect on cerebral arteries than arteries in other areas of the body. The most frequent adverse effects are hypotension, edema, and headache. This drug carries a black box warning that it should never be given by the parenteral route because life-threatening adverse events have occurred when administered by this route. This drug is pregnancy category C.

PharmFACT

It is estimated that 10% to 20% of patients taking calcium channel antagonists will develop gingival hyperplasia. This condition can be successfully managed by professional dental care and oral antiseptic rinses such as chlorhexidine (Peridex) (Mejia, 2016).

Nisoldipine (Sular): Approved in 1995, nisoldipine is selective for vascular smooth muscle and has no significant effect on the myocardium. It is approved only for HTN but may be used off-label for angina. The extended release form, Sular, allows for once-daily dosing. Peripheral edema and headache are relatively common in patients taking this drug. Reflex tachycardia may cause angina pain in patients with myocardial ischemia. Like other CCBs, it should be used with caution in patients with hypotension, peripheral edema, or HF. This drug is pregnancy category C.

30.6 The nondihydropyridines act on both vascular smooth muscle and the myocardium.

The nondihydropyridine group of CCBs consists of two drugs, verapamil (Calan, Isoptin, Verelan) and diltiazem (Cardizem, Dilacor, Taztia XT, Tiazac, others). Although the two drugs are chemically dissimilar, they share common physiologic actions, adverse effects, and indications.

Like the dihydropyridines, drugs in this class block L-type calcium channels in vascular smooth muscle, causing vasodilation. As expected from this physiologic action, the nondihydropyridines are used in the pharmacotherapy of HTN and angina. Thus the dihydropyridines and nondihydropyridines share these two indications. Doses for the nondihydropyridines are listed in Table 30.2.

It is important to note that verapamil and diltiazem have actions on the heart that the dihydropyridines do not possess. These drugs block calcium channels in the myocardium, causing a negative inotropic effect. In addition, the nondihydropyridines decrease the speed of myocardial conduction, resulting in a slower heart rate.

These cardiac effects of the nondihydropyridines may be viewed as therapeutic or adverse, depending on the patient and the reasons for administering the drugs. For example, by slowing conduction across the heart, verapamil and diltiazem can suppress abnormal cardiac rhythms. They are indicated for specific types of dysrhythmias, such as atrial flutter or fibrillation (see Chapter 37). In certain patients, however, slowing the speed of conduction may result in serious adverse effects. For example, slowing the heart rate can diminish cardiac output in patients with moderate or severe HF and worsen this condition. Slowing impulse conduction may cause partial or complete heart block in patients with bradycardia or second-degree or third-degree AV block. Concurrent treatment with a beta-adrenergic agonist may be necessary to counteract these adverse cardiac effects.

Other adverse effects from the nondihydropyridines include constipation, flushed skin, headache, dizziness, edema of the ankles and feet, and lightheadedness. Gingival hyperplasia is an uncommon adverse effect that occurs with long-term therapy and usually reverses after the drugs are discontinued. Most patients tolerate the nondihydropyridine CCBs well and experience few serious adverse effects.

PROTOTYPE DRUG **Verapamil (Calan, Isoptin, Verelan)**

Classification **Therapeutic:** Antihypertensive, antianginal, antidysrhythmic
Pharmacologic: Calcium channel blocker; phenylalkylamine type

Therapeutic Effects and Uses: Verapamil was the first CCB approved by the FDA in 1981. The drug is a class IV antidysrhythmic (see Chapter 37) because it slows myocardial conduction velocity, especially through the AV node, and stabilizes certain types of abnormal heart rhythms. In the vasculature, calcium channel blockade causes vasodilation of arterioles, which lowers blood pressure and reduces cardiac workload. Verapamil also dilates the coronary

CONNECTIONS: Lifespan Considerations

Calcium Channel Blockers and Dementia

Dementia, particularly when associated with Alzheimer's disease, is a devastating degenerative illness affecting over 5 million people (Alzheimer's Association, 2016). Although drug therapy can ease symptoms, there are no known cures at this time. Drugs such as cholinesterase inhibitors and N-methyl-D-aspartate (NMDA) antagonist drugs may be used to delay symptoms, but do not alter the disease's progression (see Chapter 21). Past studies have indicated that antihypertensive drugs may give some protection against the progression of symptoms from mild cognitive impairment to dementia. Although the use of CCBs has not been definitively proven to exert this positive effect, the evidence is growing (Lovell et al., 2015; Peters, Booth, & Peters, 2015). In a postmortem longitudinal study, Lovell et al. (2015) found that CCBs, but not other antihypertensive drugs, seemed to significantly alter dementia progression and effects on the production of amyloid were noted. The authors caution that further clinical trials are needed to demonstrate effects and determine the mechanism of action. However, for the older adult with HTN at higher risk for dementia, CCBs may become a drug group of choice if such positive effects can be determined.

arteries, an action that is important when the drug is used to treat angina. It is approved to treat variant, unstable, and chronic angina (see Chapter 35). Off-label indications include cluster headache and migraine prophylaxis.

Verapamil is available in PO, oral extended release, and IV formulations. Covera-HS is a unique formulation that delays the release of verapamil until 4 to 5 hours after ingestion and then releases it slowly. Covera-HS should be taken at night so that the drug is in the bloodstream on awakening. The inert shell of the drug is sometimes found in the stool. The therapeutic serum level of verapamil is 0.08 to 0.3 mcg/mL. Tarka is a fixed-dose combination of verapamil with trandolapril for HTN.

Mechanism of Action: Verapamil acts by inhibiting the flow of calcium ions into both cardiac muscle cells and vascular smooth muscle cells. Blocking calcium entry causes vasodilation of peripheral arterioles and reduced contractility of the myocardium.

Pharmacokinetics:

Route(s)	PO and IV
Absorption	Well absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic; extensive first-pass metabolism
Primary excretion	Renal (70%) with small amounts in feces (16%)
Onset of action	PO: 1–2 h; IV: 1–5 min
Duration of action	PO: 3–7 h (extended release: 24 h); IV: 2 h
	Half-life: 2–8 h

Adverse Effects: Most adverse effects of verapamil are extensions of its actions on the cardiovascular system. Peripheral vasodilation may cause flushed skin, headache, dizziness, lightheadedness, and peripheral edema. High doses and IV administration may cause serious hypotension. The most serious adverse effects of verapamil are cardiac related, including worsening of HF, bradycardia, reflex tachycardia, and AV block. Constipation is relatively common. CNS effects such as confusion, drowsiness, and mood changes have been reported, though they are uncommon. Elevated hepatic enzymes and rare cases of liver damage have been reported.

Contraindications/Precautions: Verapamil is contraindicated in patients with AV heart block, sick sinus syndrome, severe hypotension, bleeding aneurysm, or those undergoing intracranial surgery. Because verapamil can cause bradycardia and pulmonary edema, patients with HF should be carefully monitored, especially when the drug is administered IV. The drug should be used with caution in patients with chronic kidney disease or hepatic impairment because this can delay clearance of verapamil and its metabolites.

Drug Interactions: Verapamil is metabolized by hepatic CYP450 enzymes and exhibits many drug–drug interactions. Verapamil has the ability to elevate blood levels of digoxin. Because digoxin and verapamil both slow conduction through the AV node, their concurrent use must be carefully monitored to avoid bradycardia. Use with other antihypertensive drugs, including ACE inhibitors or beta-adrenergic blockers, may cause additive hypotension or bradycardia. Concurrent administration of verapamil with buspirone can triple the plasma concentration of buspirone. Verapamil should not be administered with statins because the risk of myopathy increases significantly. Carbamazepine serum concentration may increase during concurrent therapy with verapamil, causing adverse effects such as diplopia, ataxia, or dizziness. Use with alcohol can raise serum levels of the CCB and prolong its effects. **Herbal/Food:** Grapefruit juice may increase verapamil levels. Use with caution with herbal supplements, such as hawthorn, which may have additive hypotensive effects. High doses of calcium supplements may diminish the effects of CCBs and should not be used without consulting the healthcare provider.

Pregnancy: Category C.

Treatment of Overdose: Treatment of overdose is aimed at reversing hypotension with vasopressors such as dopamine or norepinephrine. Atropine, levarterenol, or isoproterenol may be administered to treat bradycardia. Calcium salts may be administered to increase calcium available to the myocardium and arterioles.

Nursing Responsibilities: Key nursing implications for patients receiving verapamil are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Calcium Channel Blockers.

Drugs Similar to Verapamil (Calan, Isoptin, Verelan)

The only other nondihydropyridine is diltiazem.

Diltiazem (Cardizem, Dilacor, Taztia XT, Tiazac, others): Like other nondihydropyridines, diltiazem has the ability to relax both coronary and peripheral blood vessels. Approved in 1982, diltiazem reduces heart rate, blood pressure, and cardiac workload. The drug slows electrical conduction through the AV node. It is useful in the treatment of atrial dysrhythmias and HTN as well as stable and vasospastic angina. Migraine prophylaxis is an off-label indication. When given as extended release capsules (Cardizem LA, Dilacor XR, Taztia XT), it is administered once daily. An IV formulation is available to treat atrial fibrillation. The drug is well tolerated and serious adverse effects are uncommon and similar to those of verapamil. Like verapamil, diltiazem should be used cautiously in patients with bradycardia, AV block, HF, or serious hypotension.

There are several formulations of diltiazem and not all are approved for the same indications (see Table 30.1). The doses among the forms are not always equivalent. Even more confusing is that generics are labeled as "diltiazem extended release," which does not tell the prescriber which trade-name product the generic is equivalent to. Caution must always be used when administering this drug to ensure that the patient is receiving the correct dose and form of diltiazem.

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular (MI or HF), musculoskeletal (preexisting conditions that might result in fatigue, weakness, muscle or joint pain), and the possibility of pregnancy. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings: electrolytes, especially potassium level, liver function studies, and lipid profiles.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), breath sounds, and cardiac monitoring (e.g., electrocardiogram [ECG], cardiac output) if appropriate. Assess for location, character, and amount of edema, if present.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., lowered blood pressure within established limits; lessened or absent angina and dysrhythmias if present).
- Continue periodic monitoring of electrolytes, especially potassium.
- Assess for adverse effects: nausea, headache, constipation, musculoskeletal fatigue or weakness, flushing, lightheadedness or dizziness, sexual dysfunction, or impotence. Myalgia, arthralgia, peripheral edema, facial edema, significant constipation, inability to maintain activities of daily living (ADLs) due to musculoskeletal weakness or pain, or unexplained numbness or tingling of extremities should be reported immediately to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Blood pressure and pulse should be within normal limits or within parameters set by the healthcare provider. If the drug is given for angina or dysrhythmias, significant improvement in reports of pain, palpitations, or ECG demonstrates improvement.)	• Teach the patient, family, or caregiver how to monitor pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained.
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient, as well as the family or caregiver, to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation.
Minimizing adverse effects: • Continue to monitor vital signs. Take the blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension. Ensure patient safety. (CCBs cause vasodilation, resulting in lowered blood pressure. Orthostatic hypotension may increase the risk of falls and injury. **Diverse Patients:** Because CCBs metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and minimize adverse effects.)	Instruct the patient to: • Rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes. • Stop taking the medication and promptly notify the healthcare provider if the blood pressure is 90/60 mmHg or below, or per parameters set by the provider. • Call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to monitor periodic electrolyte levels, especially potassium, ECG as appropriate, and hepatic and renal function laboratory values. (Hypokalemia may increase the risk for dysrhythmias.)	• Instruct the patient on the need to return periodically for laboratory work or ECGs. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating CCB therapy. • **Lifespan:** The drug should not be taken during pregnancy, if pregnancy is suspected, or while breastfeeding.
• Weigh the patient daily and report weight gain or loss of 1 kg (2 lb) or more in a 24-h period or 2 kg (5 lb) per week. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may signal blood pressure has lowered too quickly, stimulating renin release or is an adverse effect.)	• Have the patient weigh self daily, ideally at the same time of day, and record weight along with blood pressure and pulse measurements. Have the patient report weight loss or gain of more than 1 kg (2 lb) in a 24-h period.
• Observe for paradoxical increase in chest pain or angina symptoms. (Severe hypotension may cause this and may indicate blood pressure has decreased too quickly or too substantially.)	• Instruct the patient to report chest pain or other angina-like symptoms, especially if increasing.
• Monitor for signs of HF (e.g., increasing dyspnea or postural nocturnal dyspnea, rales or crackles in the lungs, and frothy pink-tinged sputum). (CCBs are negative inotropes and can decrease myocardial contractility, increasing the risk of, or precipitating HF.)	• Instruct the patient to immediately report any severe shortness of breath, frothy sputum, profound fatigue, or swelling of extremities because they are possible signs of HF.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION *(continued)*

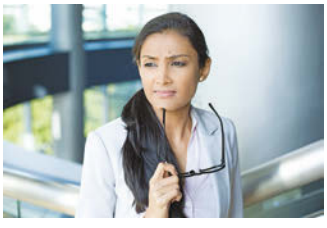
Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Observe for hypersensitivity reaction or angioedema, especially of the facial area.	• Instruct the patient to immediately seek medical attention for difficulty breathing, throat tightness, hives or rash, muscle cramps, or tremors. Promptly report any angioedema around the facial area.
• Observe for constipation. (CCBs may cause constipation due to decreased peristalsis. **Lifespan:** The older adult is at increased risk of constipation due to slowed peristalsis.)	• Instruct the patient to increase fluid and fiber intake to facilitate stool passage. • If constipation persists, consider use of stool softener or laxative (such as MiraLAX) or as recommended by the healthcare provider.
• Assess the condition of gums and oral hygiene measures. (While uncommon, CCBs may cause gingival hyperplasia, increasing the risk of oral infections.)	• Instruct the patient to maintain excellent oral hygiene and keep regularly scheduled dental appointments.
• Monitor patient diet and medications for concurrent use of alcohol, grapefruit or grapefruit juice, herbal supplements, and alternative medications. (Alcohol and melatonin use may increase risk for hypotension, drowsiness, and dizziness. Grapefruit juice may increase drug levels with increased adverse effects.)	• Provide the patient with information on products to avoid while taking CCBs, specific to the drug ordered.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 30

Key Concepts Summary

30.1 Calcium channels facilitate contraction in cardiac and smooth muscles.

30.2 The calcium channel consists of multiple subunits and is present in many tissues.



30.3 Blocking calcium channels has significant physiologic effects on the heart and vascular smooth muscle.

30.4 Calcium channel blockers are classified by their chemical structures as dihydropyridines or nondihydropyridines.

30.5 The dihydropyridines are selective for vascular smooth muscle and are used to treat hypertension and angina pectoris.

30.6 The nondihydropyridines act on both vascular smooth muscle and the myocardium.

CASE STUDY: Making the Patient Connection

Remember the patient "Angela Rivera" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Angela Rivera, a 40-year-old interior designer, had no idea that her blood pressure was elevated. One day at the shopping mall she saw an automatic blood pressure machine and thought she would try it. She could hardly believe the machine's reading when it revealed her blood pressure was 150/92 mmHg. She was certain that there must be something wrong with the machine. After all, she felt fine. In fact, she is rarely ill and never misses work due to illness.

Just to be certain, Angela made an appointment with her doctor for a checkup. During her first clinic visit, her blood pressure was 146/90 mmHg, heart rate was 78 beats/min, respiratory rate was 16 breaths/min, and temperature was 36.8°C (98.2°F). Angela was instructed on lifestyle modifications for HTN and told to return to the clinic in 1 month. The next month, Angela's blood pressure remained elevated. Multiple diagnostic studies, which included an ECG and blood chemistry levels, were completed. Her healthcare provider prescribed felodipine (Plendil) and instructed her to return in 1 week.

All of this has caused Angela to be concerned and worried about her health. She has accessed the internet to learn as much about HTN as possible and felodipine in particular. With all the information about high blood pressure, she is even more confused and anxious.

Critical Thinking Questions

1. Describe how calcium channel blockers control HTN.
2. Angela asks you, the nurse, if calcium channel blockers can cure HTN. How would you respond?
3. What adverse effects are associated with CCBs?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Mabel Hillside was prescribed amlodipine (Norvasc) 5 mg once daily. However, Mabel's health insurance does not cover prescription drug costs and she will be required to self-pay for the drug. As you are talking with this patient, she says, "Why should I take this medicine? After all, I feel just fine and it is very expensive. Plus I keep forgetting to take it."

1. How would you respond to Mabel's remark about feeling "just fine"?
2. What adverse effects related to amlodipine might cause the patient to stop taking the medication?
3. List strategies that Mabel can use to remember to take her HTN medication.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Nifedipine (Procardia) is being initiated for a patient with elevated blood pressure. What health teaching would be most appropriate? The patient should:
    1. Weigh daily at the same time each day.
    2. Avoid crowds while taking this medication.
    3. Increase intake of calcium-containing foods.
    4. Take this medication only when feeling that blood pressure is elevated.
2. A patient is receiving felodipine (Plendil) for hypertension. In the care plan the nurse includes the need to monitor the patient for which adverse effect?
    1. Rash and chills
    2. Increased urinary output
    3. Weight loss
    4. Reflex tachycardia
3. A patient with primary hypertension has started therapy with verapamil (Calan). The nurse performs what important intervention during the initial course of this treatment?
    1. Uses an electric razor to shave the patient
    2. Monitors the patient for increased thrombocyte levels
    3. Administers the medication only during waking hours
    4. Measures intake and output ratio and daily weight
4. The nurse determines that the patient understands an important principle in self-administration of nifedipine (Procardia) when the patient makes which statement?
    1. "The use of antacids when taking the medication will enhance absorption."
    2. "Grapefruit juice may enhance the absorption of nifedipine."
    3. "If I miss a dose, I should take two nifedipine capsules when I remember."
    4. "This drug will make my birth control pills ineffective."
5. What health teaching should the nurse provide for a patient receiving diltiazem (Cardizem)? (Select all that apply.)
    1. Avoid driving or performing other activities requiring mental alertness until the effects of the drug are known.
    2. Maintain adequate fluid and fiber intake to facilitate stool passage.

3. Report weight gain of 2 kg (5 lb) per week.
4. Rise slowly from prolonged periods of sitting or lying down.
5. Immediately stop taking the medication if sexual dysfunction is noted.

6. A healthcare provider has ordered nifedipine (Procardia XL) for each of the following patients. A nurse will most closely monitor which patient for drug-related problems?
   1. A patient who is admitted for an appendectomy in the morning
   2. A patient who is receiving renal dialysis 3 times per week
   3. A patient who develops pulmonary edema in the intensive care unit
   4. A patient who receives psychotropic drugs for bipolar disease

Chapter 31
Drugs Affecting the Renin-Angiotensin-Aldosterone System

Chapter Outline

- Components of the Renin-Angiotensin-Aldosterone System
- Physiologic Actions of the Renin-Angiotensin-Aldosterone System
- Drugs Affecting the Renin-Angiotensin-Aldosterone System

  Angiotensin-Converting Enzyme Inhibitors

  PROTOTYPE *Lisinopril (Prinivil, Zestril), p. 529*

  Angiotensin II Receptor Blockers

  PROTOTYPE *Losartan (Cozaar), p. 532*

  Aldosterone Antagonists

Learning Outcomes

After reading this chapter, the student should be able to:

1. Illustrate the steps in the renin-angiotensin-aldosterone pathway.
2. Identify the primary physiologic factors that control renin secretion.
3. Explain the two primary functions of angiotensin-converting enzyme.
4. Describe multiple mechanisms by which angiotensin II raises blood pressure.
5. Explain how the actions of aldosterone can lead to high blood pressure.
6. Identify the specific steps in the renin-angiotensin-aldosterone system that can be blocked by medications.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy with angiotensin-converting enzyme inhibitors and angiotensin receptor blockers.

Key Terms

angioedema, 528
angiotensin I, 524
angiotensin II, 524
angiotensinogen, 524
bradykinin, 526
cardiac remodeling, 526
juxtaglomerular (JG) cells, 525
macula densa, 525
renin, 525

The renin-angiotensin-aldosterone system (RAAS) is a key homeostatic mechanism regulating blood pressure and fluid balance. The RAAS is presented early in the study of cardiovascular pharmacology because the drugs affecting this pathway are frequently used to treat hypertension (HTN) and heart failure (HF). This chapter examines components of the RAAS and describes how drugs affecting this system are used for therapeutic benefit.

Components of the Renin-Angiotensin-Aldosterone System

31.1 The formation of angiotensin II requires two enzymatic steps.

In the mid-1900s, scientists discovered a peptide circulating in the blood that caused profound vasoconstriction. Named angiotensin (*angio* = blood vessel; *tensin* = pressure), high levels of this substance were found in people with HTN. Thus began the search for components of what is now called the renin-angiotensin-aldosterone system.

We now know that there are several forms of angiotensin. **Angiotensin II** is the vasopressor substance originally isolated by scientists in the 1900s. The formation of angiotensin II requires two key enzymatic steps, and an understanding of these steps is critical to learning the pharmacology of drugs affecting the RAAS. The RAAS is illustrated in Figure 31.1.

Step 1—Formation of angiotensin I: **Angiotensinogen** is a protein synthesized by the liver that is continuously circulating in the bloodstream. In the blood, angiotensinogen is split by the enzyme renin to form **angiotensin I**. Neither angiotensinogen nor angiotensin I has any significant physiologic actions; they simply serve as precursors to angiotensin II.

Step 2—Formation of angiotensin II: Angiotensin I travels through the circulation until it encounters angiotensin-converting enzyme (ACE), which cleaves two amino acids to form angiotensin II. ACE is located on the membrane surface of the blood vessel endothelium. Because the lung possesses such an extensive number of capillaries, it is the primary organ responsible for converting angiotensin I to angiotensin II. Angiotensin II is one of the most potent natural vasoconstrictors known; it is approximately 40 times more potent at raising blood pressure than norepinephrine.

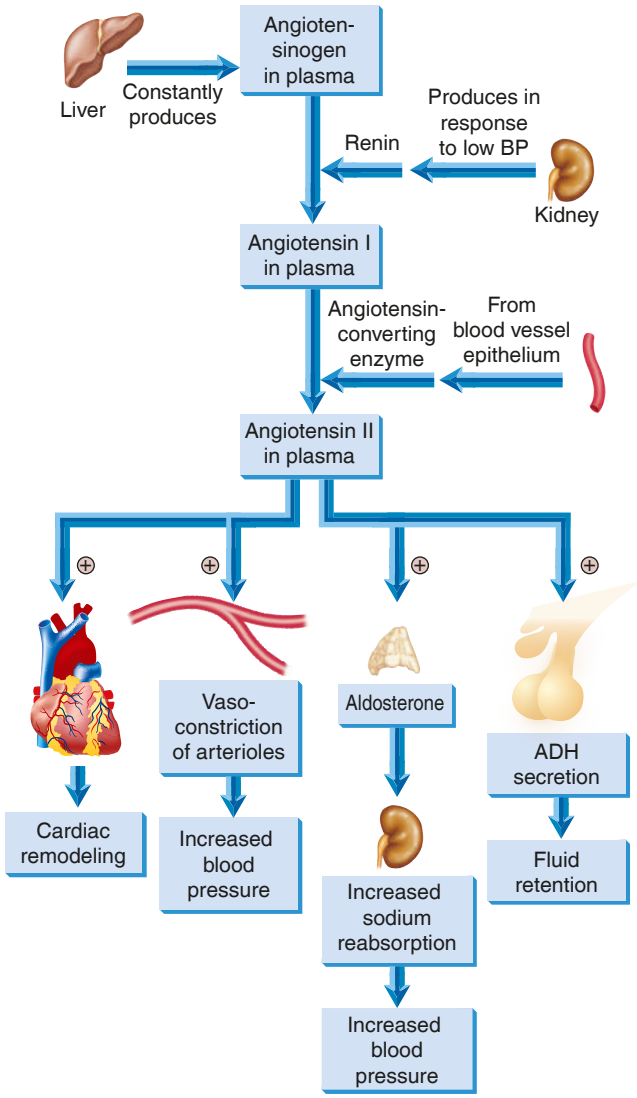

Figure 31.1 The renin-angiotensin-aldosterone pathway.

31.2 Renin secretion is controlled by the juxtaglomerular cells of the kidney and the sympathetic nervous system.

Because renin is responsible for the first step in the RAAS pathway, it is a major factor in determining the amount of angiotensin II produced in the body. Therefore, factors affecting the secretion of renin are important to understanding the pharmacotherapy associated with this system.

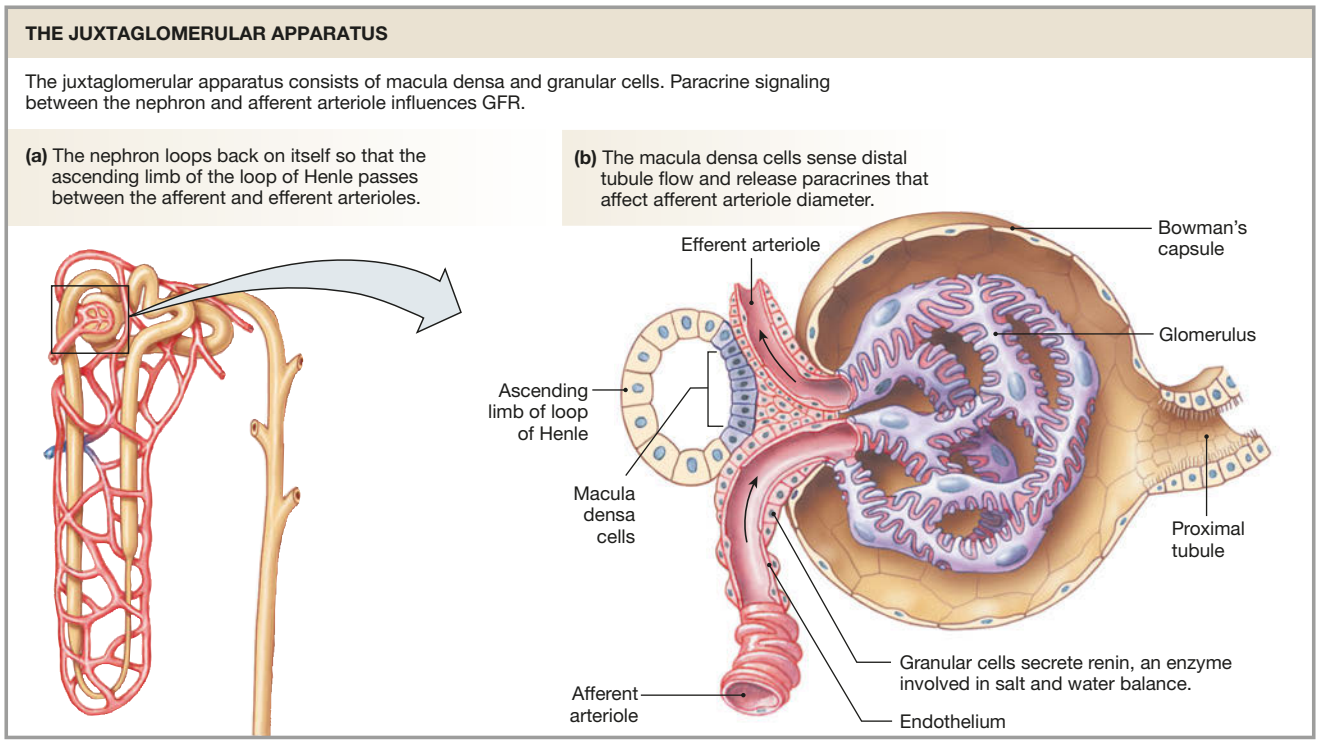

Figure 31.2 The macula densa and the juxtaglomerular (JG) cells. Osmoreceptors in the macula densa sense low sodium levels, which signals the JG cells to release renin.

From *Human Physiology: An Integrated Approach* (6th ed., p. 639), by D. U. Silverthorn, © 2013. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

Renin is an enzyme that is synthesized, stored, and secreted by specialized cells in the kidney known as **juxtaglomerular (JG) cells** (also called granular cells). Found in the afferent arteriole that supplies blood to the glomerulus, JG cells are specialized smooth muscle cells that act as pressure sensors. As blood pressure falls, there is less pressure on the JG cells, which respond by releasing renin to the circulation. The increase in renin ultimately leads to larger amounts of circulating angiotensin II, which returns blood pressure to normal. The release of renin is caused by factors that lower blood pressure, such as a loss of blood volume due to dehydration or hemorrhage. Through negative feedback, increased blood pressure is sensed by the JG cells, which then turn off renin secretion.

Several other important factors influence the release of renin. Adjacent to the JG cells in the distal convoluted tubule of the nephron is a specialized cluster of cells called the macula densa. The macula densa is in a perfect location to sense the flow rate and the concentration of sodium ions (osmolality) in the urinary filtrate. As blood pressure falls, blood flow through the kidney diminishes and the flow of renal tubular filtrate slows. The **macula densa** recognizes the decreased flow rate (and less sodium) and sends a chemical message to the JG cells to release more renin. The renin release forms more angiotensin II and blood pressure rises.

Anatomically, the JG cells and the macula densa are in proximity, as shown in Figure 31.2. The JG cells and the macula densa are sometimes considered a single anatomic unit called the juxtaglomerular complex.

CONNECTION Checkpoint 31.1

Substances that lower blood pressure may trigger reflex tachycardia. From what you learned in Chapter 28, explain the mechanism involved in this reflex. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

A third mechanism for controlling the release of renin is more direct: activation of the sympathetic nervous system. JG cells contain $beta_1$-adrenergic receptors, which are activated by the classic fight-or-flight response of the sympathetic nervous system (see Chapter 12). The release of renin helps to raise blood pressure when dealing with a stressful or harmful situation.

To summarize, factors that promote the release of renin by JG cells will raise blood pressure. The three primary factors causing an increase are decreased pressure in blood flowing through the kidney, decreased tubular flow rate (or fewer sodium ions) sensed by the macula densa, and activation of the sympathetic nervous system. Conversely, the factors that decrease renin secretion lower blood pressure. These factors are illustrated in Figure 31.3.

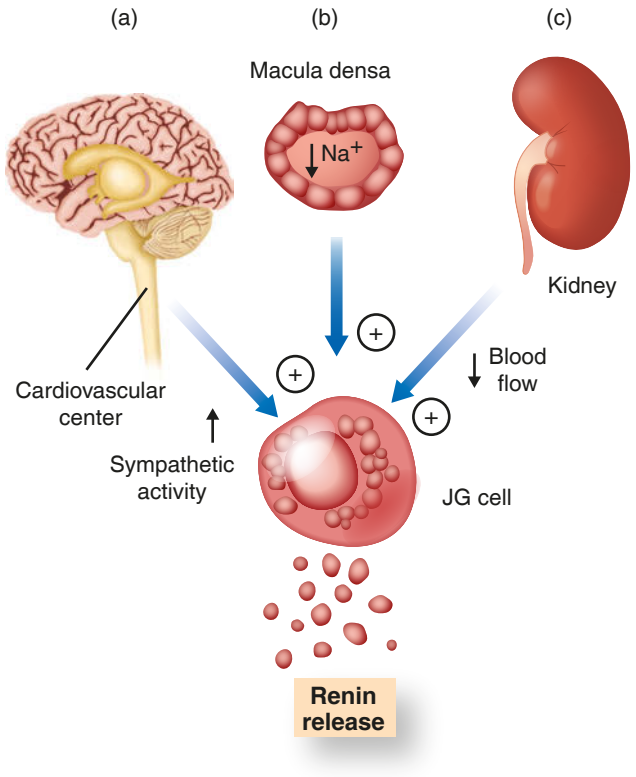

Figure 31.3 Overview of factors affecting renin release: (a) activation of the sympathetic nervous system; (b) low osmolarity in the macula densa; (c) low blood flow through the kidney.

Increasing renin secretion will not always cause an increase in blood pressure. Remember that RAAS is a two-step pathway, and both steps are essential to produce a physiologic response. Section 31.3 examines this second step.

CONNECTION Checkpoint 31.2

From what you learned in Chapter 12, other than JG cells, in what organ are beta$_1$-adrenergic receptors predominantly located? What is the response of that organ when these receptors are activated? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

31.3 Angiotensin-converting enzyme is responsible for the formation of angiotensin II.

Once angiotensin I is formed, its conversion to angiotensin II by ACE is almost instantaneous. A single pass of the blood through lung capillaries converts most of the circulating angiotensin I to angiotensin II.

In addition to its role in the formation of angiotensin II, ACE has a second function important to homeostasis and pharmacotherapy. ACE is one of several enzymes that break down **bradykinin**, a natural mediator of inflammation and pain. Bradykinin has many of the same effects as histamine (see Chapter 44), including increasing arteriolar vasodilation and vascular permeability, and is likely responsible for some of the adverse effects of the ACE inhibitor medications. When referring to its actions on bradykinin, ACE is sometimes called kininase II; *kininase* is the general term for an enzyme that breaks down kinins. ACE and kininase II refer to the identical enzyme.

Pharmacologically, ACE is an important enzyme in the RAAS because it serves as a target molecule for drugs in the ACE inhibitor class of medications. Inhibition of ACE will prevent the formation of angiotensin II, thus interrupting the RAAS pathway. These medications also inhibit kininase II, thus preventing the breakdown of bradykinin. Accumulation of bradykinin in certain tissues can cause several adverse effects of ACE inhibitors, such as angioedema and cough.

Physiologic Actions of the Renin-Angiotensin-Aldosterone System

31.4 Angiotensin II has multiple effects on the cardiovascular system that raise blood pressure and affect cardiac function.

The final product of the two-step renin-angiotensin pathway is angiotensin II. Angiotensin II has several important physiologic effects important to homeostasis and to pharmacotherapy.

Direct vasoconstriction: Angiotensin II acts directly on vascular smooth muscle to cause vasoconstriction and increased systemic blood pressure. This effect is rapid; formation of angiotensin II results in a nearly instantaneous increase in blood pressure. This vasopressor action of angiotensin II is much greater on arterioles compared to veins; arterioles serving the kidneys are especially sensitive to this vasopressor action.

Increased sympathetic nervous system activity: Angiotensin II activates the sympathetic nervous system by causing the release of norepinephrine from sympathetic nerve terminals. The adrenal medulla is also affected by angiotensin II, which responds by releasing additional epinephrine to the circulation. Furthermore, through largely unknown mechanisms, angiotensin II increases sympathetic outflow from the brain. All three of these actions increase peripheral resistance and raise blood pressure.

Alteration of cardiovascular structure: The long-term presence of angiotensin II can also cause hypertrophy of myocardial cells (myocytes) and promote collagen deposits in the cardiac matrix, essentially forming scar-like tissue in the heart. These changes are known as **cardiac remodeling**. The hypertrophy, fibrosis, and remodeling of cardiac structure have been correlated with increased morbidity and mortality associated with HF. In blood vessels, angiotensin II causes the release of multiple chemical

mediators of atherosclerosis, accelerating the deposition of fatty plaque on the walls of the vessels. Increased plaque deposits lead to an increased risk for myocardial infarction (MI) and stroke.

Release of aldosterone and effects on the renal tubule: Angiotensin II has two primary effects on the kidney that promote an increase in blood pressure. First, angiotensin II has a direct effect on the nephron that increases Na^+ and Cl^- reabsorption in the proximal tubule. Second, angiotensin II indirectly affects sodium reabsorption by stimulating the adrenal cortex to synthesize and secrete additional amounts of the hormone aldosterone. Aldosterone acts on the distal and collecting tubules of the nephron to increase Na^+ reabsorption and K^+ and H^+ excretion. The enhanced sodium reabsorption from both direct and indirect actions of angiotensin II causes the body to retain water, thus increasing blood volume and raising blood pressure. Aldosterone is a key component of the RAAS.

Unlike its immediate and direct effects on sympathetic nerves, the actions of angiotensin II on the kidney develop more slowly. This slow vasopressor response is believed to be responsible for producing a sustained elevation of blood pressure and a gradual decline of renal function.

Students often think of angiotensin II as a "bad actor" because it can create HTN and cause the damaging effects of cardiac remodeling. Remember, however, that the cardiovascular and renal effects of angiotensin II serve an essential homeostatic function. Should blood pressure fall, the increased synthesis and production of angiotensin II help return blood pressure to normal levels to maintain blood flow to vital organs. When the body is subjected to chronically elevated levels of angiotensin II, however, the once vital reflex pathway becomes a detriment to the body.

CONNECTION Checkpoint 31.3

From what you learned in Chapter 28, what effect would you expect angiotensin II formation to have on cardiac output and afterload? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

31.5 The renin-angiotensin-aldosterone pathway offers multiple points for drug intervention.

Having learned details of the different components in the short pathway leading from angiotensinogen to angiotensin II, the student should recognize several potential mechanisms by which drugs could intervene:

- **ACE inhibitors.** These are the largest and most important class of drugs modifying the RAAS. ACE inhibitors block the conversion of angiotensin I to angiotensin II.
- **Angiotensin receptor blockers.** After angiotensin II is formed, it must interact with its receptors on target cells to cause its biologic actions. There are two primary receptor subtypes, known as AT_1 and AT_2 receptors. Blocking AT_1 receptors prevents angiotensin from raising blood pressure and from causing cardiac remodeling. Angiotensin receptor blockers are medications that intervene at this step in the RAAS by blocking the AT_1 receptor. The role of AT_2 receptors, which are found in greatest abundance in the fetus, is largely unknown but is an area of active research.
- **Aldosterone antagonists.** Much of the blood pressure increase resulting from the formation of angiotensin II is caused by its stimulation of aldosterone secretion. Two drugs are available that block receptors for aldosterone in the kidney, thus preventing the aldosterone-induced increase in blood pressure.
- **Renin inhibitors.** In 2007, the U.S. Food and Drug Administration (FDA) approved the first renin inhibitor. Aliskiren (Tekturna) is approved to treat HTN as monotherapy or in combination with other antihypertensives. It is likely that other renin inhibitors will be approved in the future.

Drugs Affecting the Renin-Angiotensin-Aldosterone System

31.6 ACE inhibitors are key drugs in the pharmacotherapy of hypertension and heart failure.

First detected in the venom of pit vipers in the 1960s, inhibitors of ACE have been approved for HTN since the 1980s. Since then drugs in this class have become first-line drugs in the treatment of HTN and HF. Doses for the ACE inhibitors are listed in Table 31.1.

ACE inhibitors block the conversion of angiotensin I to angiotensin II. The decline in angiotensin II levels causes blood pressure to decrease because there is less sympathetic activation and, thus, lower peripheral resistance. In addition, the decreased aldosterone secretion reduces blood volume, which also contributes to blood pressure reduction.

Research studies have clearly demonstrated that ACE inhibitors can slow the progression of HF and reduce mortality from this disease. This is likely due to both the reduction in systemic blood pressure and a reversal of the angiotensin II–induced structural changes in the heart. Because of their relative safety, they have replaced digoxin (Lanoxin) as the first-line drugs for the treatment of chronic HF. Indeed, unless specifically contraindicated, all patients with HF usually receive an ACE inhibitor, as discussed in Chapter 36.

Research has also indicated a clear benefit for administering ACE inhibitors to patients who have experienced a recent MI. If therapy is begun immediately after the

Table 31.1 ACE Inhibitors

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
benazepril (Lotensin)	PO: 10–40 mg in 1–2 divided doses (max: 40 mg/day)	*Headache, dry cough, dizziness, orthostatic hypotension, rash* Angioedema, acute renal failure, first-dose phenomenon, fetal toxicity
captopril (Capoten)	PO: 6.25–25 mg tid (max: 450 mg/day)	
enalapril (Vasotec)	PO: 5–40 mg in 1–2 divided doses (max: 40 mg/day)	
fosinopril (Monopril)	PO: 5–40 mg once daily (max: 40 mg/day)	
lisinopril (Prinivil, Zestril)	PO: 5–10 mg daily (max: 80 mg/day)	
moexipril (Univasc)	PO: 7.5–30 mg once daily (max: 30 mg/day)	
perindopril (Aceon)	PO: 4 mg once daily (max: 16 mg/day for HTN; 4 mg/day for HF)	
quinapril (Accupril)	PO: 10–20 mg once daily (max: 80 mg/day)	
ramipril (Altace)	PO: 2.5–20 mg daily (max: 20 mg/day)	
trandolapril (Mavik)	PO: 1–4 mg once daily (max: 8 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

infarction and continued for several weeks, these drugs lower the mortality associated with an acute MI. The mechanism by which these drugs improve the outcome following an acute MI involves reduced peripheral vascular resistance, improved perfusion, and a direct action on the myocardium that reduces the cardiac workload.

ACE inhibitors may also be prescribed as prophylaxis therapy in patients at high risk for an adverse cardiovascular event. ACE inhibitors can reduce the incidence of a stroke or MI in these high-risk patients. They may also prevent or delay the progression of renal disease and retinopathy in patients with diabetes.

All ACE inhibitors have very similar indications and adverse effect profiles. All drugs in this class are approved to treat HTN, and a few are approved for HF and acute MI and for prophylaxis of cardiovascular disease. With the exception of enalaprilat, ACE inhibitors are administered orally (PO), and nearly all offer the convenience of once-daily dosing. Many of the ACE inhibitors are prodrugs, which are converted to active metabolites by enzymes in the liver. Most ACE inhibitors are excreted by the kidneys; thus dose reductions may be required in patients with advanced chronic kidney disease (CKD).

The low incidence of serious adverse effects is a major contributing factor to the widespread use of the ACE inhibitors. Orthostatic hypotension following the first few doses of the drug can be severe in patients who are on low-sodium diets or who have HF. Drug therapy is sometimes begun with very low doses and increased gradually to avoid orthostatic hypotension. Hyperkalemia may occur during ACE inhibitor therapy; however, this is predominantly a major concern only for patients with diabetes, those with CKD, and those who are taking potassium supplements or potassium-sparing diuretics. Persistent, dry cough is an annoying adverse effect that occurs in 5% to 20% of patients taking ACE inhibitors. This adverse effect is likely due to a buildup of bradykinin in the lungs. Drugs in this class have minimal or no effect on serum glucose or uric acid levels.

Though rare, the most serious adverse effect of ACE inhibitors is the development of **angioedema**, a rapid swelling of the throat, face, larynx, and tongue that can lead to airway obstruction and death. When it does occur, angioedema most often develops within a few hours after the first dose, although it may occur after several days of ACE inhibitor therapy. Accumulation of bradykinin is

CONNECTIONS: Community-Oriented Practice

Angiotensin-Converting Enzyme Inhibitors and Angioedema

Angioedema is the development of edema of the mouth, lips, tongue, pharynx, larynx, and epiglottis that can be fatal if respiratory distress occurs secondary to the swelling of the upper airway. Less commonly, intestinal edema may also occur, causing a sudden onset of abdominal pain, vomiting, and diarrhea. Angioedema is associated with ACE inhibitors and appears to be related to the increase in bradykinin levels when ACE is no longer available to break down circulating bradykinin. Although angioedema occurs in less than about 1% of patients taking ACE inhibitors, it is more common in African Americans, particularly those of Caribbean descent, and in older adults.

In 50% of patients, angioedema occurs after the first dose of an ACE inhibitor, although it may occur anytime during therapy. Patients who have had a previous episode of angioedema after taking an ACE inhibitor are at greater risk for developing angioedema from other ACE inhibitors. It may also be caused by angiotensin receptor blockers, although less commonly. Itching and urticaria may occur prior to the development of angioedema but are not good predictors as to whether or not angioedema will develop. Immediate treatment may include administration of epinephrine, antihistamines (both H_1 and H_2 blockers), corticosteroids, and fresh frozen plasma. The ACE in fresh plasma accelerates the breakdown of bradykinin. The patient should be observed closely after the first dose, and any subsequent swelling of the facial, oral, or pharynx areas should be immediately reported to the provider.

thought to be responsible. Treatment of angioedema is to discontinue the drug immediately and maintain the airway until the effects of the drug wear off.

All the ACE inhibitors carry a black box warning regarding the risk for major congenital defects if the drugs are taken during pregnancy. This risk for fetal kidney malformation is well documented for the second and third trimesters, which has resulted in a pregnancy category D rating during these pregnancy periods. The risk for other congenital defects such as heart and neural tube defects during the first trimester is not as clear, causing some of the drugs to be rated category C during this period. Most healthcare providers will discontinue ACE inhibitors as soon as pregnancy is determined. Women with HTN should be advised not to discontinue these drugs during pregnancy without healthcare provider knowledge because HTN itself is a risk factor for congenital defects.

PROTOTYPE DRUG **Lisinopril (Prinivil, Zestril)**

Classification **Therapeutic:** Antihypertensive
Pharmacologic: ACE inhibitor

Therapeutic Effects and Uses: Approved for the treatment of HF, HTN, and acute MI, lisinopril is one of the most frequently prescribed medications. Approved in 1987, it may be used as monotherapy or combined with other drugs: Fixed-dose combinations of lisinopril and hydrochlorothiazide (a diuretic) are marketed for HTN as Prinzide and Zestoretic. Unlike many drugs in this class, lisinopril is active itself; it is not a prodrug. Treatment of migraines is an off-label indication for lisinopril.

Although captopril was the first drug that was marketed in this class, lisinopril is more widely prescribed because it has a longer duration of action that allows for once-daily dosing. Like other ACE inhibitors, 2 to 3 weeks of therapy may be required to achieve maximum therapeutic outcomes.

Mechanism of Action: Lisinopril binds to and inhibits the action of ACE, thus preventing the conversion of angiotensin I to angiotensin II. The decrease in serum angiotensin II reduces aldosterone secretion, which results in less sodium and water retention. In patients with HTN, blood pressure is reduced with minimal effect on heart rate, stroke volume, or cardiac output.

Pharmacokinetics:

Route(s)	PO
Absorption	25–30% absorbed from the gastrointestinal (GI) tract
Distribution	Small amount crosses the blood–brain barrier; crosses the placenta; limited amounts are secreted in breast milk; not bound to plasma protein
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	1 h; peak effect: 6–8 h
Duration of action	24 h; half-life: 12 h

Adverse Effects: Lisinopril is well tolerated and adverse effects are uncommon and transient. The most common adverse effects are cough, headache, dizziness, orthostatic hypotension, and rash. Hyperkalemia occurs in about 2% to 5% of patients taking ACE inhibitors, although this usually resolves during therapy. Patients with HF or CKD or who are taking potassium supplements or potassium-sparing diuretics are at highest risk for hyperkalemia. Rare, though serious, adverse effects include angioedema, agranulocytosis, and hepatotoxicity. **Black Box Warning:** Fetal injury and death may occur when ACE inhibitors are taken during pregnancy. When pregnancy is detected, they should be discontinued as soon as possible.

Contraindications/Precautions: Lisinopril should be used with extreme caution in patients with hyperkalemia because they may experience serious and even fatal dysrhythmias. Patients with a history of angioedema should not receive lisinopril. Caution should be used when treating patients with advanced CKD: Dosage should be reduced. Lisinopril is contraindicated during pregnancy.

Drug Interactions: Indomethacin and other nonsteroidal anti-inflammatory drugs (NSAIDs) interact with lisinopril to decrease antihypertensive activity. The combination of lisinopril and NSAIDs may also worsen preexisting renal disease. Because of synergistic hypotensive action, concurrent therapy with diuretics and other antihypertensives such as ACE inhibitors should be carefully monitored. When taken with potassium supplements or potassium-sparing diuretics, hyperkalemia may result. Lisinopril may increase lithium levels and toxicity. **Herbal/Food:** Hawthorn should not be taken concurrently with lisinopril due to the possibility of additive hypotensive action.

Pregnancy: Categories C (first trimester) and D (second and third trimesters).

Treatment of Overdose: Overdose will cause hypotension, which may be treated with normal saline or a vasopressor. The drug may also be removed by hemodialysis.

Nursing Responsibilities: Key nursing implications for patients receiving lisinopril are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers.

Drugs Similar to Lisinopril (Prinivil, Zestril)

In addition to lisinopril, there are nine other ACE inhibitors on the market. All have very similar actions and adverse effects.

Benazepril (Lotensin): Approved in 1991, benazepril is approved only for HTN, although an off-label indication is HF. It is a prodrug that is metabolized by hepatic enzymes to its active form, benazeprilat. It has a long duration of action that allows for once-daily dosing and is excreted by the kidneys. Orthostatic hypotension is the most common adverse effect, especially after the first dose. Other adverse effects, contraindications, and indications are the same as those of lisinopril. Lotensin HCT is a fixed-dose combination of benazepril and hydrochlorothiazide. Lotrel is a combination of benazepril with amlodipine. This drug is pregnancy category C (first trimester) and D (second and third trimesters).

Captopril (Capoten): Captopril, the first ACE inhibitor marketed in 1981, is approved for HTN, HF, left ventricular dysfunction after an acute MI, and diabetic nephropathy. It has a short half-life, which requires multiple daily doses for some patients. The drug should be taken on an empty stomach, because food reduces its bioavailability. Neutropenia and agranulocytosis have occurred during captopril use. Other adverse effects, contraindications, and indications are the same as those of lisinopril. Capozide is a fixed-dose combination of captopril and hydrochlorothiazide. This is a pregnancy category D drug.

Enalapril (Vasotec): Approved in 1985, enalapril is indicated for HTN, HF, and asymptomatic left ventricular dysfunction in post-MI patients. Like most drugs in this class, it has an extended half-life and is excreted by the kidneys. It has a shorter half-life than some other ACE inhibitors and may require twice-daily dosing. Enalapril is a prodrug, being converted by hepatic enzymes to enalaprilat, which is its active form. The most frequent adverse effect is hypotension, which can be especially troublesome in patients with HF. Adverse effects, contraindications, and indications are the same as those of lisinopril. Enalaprilat (Vasotec IV) is available as a drug for severe HTN and is the only ACE inhibitor administered parenterally. Vaseretic is a fixed-dose combination of enalapril and hydrochlorothiazide. Both enalapril and enalaprilat are pregnancy category D drugs.

Fosinopril (Monopril): Approved in 1991, fosinopril is used to treat HTN and HF. It is a prodrug that is metabolized by hepatic enzymes to its active form, fosinoprilat. An extended half-life allows for once-daily dosing, and it may be taken without regard to meals. It is excreted by both the liver and kidneys and does not require a dosage adjustment in patients with CKD. The most common adverse effects of fosinopril are orthostatic hypotension, dizziness, and headache. Monopril HCT is a fixed-dose combination of Monopril and hydrochlorothiazide. This drug is pregnancy category C (first trimester) and D (second and third trimesters).

Moexipril (Univasc): Approved in 1995, moexipril is indicated only for HTN. It is a prodrug that is metabolized to its active form, moexiprilat, by hepatic enzymes. An extended half-life allows for once-daily dosing. This drug should be taken on an empty stomach, because food reduces its bioavailability by 40% to 50%. It is excreted by the kidneys, and dosage should be reduced in patients with CKD. Dizziness is one of the most common adverse effects. Adverse effects, contraindications, and indications are the same as those of lisinopril. Uniretic is a fixed-dose combination of moexipril and hydrochlorothiazide. Moexipril is a pregnancy category D drug.

Perindopril (Aceon): Approved in 1993, perindopril is approved for HTN and the prophylaxis of cardiovascular events such as MI in patients with coronary artery disease. HF is an off-label use. It is a prodrug that is metabolized by hepatic enzymes to its active form, perindoprilat. It is excreted by the kidneys, and its long half-life allows for once- or twice-daily dosing. Food may reduce the bioavailability of the drug by as much as 35%. Cough and dizziness are the most frequent adverse effects of perindopril. Other adverse effects, contraindications, and indications are the same as those of lisinopril. Prestalia is a fixed-dose combination of perindopril and amlodipine that was approved in 2015. This is a pregnancy category D drug.

Quinapril (Accupril): Approved in 1991, quinapril is indicated for HTN and as adjunctive therapy for HF in combination with diuretics or digoxin. It is a prodrug that is metabolized by hepatic enzymes to its active form, quinaprilat, and may be dosed either once or twice daily. Because the kidney contributes to about 96% of the excretion of the drug, doses should be reduced in patients with CKD. Adverse effects are generally mild and transient and include dizziness, cough, and diarrhea. Other adverse effects, contraindications, and indications are the same as those of lisinopril. Accuretic is a fixed-dose combination of quinapril and hydrochlorothiazide. This is a pregnancy category D drug.

Ramipril (Altace): Approved in 1991, ramipril is indicated for HTN, HF following an MI, and to reduce mortality and stroke in high-risk patients with left ventricular dysfunction after an acute MI. It is a prodrug that is metabolized by hepatic enzymes to its active form, ramiprilat. Excretion is predominantly renal, and dosage should be reduced in patients with advanced CKD. It may be administered without regard to meals. The most common adverse effects are orthostatic hypotension, dizziness, and headache. Other adverse effects, contraindications, and indications are the same as those of lisinopril. This is a pregnancy category D drug.

Trandolapril (Mavik): Approved in 1996, trandolapril is indicated for HTN and HF following an MI and to reduce

Table 31.2 Angiotensin II Receptor Blockers, Aldosterone Antagonists, and Renin Inhibitors

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Angiotensin II Receptor Blockers		
azilsartan (Edarbi)	PO: 40–80 mg once daily	*Headache, dizziness, orthostatic hypotension, fatigue, diarrhea, upper respiratory infection* Angioedema, acute renal failure, first-dose phenomenon, hyperkalemia, fetal toxicity and neonatal mortality
candesartan (Atacand)	PO: Start at 16 mg/day for HTN and 4 mg/day for HF (max: 32 mg/day)	
eprosartan (Teveten)	PO: 600 mg/day or 400 mg qid–bid (max: 800 mg/day)	
irbesartan (Avapro)	PO: 150–300 mg/day (max: 300 mg/day)	
losartan (Cozaar)	PO: 25–50 mg in 1–2 divided doses (max: 100 mg/day)	
olmesartan medoxomil (Benicar)	PO: 20–40 mg/day	
telmisartan (Micardis)	PO: 40–80 mg once daily	
valsartan (Diovan)	PO: 80 mg/day (max: 320 mg/day)	
Aldosterone Antagonists		
eplerenone (Inspra)	PO: Start with 25–50 mg/day (max: 100 mg/day for HTN; 50 mg/day for HF)	*Minor hyperkalemia, headache, fatigue, gynecomastia (spironolactone)* Dysrhythmias (from hyperkalemia), dehydration, hyponatremia, agranulocytosis and other blood dyscrasias
spironolactone (Aldactone)	PO: 50–100 mg/day in single or divided doses (max: 400 mg/day)	
Renin Inhibitor		
aliskiren (Tekturna)	PO: 150 mg/day (max: 300 mg/day)	*Diarrhea, hypotension, cough* Angioedema

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

the mortality in high-risk patients with left ventricular dysfunction after an acute MI. It is a prodrug that is metabolized by hepatic enzymes to trandolaprilat, its active form. It has an extended half-life that permits once-daily dosing and may be administered without regard to meals. Unlike other ACE inhibitors, a large amount of trandolapril (66%) is excreted in the feces. Dosages should be lowered in patients with chronic kidney disease (CKD) or hepatic impairment. The most common adverse effects are cough, dizziness, and fatigue. Other adverse effects, contraindications, and indications are the same as those of lisinopril. Tarka is a fixed-dose combination of trandolapril and the calcium channel blocker verapamil SR, which is prescribed for HTN. This is a pregnancy category D drug.

CONNECTION Checkpoint 31.4

ACE inhibitors decrease sympathetic activation. From what you learned in Chapters 15 and 16, what type of interactions (additive or antagonistic) would you expect from the autonomic drugs epinephrine and propranolol? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

31.7 Angiotensin II receptor blockers act by inhibiting the AT_1 receptor and are used for hypertension and heart failure.

While pharmacologists were examining the mechanism of action of the ACE inhibitors in the 1980s and developing new drugs in this class, research continued on the other enzymes and components of the RAAS. The receptors for angiotensin II in smooth muscle, known as AT_1 and AT_2, were discovered, and a new class of drugs, the angiotensin II receptor blockers (ARBs), was developed. The ARBs are selective for AT_1-type receptors. Unlike the ACE inhibitors, ARBs do not prevent the formation of angiotensin II, but they do effectively block it from activating their target receptors. Doses for the ARBs are listed in Table 31.2.

The ARBs cause vasodilation, with a resultant reduction in peripheral resistance and fall in blood pressure, by blocking angiotensin II receptors in arteriolar smooth muscle. The blockade of AT_1 receptors in the adrenal gland prevents secretion of aldosterone and promotes increased Na^+ and excretion of water by the kidneys. Blockade of AT_1 receptors in the heart prevents the destructive effects of angiotensin-induced cardiac remodeling. Although they act by a different mechanism, ARBs essentially produce the same pharmacologic actions as the ACE inhibitors.

The indications for ARBs are the same as those for the ACE inhibitors. All are approved to treat HTN, and they are often combined with drugs from other classes. Valsartan (Diovan) and candesartan (Atacand) were subsequently approved to treat HF. Some are approved to treat MI and are used for the prophylaxis of stroke. All are administered orally and have prolonged half-lives that permit once-daily dosing. A few are prodrugs, and most are extensively bound to plasma proteins.

Are the ARBs identical to the ACE inhibitors? Not exactly. Unlike the ACE inhibitors, they do not cause cough, and angioedema is less common. This is because ARBs do not promote the accumulation of bradykinin, as do the ACE inhibitors. ARBs can, however, cause dizziness,

hypotension, and hyperkalemia, especially in patients with CKD or who are concurrently taking potassium supplements or potassium-sparing diuretics. Caution should be used with concurrent administration of ARBs and ACE inhibitors due to an increased risk for hypotension, hyperkalemia, and diminished renal function.

If ARBs have the same pharmacologic actions and an improved safety profile, why have they not replaced the ACE inhibitors? The answer is because the ACE inhibitors are generally less expensive, and healthcare providers have much more clinical experience prescribing them. Because the ARBs are newer, a significant body of research has not yet accumulated that demonstrates clear benefits over the ACE inhibitors. Because of these factors, the ARBs are usually reserved for patients unable to tolerate the adverse effects of ACE inhibitors.

PROTOTYPE DRUG Losartan (Cozaar)

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Angiotensin II receptor blocker

Therapeutic Effects and Uses: Approved for the treatment of HTN, stroke prophylaxis in patients with left ventricular hypertrophy, and the prevention of type 2 diabetic nephropathy, losartan was the first ARB marketed in 1995. An off-label use is for HF. Although losartan undergoes extensive first-pass metabolism and has a short half-life, it is metabolized to an active intermediate that prolongs the drug's action, allowing for once-daily dosing. Two daily doses may be necessary in some patients. Its actions include vasodilation and reduced blood volume, due to the drug blocking the release of aldosterone by angiotensin II. Hyzaar is a fixed-dose combination of losartan and hydrochlorothiazide.

Mechanism of Action: Losartan selectively blocks angiotensin AT_1 receptors, resulting in a decline in blood pressure. The blockade of angiotensin II receptors prevents cardiac remodeling and deterioration of renal function in patients with diabetes.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed from the GI tract
Distribution	Does not appear to cross the blood–brain barrier or the placenta or to be secreted in breast milk; approximately 99% bound to protein
Primary metabolism	Hepatic: extensive first-pass metabolism; converted to active metabolite
Primary excretion	35% renal, 60% in feces
Onset of action	6 h
Duration of action	Half-life: 1.5–2 h (losartan), 6–9 h (highly active metabolite)

Adverse Effects: The incidence of adverse effects of losartan is very low. The most common adverse effects are headache, dizziness, nasal congestion, fatigue, and insomnia. Serious adverse effects include angioedema and acute renal failure. **Black Box Warning:** Fetal injury and death may occur when ARBs are taken during pregnancy. When pregnancy is detected, they should be discontinued as soon as possible.

Contraindications/Precautions: Losartan is contraindicated in patients with prior hypersensitivity to the drug. Because ARBs exhibit the same teratogenic effects as ACE inhibitors, they should not be used during pregnancy and lactation. Caution should be used in treating patients with serious hepatic impairment or advanced CKD; dosage may need to be reduced. Patients with a history of angioedema should be monitored carefully. Patients with hypovolemia are at high risk of symptomatic hypotension during therapy. Hypovolemia should be corrected prior to administration of losartan.

Drug Interactions: The drug interactions of losartan and other ARBs are similar to those of the ACE inhibitors. Indomethacin and other NSAIDs may decrease the antihypertensive activity of losartan. When taken concurrently with potassium supplements or potassium-sparing diuretics, care must be taken to avoid hyperkalemia. Concurrent use of losartan with diuretics and other antihypertensives may cause additive hypotensive effects. Use with alcohol may also add to the hypotensive effects of losartan. Losartan may increase lithium levels and toxicity. In patients with diabetes, losartan should not be administered concurrently with aliskiren. **Herbal/Food:** Hawthorn should not be taken concurrently with losartan due to the possibility of additive hypotensive action.

Pregnancy: Categories C (first trimester) and D (second and third trimesters).

Treatment of Overdose: Overdose will cause hypotension, which may be treated with an infusion of normal saline or a vasopressor. The drug is not removed by hemodialysis.

Nursing Responsibilities: Key nursing implications for patients receiving losartan are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers.

Drugs Similar to Losartan (Cozaar)

In addition to losartan, seven other ARBs are available. They all have similar indications, actions, and adverse effects.

Azilsartan medoxomil (Edarbi): One of the newer ARBs, azilsartan was approved in 2011 for the treatment of HTN, either as monotherapy or in combination with other antihypertensives. The drug is sometimes listed by its potassium salt, azilsartan kamedoxomil. Both the medoxomil and kamedoxomil salts are prodrugs that are converted to their active form (azilsartan) when absorbed across the GI tract. Azilsartan appears to lower blood pressure faster than other drugs in its class. The drug is well tolerated, with diarrhea being the most frequent adverse effect. Caution should be used in treating volume or salt-depleted patients because transient hypotension may occur. Edarbyclor is a fixed-dose combination of azilsartan with chlorthalidone approved to treat HTN. This drug is pregnancy category C (first trimester) and D (second and third trimesters).

Candesartan (Atacand): Approved in 1998, candesartan is indicated for HTN and HF in patients with left ventricular dysfunction. It is a prodrug that is metabolized to its active form during its absorption from the GI tract. Optimal therapeutic effects may take up to 4 weeks. The drug is 99% protein bound and is primarily excreted in the bile (66%). Adverse effects are generally mild and include headache and dizziness. Other adverse effects, contraindications, and indications are the same as those of losartan. Atacand HCT is a fixed-dose combination of candesartan and hydrochlorothiazide. This drug is pregnancy category D.

Eprosartan (Teveten): Approved in 1997, eprosartan is indicated only for HTN. It is mostly unmetabolized and primarily excreted in the feces (90%). Optimal blood pressure reduction may require 2 to 3 weeks of therapy. The most common adverse effects are upper respiratory infection, cough, abdominal pain, and fatigue. Other adverse effects, contraindications, and indications are the same as those of losartan. Teveten HCT is a fixed-dose combination of eprosartan and hydrochlorothiazide. This drug is pregnancy category D.

Irbesartan (Avapro): Approved in 1997, irbesartan is indicated for HTN and type 2 diabetic nephropathy. The drug is 90% protein bound and is primarily excreted in the feces (80%). Adverse effects are generally mild and include dizziness, upper respiratory infection, orthostatic hypotension, diarrhea, dyspepsia, and fatigue. Hyperkalemia may occur in 19% of patients taking this medication. Other adverse effects, contraindications, and indications are the same as those of losartan. Avalide is a fixed-dose combination of irbesartan and hydrochlorothiazide. This drug is pregnancy category D.

Olmesartan medoxomil (Benicar): Approved in 2002, olmesartan is indicated only for HTN. Olmesartan medoxomil is a prodrug that is metabolized to its active form (olmesartan) during its absorption from the GI tract. Olmesartan is 99% protein bound and excreted equally in urine and the feces. The drug is administered once daily, and optimal blood pressure reduction may require 2 weeks of therapy. The drug exhibits few adverse effects, with dizziness being the most common complaint. Other adverse effects, contraindications, and indications are the same as those of losartan. There are three fixed-dose combinations of olmesartan: Benicar HCT (with hydrochlorothiazide), Azor (with amlodipine), and Tribenzor (with amlodipine and hydrochlorothiazide). This drug is pregnancy category D.

CONNECTIONS: Complementary and Alternative Therapies

Hawthorn

Description

Hawthorn (*Crataegus*) is a thorny shrub or small tree that is widespread in North America, Europe, and Asia. Leaves, flowers, and berries of the plant are dried or extracted in liquid form.

History and Claims

Hawthorn, sometimes called May bush, was used in ancient Greece. In traditional Chinese medicine, hawthorn is used as a digestive aid. European and American interest in the herb began in the late 1800s. It has been widely used in European countries to treat HTN and HF. The berries may be consumed raw or made into jellies, juices, and alcoholic beverages. Some cultures believe that the shrub is magical, and it is used in religious rites to ward off evil spirits.

Standardization

Active ingredients in hawthorn include flavonoids and procyanidins. A typical dose is 4.5 to 6 g of dried leaves or flowers or 160 to 900 mg of extract per day.

Evidence

Hawthorn has been well studied (National Center for Complementary and Integrative Health, 2016). Some studies have reported positive effects in patients with HF, although the mechanism has not been determined. Hawthorn is known to contain flavonoids and studies have suggested that it has antioxidant, antilipid, cardioprotective, and antitumor, particularly melanoma, effects (Diane et al., 2016; Mustapha et al., 2016). Hawthorn has few adverse effects at normal doses but has been noted to increase the risk of postoperative bleeding (Rababa'h et al., 2016). This product should be used with caution in patients taking cardiac glycosides and other prescription medications for cardiovascular disease. Because hypotension may occur, frequent blood pressure measurements, and observation for any increased bleeding, particularly occult bleeding, should be monitored when using this therapy.

Telmisartan (Micardis): Approved in 1998, telmisartan is indicated for HTN and for cardiovascular risk reduction in patients unable to take ACE inhibitors. An off-label use is for the treatment of renal dysfunction in patients with diabetic nephropathy. It is mostly unmetabolized, 99% protein bound, and excreted primarily in the feces. Initial doses should be reduced in patients with hepatic impairment. The drug is well tolerated and serious adverse effects are uncommon. Adverse effects, contraindications, and indications are the same as those of losartan. Fixed-dose combinations include Micardis HCT (with hydrochlorothiazide) and Twynsta (with amlodipine). This drug is pregnancy category D.

Valsartan (Diovan): Approved in 1996, valsartan is indicated for HTN, HF, and MI when the patient is unable to tolerate an ACE inhibitor. It undergoes hepatic metabolism, is 95% protein bound, and is eliminated in the feces. Because food can reduce drug absorption by as much as 40%, the drug should be given on an empty stomach. Headache and dizziness are common adverse effects. Other adverse effects, contraindications, and indications are the same as those of losartan. Fixed-dose combinations include Diovan HCT (with hydrochlorothiazide), Byvalson (with nebivolol), and Exforge (with amlodipine). This drug is pregnancy category D.

31.8 Aldosterone antagonists block the biological effects of aldosterone in the renal tubule.

As described in Section 31.3, angiotensin II causes the release of aldosterone, which subsequently contributes to increased blood pressure due to sodium and water retention. Receptors for aldosterone are located in the distal tubule and collecting ducts of the nephron. Two drugs are available that block these receptors in the kidney, thus inhibiting the physiologic actions of aldosterone. Both spironolactone (Aldactone) and eplerenone (Inspra) are used to treat edema and HTN. Doses for these drugs are listed in Table 31.2.

Spironolactone is an aldosterone antagonist that has been used for its diuretic action for many decades. By binding to aldosterone receptors, spironolactone produces a mild diuresis by promoting Na^+ and Cl^- excretion. Because it has little or no effect on the excretion of potassium, spironolactone is also classified as a potassium-sparing diuretic and is featured as a prototype diuretic in Chapter 32. Because spironolactone produces only a mild diuresis, it is often combined with drugs from other diuretic classes when used for HTN. It is also useful in treating primary aldosteronism, a rare condition in which the body produces an overabundance of aldosterone, usually due to a tumor of the adrenal gland. Spironolactone has been shown to reduce morbidity, mortality, and dysrhythmias associated with HF.

The primary concern with spironolactone is potassium retention, which can result in serious hyperkalemia. Some patients experience GI-related adverse effects such as nausea, vomiting, and diarrhea. Because spironolactone has a chemical structure similar to that of steroid hormones, it sometimes causes endocrine adverse effects in men, such as gynecomastia and erectile dysfunction. Women may experience menstrual irregularities and breast tenderness.

Eplerenone (Inspra) is a second aldosterone antagonist that has a very different chemical structure than spironolactone. It is more selective for aldosterone receptors and has a very low incidence of endocrine-related adverse effects. Like spironolactone, hyperkalemia is a potentially serious adverse effect. Headache and dizziness are common adverse effects. Eplerenone is approved to treat HTN and HF and to reduce morbidity and mortality associated with post-MI in patients with left ventricular dysfunction.

For additional information on aldosterone antagonists, see Chapter 32.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular (MI, HF), diabetes, CKD, and the possibility of pregnancy. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings, electrolytes, especially potassium level, liver function studies, and lipid profiles.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), breath sounds, and cardiac monitoring (e.g., electrocardiogram [ECG], cardiac output) if appropriate. Assess for location, character, and amount of edema, if present.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., lowered blood pressure within established limits).
- Continue periodic monitoring of electrolytes, especially potassium.
- Assess for adverse effects: headache, cough, orthostatic hypotension, fatigue or weakness, lightheadedness or dizziness, symptoms of hyperkalemia, sexual dysfunction, or impotence. Angioedema should be immediately reported to the healthcare provider.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Blood pressure and pulse should be within normal limits or within parameters set by the healthcare provider.)	• Teach the patient, family, or caregiver how to monitor pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained.
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation.
Minimizing adverse effects: • Continue to monitor vital signs. Take the blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with the first few doses of the drug and with older adults who are at increased risk for hypotension. Ensure patient safety. (ACE inhibitors and ARBs cause vasodilation, resulting in lowered blood pressure. A first-dose effect may occur with a significant drop in blood pressure with the first few doses. Orthostatic hypotension may increase the risk of falls and injury.)	Instruct the patient to: • Take the first dose of the new prescription in the evening before bed and to be cautious during the next few doses until drug effects are known. • Rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes. • Stop taking the medication if the blood pressure is 90/60 mmHg or below, or per parameters set by the healthcare provider, and promptly notify the provider. • Call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to monitor periodic electrolyte levels, especially potassium, hepatic and renal function laboratory values, and ECG as appropriate. (Hyperkalemia may occur and may increase the risk of dysrhythmias.)	Instruct the patient on the need to: • Return periodically for laboratory work. • Carry a wallet identification card or wear medical identification jewelry indicating ACE inhibitor or ARB therapy.
• Monitor for persistent dry cough or increasing cough severity. (ACE inhibitors increase bradykinin levels, which results in a dry cough. A change in the severity of the cough may indicate another disease process or may result in the need to consider other medications.)	Teach the patient: • To anticipate a dry cough that may persist and to use nonmedicinal measures to treat (e.g., OTC cough lozenges, hard candy, or increased fluid intake). • That if the cough becomes troublesome when in a supine position, sleep with the head elevated on additional pillows. • To consult with the healthcare provider about the use of antihistamines to treat a persistent cough unrelieved by nonmedicinal measures. • To promptly report any change in the severity or frequency of a cough. Any cough accompanied by shortness of breath, fever, or chest pain should be reported immediately because it may indicate more severe pathologic conditions.
• Monitor for hyperkalemia. (Reduced aldosterone levels may cause hyperkalemia, especially in patients with diabetes or impaired kidney function. **Lifespan:** The older adult may be at greater risk for hyperkalemia related to renal effects of aging.)	Instruct the patient: • On the signs of hyperkalemia (nausea, irregular heartbeat, profound fatigue or muscle weakness, and slow or faint pulse) and to report them immediately. • To avoid salt substitutes containing potassium chloride, consuming snacks advertised as "electrolyte-fortified," specialized sports drinks that contain high levels of potassium, or excessive intake of foods high in potassium different from their normal diet.
• Monitor for the development of angioedema. **(Lifespan and Diverse Patients:** The older adult and patients of African American heritage are at higher risk for the development of angioedema.)	• Teach the patient to observe for and immediately report swelling of the mouth, lips, tongue, or throat, hoarseness, or sudden difficulty with breathing.
• Assess for the possibility of pregnancy or breastfeeding. **(Lifespan:** The drugs may cause birth defects if taken during pregnancy and may have adverse effects on the breastfeeding child.)	• **Lifespan:** The drug should not be taken during pregnancy, if pregnancy is suspected, or while breastfeeding.
Patient understanding of drug therapy: • Use opportunities during the administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the first dose of the new prescription at bedtime. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 31

Key Concepts Summary

31.1 The formation of angiotensin II requires two enzymatic steps.

31.2 Renin secretion is controlled by the juxtaglomerular cells of the kidney and the sympathetic nervous system.

31.3 Angiotensin-converting enzyme is responsible for the formation of angiotensin II.

31.4 Angiotensin II has multiple effects on the cardiovascular system that raise blood pressure and affect cardiac function.

31.5 The renin-angiotensin-aldosterone pathway offers multiple points for drug intervention.

31.6 ACE inhibitors are key drugs in the pharmacotherapy of hypertension and heart failure.

31.7 Angiotensin II receptor blockers act by inhibiting the AT_1 receptor and are used for hypertension and heart failure.

31.8 Aldosterone antagonists block the biological effects of aldosterone in the renal tubule.

CASE STUDY: Making the Patient Connection

Remember the patient "Carlos Avaya" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Carlos Avaya is a 26-year-old single man who was diagnosed with primary HTN 4 months ago. Carlos has been taking losartan (Cozaar) 50 mg daily PO and has been faithful in taking the medication as prescribed. When Carlos was told that his blood pressure was still elevated during this clinic visit, he was obviously distressed and concerned.

The healthcare team begins to investigate external factors that may be causing his blood pressure to remain elevated. Carlos has never smoked or used alcohol. He does not like to exercise but participates in a weekly game of soccer at the nearby community center. He denies being overly stressed with work or home life. Furthermore, he claims that he rarely salts his food.

The nurse asks Carlos to describe a typical day. During the description the nurse notices a concerning pattern. Because Carlos lives alone, he frequently cooks for himself. He admits that he enjoys salty foods such as pretzels and popcorn. He denies having consumed either prior to the visit to the clinic. However, to Carlos, cooking a meal involves preparing canned processed foods and frozen dinners. He never reads food labels. Without recording a complete dietary history, the nurse is able to determine that Carlos's intake of sodium-rich foods is quite extensive.

Critical Thinking Questions

1. How does losartan (Cozaar) work to reduce blood pressure?
2. Considering the adverse effects of losartan (Cozaar), when would you instruct Carlos to notify the prescriber?
3. In addition to teaching Carlos about losartan (Cozaar), what additional health teaching should he receive?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Ella Daniels, a middle-aged African American woman, takes spironolactone (Aldactone) for HTN. As the nurse responsible for providing her with health information, you plan to talk with her about this drug.

1. How does the mechanism of action of spironolactone differ from that of lisinopril (Prinivil, Zestril)?
2. What are the main precautions specific to spironolactone that should be included in the teaching plan?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The community health nurse teaches a patient at home. Lisinopril (Prinivil) has been prescribed for the patient. Which statement, if made by the patient, indicates that further teaching is necessary?
    1. "I should notify my healthcare provider of symptoms of hypotension such as dizziness or fainting."
    2. "I should avoid the use of salt substitutes containing potassium."
    3. "If a dose is missed, I will take it as soon as possible but not too close to the next dose."
    4. "Too much calcium in my diet will elevate my blood pressure."

2. The patient states, "I always keep my lisinopril (Prinivil) on my kitchen window sill. It helps me to remember to take it." The nurse's response would be based on which pharmacologic concept about heat and moisture?
    1. They cause the medicine to break down.
    2. They enhance the strength of the drug.
    3. They crystallize the medication.
    4. They convert the medicine to toxic metabolites.

3. A patient is hospitalized for uncontrolled hypertension and is receiving enalapril (Vasotec). The nurse should notify the healthcare provider if the patient exhibits:
    1. Dry mucous membranes.
    2. A decline in systolic blood pressure.
    3. Nonproductive cough.
    4. A reduction of diastolic blood pressure.

4. The nurse is caring for a patient with chronic hypertension. The patient is receiving losartan (Cozaar) daily. Which patient manifestations would the nurse conclude is an adverse effect of this medication?
    1. Irritability and tremors
    2. Headache and dizziness
    3. Sleepiness and slurred speech
    4. Pruritus and rash

5. Irbesartan (Avapro) is prescribed for each of the following patients. A nurse should question the order for a patient who has:
    1. Severe dehydration from diuretic therapy.
    2. Long-term diabetes mellitus.
    3. A systolic blood pressure of 162.
    4. A 5-year history of heart failure.

6. The nurse determines that the patient does not understand an important principle in self-administration of benazepril (Lotensin) when the patient makes which statement?
    1. "I will learn to monitor my own blood pressure and write down all my daily measurements."
    2. "While taking this medication, I should avoid over-the-counter medications for colds, sinus, or appetite control."
    3. "This drug will not impair thinking and reaction time. I don't need to wait to start driving my car."
    4. "Drinking alcohol while on this medication can lower my blood pressure and lead to dizziness and faintness."

Chapter 32
Diuretic Therapy and the Pharmacotherapy of Chronic Kidney Disease

Chapter Outline

- Review of Renal Physiology
- Pharmacotherapy for Patients with Chronic Kidney Disease
- Diuretic Therapy

  Loop (High-Ceiling) Diuretics

  PROTOTYPE *Furosemide (Lasix), p. 546*

  Thiazide and Thiazide-Like Diuretics

  PROTOTYPE *Hydrochlorothiazide (Microzide), p. 549*

  Potassium-Sparing Diuretics

  PROTOTYPE *Spironolactone (Aldactone), p. 551*

  Osmotic Diuretics

  PROTOTYPE *Mannitol (Osmitrol), p. 553*

  Carbonic Anhydrase Inhibitors

  PROTOTYPE *Acetazolamide (Diamox), p. 554*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the role of the urinary system in maintaining fluid, electrolyte, and acid–base homeostasis.
2. Explain the physiologic processes that change the composition of filtrate as it travels through the nephrons.
3. Explain how pharmacotherapy is modified in patients with chronic kidney disease.
4. Identify indications for diuretics.
5. Compare and contrast the loop, thiazide, potassium-sparing, osmotic, and carbonic anhydrase inhibitor diuretics.
6. Describe the nurse's role in the pharmacologic management of chronic kidney disease and in diuretic therapy.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients who are receiving pharmacotherapy with diuretics.

Key Terms

carbonic anhydrase, 554
chronic kidney disease, 541
diuretic, 543
filtrate, 540
glomerular filtration rate (GFR), 542
glomerulus, 540
natriuresis, 543
nephrons, 540
osmotic pressure, 552
reabsorption, 541
secretion, 541
symporter, 545

The kidneys serve an amazing role in maintaining homeostasis. By filtering a volume equivalent to all of the body's extracellular fluid every 100 minutes, the kidneys are able to make immediate adjustments to fluid volume, electrolyte composition, and acid–base balance. Failure of the kidneys to adjust to changing internal conditions of the body may result in dire consequences, and pharmacotherapy is often used to correct these imbalances. This chapter examines diuretics, drugs that increase urine output, and other medications used to treat patients with renal dysfunction.

PharmFACT

More than 17,000 kidney transplants were performed in 2014. Over 100,000 people are on the waiting list for kidney transplants (National Kidney Foundation, 2016).

Review of Renal Physiology

32.1 The kidneys are major organs of excretion and body homeostasis.

When most people think of the kidneys, they think of excretion. Although this is certainly true, the kidneys have many other essential homeostatic functions. The kidneys are the primary organs for regulating fluid balance, electrolyte composition, and the pH of body fluids. They also secrete the enzyme renin, which helps to regulate blood pressure (see Chapter 31), and erythropoietin, a hormone that stimulates red blood cell production (see Chapter 39). In addition, the kidneys are responsible for the production of calcitriol, the active form of vitamin D, which helps maintain bone homeostasis (see Chapter 72). It is not surprising that our overall health is strongly dependent on the proper functioning of the kidneys.

The urinary system consists of two kidneys, two ureters, one urinary bladder, and a urethra. Blood enters the kidneys through the large renal arteries, bringing 25% of the total cardiac output to the kidneys each minute. After a series of branches, blood enters the **nephrons**, the functional units of the kidney. Each kidney contains over 1 million nephrons.

In the nephron, blood travels at high pressure through the **glomerulus**, a specialized capillary containing pores. The fluid portion of the blood is filtered through the glomerular pores and collected by Bowman's capsule, the first portion of the collecting system of the nephron. Together, the glomerulus and Bowman's capsule are called the renal corpuscle. During filtration, not all substances in the blood reach Bowman's capsule. Plasma proteins and the formed elements of the blood—the erythrocytes, leukocytes, and platelets—are too large to pass through the pores of the glomerulus and thus continue circulating through the bloodstream. Water and other small molecules in plasma, however, readily pass through the glomerular pores and enter the next section of the nephron.

The fluid filtered into Bowman's capsule is called **filtrate**. Essentially, the initial composition of filtrate may be thought of as plasma minus proteins. After leaving Bowman's capsule, the filtrate enters the proximal tubule, travels through the loop of Henle and, subsequently, the distal tubule. The proximal and distal tubules are twisted and highly convoluted, which greatly increases the length of the nephron, allowing for enhanced processing of substances in the filtrate. The filtrate eventually reaches common collecting ducts, which empty into increasingly larger collecting structures inside the kidney. Fluid leaving the collecting ducts and entering subsequent portions of the kidney is called urine. Approximately 1 mL of urine is produced each minute. Parts of the nephron and their functions are illustrated in Figure 32.1.

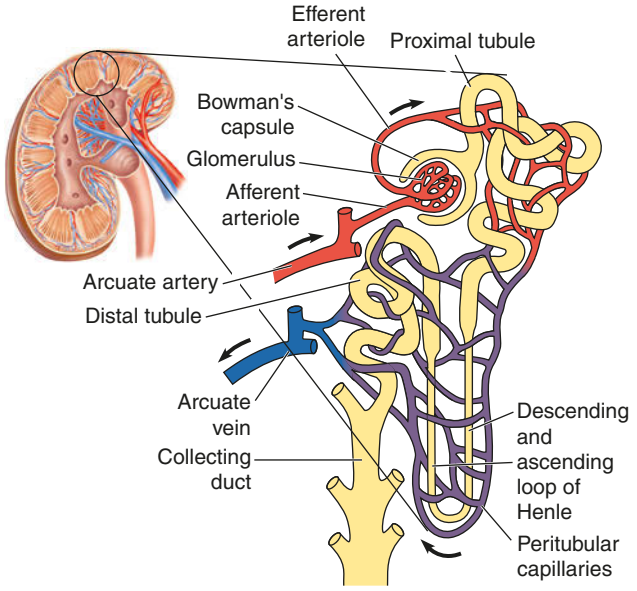

Figure 32.1 The nephron.

Many drugs are small enough to pass through the glomerulus and enter the filtrate. If the drug is bound to a plasma protein, however, the drug–protein complex will be too large to be filtered and will continue circulating in the blood. Plasma proteins such as albumin are also too large to pass through the filter and will not be present in the filtrate or in the urine of healthy patients. The appearance of excess plasma proteins in urine (proteinuria or albuminuria) is a sign of kidney pathology. For example, during glomerulonephritis the glomeruli become inflamed and the size of the pores increases, allowing larger substances such as proteins to enter the filtrate.

CONNECTION Checkpoint 32.1

From what you learned in Chapter 3, explain how plasma protein binding markedly affects the excretion of a drug. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

32.2 The composition of filtrate changes dramatically as a result of the processes of reabsorption and secretion.

The filtrate's composition changes dramatically as it makes its long journey through the nephron. Some substances in the filtrate cross the tubule walls to reenter the blood; this process is known as tubular **reabsorption**. Water is the most important molecule reabsorbed in the tubule. For every 180 L of water entering the filtrate each day, approximately 178.5 L are reabsorbed, leaving only 1.5 L to be excreted in the urine. Over 65% of the filtered sodium is reabsorbed in the proximal tubule, and 25% in the loop of Henle. Glucose, amino acids, and essential ions such as chloride, calcium, and bicarbonate are also reabsorbed.

Hormones can markedly affect the degree of reabsorption in the renal tubule. Aldosterone, for example, exerts a major effect on the tubule by stimulating sodium reabsorption in the distal portions of the nephron. Under the influence of aldosterone, potassium excretion is increased because this ion is "exchanged" for sodium ions, which are reabsorbed. Antidiuretic hormone (ADH) also affects kidney function, increasing water reabsorption by making the collecting ducts become more permeable to water. The formation of urine is indeed a dynamic process that undergoes continuous modification as the filtrate travels down the tubule. Many drugs have the ability to either enhance or block the effects of hormones on tubular processes.

Certain ions and molecules too large to pass through Bowman's capsule may still enter the urine by crossing from the blood to the filtrate using a process known as tubular **secretion**. The tubule contains molecular pumps for organic acids and bases. Acidic drugs secreted in the proximal tubule include penicillin G, ampicillin, sulfisoxazole, nonsteroidal anti-inflammatory drugs (NSAIDs), and furosemide. Basic drugs include procainamide, epinephrine, dopamine, neostigmine, and trimethoprim. Potassium, phosphate, hydrogen, and ammonium ions also enter the filtrate through active secretion. The amounts of selected substances filtered, reabsorbed, and excreted are shown in Table 32.1.

Table 32.1 Substances Filtered, Reabsorbed, and Excreted by the Kidneys

Substance	Filtered	Reabsorbed	Excreted
Water	180 L	178–179 L	1–2 L
Glucose	162 g	162 g	0 g
Proteins	2 g	1.9 g	0.1 g
Ions			
Sodium	579 g	575 g	4 g
Potassium	29.6 g	29.6 g	2 g
Bicarbonate	275 g	274.97 g	0.03 g
Metabolic Waste Products			
Creatine	1.6 g	0 g	1.6 g
Urea	54 g	24 g	30 g
Uric acid	8.5 g	7.7 g	0.8 g

Reabsorption and secretion are critical to the pharmacokinetics of drugs. Some drugs are reabsorbed, whereas others are secreted into the filtrate. For example, approximately 90% of a dose of penicillin G enters the urine through secretion. When the kidney is diseased, reabsorption and secretion mechanisms are impaired and serum drug levels may be dramatically affected. Figure 32.2 illustrates the possible fates of drugs entering the glomerulus.

CONNECTION Checkpoint 32.2

From what you learned in Chapter 31, explain the relationship between angiotensin II and the release of aldosterone by the adrenal gland and its significance to pharmacology. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy for Patients with Chronic Kidney Disease

32.3 Chronic kidney disease may significantly impact the success of pharmacotherapy.

Chronic kidney disease (CKD), sometimes called renal failure, is a condition characterized by a gradual loss of kidney function, usually over a period of months or years. The kidneys lose their ability to maintain electrolyte and fluid balance and excrete waste products. Due to its prolonged, gradual development and its nonspecific symptoms, CKD may go undetected for many years. By the time the disease is diagnosed, the loss of renal function may be irreversible. The leading causes of CKD are diabetes and uncontrolled hypertension (HTN).

Pharmacotherapy with nephrotoxic drugs can lead to either CKD or acute renal failure. It is good practice for the

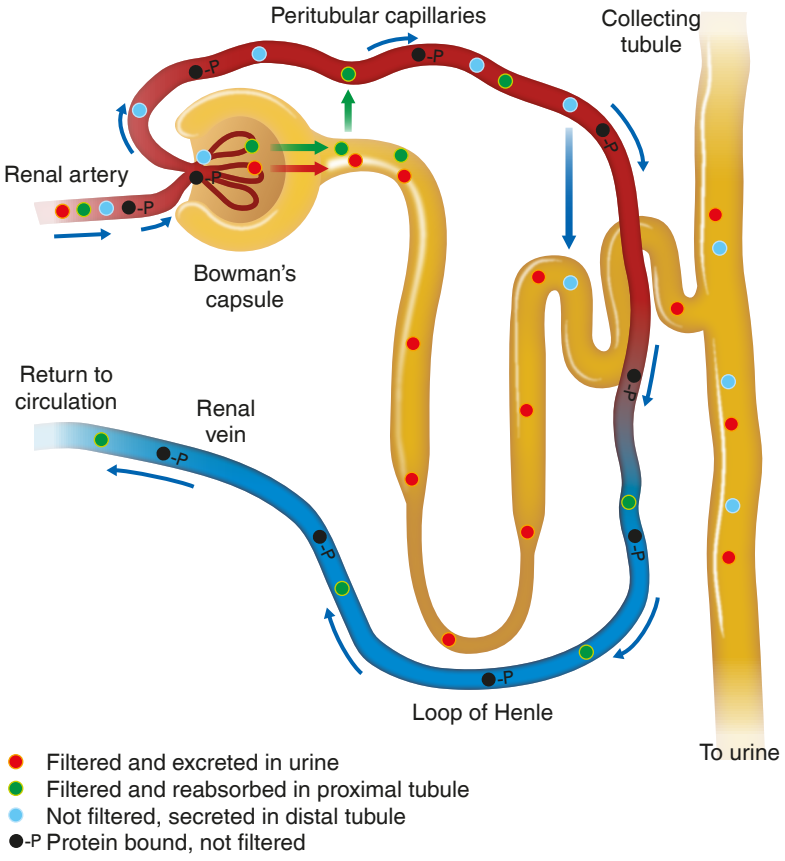

Figure 32.2 Fates of drugs entering the glomerulus: filtration, reabsorption, secretion, and excretion.

nurse to remember common nephrotoxic drugs, which are listed in Table 32.2, so that kidney function may be continuously monitored during therapy with these drugs.

The last stage of CKD, which requires dialysis or a transplant for survival, is called end-stage renal disease (ESRD). The primary treatment goal for a patient with CKD is to maintain blood flow through the kidneys and adequate urine output so that metabolic wastes can be removed from the body.

Table 32.2 Selected Nephrotoxic Drugs

Drug or Class	Indication/Classification
aminoglycosides	Antibiotics
amphotericin B (Amphotec, AmBisome)	Systemic antifungal
angiotensin-converting enzyme (ACE) inhibitors	HTN, HF
cisplatin (Platinol), carboplatin (Paraplatin)	Antineoplastics
cyclosporine (Neoral, Sandimmune), tacrolimus (Prograf)	Immunosuppressants
foscarnet (Foscavir)	Antiviral
nonsteroidal anti-inflammatory drugs (NSAIDs)	Inflammation and pain
pentamidine (NebuPent, Pentam)	Anti-infective (*Pneumocystis*)
radiographic intravenous (IV) contrast agents	Diagnosis of kidney and vascular disorders

PharmFACT

More than 661,000 Americans have CKD—about 14% of the general population. African Americans have a 3 to 4 times greater risk for CKD than Caucasians (National Institute of Diabetes and Digestive and Kidney Diseases, 2016).

The most basic diagnostic test of kidney function is a urinalysis, which examines urine for the presence of blood cells, proteins, pH, specific gravity, ketones, glucose, and microorganisms. The urinalysis can detect proteinuria and albuminuria, which are the primary measures of structural kidney damage. Although easy to perform, the urinalysis is nonspecific: Many diverse diseases and conditions can cause abnormal urinalysis values. Serum creatinine and blood urea nitrogen (BUN) are additional laboratory measures for detecting kidney disease. To provide a more definitive diagnosis, diagnostic imaging such as computed tomography, sonography, or magnetic resonance imaging may be necessary. Renal biopsy may be performed to obtain a more specific diagnosis.

The best marker for estimating kidney function is the **glomerular filtration rate (GFR)**, which is the volume of water filtered through the Bowman's capsules per minute. The GFR can be used to predict the onset and progression of CKD and it is a measure of the kidneys' ability to excrete

drugs from the body. With normal values ranging from 90 to 120 mL/min, a progressive decline in GFR indicates a reduction in the number of functioning nephrons. As nephrons "die," however, the remaining healthy ones have the ability to compensate by increasing their filtration capacity. Because of this, patients with significant kidney damage may be asymptomatic until 50% or more of the nephrons have become nonfunctional and the GFR has fallen to less than half its normal value.

Kidney disease may also be acute. Acute kidney injury (AKI) (also called acute renal failure) requires immediate treatment because retention of nitrogenous waste products in the body such as urea and creatinine can result in death if left untreated. The most common cause of acute kidney injury is renal hypoperfusion, the lack of sufficient blood flow through the kidneys. Hypoperfusion can lead to permanent destruction of kidney cells and nephrons. To prevent AKI, the cause of the hypoperfusion must be quickly identified and corrected. Potential causes include heart failure (HF), dysrhythmias, hemorrhage, toxins, and dehydration.

Pharmacotherapy of CKD attempts to find and correct the cause of the dysfunction. Diuretics are given to increase urine output, and cardiovascular drugs are administered to treat underlying HTN or HF. Dietary management is often necessary to prevent worsening of CKD. Depending on the stage of the disease, dietary management may include restriction of protein and reduction of sodium, potassium, phosphorous, and magnesium intake. For patients with diabetes, control of blood glucose through intensive insulin therapy may reduce the risk of renal damage. See Table 32.3 for a summary of selected medications used to prevent and treat the complications of CKD.

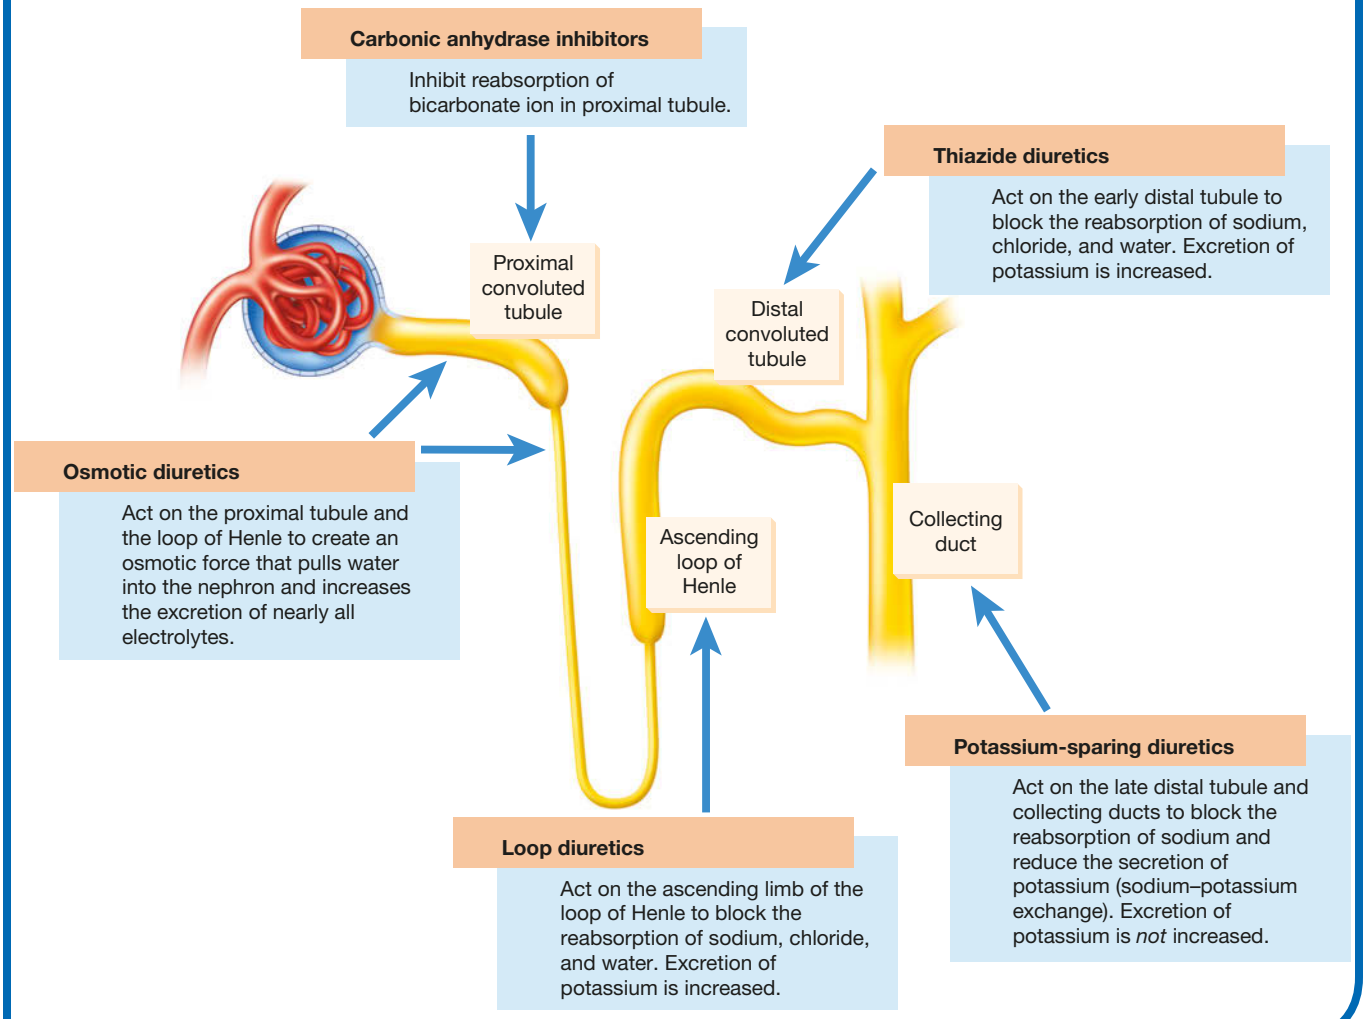
The nurse serves a key role in assessing and providing interventions for patients with CKD. Once a diagnosis has been established, all nephrotoxic medications should be either discontinued or used with extreme caution. Because the kidneys excrete most drugs or their metabolites, many medications will require a significant dosage reduction in patients with moderate to severe renal disease. The importance of this cannot be overemphasized: Administering the "average" dose to a patient with severe kidney disease can have fatal consequences.

Diuretic Therapy

32.4 Diuretics are used to treat hypertension, heart failure, accumulation of edema fluid, and chronic kidney disease.

A **diuretic** is a drug that increases the formation of urine by the body. Diuretics do more than increase urine flow; they also change the rate of excretion of specific electrolytes, most importantly sodium and potassium. The goal of most diuretic therapy is to reduce extracellular fluid volume, so that abnormal fluid retention (edema) by the body may be reversed. Excretion of excess fluid in the body is particularly important in the management of the following conditions:

- HTN
- HF
- CKD
- Liver failure or cirrhosis
- Pulmonary edema.



The most common mechanism by which diuretics act is by blocking sodium ion (Na^+) reabsorption in the nephron, thus sending more Na^+ to the urine (**natriuresis**). The human body is particularly sensitive to sodium imbalances; dietary intake must be balanced with excretion mechanisms. For example, a 1% increase in sodium reabsorption (retention) could potentially cause a 1.8-L net gain of water each day, which is equivalent to 4 lb of body weight. On the other hand, even small decreases in sodium reabsorption can cause net losses of sodium from the body, resulting in volume depletion and circulatory collapse.

Table 32.3 Pharmacologic Management of Chronic Kidney Disease

Complication	Pathogenesis	Selected Therapies
Anemia	Kidneys are unable to synthesize sufficient erythropoietin for red blood cell production.	Epoetin alfa (Epogen, Procrit)
Hyperkalemia	Kidneys are unable to adequately excrete potassium.	Dietary restriction of potassium; polystyrene sulfate (Kayexalate) with sorbitol
Hyperphosphatemia	Kidneys are unable to adequately excrete phosphate.	Dietary restriction of phosphate; phosphate binders such as calcium carbonate (Os-Cal 500, others), calcium acetate (Calphron, PhosLo), lanthanum carbonate (Fosrenol), sucroferric oxyhydroxide (Velphoro), or sevelamer (Renagel)
Hypervolemia	Kidneys are unable to excrete sufficient sodium and water, leading to water retention.	Dietary restriction of sodium; loop diuretics in acute conditions, thiazide diuretics in mild conditions
Hypocalcemia	Hyperphosphatemia leads to loss of calcium.	Usually corrected by reversing the hyperphosphatemia, but additional calcium supplements may be necessary
Metabolic acidosis	Kidneys are unable to adequately excrete metabolic acids.	Sodium bicarbonate or sodium citrate

Pharmacotherapy Illustrated 32.1

Sites of Action of the Diuretics

These examples illustrate the need for patients to monitor their weight daily when taking diuretics.

Natriuresis results in two other important effects. Chloride ions (Cl^-) follow sodium, potentially causing hypochloremia, a net loss of chloride from the body. In addition, because water molecules travel passively with sodium ions, blocking the reabsorption of Na^+ increases the total volume of urination, or diuresis. The amount of diuresis produced by a diuretic is directly related to the amount of sodium reabsorption that is blocked: Those that block the most sodium are the most effective at increasing urine output. Diuretics also affect the renal excretion of ions such as magnesium, potassium, phosphate, calcium, and bicarbonate. It is important to remember that imbalances may occur in virtually any electrolyte during diuretic therapy.

Diuretics are classified into five major groups, based on differences in their chemical nature and mechanism of action. The sites in the nephron at which the various diuretics act are shown in Pharmacotherapy Illustrated 32.1.

- **Loop or high-ceiling.** These drugs prevent the reabsorption of Na^+ in the loop of Henle; thus, they are called loop diuretics. Because there is an abundance of Na^+ in the filtrate within the loop of Henle, drugs in this class are capable of producing large increases in urine output.
- **Thiazides.** The largest diuretic class, the thiazides act by blocking Na^+ in the distal tubule. Because most Na^+ has already been reabsorbed from the filtrate by the time it reaches this part of the nephron, the thiazides produce less diuresis than loop diuretics.
- **Potassium-sparing.** The third major class is named potassium-sparing diuretics, because they have minimal effect on potassium ion (K^+) excretion. These drugs produce a mild diuresis.
- **Osmotic.** These drugs are relatively inert drugs that change the osmolality of filtrate, causing water to remain in the nephron for excretion. These drugs are very effective but are rarely prescribed because they can produce potentially serious adverse effects.

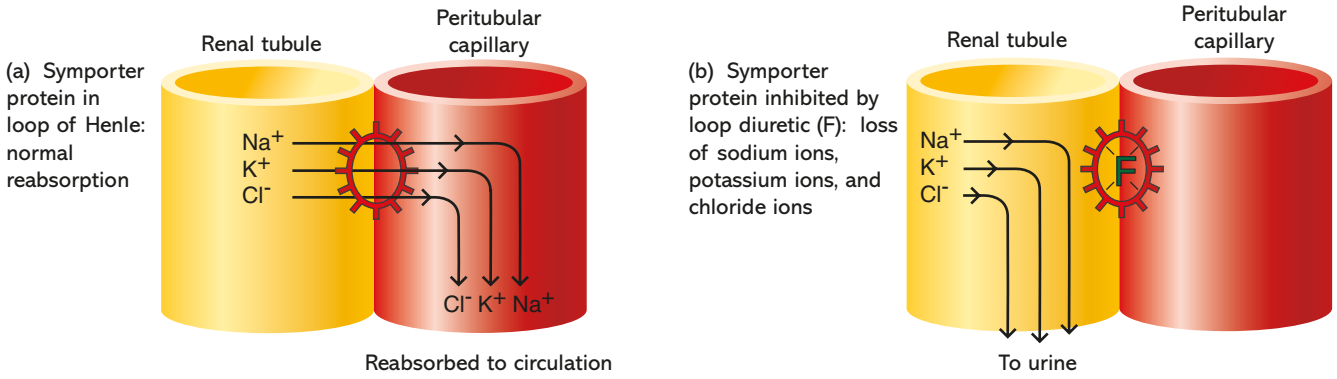


Figure 32.3 Symporter protein in the loop of Henle: (a) normal reabsorption of the Na^+, K^+, and Cl^- ions; (b) inhibition of symporter by furosemide causes excretion of Na^+, K^+, and Cl^- ions.

- **Carbonic anhydrase inhibitors.** These drugs block the enzyme in the nephron responsible for bicarbonate reabsorption. They produce a weak diuresis and are rarely used.

It is common practice to combine two or more drugs in the pharmacotherapy of HTN and fluid retention disorders. Diuretics are often a component of fixed-dose combinations with drugs from other classes. The primary rationales for combination therapy are that the incidence of adverse effects is decreased and the pharmacologic effects (such as diuresis or blood pressure reduction) may be enhanced. For patient convenience, some of these drugs are available in single-tablet formulations. Examples of single-tablet diuretic combinations include the following:

- **Aldactazide.** Hydrochlorothiazide and spironolactone
- **Apresazide.** Hydrochlorothiazide and hydralazine
- **Dyazide.** Hydrochlorothiazide and triamterene
- **Moduretic.** Hydrochlorothiazide and amiloride.

Loop (High-Ceiling) Diuretics

32.5 The most effective diuretics are the loop diuretics that block sodium reabsorption in the loop of Henle.

The most effective diuretics, the loop or high-ceiling diuretics, act by blocking the reabsorption of sodium and chloride in the loop of Henle. This occurs when the drug inhibits the molecule responsible for transporting sodium and chloride from the filtrate to the blood, known as the Na^+-K^+-$2Cl^-$ symporter. A **symporter** is a membrane protein that transports two molecules at the same time. When the loop diuretics block this symporter, sodium and chloride are prevented from being reabsorbed, and diuresis is increased. All loop diuretics have an additional action that is responsible for a major adverse effect of drugs in this class: increasing potassium excretion. An illustration showing the effects caused when this symporter is inhibited is shown in Figure 32.3.

All loop diuretics are available for either oral (PO) or parenteral administration and are extensively bound to plasma proteins. They have relatively short half-lives, and extended release preparations are not available. When given intravenously (IV), loop diuretics have the ability to cause large amounts of fluid to be excreted by the kidney in a very short time. Loop diuretics are used to reduce the edema associated with HF, hepatic cirrhosis, or CKD. Furosemide and torsemide are also approved for HTN, although their short half-lives make them less suitable for this indication than thiazide diuretics. Occasionally, loop diuretics are given to speed the renal excretion of a drug that has been overdosed or a toxin that has been unintentionally ingested. Doses of the loop diuretics are listed in Table 32.4.

Table 32.4 Loop Diuretics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
bumetanide (Bumex)	PO: 0.5–2 mg/day, may repeat at 4- to 5-h intervals if needed (max: 10 mg/day) IV/IM: 0.5–1 mg over 1–2 min, repeated q2–3h prn (max: 10 mg/day)	*Minor hypokalemia, orthostatic hypotension, tinnitus, nausea, diarrhea, dizziness, fatigue*
ethacrynic acid (Edecrin)	PO: 50–100 mg 1–2 times/day; may increase by 25–50 mg prn (max: 400 mg/day) IV: 0.5–1 mg/kg or 50 mg (max: 100 mg/dose)	Serious hypokalemia, blood dyscrasias, dehydration, ototoxicity, electrolyte imbalances, circulatory collapse
furosemide (Lasix)	PO: 20–80 mg in 1 or more divided doses (max: 600 mg/day) IV/IM: 20–40 mg in 1 or more divided doses (max: 600 mg/day)	
torsemide (Demadex)	PO/IV: 10–20 mg/day (max: 200 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTIONS: Preparing for Advanced Practice

Chronic Kidney Disease and Prescribing Considerations

Case

Nolan is a 71-year-old African American man who was admitted to the hospital for altered mental status. His daughter Renee reported that her father had become progressively confused and had been having visual and auditory hallucinations, seeing and hearing people and animals that were not really there. In the past 24 hours, Nolan's symptoms had become more persistent and she became more and more concerned. Nolan has a 9-year history of HF and type 2 diabetes, and was diagnosed 10 months ago with stage V CKD, thought to be primarily due to his diabetic nephropathy.

On admission, the nurse practitioner hospitalist, his bedside nurse, and the unit's Pharm D. reviewed his medications with Renee. Nolan was taking 81 mg of aspirin, atenolol, atorvastatin, calcium acetate, insulin, and had recently started 300 mg of gabapentin 3 times daily for the diabetic neuropathy. On physical examination, he was sleepy but arousable. His blood pressure was 136/86 mmHg; pulse was 72 beats/min (regular); respiratory rate was 14 breaths/min; and oxygen saturation 96%. What pharmacologic factors should the team be considering for Nolan?

Discussion

Kidney disease, both acute kidney injury (AKI) and CKD, affects every organ system in the body. The number of patients with AKI and CKD has increased due to the aging populations and medical advancements. Prescribing considerations for patients with CKD and AKI therefore require more thought, especially for medications that are renally excreted. For prescribing purposes, CKD is divided into three grades:

- Mild: GFR 20–50 mL/min; serum creatinine 150–300 µmol/L
- Moderate: GFR 10–20 mL/min; serum creatinine 300–700 µmol/L
- Severe: GFR less than 10 mL/min; serum creatinine more than 700 µmol/L (GFR above 50 mL/min does not usually require any dosage adjustment.)

Drugs to which particular attention should be given include histamine H_2-receptor antagonists, specific antibiotics, anticonvulsants, digoxin, and NSAIDs. Prescribing any medication that increases potassium levels, such as potassium supplements and potassium-sparing diuretics, is potentially very dangerous. Additionally, methotrexate, enoxaparin, and metformin should no longer be prescribed even with a mild grade of CKD. With cardiovascular (e.g., atenolol), antidiabetic (e.g., glibenclamide), or anticonvulsive (e.g., gabapentin) drugs, the recommendation is to use alternative medications, such as metoprolol, gliquidone, or carbamazepine, that are not renally excreted or are independent of kidney function. Drug dose adjustments should be considered with antimicrobial (e.g., ampicillin), antiviral (e.g., acyclovir), and some chemotherapeutic and cytotoxic drugs (e.g., cisplatin). Products with a high sodium content (e.g., antacids) should be avoided because they may cause sodium and water retention in patients with CKD (Carville, Wonderling, & Stevens, 2014).

The rapid excretion of large amounts of fluid has the potential to produce serious adverse effects, including dehydration and electrolyte imbalances. Signs of dehydration include thirst, dry mouth, weight loss, and headache. Dizziness and fainting can result from the fall in blood pressure caused by the rapid fluid loss. Potassium depletion can be serious and result in dysrhythmias. Potassium supplements are often prescribed concurrently with these diuretics to prevent hypokalemia. Potassium loss is of particular concern to those concurrently taking digoxin (Lanoxin), because hypokalemia predisposes these patients to dysrhythmias. With large doses, significant loss of sodium, magnesium, and calcium is possible. Continuous use of loop diuretics in postmenopausal women may affect bone metabolism due to excessive calcium loss. Loop diuretics can cause gout in some patients due to hyperuricemia, the accumulation of uric acid in the blood.

Although rare, loop diuretics may cause ototoxicity, which may manifest as tinnitus, vertigo, or deafness. Use of other ototoxic drugs such as the aminoglycoside antibiotics should be avoided during loop diuretic therapy due to the potential for additive hearing impairment. Due to the risk for serious adverse effects, loop diuretics are normally prescribed for patients with moderate to severe fluid retention, such as acute pulmonary edema, or when thiazide diuretics have failed to achieve therapeutic goals.

PROTOTYPE DRUG **Furosemide (Lasix)**

Classification **Therapeutic:** Antihypertensive drug for heart failure and edema
Pharmacologic: Loop- or high-ceiling-type diuretic

Therapeutic Effects and Uses: An established diuretic approved in 1966, furosemide is frequently used in the treatment of acute edema associated with liver cirrhosis, CKD, or HF because it has the ability to remove large amounts of edema fluid from the patient in a short time. When given IV, diuresis begins within 5 minutes, providing rapid relief from distressing symptoms such as dyspnea. Unlike the thiazide diuretics, furosemide is able to increase urine output even when blood flow to the kidneys is diminished, which makes it of particular value in patients with low cardiac output or CKD. It is also approved for HTN, although it is not a preferred drug for this indication because of its short half-life and potential for serious adverse effects.

Mechanism of Action: Furosemide prevents the reabsorption of sodium and chloride by blocking the Na^+-K^+-$2Cl^-$ symporter in the loop of Henle. Because this is the region of the nephron that normally filters the bulk of sodium, furosemide can cause a profound diuresis. The extensive diuresis results in the increased urinary excretion of sodium, chloride, potassium, and hydrogen ions.

Pharmacokinetics:

Route(s)	PO, IV, intramuscular (IM)
Absorption	60% absorbed PO
Distribution	Distributed to most tissues; crosses the placenta; secreted in breast milk; 95% bound to plasma protein
Primary metabolism	Hepatic (small amounts)
Primary excretion	Renal
Onset of action	PO: 30–60 min; IV: 5 min; IM: 10–30 min
Duration of action	PO: 6–8 h; IV: 2 h; IM: 4–8 h

Adverse Effects: The greatest concerns during furosemide therapy are excessive fluid loss and electrolyte imbalances. Hypovolemia may cause orthostatic hypotension and syncope. Imbalances may occur in any or all electrolytes, causing symptoms such as tachycardia, dysrhythmias, nausea, and vomiting. Ototoxicity is rare but may result in permanent hearing deficit. Hyperuricemia caused by the drug may cause exacerbations of gout. In patients with hypokalemia and hypochloremia, furosemide may induce metabolic alkalosis. **Black Box Warning:** Furosemide is a potent diuretic that, if given in excessive amounts, may lead to profound diuresis with water and electrolyte depletion. Careful medical supervision is required.

Contraindications/Precautions: Contraindications include hypersensitivity to furosemide or sulfonamide antibiotics, anuria, hepatic coma, or severe fluid or electrolyte depletion. Due to its high potency, fluid loss must be carefully monitored to avoid possible dehydration and hypotension. Any preexisting hypovolemia or hypotension should be corrected before furosemide therapy is initiated. Because loop diuretics can increase blood glucose, serum glucose levels should be assessed in patients with diabetes mellitus.

Drug Interactions: Hypokalemia from the use of furosemide may cause dysrhythmias in patients taking digoxin; therefore, combination therapy with furosemide and digoxin should be avoided or carefully monitored. Concurrent use with corticosteroids, amphotericin B, or other potassium-depleting drugs can result in hypokalemia. When given with lithium, elimination of lithium is decreased, causing a higher risk of toxicity. Furosemide may diminish the hypoglycemic effects of sulfonylureas and insulin. Concurrent use with NSAIDs can result in a diminished diuretic effect. Additive hypotension will occur if furosemide is given concurrently with antihypertensives, including other diuretics. Use of ethanol should be restricted because it may add to the hypotensive and diuretic actions of furosemide. Furosemide should not be used concurrently with aminoglycoside antibiotics due to the possibility of additive nephrotoxicity and ototoxicity. **Herbal/Food:** Oral aloe can decrease the levels of potassium and should not be used concurrently with loop diuretics. Use with hawthorn could result in additive hypotensive effects. Ginseng may decrease the effectiveness of loop diuretics. High sodium intake can reduce the effectiveness of diuretics; patients should be placed on a sodium-restricted intake of 1500 to 2300 mg/day.

Treatment of Overdose: Overdose with furosemide can result in serious hypotension, fluid loss, and electrolyte imbalances. Treatment is supportive with replacement of fluids and electrolytes and the possible administration of a vasopressor.

Pregnancy: Category C.

Nursing Responsibilities: Key nursing implications for patients receiving furosemide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Diuretics.

Drugs Similar to Furosemide (Lasix)

Furosemide is the most commonly prescribed drug in this class. Other loop diuretics include bumetanide, ethacrynic acid, and torsemide.

Bumetanide (Bumex): Approved in 1983, bumetanide is indicated for ascites (excess fluid in the abdomen) and the treatment of peripheral edema, usually associated with HF or CKD. This drug is available by the PO, IV, and IM routes and is 40 times more potent than furosemide but has a shorter duration of action. It may be used in acute clinical situations when furosemide has proved ineffective in patients with severe CKD. Like furosemide, bumetanide can cause electrolyte imbalances, hypotension, and dehydration. Unlike furosemide and torsemide, bumetanide is not approved for HTN, although it may be used off-label for that indication. This drug is pregnancy category C.

Ethacrynic acid (Edecrin): Approved in 1967, ethacrynic acid is indicated for the treatment of edema, usually associated with HF, hepatic cirrhosis, or CKD. Given by either the oral or IV route, ethacrynic acid is the only loop diuretic that does not contain a sulfur group in its structure; thus it can safely be used in patients allergic to sulfonamides. Of the loop diuretics, ethacrynic acid causes the most severe hearing loss, which may be irreversible. The patient must be carefully monitored to prevent excessive electrolyte and fluid losses. Although ethacrynic acid

CONNECTIONS: Community-Oriented Practice

Diuretics: A Banned Substance?

Diuretics are included in the banned substance list by the International Olympic Committee (IOC) and the World Anti-Doping Agency (WADA, 2017) except under highly regulated use for clinical conditions. Elite athletes seeking a competitive edge may use diuretics to achieve rapid weight loss to meet specific weight categories in some sports. Diuretics have also been used illicitly to mask the presence of other banned substances by reducing their concentration in urine (by increasing urine volume) or increasing their excretion (by altering urine pH). Hydrochlorothiazide and furosemide are the most commonly detected diuretics, although all classifications have been detected. Not all drugs are able to be detected, however, and until better drug detection techniques are developed, drug use in athletics for competitive advantage, including the use of diuretics, will continue.

is not approved for HTN, it may be prescribed off-label for this indication. This drug is pregnancy category B.

Torsemide (Demadex): Approved in 1993, torsemide is indicated for the treatment of HTN and edema, usually associated with HF, hepatic cirrhosis, or CKD. Given by either the oral or IV route, torsemide is twice as potent as furosemide and has a longer half-life, which offers the advantage of once-a-day dosing. The incidence of ototoxicity with torsemide is low, and the risk of hypokalemia is less than that of other drugs in this class. At higher doses, however, torsemide carries the same potential risks as furosemide and other loop diuretics, including electrolyte imbalances and hypovolemia. Torsemide is contraindicated in patients with sensitivity to sulfonylureas. This drug is pregnancy category B.

Thiazide and Thiazide-Like Diuretics

32.6 The thiazides are the most commonly prescribed class of diuretics.

The thiazides comprise the largest and most commonly prescribed class of diuretics. Like the loop diuretics, the thiazides block a symport protein in the renal tubule wall that is responsible for reabsorbing sodium and chloride ions from the filtrate. However, the thiazides block a different symport protein and in a different location than the loop diuretics. The thiazides act on the Na^+Cl^- symporter in the distal tubule to block Na^+ reabsorption and increase K^+ and water excretion. The thiazides are less effective than the loop diuretics because over 90% of the Na^+ has already been reabsorbed by the time the filtrate reaches the distal tubule. There are simply fewer Na^+ to block; thus the maximum diuresis produced by thiazides is less than the loop diuretics.

The primary indication for thiazide diuretics is the treatment of mild to moderate HTN. Mild HTN can often be managed with only a thiazide diuretic, whereas moderate to severe HTN often requires two or more antihypertensive drugs. Thiazides are also indicated for mild to moderate edema due to HF, hepatic cirrhosis, or CKD. They are not effective in patients with severe organ impairment because their ability to produce a diuresis diminishes as blood flow through the kidneys is reduced. Doses of the thiazide diuretics are listed in Table 32.5.

Thiazides are available only by the PO route with the exception of chlorothiazide (Diuril), which may be administered PO or parenterally. All the thiazide diuretics have equivalent effectiveness and safety profiles. They differ, however, in their potency and duration of action. For example, metolazone (Zaroxolyn) is 10 times more potent than hydrochlorothiazide (Microzide). At

Table 32.5 Thiazide and Thiazide-Like Diuretics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Short Acting		
chlorothiazide (Diuril)	PO: 250 mg–1 g/day in 1–2 divided doses IV: 250 mg–1 g/day in 1–2 divided doses (max: 2 g/day)	*Minor hypokalemia, fatigue* Serious hypokalemia, electrolyte depletion, dehydration, hypotension, hyponatremia, hyperglycemia, coma, blood dyscrasias
hydrochlorothiazide (Microzide)	PO: 25–100 mg/day as a single or divided dose (max: 50 mg/day for HTN; 100 mg/day for edema)	
Intermediate Acting		
bendroflumethiazide and nadolol (Corzide)	PO: 1 tablet/day (40–80 mg nadolol and 5 mg bendroflumethiazide)	
metolazone (Zaroxolyn)	PO: 2.5–10 mg once daily (max: 20 mg/day)	
Long Acting		
chlorthalidone	PO: 50–100 mg/day (max: 50 mg/day for HTN; 200 mg/day for edema)	
indapamide	PO: 1.25–2.5 mg once daily (max: 5 mg/day)	
methyclothiazide (Enduron)	PO: 2.5–5 mg once daily (max: 5 mg/day for HTN; 10 mg/day for edema)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

therapeutic doses all thiazides produce the same level of diuresis.

Three drugs in Table 32.5, chlorthalidone, indapamide, and metolazone (Zaroxolyn), are not true thiazides because they do not contain the two-ring structure that chemically defines a thiazide. However, these drugs block the same symport protein and have the same pharmacologic effects as thiazides. They are sometimes called "thiazide-like" and are always considered along with the true thiazides because of their similar mechanism of action, indications, and adverse effects.

The adverse effects of thiazides are similar to those of the loop diuretics, though their frequency is less and they do not cause ototoxicity. Dehydration and excessive loss of sodium, potassium, or chloride ions may occur with overtreatment: Hypokalemia and hypochloremia can cause metabolic alkalosis. Concurrent therapy with digoxin requires careful monitoring to avoid dysrhythmias caused by excessive potassium loss. Potassium supplements are sometimes prescribed during thiazide therapy to prevent hypokalemia. Patients with diabetes should be aware that thiazide diuretics sometimes increase blood glucose levels. Like the loop diuretics, thiazides can increase serum levels of uric acid, although this is only clinically significant in patients with a history of gout.

PROTOTYPE DRUG Hydrochlorothiazide (Microzide)

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Thiazide-type diuretic

Therapeutic Effects and Uses: Approved in 1959, hydrochlorothiazide (sometimes abbreviated HCTZ) is the most widely prescribed diuretic for HTN. Like many diuretics, it produces few adverse effects and is effective at producing a 10- to 20-mmHg reduction in blood pressure. Patients with severe HTN or a compelling condition such as HF, postmyocardial infarction (post-MI), high risk for coronary artery disease, diabetes, CKD, or recurrent stroke prevention may require the addition of a second drug from a different class to control the disease.

Hydrochlorothiazide is approved to treat ascites, edema, HF, HTN, and nephrotic syndrome. Off-label indications include premenstrual syndrome (PMS), diabetes insipidus, hypercalciuria, and nephrolithiasis. Hydrochlorothiazide is the most common agent found in fixed-dose combination drugs for HTN.

Mechanism of Action: Hydrochlorothiazide acts on the distal tubule to decrease the reabsorption of Na^+. This results in less water reabsorption, increased diuresis, and removal of edema fluid. Blood volume decreases and blood pressure falls. Increasing the amount of sodium in the distal tubule also increases potassium excretion via a sodium–potassium exchange mechanism.

Pharmacokinetics:

Route(s)	PO
Absorption	Variable; incompletely absorbed
Distribution	Distributed to most tissues; crosses the placenta and is secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	2 h; peak effect: 4 h
Duration of action	6–12 h; half-life: 45–120 min

Adverse Effects: Hydrochlorothiazide is generally well tolerated and exhibits few serious adverse effects. Hypotension may cause dizziness or headache. Electrolyte imbalances such as hypochloremia, hypomagnesemia, hypokalemia, and hyponatremia may occur. Dysrhythmias due to hypokalemia may be serious if not prevented by maintaining normal serum potassium levels, usually by the administration of potassium supplements during therapy. Hydrochlorothiazide may precipitate gout attacks due to its tendency to cause hyperuricemia. Blood dyscrasias such as leukopenia, agranulocytosis, and aplastic anemia are rare, though serious, adverse effects.

Contraindications/Precautions: Contraindications include anuria and prior hypersensitivity to thiazide diuretics or sulfonamide antibiotics. Because hydrochlorothiazide can cause glycosuria and hyperglycemia, serum glucose levels must be carefully monitored in patients with diabetes. Preexisting hypovolemia or hypotension should be corrected before thiazide therapy is initiated because diuretics can worsen these conditions. Hydrochlorothiazide should not be used in neonates with jaundice because it can cause hyperbilirubinemia.

Drug Interactions: When given concurrently with other antihypertensives, additive effects on blood pressure usually occur. Thiazides may reduce the effectiveness of anticoagulants, sulfonylureas, and antidiabetic drugs, including insulin. Cholestyramine and colestipol bind to and decrease the absorption of HCTZ, thus reducing its effectiveness. Hydrochlorothiazide increases the risk of renal toxicity from NSAIDs. Corticosteroids and amphotericin B increase potassium loss when given with HCTZ. Hypokalemia caused by HCTZ may increase digoxin toxicity and the possibility of dysrhythmias. Hydrochlorothiazide decreases the excretion of lithium and can lead to lithium toxicity. Because thiazides decrease the renal excretion of calcium, concurrent administration with calcium supplements may lead to hypercalcemia. **Herbal/Food:** Ginkgo biloba may produce a paradoxical increase in blood pressure. Oral aloe can decrease levels of potassium and should not be used concurrently with thiazide diuretics. Use with hawthorn could result in additive

hypotensive effects. High sodium intake can reduce the effectiveness of diuretics; patients should be placed on a sodium-restricted diet of 1500 to 2300 mg/day.

Treatment of Overdose: Overdose is manifested as electrolyte depletion, which is treated with infusions of fluids containing electrolytes. Infusion of fluids also prevents dehydration and hypotension.

Pregnancy: Category B.

Nursing Responsibilities: Key nursing implications for patients receiving hydrochlorothiazide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Diuretics.

Drugs Similar to Hydrochlorothiazide (Microzide)

Many thiazide and thiazide-like diuretics are available. They may be grouped into subclasses based on their relative duration of action.

Short-acting thiazides: This group includes chlorothiazide (Diuril) and hydrochlorothiazide (Microzide). These drugs have a rapid onset of 1 to 2 hours with a duration of action of 6 to 12 hours. Chlorothiazide is available by the IV route for patients who are unable to take PO thiazides.

Intermediate-acting thiazides: This group includes metolazone (Zaroxolyn) and Corzide, a fixed-dose combination of bendroflumethiazide (a thiazide) with nadolol (a beta-adrenergic blocker). These drugs have an onset time of about 2 hours with a duration of action of 12 to 24 hours.

Long-acting thiazides: This group includes chlorthalidone, indapamide, and methyclothiazide (Enduron). These drugs have a 2-hour onset with a duration of action ranging from 24 to 72 hours.

CONNECTION Checkpoint 32.3

The use of lithium is often contraindicated when a patient is taking diuretics. From what you learned in Chapter 19, identify the indications for lithium and explain how the use of a diuretic can lead to lithium toxicity. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Potassium-Sparing Diuretics

32.7 Potassium-sparing diuretics have low effectiveness but can help prevent hypokalemia.

As discussed in Sections 32.5 and 32.6, hypokalemia is a potentially serious adverse effect of the loop and thiazide diuretics. The therapeutic advantage of the potassium-sparing diuretics is that increased diuresis can be obtained without lowering blood potassium levels. The potassium-sparing diuretics are listed in Table 32.6. There are two subclasses of potassium-sparing diuretics: sodium ion channel inhibitors and aldosterone antagonists.

Sodium ion channel inhibitors: In the distal tubule, Na^+ is reabsorbed from the filtrate through sodium ion channels. As the sodium ion in the filtrate travels across the renal tubule cell and returns to the bloodstream, potassium ion moves in the opposite direction. In other words, as sodium ion is reabsorbed, potassium ion is secreted.

Triamterene (Dyrenium) and amiloride (Midamor) block the Na^+ channel, causing sodium to stay in the filtrate. Because water always follows sodium ions, additional water is retained in the filtrate and ultimately leaves in the urine. When the sodium ion channel is blocked, another important action occurs: The potassium ion is no longer secreted to the filtrate. The body, therefore, does not lose potassium, as is the case with the thiazide and loop diuretics. Because most of the sodium ion has already been removed before the filtrate reaches the distal tubule, these potassium-sparing diuretics produce only a mild diuresis. Drugs in this class are rarely prescribed alone, but they may be used in combination with thiazide or loop diuretics to minimize loss of potassium ions in the pharmacotherapy of HTN or edema.

Aldosterone antagonists: Aldosterone is the primary mineralocorticoid hormone secreted by the adrenal gland. The physiologic targets, or membrane receptors (MRs), for aldosterone are located in the distal tubule and collecting ducts of the nephron. Once bound to its receptors, the MR–aldosterone complex causes the renal tubule cells to synthesize more Na^+ channels, thereby allowing for more

Table 32.6 Potassium-Sparing Diuretics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Sodium Ion Channel Inhibitors		
amiloride (Midamor)	PO: 5–10 mg/day (max: 20 mg/day)	*Minor hyperkalemia, headache, fatigue, gynecomastia (spironolactone)* Dysrhythmias (from hyperkalemia), dehydration, hyponatremia, agranulocytosis, and other blood dyscrasias
triamterene (Dyrenium)	PO: 50–100 mg bid (max: 300 mg/day)	
Aldosterone Antagonists		
eplerenone (Inspra)	PO: 25–50 mg once daily (max: 100 mg/day for HTN; 50 mg/day for HF)	
spironolactone (Aldactone)	PO: 25–100 mg 1–2 times/day (max: 400 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

reabsorption of Na^+ from the filtrate. Simply stated, aldosterone increases sodium reabsorption.

Spironolactone (Aldactone) and eplerenone (Inspra) prevent the formation of the MR–aldosterone complex and are called aldosterone antagonists. By blocking the actions of aldosterone, these drugs enhance the excretion of sodium and the retention of potassium. Like the sodium ion channel inhibitors, spironolactone and eplerenone produce only a weak diuresis, and they are normally combined with drugs from other classes when treating HTN or edema. Spironolactone has also been found to significantly reduce mortality in patients with HF and, because of this important beneficial effect, its use has increased. The aldosterone antagonists are also used to treat hyperaldosteronism, a rare disorder in which a tumor of the adrenal gland secretes large amounts of aldosterone.

Using potassium supplements or adding potassium-rich foods to the diet when taking these medications may lead to life-threatening hyperkalemia. Signs and symptoms of hyperkalemia include muscle weakness, ventricular tachycardia, or fibrillation. Minor adverse effects of the drugs include headache, dizziness, nausea, and vomiting. Spironolactone binds to progesterone and androgen receptors, resulting in a small incidence of gynecomastia, menstrual abnormalities, and impotence. Gynecomastia, abnormal enlargement of the breasts in men, appears to be related to dosage level and duration of therapy; it may persist after the drug is discontinued. The incidence of adverse reproductive system effects is lower with eplerenone.

PROTOTYPE DRUG Spironolactone (Aldactone)

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Potassium-sparing diuretic/aldosterone antagonist

Therapeutic Effects and Uses: Approved in 1960, spironolactone is the most frequently prescribed potassium-sparing diuretic. The most common indication for spironolactone is mild HTN. Because it does not cause potassium depletion, the drug is particularly useful in patients who are at high risk for hypokalemia. However, spironolactone does such an efficient job of retaining potassium that hyperkalemia may develop, especially if the patient is taking potassium supplements or is receiving angiotensin-converting enzyme (ACE) inhibitors. When serum potassium levels are monitored carefully and maintained within normal values, serious adverse effects from spironolactone are uncommon.

Spironolactone is approved for the management of edema associated with hepatic cirrhosis, HF, or nephrotic syndrome. It is particularly useful in treating edema or ascites in patients with hepatic cirrhosis, because it counteracts the large amount of aldosterone secreted by these patients. Spironolactone may also be used for the short-term, preoperative treatment of primary hyperaldosteronism. An off-label indication is to improve survival and reduce hospitalizations in patients with severe HF. Other off-label indications include treatment of minor edema associated with PMS, polycystic ovary, acne, and hirsutism in females. Aldactazide is a fixed-dose combination of spironolactone with hydrochlorothiazide.

Mechanism of Action: Spironolactone acts by inhibiting the actions of aldosterone in the distal tubule and collecting ducts of the nephron. When the actions of aldosterone are blocked by spironolactone, sodium, chloride, and water excretion are increased and the body retains potassium.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapid absorption; 73% absorbed
Distribution	Distributed to most tissues; crosses the placenta; secreted in breast milk; more than 90% bound to plasma protein
Primary metabolism	Hepatic and renal; converted to active metabolites
Primary excretion	Renal (40–57%) and feces (35–40%)
Onset of action	2–3 days; may take 2 weeks for maximum effect
Duration of action	2–3 days; half-life: 1.3–2.4 h for parent compound, and 18–23 h for active metabolites

Adverse Effects: Hyperkalemia induced by spironolactone can cause life-threatening cardiac dysrhythmias. Signs and symptoms associated with spironolactone-induced hyperkalemia include muscle weakness, paresthesia, fatigue, bradycardia, flaccid paralysis of the extremities, and shock. In men, spironolactone can cause gynecomastia, impotence, and diminished libido. Women may experience menstrual irregularities, hirsutism, and breast tenderness. Fertility may decrease during therapy. Agranulocytosis and other blood dyscrasias are rare adverse effects. **Black Box Warning:** Spironolactone produces tumors in laboratory animals; unnecessary use of the drug should be avoided.

Contraindications/Precautions: Contraindications include anuria, severe CKD, pregnancy, and hyperkalemia. Older patients and those with renal insufficiency or diabetes mellitus are at greatest risk for hyperkalemia. At high doses, spironolactone produces teratogenic effects in laboratory animals; thus it should not be used during pregnancy. A major metabolite of spironolactone is secreted in breast milk; thus this drug should not be given during lactation.

Drug Interactions: Spironolactone should not be administered concurrently with eplerenone due to the potential for hyperkalemia. Aspirin and other salicylates may decrease the diuretic effect of the medication. Concurrent

use with digoxin may decrease the effects of digoxin. When taken with potassium supplements, ACE inhibitors, angiotensin receptor blockers (ARBs), or the potassium salts of other drugs (such as penicillin G potassium), severe hyperkalemia and possible dysrhythmias may result. Concurrent use with other antihypertensives will result in an additive hypotensive effect. **Herbal/Food:** Licorice extract contains a substance with aldosterone-like actions and should be avoided. Use with hawthorn may result in hypotension.

Treatment of Overdose: Acute overdoses produce drowsiness, mental confusion, rash, nausea, vomiting, dizziness, or diarrhea. The most serious symptoms of spironolactone overdose are related to hyperkalemia. If severe, therapies are administered to counteract the hyperkalemia. These include IV calcium chloride, calcium gluconate, sodium bicarbonate, or the administration of glucose with rapid-acting insulin. Cationic exchange resins such as sodium polystyrene sulfonate (Kayexalate) may be administered.

Pregnancy: Category D.

Nursing Responsibilities: Key nursing implications for patients receiving spironolactone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Diuretics.

Drugs Similar to Spironolactone (Aldactone)

The three other potassium-sparing diuretics include amiloride, eplerenone, and triamterene.

Amiloride (Midamor): Approved in 1981, amiloride is an oral Na^+ channel inhibitor with weak diuretic activity whose major indication is HTN. It is also used to treat peripheral edema due to HF and to reverse thiazide-induced hypokalemia. When combined with a thiazide diuretic, additive hypotensive action is achieved, and potassium balance is maintained. It should not be used as monotherapy or in combination with other potassium-sparing diuretics because hyperkalemia may develop. Contraindications and adverse effects are similar to those of spironolactone, including a black box warning for the risk of severe hyperkalemia in patients receiving other potassium-containing drugs. Moduretic is a fixed-dose combination of amiloride and hydrochlorothiazide. Amiloride is pregnancy category B.

Eplerenone (Inspra): Approved in 2002, eplerenone is an aldosterone antagonist administered by the oral route that is approved for HTN and the post-MI management of HF. Two to four weeks of therapy are required to achieve maximum therapeutic effects. Eplerenone is more selective for the aldosterone receptor than spironolactone, and it has the advantage of producing a lower incidence of endocrine-related adverse effects such as gynecomastia, impotence, or menstrual irregularities. Like other drugs in this class, however, the development of hyperkalemia is a potentially serious adverse effect, especially if the drug is used concurrently with ACE inhibitors. Eplerenone is sometimes referred to as a selective aldosterone receptor antagonist. This drug is pregnancy category B.

Triamterene (Dyrenium): Approved in 1964, triamterene is an oral drug that acts by the same mechanism as amiloride and has the same indications and adverse effects. It is a relatively weak diuretic and is sometimes used to manage hypokalemia in patients who are unable to tolerate potassium supplements. Triamterene is rarely prescribed as monotherapy and should not be used concurrently with other potassium-sparing diuretics due to the potential for hyperkalemia. Dyazide is a fixed-dose combination of triamterene and hydrochlorothiazide. This drug is pregnancy category C.

CONNECTION Checkpoint 32.4

From what you learned in Chapter 31, explain why patients who are taking an ACE inhibitor should probably not receive an aldosterone antagonist. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Osmotic Diuretics

32.8 Osmotic diuretics cause diuresis by increasing the osmolality of the filtrate.

The osmotic diuretics, shown in Table 32.7, are a small class of drugs that are reserved for very specific indications. Unlike the thiazides and loop diuretics that block transport proteins, osmotic diuretics are mostly inert and act by raising the osmolality, which is a measure of the amount of dissolved particles, or solutes in a solution. This in turn increases the **osmotic pressure**, which creates a force that moves substances between compartments. Osmotic diuretics cause water to shift compartments by creating a difference in osmotic pressure across a membrane or between two body compartments.

When given IV, osmotic diuretics are filtered at the glomerulus and readily enter the renal filtrate. Once in the tubule, they remain unchanged. As normal sodium and water reabsorption progresses in the proximal tubule, the diuretic remains behind, and its concentration in the tubule begins to increase. The osmolality of the filtrate increases due to the presence of the osmotic diuretic in the tubule. This osmotic force draws water into the filtrate, resulting in increased diuresis. The influence of osmotic pressure on water movement is presented in greater detail in Chapter 33.

A second action of osmotic diuretics is their ability to raise the osmolality of the plasma. This creates an osmotic force that moves water from the intracellular and extravascular spaces to the plasma. The increased volume of water in the plasma is filtered by the kidney, resulting in enhanced

Table 32.7 Miscellaneous Diuretics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Carbonic Anhydrase Inhibitors		
acetazolamide (Diamox)	PO: 250–375 mg/day (max: 1500 mg/day) IM/IV: 250–375 mg/day	*Electrolyte imbalances, fatigue, nausea, vomiting, dizziness* Dehydration, blood dyscrasias, pancytopenia, flaccid paralysis, hemolytic anemia, aplastic anemia
methazolamide (Neptazane)	PO: 50–100 mg bid–tid (max: 300 mg/day)	
Osmotic Diuretics		
glycerin	PO: 1–1.8 g/kg, 1–2 h before ocular surgery	*Electrolyte imbalances, fatigue, nausea, vomiting, dizziness* Hyponatremia, edema, convulsions, tachycardia
mannitol (Osmitrol)	IV: 100 g infused over 2–6 h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

diuresis. This action is used to advantage in the treatment of two conditions where fluid has accumulated in extravascular spaces. For example, following a traumatic head injury, fluid accumulates in the brain, causing dangerously high intracranial pressure. Osmotic diuretics create an osmotic force that promotes the fluid to leave the brain and enter the blood, thus reducing cerebral edema. A second example is high intraocular pressure caused by excess fluid accumulation in the eye (glaucoma). Osmotic diuretics can cause the fluid to leave the eye and enter the blood, thus relieving the high intraocular pressure.

Osmotic diuretics are rarely the drugs of first choice due to their potential toxicity. Although as diuretics they are useful in increasing urine output, they are contraindicated in patients with severe kidney disease. The rapid movement of water from the extravascular spaces to the blood can result in severe dehydration in the tissues and cause a serious fluid overload in patients with severe HF. Electrolyte imbalances, especially hyponatremia, may occur with these drugs.

PROTOTYPE DRUG Mannitol (Osmitrol)

Classification **Therapeutic:** Drug for acute kidney injury
Pharmacologic: Osmotic diuretic

Therapeutic Effects and Uses: Approved in 1944, mannitol is a parenteral diuretic primarily used to prevent or treat AKI in patients experiencing oliguria before the loss of renal function becomes irreversible. In addition, by its ability to increase the osmolality of plasma, this drug is able to "pull" fluid out of extravascular spaces; thus it is used to reduce intracranial pressure following head trauma and to lower intraocular pressure in patients with acute glaucoma. Reduction in the amount and pressure of cerebrospinal fluid can occur as quickly as 15 minutes after initiating the infusion; intraocular pressure reduction may take up to an hour. Mannitol may be administered concurrently with nephrotoxic drugs such as cisplatin (an antineoplastic drug) to speed them through the kidney and reduce damage to the walls of the renal tubules.

Mannitol has nondrug uses as a sweetener and food stabilizer. When taken PO, it is absorbed so slowly that it has no effect on insulin levels, making it an alternative sweetener in foods for patients with diabetes. The drug has a laxative effect when taken in large quantities.

Mechanism of Action: Administered by the IV route, mannitol is filtered by the glomerulus of the kidney but is incapable of being reabsorbed from the renal tubule. This creates an osmotic gradient, resulting in decreased water and Na^+ reabsorption and increased diuresis.

Pharmacokinetics:

Route(s)	IV
Absorption	Does not cross biological membranes
Distribution	Remains in extracellular space; does not cross the blood–brain barrier
Primary metabolism	Hepatic (small amounts)
Primary excretion	Renal
Onset of action	1–3 h
Duration of action	4–6 h; half-life: 100 min

Adverse Effects: Electrolyte imbalances, either deficiencies or excesses, can occur during mannitol therapy. For example, as mannitol draws fluid from the intravascular spaces, hyperkalemia or hypernatremia may occur. However, mannitol also increases the excretion of sodium and potassium ions, which can result in hypokalemia or hyponatremia. The same holds true for fluid balance. As mannitol draws fluid into the extracellular spaces, peripheral edema, HF, or pulmonary edema may occur. As diuresis progresses, the patient may become hypovolemic and dehydrated. Other adverse effects include fatigue, nausea, vomiting, dizziness, convulsions, and tachycardia.

Contraindications/Precautions: Contraindications include anuria, severe HF, organic central nervous system (CNS) disease or intracranial bleeding, severe dehydration, and shock. A test dose may be given to patients with oliguria to determine renal function. Function is considered

satisfactory if urine flow is at least 30 to 50 mL/h over 2 to 3 hours following an IV test dose of 0.2 g/kg. If this response is not achieved, the kidneys are too impaired to administer a full dose of mannitol.

There is evidence that high doses of mannitol may open the blood–brain barrier by temporarily shrinking the endothelial cells that line the barrier. Should this happen, mannitol will enter the brain (bringing water with it) and increase intracranial pressure. Extreme precautions must be taken when treating patients with high intracranial pressure. Experimentally, mannitol is used to intentionally open the blood–brain barrier to deliver higher doses of various drugs, such as antineoplastic drugs, directly to the brain.

Drug Interactions: Because of its intense diuretic effect, mannitol can increase the excretion of many drugs. This results in a decreased effect for drugs such as lithium, imipramine, salicylates, barbiturates, and potassium supplements. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose will result in a shift of fluid to the vascular compartment, resulting in HF and pulmonary edema. Intense diuresis may cause significant electrolyte imbalances, especially hyponatremia. No specific antidote is available and treatment is supportive to the presenting symptoms.

Nursing Responsibilities: Key nursing implications for patients receiving mannitol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Diuretics.

Drugs Similar to Mannitol (Osmitrol)

There is only one other osmotic diuretic, glycerin.

Glycerin: Also known as glycerol, glycerin is given for a large number of indications. When given by the oral route, glycerin creates an osmotic gradient like mannitol that can reduce intraocular and intracranial pressure. As a laxative suppository, glycerin draws water into the colon, creating more bulk and promoting defecation. It is used in a variety of over-the-counter (OTC) products as an emollient or lubricant, including toothpaste, shaving cream, hair products, soaps, and skin care products. Like mannitol, it tastes sweet and is used as a food additive to sweeten and keep products moist.

Carbonic Anhydrase Inhibitors

32.9 Carbonic anhydrase inhibitors are weak diuretics that have specific indications.

Carbonic anhydrase is an essential enzyme that helps regulate acid–base balance in the body. Carbonic anhydrase converts CO_2 to carbonic acid (H_2CO_3), which immediately dissociates to bicarbonate ion (HCO_3^-). Note that these reactions are reversible.

$$CO_2 + H_2O \longleftrightarrow H_2CO_3 \longleftrightarrow HCO_3^- + H^+$$

Carbonic acid is present in multiple tissues. In red blood cells, it converts CO_2 (an acidic, poorly soluble gas) to bicarbonate, which can be transported to the lungs, reconverted to CO_2, and exhaled. In the mucosa of the stomach, carbonic anhydrase is responsible for forming gastric acid (H^+). For this chapter, the most important action of carbonic anhydrase occurs in the renal tubule cells.

In the kidney tubules, carbonic anhydrase is necessary for the formation and reabsorption of bicarbonate ion, which is essential for maintaining proper acid–base balance. Sodium ions are reabsorbed with bicarbonate ion in the proximal tubule using a symporter protein.

Several drugs that inhibit carbonic anhydrase are available as shown in Table 32.7. Blocking carbonic anhydrase prevents bicarbonate formation and reabsorption in the renal tubule. Without bicarbonate ion, sodium reabsorption does not occur, more water remains in the filtrate, and diuresis is promoted. The reduction in plasma bicarbonate eventually causes metabolic acidosis, which tends to reverse the diuretic action of this drug.

The carbonic anhydrase inhibitors are rarely prescribed as diuretics because they produce only a weak, short-lived diuresis and can contribute to metabolic acidosis. Carbonic anhydrase inhibitors that are given by the oral route include acetazolamide (Diamox) and methazolamide (Neptazane). Methazolamide is approved only for reducing intraocular pressure in patients with open-angle glaucoma. Acetazolamide (Diamox), also used to decrease intraocular fluid pressure, has several other indications. Two drugs in this class, dorzolamide (Trusopt) and brinzolamide (Azopt), are administered topically to the eye for open-angle glaucoma. The antiglaucoma drugs in this class are discussed in Chapter 74.

PROTOTYPE DRUG **Acetazolamide (Diamox)**

Classification **Therapeutic:** Drug for edema, antiglaucoma drug
Pharmacologic: Carbonic anhydrase inhibitor

Therapeutic Effects and Uses: Given by either the oral or parenteral route, acetazolamide produces a mild diuresis and is occasionally used to reduce edema fluid in patients with HF. An older drug approved in 1953, it has largely been replaced by thiazide diuretics.

Acetazolamide also has applications for treating absence seizures and in relieving motion sickness. It has been used to acclimatize people to high altitudes to prevent or treat acute mountain sickness. It accomplishes this by increasing the renal excretion of bicarbonate, which accumulates in the body because of the hyperventilation that

occurs at high altitude. Acetazolamide is effective in treating open-angle glaucoma and for preoperative treatment of acute closed-angle glaucoma, although it is not a preferred drug for these disorders.

Mechanism of Action: Acetazolamide produces its diuretic effect by inhibiting carbonic anhydrase activity in the proximal renal tubule, causing increased excretion of sodium and bicarbonate. In the eye, the inhibition of carbonic anhydrase reduces the rate of aqueous humor formation and consequently lowers intraocular pressure.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	75% absorbed when given with food
Distribution	Distributed to most tissues; crosses the placenta and is secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	PO: 90 min; IV: 2 min
Duration of action	PO: 8–12 h; PO extended release: 18–24 h; IV: 15 min; half-life: 2.4–5.8 h

Adverse Effects: Acetazolamide can cause various electrolyte imbalances, including hyperchloremia and hypokalemia. Gastrointestinal adverse effects include nausea, vomiting, diarrhea, and anorexia. CNS effects may occur, such as dizziness, fatigue, and numbness in the extremities, lips, or facial muscles. Metabolic acidosis may result from excess bicarbonate loss.

Contraindications/Precautions: Acetazolamide is contraindicated in patients who have hypersensitivity to sulfonamides and similar drugs such as thiazide diuretics. Other contraindications include severe renal or hepatic impairment and adrenocortical insufficiency. Patients with preexisting electrolyte imbalances such as hyponatremia, hypokalemia, or hypochloremic acidosis should be treated with caution because acetazolamide may worsen these conditions.

Drug Interactions: The potential for hypokalemia is greatest early in the course of acetazolamide therapy and is accelerated by amphotericin B and corticosteroids. Because acetazolamide alkalinizes the urine, the renal excretion of many drugs may be decreased, including tricyclic antidepressants, procainamide, amphetamines, ephedrine, and quinidine. Renal excretion of lithium and phenobarbital may be increased. High-dose aspirin therapy can compete with tubular secretory mechanisms with acetazolamide, causing the carbonic anhydrase inhibitor to accumulate to toxic levels. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with acetazolamide results in metabolic acidosis, which may be treated by administering sodium bicarbonate. Electrolyte depletion and dehydration are treated with infusions of fluids containing electrolytes.

Nursing Responsibilities: Key nursing implications for patients receiving acetazolamide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Diuretics.

Drugs Similar to Acetazolamide (Diamox)

The other oral carbonic anhydrase inhibitor is methazolamide (Neptazane), which is used as a systemic antiglaucoma drug (see Chapter 74) rather than a diuretic.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Diuretics

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular disease, diabetes, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, use of digoxin, lithium, or antihypertensive drugs, and alcohol use. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings such as electrolytes, glucose, complete blood count (CBC), hepatic or renal function studies, uric acid levels, and lipid profiles.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), breath sounds, and cardiac monitoring (e.g., electrocardiogram [ECG], cardiac output) if appropriate. Assess for location, character, and amount of edema, if present. Assess baseline hearing and balance.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., adequate urine output, decreased edema or lowered blood pressure if given for HTN).
- Continue periodic monitoring of electrolytes, glucose, CBC, lipid profiles, liver function studies, creatinine, and uric acid levels.
- Assess for and promptly report adverse effects: hypotension, palpitations, dizziness or lightheadedness, musculoskeletal weakness or cramping, nausea, vomiting, abdominal cramping, diarrhea, or headache. Immediately report tinnitus or hearing loss, loss of balance or incoordination, severe hypotension accompanied by reflex tachycardia, dysrhythmias, decreased urine output, or weight gain or loss over 1 kg (2 lb) in a 24-h period.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects: Urine output is increased, blood pressure and pulse are within normal limits or within the parameters set by the healthcare provider. (Diuresis may be moderate to extreme depending on the type of diuretic given. Blood pressure should be within normal limits without the presence of reflex tachycardia.) • Daily weights should remain at or close to baseline weight. (An increase in weight over 1 kg [2 lb] per day may indicate excessive fluid gain. A decrease of over 1 kg [2 lb] per day may indicate excessive diuresis and dehydration.)	• Teach the patient, family, or caregiver how to monitor the pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained. • Have the patient weigh self daily and record weight along with blood pressure and pulse measurements.
Minimizing adverse effects: • Continue to monitor vital signs. Take blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for hypotension. (Diuretics reduce circulating blood volume, resulting in lowered blood pressure. Orthostatic hypotension may increase the risk of falls and injury.)	Teach the patient to: • Rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down, and not attempt to stand or walk, until the sensation passes. • Stop taking the medication and promptly notify the healthcare provider if blood pressure is 90/60 mmHg or lower, or is below the parameters set by the provider.
• Continue to monitor electrolytes, glucose, CBC, lipid profiles, liver function studies, creatinine, and uric acid levels. (Most diuretics cause loss of Na^+ and K^+ and may increase lipid, glucose, and uric acid levels.)	• Instruct the patient on the need to return periodically for laboratory work and to inform laboratory personnel of diuretic therapy when providing blood or urine samples. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating diuretic therapy.
• Continue to monitor hearing and balance, reporting persistent tinnitus or vertigo promptly. (Ototoxicity of cranial nerve VIII may occur, especially with loop diuretics. **Lifespan:** Because of pharmacokinetic differences, exercise additional caution when administering diuretics to infants and very young children. Audiology and additional monitoring may be ordered.)	• Have the patient report persistent tinnitus or balance or coordination problems immediately.
• Ensure patient safety, especially in the older adult. Observe for lightheadedness or dizziness. Monitor ambulation until the effects of the drug are known. (Dizziness from orthostatic hypotension may occur.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Weigh the patient daily and report weight gain or loss of 1 kg (2 lb) or more in a 24-h period. Measure intake and output in the hospitalized patient. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Diuresis is indicated by output significantly greater than intake.)	• Have the patient weigh self daily, ideally at the same time of day, and record weight along with blood pressure and pulse measurements. Have the patient report weight loss or gain of more than 1 kg (2 lb) in a 24-h period. • Advise the patient to continue to consume enough liquids to remain adequately, but not overly, hydrated. Drinking when thirsty, avoiding alcoholic beverages, and ensuring adequate but not excessive salt intake will assist in maintaining normal fluid balance. • Teach the patient that excessive heat conditions contribute to excessive sweating and fluid and electrolyte loss. Extra caution is warranted in these conditions.
• Monitor nutritional status and encourage appropriate intake to prevent electrolyte imbalances. (Electrolyte imbalances may occur dependent on the type of diuretic used. Most diuretics cause Na^+ and K^+ loss. Potassium-sparing diuretics may result in Na^+ loss but K^+ increase. **Lifespan:** Monitor electrolyte levels frequently in older adults, who are at greater risk for derangement related to age-related physiologic changes.)	• Instruct patients taking potassium-wasting diuretics (e.g., thiazide, thiazide-like, and loop diuretics) to consume foods high in potassium: fresh fruits such as strawberries and bananas; dried fruits such as apricots and prunes; vegetables and legumes such as tomatoes, beets, and dried beans; juices such as orange, grapefruit, or prune; and fresh meats. • Instruct patients taking potassium-sparing diuretics to avoid foods high in potassium such as above, not to use salt substitutes (which often contain potassium salts), and to consult with a healthcare provider before taking vitamin and mineral supplements or specialized sports beverages. (Typical OTC sports beverages, e.g., Gatorade and Powerade, may have lesser amounts of potassium but have high carbohydrate amounts that may lead to increased diuresis, diarrhea, and the potential for dehydration from the hyperosmolarity.)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Observe for signs of hypokalemia or hyperkalemia. Use with caution in patients taking corticosteroids, ACE inhibitors, ARBs, digoxin, or lithium. Report symptoms to the healthcare provider promptly. (Thiazide, thiazide-like, and loop diuretics can cause hypokalemia; potassium-sparing diuretics may cause hyperkalemia. Symptoms of *hypokalemia* include muscle weakness or cramping and palpitations. Symptoms of *hyperkalemia* include irritability or anxiety, fatigue, palpitations, nausea, and abdominal cramping. Concurrent use with corticosteroids may increase the risk of hypokalemia. Concurrent use with ACE inhibitors or ARBs may increase the risk of hyperkalemia. Concurrent use with digoxin increases the risk of potentially fatal dysrhythmias and with lithium may cause toxic levels of the drug.)	• Instruct the patient to report signs and symptoms of hypokalemia or hyperkalemia immediately to the healthcare provider. • Teach the patient to follow recommended dietary intake of high- or low-potassium foods as appropriate to the type of diuretic taken to avoid hypokalemia or hyperkalemia.
• Observe for signs of hyperglycemia. Use with caution in patients with diabetes. (Thiazide, thiazide-like, and loop diuretics may cause hyperglycemia, especially in patients with diabetes.)	• Instruct the patient to report signs and symptoms of diabetes mellitus (e.g., polydipsia, polyphagia) or elevated blood glucose to the healthcare provider. Patients with diabetes may need to monitor their blood glucose levels more frequently until the effects of the diuretic are known.
• Observe for symptoms of gout. (Diuretics may cause hyperuricemia, which may result in gout-like symptoms including warmth, pain, tenderness, swelling, and redness around the joints, especially great toes, hand joints, elbows, and around ears; tophi [nodules]; arthritis-like symptoms; and limited movement in affected joints.)	• Instruct the patient to report signs and symptoms of gout promptly to the healthcare provider. • Teach gout-prone patients to increase fluid intake and to avoid shellfish, organ meats (e.g., liver, kidneys), alcohol, and high-fructose beverages.
• Observe for sunburning if prolonged sun exposure has occurred. (Many diuretics cause photosensitivity and an increased risk of sunburning.)	• Instruct patients to wear sunscreen and protective clothing if prolonged sun exposure is anticipated.
• Observe for signs of infection. (Some diuretics may decrease white blood cell counts and the body's ability to fight infection. Agranulocytosis is a possible adverse effect of diuretic therapy.)	• Instruct the patient to report any flulike symptoms: shortness of breath, fever, sore throat, malaise, joint pain, or profound fatigue.
• **Lifespan:** Assess for the possibility of pregnancy or breastfeeding before beginning the drug. (Some diuretics are pregnancy category D drugs and should not be used during pregnancy.)	• Instruct female patients who may be considering pregnancy, or are pregnant or breastfeeding, to notify their provider before starting the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., early in the day to prevent disruption of sleep from nocturia. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 32

Key Concepts Summary

32.1 The kidneys are major organs of excretion and body homeostasis.

32.2 The composition of filtrate changes dramatically as a result of the processes of reabsorption and secretion.

32.3 Chronic kidney disease may significantly impact the success of pharmacotherapy.

32.4 Diuretics are used to treat hypertension, heart failure, accumulation of edema fluid, and chronic kidney disease.

32.5 The most effective diuretics are the loop diuretics that block sodium reabsorption in the loop of Henle.

32.6 The thiazides are the most commonly prescribed class of diuretics.

32.7 Potassium-sparing diuretics have low effectiveness but can help prevent hypokalemia.

32.8 Osmotic diuretics cause diuresis by increasing the osmolality of the filtrate.

32.9 Carbonic anhydrase inhibitors are weak diuretics that have specific indications.

CASE STUDY: Making the Patient Connection

Remember the patient "Katherine Crosland" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Katherine Crosland, a 79-year-old widow, has lived alone for the past 5 years. Although her son and daughters all reside in distant locations, they check on her at least weekly by telephoning. Katherine is fairly independent; however, she does not drive and is dependent on a neighbor to get her groceries and medications.

Three years ago, Katherine was hospitalized for an MI, which resulted in heart failure. She is adherent with her medications, which include digoxin (Lanoxin) 0.125 mg daily, furosemide (Lasix) 20 mg/day, and potassium supplements (K-Dur) 20 mEq daily.

Recently Katherine's neighbor went on an extended, out-of-town trip. Katherine was certain that she had enough of her medicine to last through that time. However, before the neighbor returned, Katherine discovered she had miscalculated her potassium supplement and only had enough for 10 days. Katherine figured that because the potassium was only a "supplement," she would be able to wait until her neighbor returned to get the medication refilled.

Today, she presents to the clinic with generalized weakness and fatigue. She has lost 3.6 kg (8 lb) since her last clinic visit 6 weeks ago. Her blood pressure is 104/62 mmHg, her heart rate is 98 beats/min, and she has a slightly irregular, respiratory rate of 20 breaths/min. Body temperature is 97.2°F (36.2°C). The blood specimen collected for diagnostic studies showed several outstanding findings such as a serum sodium level of 150 mEq/L and potassium level of 3.2 mEq/L. Katherine is diagnosed with dehydration and hypokalemia induced by diuretic therapy.

Critical Thinking Questions

1. Discuss fluid and electrolyte imbalances related to the following diuretic therapies:
   - **a.** Loop diuretics
   - **b.** Thiazide diuretics
   - **c.** Potassium-sparing diuretics
   - **d.** Osmotic diuretics
2. What relationship exists between this patient's diuretic therapy, digoxin therapy, and hypokalemia?
3. What patient education should the nurse provide about diuretic therapy?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

During a recent visit to the clinic, Miles Davenport learned that his antihypertensive medication was not maintaining his blood pressure at the desired level. The nurse practitioner prescribed spironolactone (Aldactone) 50 mg twice daily in addition to his regular antihypertensive medications.

1. Discuss the mechanism of action for spironolactone.
2. Prepare a list of foods that should be eaten sparingly while taking spironolactone.
3. List the symptoms of hyperkalemia that Miles needs to know to manage his disease and medications.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is teaching a group of patients with cardiac conditions who are taking diuretic therapy. The nurse explains that individuals prescribed furosemide (Lasix) should:
    1. Avoid consuming large amounts of cabbage, cauliflower, and kale.
    2. Rise slowly from sitting or lying positions.
    3. Count their pulse for 1 full minute before taking the medication.
    4. Restrict fluid intake to no more than 1000 mL in a 24-hour period.
2. The patient who is receiving bumetanide (Bumex) is instructed to watch for symptoms associated with electrolyte imbalances. Which condition would the patient most likely experience?
    1. Hypernatremia
    2. Hypokalemia
    3. Hyperkalemia
    4. Hypocalcemia
3. While preparing a patient for discharge, which of the following statements should the nurse include in the instructions regarding the patient's new prescription of hydrochlorothiazide (Microzide)?
    1. "There are no limitations on the amount of salt and fluid intake."
    2. "Ingest vitamin K–rich foods daily, such as green, leafy vegetables and broccoli."
    3. "Report muscle cramps or weakness to the healthcare provider."
    4. "Antihypertensive drugs taken concurrently may produce sleepiness."
4. Patients prescribed spironolactone (Aldactone) are often at risk for electrolyte imbalance. The nurse assesses for this adverse effect because this drug may cause the body to:
    1. Retain potassium.
    2. Release magnesium.
    3. Excrete potassium.
    4. Bind calcium.
5. Which nursing measures should be a nursing priority for a patient when first beginning mannitol (Osmitrol)?
    1. Keep the urinal or bedpan available for patients with limited mobility.
    2. Assess for hypokalemia and encourage foods high in potassium.
    3. Monitor intake and output ratio, and weigh the patient daily.
    4. Monitor blood pressure and assess for level of consciousness.
6. The nurse is monitoring a patient receiving acetazolamide (Diamox). Which acid–base imbalance is a potential risk for this patient?
    1. Metabolic acidosis
    2. Metabolic alkalosis
    3. Respiratory acidosis
    4. Respiratory alkalosis

Chapter 33
Pharmacotherapy of Fluid Imbalance, Electrolyte, and Acid–Base Disorders

Chapter Outline

- Principles of Fluid Balance
- Fluid Replacement Agents

  Blood Products

  PROTOTYPE *Normal Serum Albumin (Albuminar, Plasbumin, Others), p. 565*

  Crystalloids

  PROTOTYPE *5% Dextrose in Water (D_5W), p. 566*

  Colloids

  PROTOTYPE *Dextran 40 (Gentran 40, Others), p. 567*
- Physiology of Electrolytes
- Pharmacotherapy of Electrolyte Imbalances

  PROTOTYPE *Sodium Chloride (NaCl), p. 571*

  PROTOTYPE *Potassium Chloride (KCl), p. 572*

  PROTOTYPE *Magnesium Sulfate ($MgSO_4$), p. 574*
- Pharmacotherapy of Acid–Base Imbalances

  PROTOTYPE *Sodium Bicarbonate, p. 576*

  PROTOTYPE *Ammonium Chloride, p. 577*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the exchange of fluids that occurs among the different fluid compartments in the body.
2. Identify conditions for which intravenous fluid therapy may be indicated.
3. Explain how changes in the osmolality or tonicity of a fluid can cause water to move to a different compartment.
4. Compare and contrast the use of blood products, crystalloids, and colloids in intravenous therapy.
5. Explain the importance of electrolyte balance in the body.
6. Explain the pharmacotherapy of sodium and potassium imbalances.
7. Discuss medications used to treat acidosis and alkalosis.
8. Describe the nurse's role in the pharmacologic management of fluid imbalance, electrolyte, and acid–base disorders.
9. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
10. Apply the nursing process to care for patients receiving pharmacotherapy for fluid imbalance, electrolyte, and acid–base disorders.

Key Terms

acidosis, 575
alkalosis, 577
buffers, 575
colloids, 567
crystalloids, 566
electrolyte, 568
extracellular fluid (ECF) compartment, 562
hyperkalemia, 572
hypernatremia, 569
hypokalemia, 572
hyponatremia, 570
intracellular fluid (ICF) compartment, 562
ion trapping, 575
osmolality, 563
osmosis, 563
tonicity, 563

Can too much pure, sparkling water hurt you? As often as people hear "drink plenty of fluids," too much (or too little) can definitely be harmful. The volume and composition of fluids in the body must be maintained within narrow limits. Excess fluid volume can lead to hypertension (HTN), heart failure, or peripheral edema, while depletion results in dehydration.

Body fluids must also contain specific amounts of essential ions or electrolytes and be maintained at particular pH values. Imbalances in electrolytes or changes in the pH of body fluids may have fatal consequences if left untreated. This chapter will examine drugs used to reverse fluid imbalance, electrolyte, or acid–base disorders.

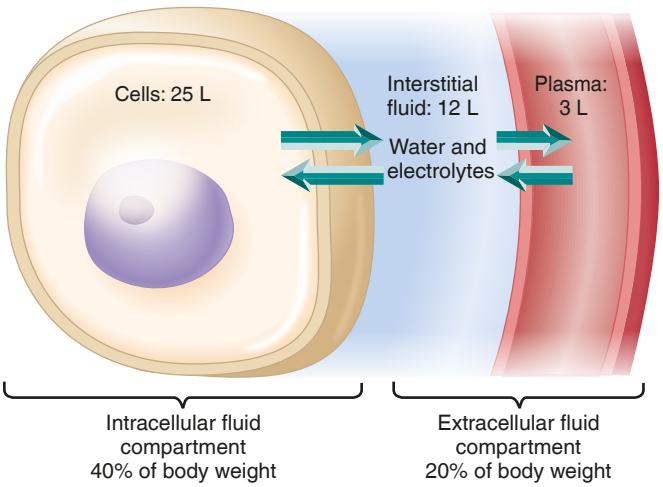

Figure 33.1 Major fluid compartments in the body.

Principles of Fluid Balance

33.1 Body fluids are exchanged between intracellular and extracellular compartments.

Body fluids travel between compartments separated by semipermeable membranes. Control of water balance in the various compartments is essential to homeostasis. Fluid imbalances are frequent indications for pharmacotherapy.

Not surprisingly, the greatest bulk of body fluid consists of water, which serves as the universal solvent in which electrolytes, minerals, and most nutrients are dissolved. Water alone is responsible for about 60% of the total body weight in a young adult. A newborn may contain 80% water, while an older adult may contain only 40%.

In a simple model, water in the body can be located in one of two places, or compartments. The **intracellular fluid (ICF) compartment**, which contains water that is inside cells, accounts for about two thirds of the total body water. The remaining one third of body fluid resides outside cells in the **extracellular fluid (ECF) compartment**. The ECF compartment is further divided into two parts: fluid in the plasma, or intravascular space, and fluid in the interstitial spaces between cells. The relationship between these fluid compartments is illustrated in Figure 33.1.

Once contained in a compartment, water and minerals do not stay there for very long. There is a continuous exchange, turnover, and mixing of fluids between compartments, as molecules travel across the membranes that separate them. For example, the plasma membranes of cells separate the ICF from the ECF. The capillary membranes separate plasma from the interstitial fluid. Although water travels freely among the compartments, processes of diffusion and active transport govern the movement of large molecules and those with electrical charges. Movement of ions and drugs across membranes is a primary topic of pharmacokinetics (see Chapter 3).

CONNECTION Checkpoint 33.1

From what you learned in Chapter 3, what barriers does an oral drug face in moving from the gastrointestinal (GI) tract to the extracellular fluid compartment (plasma)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

33.2 Osmolality or tonicity determines the movement of body fluids.

Osmolality and *tonicity* are two related terms central to understanding the pharmacotherapy of fluid imbalance disorders. Abnormalities in the osmolality or tonicity of a body fluid can cause significant shifts in water balance between compartments. The nurse will often administer intravenous (IV) fluids to compensate for these changes.

The **osmolality** is a measure of the number of dissolved particles, or solutes, in 1 kg (1 L) of water. In most body fluids, three solutes determine the osmolality: sodium, glucose, and urea. Sodium is the greatest contributor to osmolality due to its abundance in most body fluids. The normal osmolality of body fluids ranges from 275 to 295 milliosmoles per kilogram (mOsm/kg).

The term **tonicity** is sometimes used interchangeably with osmolality, although they are somewhat different. Tonicity is the ability of a solution to cause a change in water movement across a membrane due to osmotic forces. Whereas osmolality is a laboratory value that can be precisely measured, *tonicity* is a general term used to describe the *relative* concentration of IV fluids. The tonicity of normal plasma is considered isotonic and is used as the reference point when administering IV solutions. Solutions that are isotonic have the same concentration of solutes (same osmolality) as plasma. Hypertonic solutions contain a greater concentration of solutes than plasma, whereas hypotonic solutions have a lesser concentration of solutes than plasma.

Through **osmosis**, water moves from areas of low solute concentration (low osmolality) to areas of high solute concentration (high osmolality). If a hypertonic (hyperosmolar) IV solution is administered, water will move, by osmosis, from the cells, to the interstitial fluid compartment, to the plasma compartment. If a hypotonic solution is administered, water will move in the opposite direction, from plasma to the interstitial fluid, and eventually into cells. Isotonic solutions produce no net fluid shift. From a pharmacologic perspective, water movement between compartments following an IV infusion can be either a therapeutic effect or an adverse effect depending on the patient's condition and the expected outcomes of the drug administration.

33.3 Overall fluid balance is regulated primarily by hormones acting on the kidneys.

The average adult has a water intake of approximately 2500 mL per day, most of which comes from ingested food and beverages. Water output occurs through the kidneys, lungs, skin, feces, and sweat. To maintain water balance, water intake must equal water output. Net gains or losses of water can be estimated by changes in total body weight.

The most important physiologic mechanism regulating fluid intake is thirst. The sensation of thirst occurs when osmoreceptors in the hypothalamus sense that the ECF has become hypertonic. Saliva secretion diminishes and the mouth dries, motivating the individual to drink fluids. As the ingested water is absorbed, the osmolality of the ECF falls and the thirst center in the hypothalamus is no longer stimulated.

In addition to triggering thirst, the hypothalamus also directs the pituitary gland to release antidiuretic hormone (ADH) when plasma osmolality rises. ADH acts directly on the distal tubules of the kidney to increase water reabsorption. This increased water in the intravascular space dilutes the plasma, thus lowering its osmolality. In high concentrations ADH, also called vasopressin, can cause vasoconstriction, which serves as an important compensatory mechanism during hypovolemic shock.

A second set of hormones assists in the maintenance of fluid balance. Through the renin-angiotensin-aldosterone system (RAAS) (see Chapter 31), the hormone aldosterone is secreted by the adrenal cortex. Aldosterone causes the kidneys to retain sodium and water in the body, thus increasing the osmolality of the ECF.

Failure to maintain adequate intake or output can lead to fluid imbalance disorders that are indications for pharmacologic intervention. Fluid *deficit* disorders can cause dehydration or shock, which are treated by administering oral (PO) or IV fluids. Fluid *excess* disorders are treated with diuretics (see Chapter 32). When treating fluid imbalances, the ultimate goal is to diagnose and correct the underlying cause of the disorder, while administering supporting fluids and medications to stabilize the patient.

CONNECTION Checkpoint 33.2

From what you learned in Chapter 31, name the two aldosterone antagonists and provide their indications. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Fluid Replacement Agents

33.4 Dehydration may be treated with fluid volume expanders.

When fluid output exceeds fluid intake, volume deficits may result in shock, dehydration, or electrolyte loss. Left untreated, large-volume deficits may turn fatal. The following are common causes of fluid depletion:

- Loss of GI fluids due to vomiting, diarrhea, chronic laxative use, or GI suctioning
- Excessive sweating during hot weather, athletic activity, or prolonged fever
- Severe burns
- Hemorrhage
- Excessive diuresis due to diuretic therapy or uncontrolled diabetic ketoacidosis.

The immediate goal in treating a volume deficit disorder is to replace the depleted fluid so that blood volume and blood pressure can be maintained. In nonacute circumstances, this may be achieved by drinking more liquids or by administering fluids via a feeding tube. In acute situations, IV fluid therapy is indicated.

Choice of IV fluid therapy depends on the nature of the volume deficit. Careful attention must be paid to restoring

Table 33.1 Types of Dehydration Disorders and Their Treatment

Type	Isotonic Contraction	Hypotonic Contraction	Hypertonic Contraction
Fluid lost	Water and sodium in equal proportions	Sodium, without a corresponding loss of water	Water, without a corresponding loss of sodium
Pathophysiology	ECF remains isotonic; no net fluid shift	ECF becomes hypotonic; fluid shifts from ECF to ICF, lowering plasma fluid volume	ECF becomes hypertonic; fluid shifts from ICF to ECF, causing cellular dehydration
Causes	Vomiting, diarrhea, renal disease, diuretics	Diuretics, renal disease	Excessive sweating without replenishment, osmotic diuresis, burns
Treatment	Administer isotonic fluids; e.g., isotonic saline (0.9%)	Administer hypertonic fluids; e.g., hypertonic saline (3%)	Administer hypotonic fluids; e.g., hypotonic saline or 5% dextrose

normal levels of blood elements (erythrocytes, leukocytes, and thrombocytes) and electrolytes as well as total fluid volume. If significant blood loss has occurred, blood products may be indicated. Loss of substantial sodium and other salts involves replacement therapy with hypertonic fluids. Excessive sweating can result in water loss that requires hypotonic IV fluids. Treating dehydration with an IV fluid with the incorrect tonicity may worsen the condition.

Fluid replacement should always be conducted in a controlled, stepwise manner. Rapid infusions can cause fluid overload, pulmonary edema, and cardiovascular stress. Vital signs and plasma electrolytes should be carefully monitored during therapy. Therapy for dehydration is summarized in Table 33.1. The three basic classes of fluid replacement agents are blood products, crystalloids, and colloids.

33.5 Transfusions of blood products are used to treat serious conditions that cannot be managed effectively by other means.

Blood products include whole blood, packed red cells, fresh frozen plasma, cryoprecipitate, immune globulins, and platelet infusions. A single unit of whole blood can be separated into its specific constituents (erythrocytes, leukocytes, platelets, plasma proteins, fresh frozen plasma, and globulins), which can be used to treat multiple patients. Indications for the various blood products are shown in Table 33.2.

Table 33.2 Indications for Blood Products

Product	Description	Indication(s)
Whole blood	Contains all blood components	Rapid, massive blood loss when safer agents are not available
Packed RBCs	One unit of packed RBCs increases hemoglobin by about 1 g/dL and hematocrit by about 3% Washed RBCs are nearly free of plasma, white blood cells, and platelets and are reserved for patients who have severe reactions to plasma components	Preferred product to increase serum hemoglobin level
Fresh frozen plasma (FFP)	An unconcentrated source of all clotting factors, without platelets	Correction of bleeding secondary to factor deficiencies for which specific factor replacements are unavailable, multifactor deficiency states, and rapid warfarin reversal FFP should not be used for simple volume expansion
Cryoprecipitate	A concentrate prepared from FFP Each concentrate contains about 80 units each of Factor VIII and von Willebrand's factor and about 250 mg of fibrinogen It also contains fibronectin and Factor XIII	Originally used for hemophilia and von Willebrand's disease, it is also used as a source of fibrinogen in acute disseminated intravascular coagulation with bleeding, treatment of uremic bleeding, cardiothoracic surgery, and obstetric emergencies such as abruptio placentae
Immune globulins	Antibody preparations used to provide an immediate boost to the immune system	Rho(D) immune globulin (RhoGAM) prevents development of maternal Rh antibodies that can result from fetomaternal hemorrhage Other immune globulins are available for postexposure prophylaxis for patients exposed to certain infectious diseases, including cytomegalovirus, hepatitis A and B, measles, rabies, respiratory syncytial virus, rubella, tetanus, smallpox, and varicella
Platelets	One platelet concentrate increases the platelet count by about 10,000/mcL	Used to prevent bleeding in asymptomatic severe thrombocytopenia, for bleeding patients with less severe thrombocytopenia or with platelet dysfunction due to antiplatelet drugs but with normal platelet count, for patients receiving a massive transfusion that causes dilutional thrombocytopenia, and before invasive surgery

Blood products may be administered to restore deficient numbers of blood cells or proteins, or to increase fluid volume depending on the clinical situation. Whole blood is indicated for the treatment of acute, massive blood loss (depletion of more than 30% of the total volume) when there is a need to replace plasma volume and to supply erythrocytes to increase the blood's oxygen-carrying capacity.

PharmFACT

In the United States, over 13 million units of whole blood and red blood cells are donated each year. About 36,000 units of red blood cells are needed every day (American Red Cross, n.d.).

The administration of whole blood has been largely replaced by the use of blood components. Whole blood is rarely administered for several reasons. If the patient needs only one specific component in blood, there is no need to expose the patient to unnecessary components that could potentially trigger an adverse effect. The supply of blood products depends on human donors and requires careful crossmatching to ensure compatibility between the donor and the recipient.

The most common complications of whole blood transfusion include febrile nonhemolytic and chill-rigor reactions. The patient experiences symptoms of an allergic reaction that include back pain and low-grade fever and chills. Dizziness, urticaria, and headache may occur during or immediately after the transfusion. Symptoms are generally mild and treated with acetaminophen (Tylenol) and diphenhydramine (Benadryl) as needed.

The most serious adverse effect from administration of whole blood is an acute hemolytic transfusion reaction. This occurs when the patient receiving the transfusion develops antibodies against donor red blood cell (RBC) antigens. ABO blood type incompatibility is the most common cause of this rare, though sometimes fatal, disorder. Another uncommon, though serious, adverse effect from whole blood is transfusion-related acute lung injury. This injury occurs when the patient receives donor antibodies that attack normal granulocytes in the lung. Acute respiratory symptoms develop and may be fatal.

Whole blood, despite being carefully screened, also has the potential to transmit serious infections such as hepatitis, cytomegalovirus, malaria, or HIV. In addition, platelet concentrates are stored at room temperature, which may promote the growth of bacteria in the sample. Although disease transmission from donor to recipient is possible, the risk is very low.

PROTOTYPE DRUG **Normal Serum Albumin (Albuminar, Plasbumin, Others)**

Classification **Therapeutic:** Fluid replacement agent
Pharmacologic: Blood product, colloid

Therapeutic Effects and Uses: Normal serum albumin is a protein extracted from whole human blood, plasma, or placental plasma that contains 96% albumin and 4% globulins and other proteins. After extraction from blood or plasma, the albumin is sterilized to remove possible contamination by hepatitis viruses or HIV. Plasma protein fraction (Plasmanate) is another albumin product that contains 83% albumin and 17% plasma globulins. Albumin is classified as both a blood product and a colloid.

The functions of endogenous albumin are to maintain plasma osmotic pressure and to bind certain substances traveling through the blood, including fatty acids, hormones, enzymes, and a substantial number of drug molecules. Binding to albumin renders these substances inactive until they become unbound.

Normal serum albumin may be administered to restore plasma volume and maintain cardiac output in patients with hypovolemic shock. It may also be administered to restore the level of blood proteins in patients with hypoproteinemia, which occurs with hepatic cirrhosis. Albumin is occasionally administered to bind and remove toxic bilirubin in hemolytic disease of the newborn. It may also offer protection against kernicterus, a toxic accumulation of bilirubin in infants that causes brain injury. It has an immediate onset of action and is available in concentrations of 5% and 25%.

Mechanism of Action: Administered IV, normal serum albumin rapidly increases the osmotic pressure of the blood and causes fluid to move from the tissues to the general circulation.

Pharmacokinetics: Because human albumin is a natural substance, it is not possible to obtain accurate pharmacokinetic values. Endogenous albumin has a half-life of 17 to 19 days.

Adverse Effects: Hypervolemia may occur if the dosage and rate of infusion are not carefully adjusted to the patient's volume status. Signs of fluid overload include headache, dyspnea, rising blood pressure, and pulmonary edema. Normal serum albumin is a natural blood product and the patient may have antibodies to the donor's albumin that cause allergic reactions. Because coagulation factors, antibodies, and most other blood proteins have been removed, such allergic reactions from albumin are rare. Signs of allergy include fever, chills, urticaria, rash, dyspnea, and, possibly, hypotension.

Contraindications/Precautions: The drug is contraindicated in patients with severe anemia or cardiac failure in the presence of normal or increased intravascular volume and in those with known allergy to albumin.

Drug Interactions: There are no clinically significant interactions. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Protein overload may occur if excessive albumin is infused. There is no treatment for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving normal serum albumin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Normal Serum Albumin (Albuminar, Plasbumin, Others)

Other blood products are described in Table 33.2 and include whole blood, packed RBCs, fresh frozen plasma, cryoprecipitate, immune globulins, and platelet infusions.

33.6 Crystalloids are intravenous solutions that closely resemble the composition of extracellular fluid.

Crystalloids are IV solutions that contain electrolytes and other substances in concentrations that closely mimic the body's extracellular fluid. They are used to replace depleted fluids and to promote urine output. Crystalloid solutions are capable of quickly diffusing across membranes, leaving the plasma, and entering the interstitial fluid and ICF. Isotonic, hypotonic, and hypertonic solutions are available. Sodium is the most common crystalloid added to solutions, although some crystalloids contain dextrose, a form of glucose. Common crystalloids used to treat shock include normal saline, lactated Ringer's, Plasma-Lyte, and hypertonic saline. Selected crystalloids are listed in Table 33.3. Infusion of crystalloids will increase the total fluid volume in the body, but the compartment that is most expanded depends on the solute concentration of the fluid administered.

Isotonic crystalloids: Isotonic crystalloids expand the circulating intravascular (plasma) fluid volume, without causing major fluid shifts between compartments. This is because the osmotic pressures of the intravascular and extravascular compartments are equal. Isotonic crystalloids such as normal saline are often used to treat fluid loss due to vomiting, diarrhea, or surgical procedures, especially when blood pressure is low. The isotonic saline solutions may also be used to treat sodium deficiency (hyponatremia) because they contain sodium chloride. Because isotonic crystalloids can rapidly expand circulating blood volume, care must be taken not to cause fluid overload in the patient.

Hypertonic crystalloids: Infusion of hypertonic crystalloids raises the osmolality of the plasma and expands plasma volume by drawing water away from the cells and tissues. These drugs may be used to relieve cellular edema, especially cerebral edema. When patients are dehydrated and have hypertonic plasma, hypertonic solutions match the tonicity of the plasma as it is infused, but the dextrose in the IV solution is subsequently metabolized and the solution becomes hypotonic. This hypotonic solution then causes water to shift into the intracellular space, relieving the dehydration within the cells. Overtreatment with hypertonic crystalloids such as 3% normal saline can lead to excessive expansion of the intravascular (plasma) compartment, fluid overload, and HTN.

Table 33.3 Selected Crystalloid IV Solutions

Drug	Tonicity
normal saline (0.9% NaCl)	Isotonic
hypertonic saline (3% NaCl)	Hypertonic
hypotonic saline (0.45% NaCl)	Hypotonic
lactated Ringer's	Isotonic
Plasma-Lyte 148	Isotonic
Plasma-Lyte 56	Hypotonic
Dextrose Solutions	
5% dextrose in water (D_5W)	Isotonic*
5% dextrose in normal saline	Hypertonic
5% dextrose in 0.2% saline	Isotonic
5% dextrose in lactated Ringer's	Hypertonic
5% dextrose in Plasma-Lyte 56	Hypertonic

*Because dextrose is metabolized quickly, the solution is sometimes considered hypotonic.

Hypotonic crystalloids: Hypotonic crystalloid infusions lower the serum osmolality. This causes water to move out of the plasma to the tissues and cells in the intracellular compartment; thus, these solutions are not plasma volume expanders. Hypotonic crystalloids are indicated for patients with hypernatremia and cellular dehydration. Care must be taken not to cause depletion of the intravascular compartment, which can result in hypotension, or too much expansion of the extracellular compartment, which can cause peripheral edema. Patients who are dehydrated with low blood pressure should be given normal saline; the isotonic saline will expand plasma volume and increase blood pressure while hydrating the patient. Patients who are dehydrated with normal blood pressure should be given a hypotonic solution; this infusion will hydrate cells without expanding plasma volume.

PROTOTYPE DRUG 5% Dextrose in Water (D_5W)

Classification **Therapeutic:** Fluid expander
Pharmacologic: Crystalloid

Therapeutic Effects and Uses: Commonly found in concentrations of 2.5%, 5%, or 10%, dextrose solutions are infused to replace lost water and to enhance

renal function. Being a form of glucose, dextrose provides nutritional value: 1 L of 5% dextrose supplies 170 calories. In addition, water is formed during the metabolism of dextrose, adding to the rehydration of the patient. D_5W is also used as a diluent for mixing other medications for IV delivery. Dextrose 50% is indicated for the emergency treatment of insulin hypoglycemia to restore blood glucose levels.

D_5W is isotonic in the container. When infused, however, the dextrose is quickly metabolized in the body, leaving only water, and the solution becomes hypotonic. Water may then move from the plasma to the intracellular spaces, relieving cellular dehydration. Essentially, the infusion of D_5W has the same effect as administration of water. Because this may result in a lower plasma volume, patients needing fluid replacement for hypovolemia should receive lactated Ringer's or normal saline rather than D_5W.

Dextrose is added to other IV solutions, as shown in Table 33.3. It is also available in other concentrations. In all cases, the dextrose is simply added as a source of calories and nutrition.

Mechanism of Action: There are two forms of glucose in nature: L-glucose and D-glucose. Only D-glucose, also called dextrose, can be used by the human body for energy. If insulin is present, glucose (dextrose) enters cells and is converted into adenosine triphosphate (ATP), CO_2, and water.

Pharmacokinetics: Because dextrose and water are natural substances, it is not possible to obtain accurate pharmacokinetic values.

Adverse Effects: Infusion of too much D_5W may cause fluid overload, thus worsening peripheral edema, pulmonary edema, and heart failure. Hyperglycemia is possible, especially in patients with deficient insulin secretion. Pain may occur at the injection site. As D_5W dilutes the plasma, the concentration of sodium in the plasma may fall, resulting in hyponatremia. Hyponatremia in children is especially dangerous because it can lead to encephalopathy as the brain swells.

Contraindications/Precautions: Caution must be used when using D_5W in patients with heart failure or who are hyperglycemic. Patients with increased intracranial pressure should not receive hypotonic agents such as D_5W because they may worsen this condition. Dextrose is obtained from corn and patients allergic to this food may be hypersensitive to the drug.

Drug Interactions: There are no significant drug interactions with D_5W. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose is uncommon, but diuretics may be indicated in cases of fluid overload.

Nursing Responsibilities: Key nursing implications for patients receiving 5% dextrose in water are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to 5% Dextrose in Water (D5W)

Other crystalloids include Ringer's solution and Plasma-Lyte.

Ringer's and lactated Ringer's: Ringer's solution is named after the pharmacologist Sydney Ringer who created the drug in the mid-1800s. Ringer's solution is an isotonic fluid that contains sodium, chloride, potassium, and calcium ions in concentrations similar to those found in plasma. Lactated Ringer's solution also contains lactate, which serves as a chemical buffer in the blood to prevent acidosis. Lactated Ringer's is also available with 5% dextrose. Ringer's solutions are widely administered IV for fluid resuscitation following hemorrhage caused by trauma, surgery, or burns.

Plasma-Lyte: Plasma-Lyte solutions are electrolyte solutions used to correct volume and electrolyte deficiencies. The solutions also contain buffers such as lactate, acetate, or gluconate, which help to correct or prevent acidosis. Several formulations are available that differ in electrolyte composition and osmolarity. These include Plasma-Lyte-R, Plasma-Lyte-A, Plasma-Lyte 56, and Plasma-Lyte 148.

33.7 Colloids are intravenous solutions containing large molecules that remain in the blood.

Colloids are proteins, starches, or other large molecules that remain in the blood for a long time because they are too large to easily cross the capillary membranes. While circulating, they have the same effect as hypertonic solutions, drawing water molecules from the cells and tissues into the plasma through their ability to increase plasma osmolality and osmotic pressure. These drugs are sometimes called plasma volume expanders. Blood product colloids include normal serum albumin, plasma protein fraction, and serum globulins. The non–blood product colloids are dextran (40, 70, and high molecular weight) and hetastarch (Hespan). These medications are administered to provide life-sustaining support following massive hemorrhage and to treat shock, burns, acute liver failure, and neonatal hemolytic disease. Selected colloid solutions are given in Table 33.4.

PROTOTYPE DRUG **Dextran 40 (Gentran 40, Others)**

Classification **Therapeutic:** Plasma volume expander
Pharmacologic: Colloid

Therapeutic Effects and Uses: Dextran 40 is a synthetic polysaccharide that is too large to pass through

Table 33.4 Selected Colloid IV Solutions

Drug	Tonicity
5% albumin	Isotonic
dextran 40 in D_5W	Isotonic
dextran 40 in normal saline	Isotonic
dextran 70 in normal saline	Isotonic
hetastarch (Hespan) 6% in normal saline	Isotonic
plasma protein fraction	Isotonic

capillary walls. It is similar to dextran 70, except dextran 40 has a lower molecular weight. Given as an IV infusion, it has the capability of doubling plasma volume within a few minutes after administration, although its effects last only about 12 hours. Cardiovascular responses include increased blood pressure, increased cardiac output, and improved venous return to the heart. Indications include fluid replacement for patients experiencing hypovolemic shock due to hemorrhage, surgery, or severe burns. When given for acute shock, it is infused as rapidly as possible until blood volume is restored.

Dextran 40 also reduces platelet adhesiveness and improves blood flow through capillaries by its ability to reduce blood viscosity. These antithrombotic properties have led to its use in preventing deep vein thrombosis and postoperative pulmonary emboli. Dextran, however, is less effective than heparin or low-molecular-weight heparin (LMWH) in preventing thromboembolism (see Chapter 38).

Mechanism of Action: Dextran 40 acts by raising the osmotic pressure of the blood, thereby causing fluid to move from the interstitial spaces of the tissues to the blood. The larger blood volume increases cardiac output, stroke volume, blood pressure, and urinary output. Heart rate and blood viscosity decrease.

Pharmacokinetics:

Route(s)	IV
Absorption	Not absorbed
Distribution	Does not leave the vascular system
Primary metabolism	Unknown
Primary excretion	Renal
Onset of action	Several minutes
Duration of action	12–24 h

Adverse Effects: Vital signs should be monitored continuously during dextran 40 infusions to prevent HTN caused by the plasma volume expansion. Signs of fluid overload include tachycardia, peripheral edema, distended neck veins, dyspnea, or cough. A small percentage of patients are allergic to dextran 40, with urticaria being the most common sign. Anaphylaxis is possible.

Contraindications/Precautions: Dextran 40 is contraindicated in patients with severe chronic kidney disease (CKD) because fluid overload may result. Adequate fluid intake should be ensured in patients with severe dehydration who receive dextran to prevent renal failure due to high urine viscosity. Other contraindications include severe heart failure and hypervolemic disorders.

Drug Interactions: There are no clinically significant interactions. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: For patients with normal renal function, discontinuing the infusion will reduce adverse effects. Patients with CKD may benefit from an osmotic diuretic.

Nursing Responsibilities: Key nursing implications for patients receiving dextran 40 are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Dextran 40 (Gentran 40, Others)

The only solution similar to dextran is hetastarch.

Hetastarch (Hespan): Hetastarch is a complex mixture of a nonprotein polymer of the starch amylopectin. It is a synthetic colloid with properties similar to those of 5% albumin, but with an extended duration of action. Hetastarch has a half-life of about 17 days and provides volume expansion for 24 to 36 hours. It is indicated for the treatment and prophylaxis of shock and acute edematous conditions. Hetastarch provides the same physiologic actions as albumin. This drug is pregnancy category C.

Physiology of Electrolytes

33.8 Electrolytes are charged substances that are essential to homeostasis.

Minerals are inorganic substances needed in very small amounts to maintain homeostasis (see Chapter 61). Minerals are held together by ionic bonds and dissociate or ionize when placed in water. The resulting ions have positive or negative charges and are able to conduct electricity, hence the name **electrolyte**. Positively charged electrolytes are called cations; those with a negative charge are anions. Electrolyte levels are measured in units of milliequivalents per liter (mEq/L).

Electrolytes are essential to many body functions, including nerve conduction, membrane permeability, muscle contraction, water balance, and bone growth and remodeling. Levels of electrolytes in body fluids are maintained within very narrow ranges, primarily by the

Table 33.5 Electrolyte Imbalances

Ion	Condition	Abnormal Serum Value (mEq/L)	Supportive Treatment*
Calcium	Hypercalcemia	Greater than 11	Hypotonic fluid or calcitonin
	Hypocalcemia	Less than 4	Calcium supplements or vitamin D
Chloride	Hyperchloremia	Greater than 112	Hypotonic fluid
	Hypochloremia	Less than 95	Hypertonic salt solution
Magnesium	Hypermagnesemia	Greater than 4	Hypotonic fluid
	Hypomagnesemia	Less than 0.8	Magnesium supplements
Phosphate	Hyperphosphatemia	Greater than 6	Dietary phosphate restriction
	Hypophosphatemia	Less than 1	Phosphate supplements
Potassium	Hyperkalemia	Greater than 5	Hypotonic fluid, buffers, or dietary restriction
	Hypokalemia	Less than 3.5	Potassium supplements
Sodium	Hypernatremia	Greater than 145	Hypotonic fluid or dietary restriction
	Hyponatremia	Less than 135	Hypertonic salt solution or sodium supplement

*For all electrolyte imbalances, the primary therapeutic goal is to identify and correct the cause of the imbalance.

kidneys and gastrointestinal (GI) tract. Because electrolytes are lost due to normal excretory functions, they must be replaced by adequate intake; otherwise electrolyte imbalances will result, as shown in Table 33.5. Although imbalances can occur with any ion, sodium, potassium, and calcium are of greatest importance. The role of calcium in bone homeostasis is presented in Chapter 72.

An electrolyte imbalance is a sign of an underlying medical condition that needs attention. Imbalances are associated with a wide variety of acute and chronic disorders, with CKD being the most common cause. In some cases, drug therapy itself can cause the electrolyte imbalance. A classic example is the diuretic furosemide (Lasix), which can cause serious potassium depletion. In all cases, the therapeutic goal is to quickly correct the electrolyte imbalance while the underlying condition is being diagnosed and treated. Treatments for electrolyte imbalances depend on the severity of the problem and range from simple changes in dietary intake to rapid electrolyte infusions. In acute cases, serum electrolyte levels must be carefully monitored to prevent imbalances in the opposite direction; levels can change rapidly from hypoconcentrations to hyperconcentrations.

Pharmacotherapy of Electrolyte Imbalances

33.9 Sodium balance is closely associated with water balance.

Sodium is the major electrolyte in extracellular fluid. Due to its central roles in neuromuscular physiology, acid–base balance, and overall fluid distribution, sodium imbalances can have serious consequences. Although definite sodium monitors or sensors have yet to be discovered in the body, the regulation of sodium balance is well understood. The normal range of serum sodium is 135 to 145 mEq/L of plasma.

Sodium balance and water balance are intimately connected. As sodium levels increase in a body fluid, solute particles accumulate and osmolality increases. Water will move toward this area of relatively high osmolality. In simplest terms, water travels toward or with sodium. The physiologic consequences of this relationship cannot be overstated: As the sodium and water content of plasma increases, so do blood volume and blood pressure. Thus, sodium movement provides an important link between water retention, blood volume, and blood pressure.

In healthy individuals, sodium intake is equal to sodium output, which is regulated by the kidneys. High levels of aldosterone secreted by the adrenal cortex promote sodium and water retention by the kidneys as well as potassium excretion. Inhibition of aldosterone promotes sodium and water excretion. When a patient ingests high amounts of sodium, aldosterone secretion decreases, thus sending the excess sodium to the urine. This relationship is illustrated in Figure 33.2.

Hypernatremia: Sodium excess, or **hypernatremia**, occurs when the serum sodium level rises above 145 mEq/L. The most common cause of hypernatremia is decreased sodium excretion due to kidney pathology. Hypernatremia may also be caused by excessive intake of sodium, either through dietary consumption or by overtreatment with IV fluids containing sodium chloride or sodium bicarbonate. Overconsumption of table salt (NaCl) or processed foods with high sodium content will quickly exceed the daily amount needed by the body. Drinking too little water can cause hypernatremia due to the development of hypertonic plasma. Another cause of hypernatremia is high net water losses, such as that occurring from watery diarrhea, fever, or burns. High doses of glucocorticoids or estrogens also promote sodium retention.

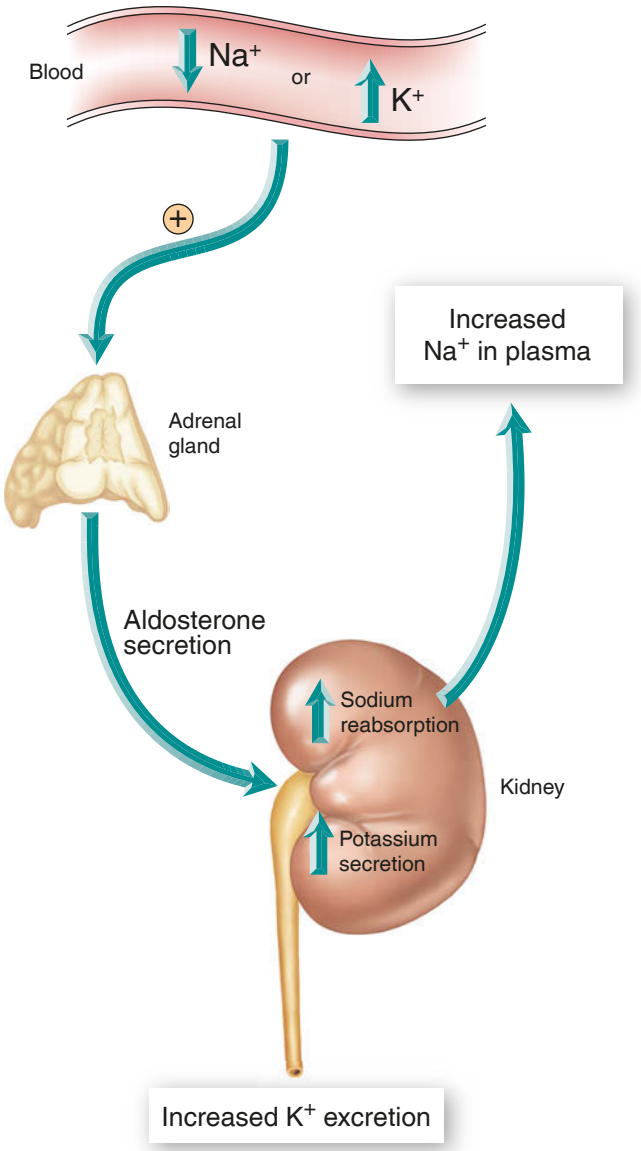

Figure 33.2 Renal regulation of sodium and potassium balance.

A high serum sodium level increases the osmolality of the plasma, making the intravascular space hypertonic and drawing fluid from interstitial spaces and cells, thus causing cellular dehydration. Ordinarily, a small increase in serum sodium will trigger thirst. Other manifestations of hypernatremia include fatigue, weakness, muscle twitching, convulsions, altered mental status, and a decreased level of consciousness (LOC). For minor hypernatremia, a low-salt diet combined with adequate water intake may be effective in returning serum sodium to normal levels. In patients with acute hypernatremia, however, the treatment goal is to rapidly return the osmolality of the plasma to normal. If the patient is hypovolemic, infusing hypotonic fluids such as 5% dextrose or 0.45% NaCl will increase plasma volume and at the same time reduce osmolality by diluting the plasma. For the patient who is hypervolemic, diuretics may be used to remove sodium and excess water from the body.

Hyponatremia: **Hyponatremia** is the most common electrolyte abnormality in hospitalized patients and is defined as a serum sodium level of less than 135 mEq/L. Hyponatremia may occur through excessive dilution of the plasma caused by administration of hypotonic IV solutions or by high ADH secretion. Hyponatremia may also result from increased sodium loss due to disorders of the skin, GI tract, or kidneys. Significant loss of sodium by the skin may occur in burn patients and in those experiencing excessive sweating or prolonged fever. GI sodium losses may occur from vomiting, diarrhea, or GI suctioning, and renal sodium loss may occur with diuretic use and in certain advanced kidney disorders.

Early symptoms of hyponatremia include nausea, vomiting, anorexia, and abdominal cramping. Later signs include altered neurologic function such as confusion, lethargy, convulsions, coma, and muscle twitching or tremors. Hyponatremia caused by excessive dilution is treated with loop diuretics, which will remove the fluid overload that caused the hyponatremia (see Chapter 32). Hyponatremia caused by sodium loss may be treated with the administration of oral or parenteral sodium chloride, or with IV fluids containing salt, such as normal saline or lactated Ringer's solution.

In 2009, tolvaptan (Samsca) was approved to quickly raise serum sodium levels in hospitalized patients experiencing symptoms of hyponatremia. Tolvaptan is a vasopressin (antidiuretic hormone) antagonist that enhances water excretion. As the amount of water in the blood is reduced, the serum sodium concentration is increased. Tolvaptan carries several black box warnings. Therapy with the drug should only be conducted in a hospital where serum sodium levels can be monitored closely, because too rapid correction of hyponatremia can result in seizures, coma, and death. In patients with advanced liver disease, severe malnutrition, or alcoholism, hyponatremia should be corrected especially slowly. Treatment should be limited to 30 days due to the risk for liver injury.

CONNECTIONS: Community-Oriented Practice

Maintaining Fluid Balance During Exercise

Hyponatremia from excessive fluid intake has been noted as a growing problem in athletes, particularly novice athletes who may have heard that they need to "keep drinking" to maintain hydration. Many sports drinks contain some electrolytes but are also high in fructose or other sugars. This creates a hypertonic solution that may paradoxically cause increased water loss. Unless exercise is extreme or prolonged, athletes, especially children, should be encouraged to drink when thirsty and maintain urine at a color of clear yellow, not dark yellow or colorless. Adequate fluid intake to match thirst will help ensure normal hydration and sodium levels and prevent complications such as exercise-associated hyponatremia (EAH).

PROTOTYPE DRUG **Sodium Chloride (NaCl)**

Classification **Therapeutic:** Drug for hyponatremia
Pharmacologic: Electrolyte, sodium supplement

Therapeutic Effects and Uses: Sodium chloride may be administered for hyponatremia when serum levels fall below 135 mEq/L. The drug is available in several concentrations; the decision on which NaCl concentration to administer is driven by the severity of the sodium deficiency. Normal saline consists of 0.9% NaCl and is used to treat mild hyponatremia. When serum sodium falls below 115 mEq/L, a highly concentrated 3% NaCl solution may be infused. Other concentrations include 0.45% and 0.22%, and both hypotonic and isotonic solutions are available. For less severe hyponatremia, 1-g tablets are available.

Ophthalmic solutions of NaCl may be used to treat corneal edema, and an over-the-counter (OTC) nasal spray is available to relieve dry, inflamed nasal membranes. In conjunction with oxytocin, 20% NaCl may be used as an abortifacient late in pregnancy when instilled into the amniotic sac.

Mechanism of Action: Sodium chloride is a replacement solution for lost sodium.

Pharmacokinetics: Because sodium ions form natural electrolytes, it is not possible to obtain accurate pharmacokinetic values. The sodium ions in the drug are widely distributed and excreted by the kidneys in the same manner as endogenous sodium ions.

Adverse Effects: Patients receiving NaCl infusions must be monitored frequently to avoid symptoms of hypernatremia, which include lethargy, confusion, muscle tremor or rigidity, hypotension, and restlessness. Because some of these symptoms are also common to hyponatremia, periodic laboratory assessments must be taken to be certain that sodium values are moving toward the normal range. When infusing 3% NaCl solutions, the nurse should continuously check for signs of pulmonary edema.

Contraindications/Precautions: This drug should not be administered to patients with hypernatremia, heart failure, or impaired renal function.

Drug Interactions: There are no clinically significant drug interactions. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: There is no specific treatment for overdose. If excess fluid accumulation has occurred, diuretics may be administered to remove excess sodium ion and water to reduce pulmonary or peripheral edema.

Nursing Responsibilities: Key nursing implications for patients receiving sodium chloride are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Sodium Chloride (NaCl)

There are no drugs similar to sodium chloride.

33.10 Potassium imbalances must be quickly corrected to prevent serious cardiac consequences.

Potassium is the most abundant intracellular cation; 98% of the potassium present in the body is found inside cells, with the majority found in skeletal muscle. Potassium serves critical roles in muscular contraction and the conduction of nerve impulses.

To prevent imbalances, adequate dietary intake of potassium must be carefully balanced to potassium excretion. Patients with normal diets consume plenty of potassium for bodily functions because the mineral is abundant in fruits, vegetables, and meats.

Insulin is a key hormone for the regulation of potassium homeostasis. The uptake of potassium ion into cells is mediated by insulin. As serum potassium levels rise, the pancreas secretes additional insulin, which causes the ion to move out of the plasma and into cells, thus preventing hyperkalemia. In a typical feedback loop, as serum potassium levels fall, insulin secretion is diminished.

Acid–base imbalances may also affect potassium homeostasis. As the blood becomes acidic, the body attempts to raise plasma pH by pumping hydrogen ions (H^+) into cells. To maintain electrical neutrality, each H^+ entering the cell is exchanged for a K^+ leaving the cell. This can raise the serum potassium level, resulting in hyperkalemia. This is sometimes called a false hyperkalemia because the total body potassium is not actually increased; it has just shifted from intracellular to extracellular spaces.

Potassium ion is freely filtered at the glomerulus but is entirely reabsorbed as it travels along the kidney tubule. In the distal tubule, however, potassium is secreted back into the renal tubule and exits in the urine. Like sodium, potassium excretion is influenced by the actions of aldosterone on the kidney. In fact, the renal excretion of sodium and potassium ions is closely linked. For every sodium ion that is reabsorbed, one potassium ion is secreted into the renal tubules.

Potassium levels must be maintained within narrow limits. Both hyper- and hypokalemia are associated with fatal dysrhythmias and serious neuromuscular disorders. Because over 98% of potassium is intracellular, serum potassium may not be an accurate reflection of total body

potassium. Normal adult values for serum potassium range from 3.5 to 5 mEq/L.

Hyperkalemia: **Hyperkalemia** occurs when the serum potassium level rises above 5 mEq/L. This condition may be caused by excessive consumption of potassium-rich foods or dietary supplements, particularly when patients are taking potassium-sparing diuretics such as spironolactone (see Chapter 32). In fact, overtreatment with potassium supplements is the most common cause of hyperkalemia. Excess potassium may also accumulate when renal excretion is diminished due to kidney pathology. The most serious consequences of hyperkalemia are related to cardiac function: dysrhythmias and heart block. Other symptoms are muscle twitching, fatigue, paresthesias, dyspnea, cramping, and diarrhea. Hyperkalemia is much less common than hypokalemia.

In mild cases of hyperkalemia, potassium levels may be returned to normal by restricting primary dietary sources of potassium such as bananas, citrus and dried fruits, peanut butter, broccoli, and green leafy vegetables. All potassium supplements and the use of salt substitutes containing potassium should be discontinued. If the patient is taking a potassium-sparing diuretic, the dose must be lowered, or a thiazide or loop diuretic substituted.

Several options are available for patients with severe hyperkalemia. Administration of the diuretic furosemide (Lasix) can significantly increase the urinary excretion of potassium within 5 to 15 minutes. Administering glucose or dextrose concurrently with insulin temporarily lowers serum potassium levels by causing potassium to leave the extracellular fluid and enter cells. In all patients who are symptomatic, calcium gluconate or calcium chloride is administered to prevent or treat potassium-induced cardiotoxicity. Sodium bicarbonate is sometimes infused to correct any acidosis that may be concurrent with the hyperkalemia.

Excess potassium may also be eliminated from the body by giving polystyrene sulfonate (Kayexalate) orally or rectally. This drug, which is not absorbed, exchanges Na^+ for K^+ as it travels through the intestine. The onset of action is 1 hour, and the dose may be repeated every 4 hours as needed. The drug is given concurrently with a laxative such as sorbitol to promote rapid evacuation of the potassium.

Patiromer (Veltassa) was approved in 2015 for hyperkalemia. Like polystyrene sulfonate, it binds potassium in the GI tract and eliminates it in the feces. This oral drug is slow-acting and is not for emergency control of hyperkalemia.

Hypokalemia: **Hypokalemia** is one of the most common electrolyte imbalances and occurs when the serum potassium level falls below 3.5 mEq/L. The most frequent cause of hypokalemia is pharmacotherapy with loop and thiazide diuretics. In addition, strenuous muscular activity and severe vomiting or diarrhea can lead to significant potassium loss. Because the body does not have large stores of potassium, adequate daily dietary intake is necessary. Neurons and muscle fibers are most sensitive to potassium loss, and muscle weakness, lethargy, anorexia, dysrhythmias, and cardiac arrest are possible consequences.

Mild hypokalemia is treated by increasing the dietary intake of potassium-rich foods. The foods highest in potassium content include dried fruit, nuts, molasses, avocados, lima beans, and bran cereals. If increasing dietary intake is not possible, a large number of potassium products are available for oral supplementation. The most common supplements are the chloride salts, because these supply both potassium and chloride, which are lost during diuretic therapy. Liquid preparations are very effective, although many must be diluted with water or fruit juices prior to administration. Extended release (K-Dur 20, Slow-K, Micro-K) and powders (Klor-Con) are also available.

Severe hypokalemia may require parenteral potassium supplements. Caution must always be used when using IV potassium because rapid administration of the drug can be fatal, especially for patients with CKD. Cardiac function should be closely monitored during IV potassium therapy.

PROTOTYPE DRUG Potassium Chloride (KCl)

Classification **Therapeutic:** Drug for hypokalemia
Pharmacologic: Electrolyte, potassium supplement

Therapeutic Effects and Uses: Potassium chloride is a preferred drug for preventing or treating hypokalemia because potassium and chloride depletion usually occur concurrently. It is also used to treat mild forms of alkalosis. Oral formulations of potassium chloride include tablets, powders, and liquids, usually heavily flavored due to its unpleasant taste. Because potassium supplements can cause peptic ulcers, the drug should be diluted with plenty of water. When given IV, potassium must be administered slowly because bolus injections can overload the heart and cause cardiac arrest. Because pharmacotherapy with loop or thiazide diuretics is the most common cause of potassium depletion, patients taking these drugs are usually prescribed PO potassium supplements to prevent hypokalemia.

Mechanism of Action: Potassium chloride is a replacement solution for lost potassium.

Pharmacokinetics: Because potassium chloride is a natural electrolyte, it is not possible to obtain accurate pharmacokinetic values. The potassium ions in the drug are widely distributed and excreted by the kidneys in the same manner as endogenous potassium ions.

Adverse Effects: Nausea, vomiting, diarrhea, and abdominal pain are common, because potassium chloride irritates the GI mucosa. The drug may be taken with

meals or antacids to lessen gastric distress. The most serious adverse effects of potassium chloride are related to the possible accumulation of excess potassium. Hyperkalemia may occur if the patient takes potassium supplements concurrently with potassium-sparing diuretics. Because the kidneys perform over 90% of the body's potassium excretion functions, reduced renal function can rapidly lead to hyperkalemia, particularly in patients taking potassium supplements.

Contraindications/Precautions: Potassium chloride is contraindicated in patients with hyperkalemia, systemic acidosis, severe dehydration, extensive tissue breakdown as in severe burns, or adrenal insufficiency. Oral potassium supplements are contraindicated in any condition for which transit through the GI tract is delayed because prolonged contact may damage the GI mucosa. The drug should be used with extreme caution in patients with CKD or acute renal failure because the drug may accumulate to high levels.

Drug Interactions: Potassium supplements should not be administered to patients who are taking potassium-sparing diuretics because hyperkalemia may result. Angiotensin-converting enzyme (ACE) inhibitors prevent aldosterone secretion and cause potassium retention, thus increasing the risk for hyperkalemia if administered with potassium supplements. Drugs that slow GI transit time, such as anticholinergics, may increase the GI toxicity of potassium supplements. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Potassium-sparing diuretics and all foods and medications containing potassium should be withheld. Treatment includes IV administration of 10% dextrose solution containing 10 to 20 units of crystalline insulin. Sodium bicarbonate may be infused to correct acidosis. Polystyrene sulfonate may be administered to enhance potassium elimination.

Nursing Responsibilities: Key nursing implications for patients receiving potassium chloride are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Potassium Chloride (KCl)

Other potassium drugs include acetate, bicarbonate, citrate, and gluconate salts. Potassium acetate is used as an IV alternative to potassium chloride. Potassium bicarbonate supplies bicarbonate ion, which is alkaline and may be useful in treating acidosis. Potassium citrate makes the urine less acidic and is primarily used to reduce the formation of kidney stones. Potassium gluconate is commonly available in tablet form and dissociates to potassium ion and gluconate ion, a form of glucose.

33.11 Magnesium imbalances significantly affect cardiovascular and neuromuscular function.

Magnesium is the second most abundant intracellular cation and, like potassium, it is essential for proper neuromuscular function. Magnesium also serves a metabolic role in activating certain enzymes in the breakdown of carbohydrates and proteins; it is a cofactor in over 300 biochemical reactions. Patients with disorders of magnesium homeostasis generally present with cardiovascular and neuromuscular symptoms. Because the majority of magnesium is found in bone, serum magnesium levels are not accurate indicators of total body magnesium.

Magnesium levels are primarily controlled by the kidney. The ion is freely filtered and reabsorbed in the loop of Henle and loop diuretics such as furosemide can cause significant magnesium loss. Magnesium imbalances may occur in individuals with CKD. Magnesium is absorbed by the small intestine and small amounts are secreted in intestinal fluid.

Hypomagnesemia: Because it produces few symptoms until serum levels fall below 1 mEq/L, hypomagnesemia is sometimes called the most common undiagnosed electrolyte abnormality. Although the overall incidence for magnesium deficiency is 6% to 12%, the majority of critically ill patients present with this condition. Renal causes of hypomagnesemia include kidney failure and therapy with loop diuretics. GI causes include malabsorption disorders and loss of significant amounts of body fluids due to diarrhea, chronic laxative abuse, or nasogastric suctioning. Hypomagnesemia may also present in people with alcoholism and in those receiving prolonged parenteral feeding with magnesium-free solutions. Patients may experience general weakness, dysrhythmias, HTN, loss of deep tendon reflexes, and respiratory depression—signs and symptoms that are sometimes mistaken for hypokalemia. Additional signs include muscle twitches, tetany, or seizures. Pharmacotherapy with magnesium sulfate can quickly reverse symptoms of hypomagnesemia (see prototype feature).

Hypermagnesemia: Advanced CKD is the only major cause of hypermagnesemia, although overtreatment with magnesium supplements may also lead to excessive serum magnesium levels. Clinical signs include central nervous system (CNS) depression, respiratory depression, hypotension, dysrhythmias, bradycardia, complete heart block, and coma. Infusions of calcium salts will immediately reverse the neuromuscular and cardiovascular signs. If the magnesium elevation is minor, treatment with furosemide to increase urinary excretion may be sufficient to reverse the hypermagnesemia.

CONNECTIONS: Patient Safety

Control of Concentrated Electrolyte Solutions

While working with a clinical nurse preceptor, a student nurse asks the preceptor, "I've noticed that we have to wait for pharmacy to deliver some medications and IVs. For example, we're supposed to hang that IV with potassium for the patient in room 318. Wouldn't it just be faster if nurses could mix the IV themselves on the unit?" How should the nurse respond?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

PROTOTYPE DRUG **Magnesium Sulfate ($MgSO_4$)**

Classification **Therapeutic:** Drug for hypomagnesemia and seizures associated with eclampsia
Pharmacologic: Electrolyte, magnesium supplement

Therapeutic Effects and Uses: Magnesium supplements are available for both PO and parenteral routes. Severe hypomagnesemia can be rapidly reversed by the administration of intramuscular (IM) or IV magnesium sulfate. Because IM preparations produce significant pain at the injection site, severe cases of hypomagnesemia are normally treated using the IV route. Parenteral formulations include 4%, 8%, 12.5%, and 50% solutions. After administration, magnesium sulfate is distributed throughout the body, and therapeutic effects are observed within 30 to 60 minutes. Plasma magnesium levels should be monitored frequently during therapy.

Oral forms of magnesium sulfate (Epsom salt) are used as cathartics, when complete evacuation of the colon is desired. Epsom salt is sometimes used in bath water to ease aching muscles, although the scientific basis for this use is lacking. Its action as a CNS depressant has led to its occasional use as an anticonvulsant in patients with preeclampsia or eclampsia (see Chapter 22). Magnesium sulfate has been used off-label to slow uterine contractions during preterm labor (see Chapter 69).

Mechanism of Action: Magnesium sulfate is a replacement solution for lost magnesium.

Pharmacokinetics:

Route(s)	PO, IM, IV
Absorption	Not absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	PO: 1–2 h; IM: 1 h; IV: immediate
Duration of action	PO and IM: 3–4 h; IV: 30 min; half-life: unknown

Adverse Effects: Patients receiving IV infusions of magnesium sulfate require careful observation to prevent toxicity. Early signs of magnesium overdose include flushing of the skin, sedation, confusion, intense thirst, and muscle weakness. Extreme levels cause neuromuscular blockade with resultant respiratory paralysis, heart block, and circulatory collapse. Because of these potentially fatal adverse effects, the use of magnesium sulfate is restricted to patients with severe magnesium deficiency. Mild to moderate hypomagnesemia is treated with oral forms of magnesium such as magnesium gluconate or magnesium hydroxide. Oral magnesium sulfate often causes diarrhea.

Contraindications/Precautions: Magnesium is contraindicated in patients with serious cardiac disease. Oral administration is contraindicated in those with undiagnosed abdominal pain, intestinal obstruction, or fecal impaction. The drug should be used cautiously in patients with CKD because the drug may rapidly rise to toxic levels.

Drug Interactions: Use with neuromuscular blockers may increase respiratory depression and apnea. Because magnesium sulfate has CNS depression effects, patients receiving other CNS depressants may experience increased sedation. **Herbal/Food:** Magnesium salts may decrease the absorption of certain anti-infectives such as tetracycline.

Pregnancy: Category A.

Treatment of Overdose: Serious respiratory and cardiac suppression may result from overdose. Calcium gluconate or gluceptate may be administered IV as an antidote.

Nursing Responsibilities: Key nursing implications for patients receiving magnesium sulfate are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Magnesium Sulfate ($MgSO_4$)

Several oral magnesium salts are available OTC. Magnesium citrate (citrate of magnesia) and magnesium hydroxide (milk of magnesia) are classified as laxatives or cathartics. Magnesium oxide (Mag-Ox) is an antacid, and magnesium salicylate (Doan's Pills) is used as an analgesic.

PharmFACT

Although the recommended dietary allowance for magnesium is 420 mg/day in men and 320 mg/day in women, certain patients need higher levels to maintain health. These include patients with Crohn's disease or poorly controlled diabetes, pregnant or lactating women, older adults, and patients with alcoholism (National Institutes of Health, Office of Dietary Supplements, 2016).

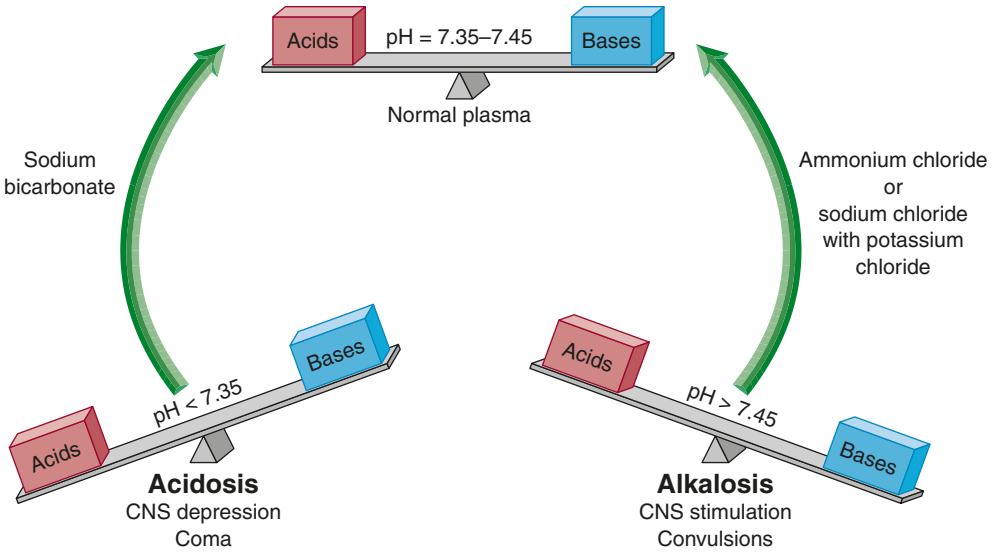

Figure 33.3 Acid–base imbalances.

Pharmacotherapy of Acid–Base Imbalances

33.12 The pH of body fluids must be maintained between very narrow limits.

The degree of acidity or alkalinity of a solution is measured by its pH. A pH of 7.0 is defined as neutral, above 7.0 as basic or alkaline, and below 7.0 as acidic. To maintain homeostasis, the pH of plasma and most body fluids must be kept within the narrow range of 7.35 to 7.45 because nearly all proteins and enzymes in the body function optimally within this range. A few enzymes, most notably those in the digestive tract, require pH values outside the 7.35 to 7.45 range to function properly.

The body generates significant amounts of acids during normal metabolic processes. Without an effective means of neutralizing these metabolic acids, the overall pH of body fluids would quickly fall below the normal range. **Buffers** are chemicals that help maintain normal body pH by neutralizing strong acids and bases. The two primary buffers in the body are bicarbonate ions and phosphate ions.

The body uses two mechanisms to remove acid. The acidic carbon dioxide (CO_2) produced during body metabolism is efficiently removed by the lungs during exhalation. The kidneys remove excess acid in the form of hydrogen ion (H^+) by excreting it in the urine. If retained in the body, either CO_2 or H^+ will lower body pH. Normal acid–base balance is maintained by the lungs and kidneys. Impairment of these organs commonly leads to change in pH.

Acidosis (excess acid) and alkalosis (excess base) are not diseases but are symptoms of an underlying medical disorder. Acidic drugs and basic drugs are administered to rapidly correct pH imbalances in body fluids, supporting the patient's vital functions while the underlying disease is being treated. The correction of acid–base imbalance is illustrated in Figure 33.3.

33.13 The pharmacotherapy of acidosis includes the administration of alkaline drugs.

Acidosis occurs when the pH of the plasma falls below 7.35, which is confirmed by measuring arterial pH, partial pressure of carbon dioxide (P_{CO_2}), and plasma bicarbonate levels. For proper pharmacotherapy, the diagnosis must differentiate between respiratory etiology and metabolic (renal) etiology. Occasionally, the cause has mixed respiratory and metabolic components.

The most profound symptoms of acidosis affect the CNS and include lethargy, confusion, and CNS depression leading to coma. A deep, rapid respiration rate indicates an attempt by the lungs to rid the body of excess acid. Common causes of acidosis are shown in Table 33.6.

In patients with acidosis, the therapeutic goal is to quickly reverse the adverse effects caused by excess acids in the blood. Mild acidosis may be treated with oral bicarbonate or citrate salts or other basic substances. For acute acidosis the preferred treatment is to administer infusions of sodium bicarbonate. Bicarbonate ion is a base that can quickly neutralize acids in the blood and other body fluids. The patient must be carefully monitored during infusions because this drug can overcorrect the acidosis, causing blood pH to turn alkaline. Sodium citrate, sodium lactate, and sodium acetate are alternative alkaline drugs that may be used in place of bicarbonate.

Alkalinizing drugs are also used to aid in the renal excretion of toxic substances through a phenomenon called **ion trapping**. Whenever a large pH gradient exists across a

Table 33.6 Causes of Acidosis and Alkalosis

Acidosis	Alkalosis
Respiratory Origins of Acidosis	**Respiratory Origin of Alkalosis**
Hypoventilation or shallow breathing Airway constriction Damage to respiratory center in medulla	Hyperventilation due to asthma, anxiety, or high altitude
Metabolic Origins of Acidosis	**Metabolic Origins of Alkalosis**
Severe diarrhea Kidney failure Diabetes mellitus Excess alcohol ingestion Starvation	Constipation for prolonged periods Ingestion of excess sodium bicarbonate Diuretics that cause potassium depletion Severe vomiting

membrane, drug molecules will accumulate on the side where the opportunity for ionization is greatest. Recall from Chapter 3 that acids ionize in a basic environment; bases ionize in acidic solutions. The infusion of an alkalinizing drug will create an alkaline filtrate in the kidney tubule, a perfect environment for ionization of an acidic drug like aspirin. Rather than being absorbed back into the body, the ionized aspirin remains trapped in the filtrate and is excreted in the urine. Thus, through ion trapping, the alkalinizing drug was able to move aspirin from the blood to the urine.

PROTOTYPE DRUG Sodium Bicarbonate

Classification **Therapeutic:** Drug to treat acidosis or bicarbonate deficiency
Pharmacologic: Electrolyte, sodium, and bicarbonate supplement

Therapeutic Effects and Uses: Sodium bicarbonate is a preferred drug for correcting metabolic acidosis. After dissociation, the bicarbonate ion directly raises the pH of body fluids. Sodium bicarbonate may be given PO if acidosis is mild, or IV in cases of acute disease. IV concentrations range from 4.2% to 8.4%. Although sodium bicarbonate also neutralizes gastric acid, it is rarely used to treat peptic ulcers due to its tendency to cause uncomfortable gastric distention. The PO form of sodium bicarbonate is commonly known as baking soda.

Sodium bicarbonate may also be used to alkalinize the urine to speed the excretion of acidic medications such as aspirin and phenobarbital and as adjunctive therapy for certain chemotherapeutic drugs such as methotrexate. Sodium bicarbonate is also used in individuals with CKD to neutralize the metabolic acidosis that occurs when the kidneys cannot excrete hydrogen ion. When IV sodium bicarbonate is given, it causes the urine to become more alkaline. Less acid is reabsorbed, so more acid and acidic medicine are excreted. This process is known as ion trapping.

Mechanism of Action: The bicarbonate ion in sodium bicarbonate buffers excess acid (H^+) to raise the pH of body fluids.

Pharmacokinetics:

Route(s)	IV, PO
Absorption	Rapidly absorbed
Distribution	Widely distributed in body fluids
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	PO: 15 min; IV: immediate
Duration of action	PO: 1–3 h; IV: 8–10 min

Adverse Effects: Most of the adverse effects of sodium bicarbonate therapy are the result of metabolic alkalosis created by receiving too much bicarbonate ion. Symptoms may include confusion, irritability, slow respiration rate, and vomiting. Discontinuing the sodium bicarbonate infusion often reverses these symptoms; however, potassium chloride or ammonium chloride may be administered to reverse acute alkalosis. During sodium bicarbonate infusions, serum electrolytes should be carefully monitored because sodium levels may lead to hypernatremia and fluid retention. In addition, high levels of bicarbonate ion passing through the kidney tubules increase potassium secretion, which could lead to hypokalemia.

Contraindications/Precautions: Patients who are vomiting, have severe diarrhea, or have continuous GI suctioning will lose acid and chloride and may be in a state of metabolic alkalosis; therefore, they should not receive sodium bicarbonate because it may worsen alkalosis. Due to the sodium content of this drug, it should be used cautiously in patients with cardiac disease, HTN, or CKD.

Drug Interactions: Sodium bicarbonate may decrease the absorption of ketoconazole and may decrease elimination of dextroamphetamine, ephedrine, pseudoephedrine, and quinidine. The elimination of lithium, salicylates, and tetracyclines may be increased. **Herbal/Food:** Chronic use with milk or calcium supplements may cause milk-alkali syndrome, a condition characterized by serious hypercalcemia and possible kidney failure.

Pregnancy: Category C.

Treatment of Overdose: Overdose results in metabolic alkalosis, which is treated by administering acidic drugs (see Section 33.14).

Nursing Responsibilities: Key nursing implications for patients receiving sodium bicarbonate are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Sodium Bicarbonate

There are no drugs similar to sodium bicarbonate.

33.14 The pharmacotherapy of alkalosis includes the administration of acidic drugs.

At plasma pH values above 7.45, **alkalosis** develops. Mortality can reach as high as 80% if the pH rises above 7.65. Like acidosis, alkalosis may have either respiratory or metabolic causes, as shown in Table 33.6. Also like acidosis, the CNS is greatly affected. Symptoms of CNS stimulation occur and include nervousness, hyperactive reflexes, and convulsions. In metabolic alkalosis, slow, shallow breathing indicates that the body is attempting to compensate by retaining acid and lowering internal pH. Life-threatening dysrhythmias are the most serious adverse effects of alkalosis.

In mild cases, alkalosis may be corrected by administering sodium chloride combined with potassium chloride. This combination increases the renal excretion of bicarbonate ion, which indirectly increases the acidity of the blood. More severe alkalosis may be treated with infusions of an acidic drug such as ammonium chloride or hydrochloric acid.

PROTOTYPE DRUG **Ammonium Chloride**

Classification **Therapeutic:** Drug for treating metabolic alkalosis and hypochloremia
Pharmacologic: Acidic drug

Therapeutic Effects and Uses: Ammonium chloride is an acidic substance that has been available as a drug to treat metabolic alkalosis for over 80 years. Ammonium chloride acidifies the urine, which is beneficial in treating certain urinary tract infections. Historically, it has been used as a mild diuretic, though safer and more effective agents have made its use obsolete. By acidifying the urine, ammonium chloride promotes the excretion of alkaline drugs such as amphetamines through ion trapping. Oral and IV forms are available; when given for alkalosis, the IV route is preferred. Because of the potential for causing acidosis, injection-site reactions, and ammonia toxicity, the drug is infused slowly.

Mechanism of Action: During the hepatic conversion of ammonium chloride to urea, Cl^- and H^+ are formed. The H^+ combines with bicarbonate to form the weak acid carbonic acid, which dissociates to water and carbon dioxide. By removing bicarbonate, ammonium chloride decreases the pH of body fluids. The chloride ion also combines with bases to reduce the alkalinity of extracellular fluids.

Pharmacokinetics:

Route(s)	IV, PO
Absorption	Rapidly absorbed
Distribution	Unknown
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Unknown
Duration of action	Unknown

Adverse Effects: Aggressive treatment with ammonium chloride can cause acidosis. Characteristic symptoms of acidosis include CNS depression, drowsiness, confusion, and coma. Periods of CNS excitement may alternate with coma. Oral forms of the drug are irritating to the gastric mucosa and may cause nausea and vomiting.

Contraindications/Precautions: Ammonium chloride should not be administered to patients with serious hepatic impairment or severe CKD because the drug will accumulate to toxic levels. It should not be administered to patients with either metabolic or respiratory acidosis.

Drug Interactions: Ammonium chloride may cause crystalluria when taken with aminosalicylic acid. Antacids should not be administered concurrently because they are alkaline and will antagonize the acidifying effects of ammonium chloride. Ammonium chloride reduces levels of amphetamines, flecainide, mexiletine, methadone, ephedrine, and pseudoephedrine. Urinary excretion of sulfonylureas and salicylates is decreased. Serum magnesium values may decrease. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Overdose results in metabolic acidosis, which is treated by administering alkaline drugs (see Section 33.13).

Nursing Responsibilities: Key nursing implications for patients receiving ammonium chloride are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances.

Drugs Similar to Ammonium Chloride

The only similar drug is hydrochloric acid.

Hydrochloric acid: Hydrochloric acid may be administered IV in severe cases of metabolic acidosis. A central venous catheter must be used to administer the drug. Hydrochloric acid is only used when sodium or potassium chloride cannot be administered due to volume overload or advanced CKD. This drug can cause severe tissue necrosis if it extravasates into the tissues.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular (including HTN, myocardial infarction [MI]), neurologic (including stroke or head injury), burns, endocrine, hepatic, or renal disease. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain baseline weight and vital signs, LOC, breath sounds, and urinary output as appropriate.
- Evaluate appropriate laboratory findings (e.g., electrolytes, complete blood count [CBC], urine specific gravity and urinalysis, blood urea nitrogen [BUN] and creatinine, total protein and albumin levels, activated partial thromboplastin time [aPTT], activated prothrombin time [aPT] or international normalized ratio [INR], renal and liver function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., electrolyte values return to within normal range, adequate urine output).
- Continue monitoring vital signs, urinary output, and LOC as appropriate.
- Assess for and promptly report adverse effects: tachycardia, HTN, dysrhythmias, decreasing LOC, increasing dyspnea, lung congestion, pink-tinged frothy sputum, decreased urinary output, muscle weakness or cramping, and allergic reactions.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. Assist the patient as needed with obtaining fluids and eating. (Urinary output is within normal limits. Electrolyte balance is restored or within the parameters set by the healthcare provider. **Lifespan:** Older adults, infants, and patients who cannot access fluids or eat by themselves [e.g., post-stroke] are at increased risk for fluid and electrolyte imbalance.)	• Teach the patient to continue to consume enough liquids to remain adequately, but not overly, hydrated. Drinking when thirsty, avoiding alcoholic beverages, maintaining a healthy diet, and ensuring adequate but not excessive salt intake will assist in maintaining normal fluid and electrolyte balance. • Have the patient weigh self daily, ideally at the same time of day, and record weight along with blood pressure and pulse measurements as appropriate. • Teach the patient, family, or caregiver how to monitor pulse and blood pressure if needed. Ensure proper use and functioning of any home equipment obtained.
Minimizing adverse effects: • Monitor for signs of fluid volume excess or deficit, e.g., HTN (excess) or hypotension (deficit), tachycardia, or changes in the quality of pulse (bounding or thready). Notify the healthcare provider if blood pressure or pulse exceeds established parameters. Monitor for signs of potential electrolyte imbalance including nausea, vomiting, GI cramping, diarrhea, muscle weakness, cramping, twitching, paresthesia, and irritability. Immediately report any confusion, decreasing LOC, or increasing hypotension or HTN, especially if associated with tachycardia, decreased urine output, or seizures. (Many fluid and electrolyte imbalances have similar symptoms. When assessing the patient for adverse effects, consider past health history, drug history, and current condition and medications to correlate symptoms to possible causes.)	• Instruct the patient to report changes in muscle strength or function; numbness and tingling in the lips, fingers, arms, or legs; palpitations; dizziness; nausea or vomiting; GI cramping; or decreased urination. • Instruct patients with hypokalemia to consume foods high in potassium: fresh fruits such as strawberries and bananas; dried fruits such as apricots and prunes; vegetables and legumes such as tomatoes, beets, and beans; juices such as orange, grapefruit, or prune; and fresh meats. Instruct patients with hyperkalemia to avoid the above as well as salt substitutes (which often contain potassium salts), and to consult with a healthcare provider before taking vitamin and mineral supplements or specialized sports beverages. Licorice should be avoided because it causes potassium loss and sodium retention.
• Frequently monitor CBC, electrolytes, aPTT, aPT, or INR levels. (Crystalloid solutions may cause electrolyte imbalances. Colloid solutions may reduce normal blood coagulation. Frequent monitoring of electrolyte levels while on replacement therapy may be needed to ensure therapeutic effects.)	• Instruct the patient on the need to return periodically for laboratory work.
• Continue to monitor vital signs. Take blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for hypotension. Ensure patient safety. (Dehydration and electrolyte imbalances may cause dizziness and hypotension. Orthostatic hypotension may increase the risk of falls and injury.)	Teach the patient to: • Rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Call for assistance prior to getting out of bed or attempting to walk alone and to avoid driving or other activities requiring mental alertness or physical coordination if dizziness or lightheadedness occurs.
• Weigh the patient daily and report a weight gain or loss of 1 kg (2 lb) or more in a 24-h period. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may signal excessive fluid volume or electrolyte imbalances.)	• Have the patient weigh self daily, ideally at the same time of day, and record weight along with blood pressure and pulse measurements. Have the patient report a weight loss or gain of more than 1 kg (2 lb) in a 24-h period. • Teach the patient that excessive heat conditions contribute to excessive sweating and fluid and electrolyte loss, and extra caution is warranted in these conditions.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Closely monitor for signs and symptoms of allergy if colloids are used. (Colloids such as plasma protein fraction, dextran, and hetastarch may cause allergic and anaphylactic reactions.)	• Instruct the patient to report dyspnea, itching, feelings of throat tightness, palpitations, chest pain or tightening, or headache immediately.
• Closely monitor IV sites when infusing potassium or ammonium. Double-check doses with another nurse before giving. (Potassium and ammonium are irritating to the vessel and phlebitis may result. Potassium is a "high-alert" medication and double-checking doses before giving prevents medication errors.)	• Instruct the patient to report any irritation, pain, redness, or swelling at the IV site or in the arm where the drug is infusing.
• Monitor LOC, deep tendon reflexes, urinary output, respiratory rate, and laboratory values frequently in patients receiving parenteral magnesium sulfate and newborns if the mother has received the drug. Keep calcium gluconate available as an antidote to magnesium toxicity. (Adverse effects from hypermagnesemia include respiratory and cardiac arrest and neuromuscular depression.)	• To allay anxiety, teach the patient and family the rationale for all equipment used and the need for frequent monitoring. • Instruct patients with hypomagnesemia to consume foods high in magnesium: green leafy vegetables and legumes such as peas, beans, nuts, and whole grains, and to increase fluid intake.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce supportive drug treatment and care.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., early in the day to prevent disruption of sleep from nocturia. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs. • **Lifespan:** Assess swallowing ability before giving or taking potassium chloride or ammonium chloride; they may cause mouth, esophageal, or gastric irritation. Liquid forms should always be diluted with water or fruit juice and tablets swallowed whole.

Understanding Chapter 33

Key Concepts Summary

33.1 Body fluids are exchanged between intracellular and extracellular compartments.

33.2 Osmolality or tonicity determines the movement of body fluids.

33.3 Overall fluid balance is regulated primarily by hormones acting on the kidneys.

33.4 Dehydration may be treated with fluid volume expanders.

33.5 Transfusions of blood products are used to treat serious conditions that cannot be managed effectively by other means.

33.6 Crystalloids are intravenous solutions that closely resemble the composition of extracellular fluid.

33.7 Colloids are intravenous solutions containing large molecules that remain in the blood.

33.8 Electrolytes are charged substances that are essential to homeostasis.

33.9 Sodium balance is closely associated with water balance.

33.10 Potassium imbalances must be quickly corrected to prevent serious cardiac consequences.

33.11 Magnesium imbalances significantly affect cardiovascular and neuromuscular function.

33.12 The pH of body fluids must be maintained between very narrow limits.

33.13 The pharmacotherapy of acidosis includes the administration of alkaline drugs.

33.14 The pharmacotherapy of alkalosis includes the administration of acidic drugs.

CASE STUDY: Making the Patient Connection

Remember the patient "Peggy Hoover" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Peggy Hoover is 26 years old and has been admitted to the short-stay surgical unit for an elective laparoscopic cholecystectomy. She has been in good health except for repeated gallbladder attacks. It is anticipated that she will be able to go home this afternoon after the surgery is completed.

As the nurse admitting Peggy, you have orders to start a D_5W infusion prior to surgery, to run at 15 mL/h. You have started the IV in her right hand. Peggy asks you why she needs it, especially since she will be returning home that afternoon.

Critical Thinking Questions

1. Why do you think an IV was ordered for Peggy, and what will you explain to her?
2. What are the two main categories of IV solutions? Which category was ordered for Peggy?
3. Dextrose 5% in water (D_5W) is a common solution. What precautions should be taken with this fluid type?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Marvin Fields has been prescribed a loop diuretic, furosemide (Lasix), 40 mg daily, and a potassium supplement tablet, 40 mEq daily. As you are preparing to discharge this patient, he states, "I understand why I need the diuretic, but why do I have to take this potassium?"

1. How would you respond to his question?
2. What adverse effect related to potassium supplementation would you advise him to watch for?
3. What advice would you give Marvin about his dietary consumption of potassium-rich foods?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient with a disorder causing metabolic acidosis is being treated with intravenous sodium bicarbonate. The nurse monitors for therapeutic effectiveness by noting which laboratory values?
   1. Serum pH
   2. Red blood cell count
   3. Liver function test
   4. Blood urea nitrogen

2. The nurse is teaching the patient about a liquid potassium chloride supplement. Which statement, if made by the patient, indicates that further teaching is necessary?
   1. "I should avoid salt substitutes unless approved by my healthcare provider."
   2. "Liquid preparations should not be diluted with other fluids."
   3. "I should report signs of potassium deficit such as weakness and fatigue."
   4. "Persistent vomiting will result in significant losses of potassium."

3. The nurse is administering dextran 40 (Gentran 40) to a patient with multiple traumatic injuries following a motor vehicle crash. The nurse knows that which adverse effect of this medication is toxic?
   1. Dehydration
   2. Increased urinary output
   3. Hypovolemic shock
   4. Bleeding

4. The patient will be receiving 5% dextrose in water (D_5W) intravenous infusion. Which statement is correct about this therapy?
   1. D_5W can cause hypoglycemia in the patient who has diabetes.
   2. D_5W may be used to dilute mixed intravenous drugs.
   3. D_5W is considered a colloid solution.
   4. D_5W has a sufficient number of calories to supply metabolic needs.

5. The healthcare provider orders intravenous magnesium sulfate for a pregnant patient with preeclampsia. The nurse should consult with the prescriber about which patient assessment finding that may affect the drug therapy?
   1. Pupil constriction to direct light
   2. Chest congestion and coughing
   3. Elevated blood pressure
   4. Decreased patellar deep tendon reflexes
6. Which of the following nursing actions should be included in the care plan for a patient receiving normal serum albumin (Albuminar)? (Select all that apply.)
   1. Document past history of blood transfusion reactions.
   2. Restrict dietary intake of food high in potassium.
   3. Monitor blood pressure and pulse rate.
   4. Measure urinary output hourly.
   5. Observe for signs related to potassium deficit.

"I'm doing everything my doctor has advised me to do to control my hypertension. My doctor has prescribed several different types of drugs over the past few months. My blood pressure is still elevated. What else can I do?"

Patient "Elmer Foley"

Chapter 34
Pharmacotherapy of Hypertension

Chapter Outline

- Etiology and Pathogenesis of Hypertension
- Nonpharmacologic Management of Hypertension
- Guidelines for the Management of Hypertension
- Pharmacotherapy of Hypertension
- Drug Classes for Hypertension
  - Diuretics
  - Calcium Channel Blockers
  - Drugs Affecting the Renin-Angiotensin-Aldosterone System
    - *Angiotensin-Converting Enzyme Inhibitors*
    - *Angiotensin II Receptor Blockers*
  - Adrenergic Antagonists
    - *Beta-Adrenergic Antagonists*
    - *Alpha$_1$-Adrenergic Antagonists*
    - *Alpha$_2$-Adrenergic Agonists (Centrally Acting Drugs)*
    - *Adrenergic Neuron Blockers*
  - Direct Vasodilators
    - **PROTOTYPE** *Hydralazine, p. 593*
- Management of Hypertensive Emergency
  - **PROTOTYPE** *Nitroprusside Sodium (Nitropress), p. 595*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Summarize the long-term consequences of untreated hypertension.
2. Compare and contrast the roles of nonpharmacologic and pharmacologic methods in the management of hypertension.
3. Describe general principles guiding the pharmacotherapy of hypertension.
4. Identify first- and second-line drug classes used in the management of hypertension.
5. Describe the pharmacologic management of hypertensive emergencies.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving antihypertensive drugs.

Key Terms

angiotensin-converting enzyme (ACE) inhibitors, 590
hypertension (HTN), 584
hypertensive emergency (HTN-E), 594
hypertensive urgency, 594
hypertrichosis, 594
primary hypertension, 583
secondary hypertension, 583

Diseases affecting the heart and blood vessels are the most frequent causes of death in the United States. Hypertension (HTN) or high blood pressure is the most common of the cardiovascular diseases. Chronic HTN affects one in every three Americans and contributes to over 410,000 deaths in the United States each year (Centers for Disease Control and Prevention [CDC], 2016 a). Although mild HTN can be controlled with lifestyle modifications, moderate to severe HTN requires pharmacotherapy.

Because nurses encounter so many patients with this disease, it is critical for them to understand the underlying principles of antihypertensive therapy. By improving public awareness of HTN and teaching the importance of early intervention, the nurse can contribute significantly to reducing cardiovascular mortality.

PharmFACT

Individuals whose blood pressure is higher than 140/90 mmHg (140 systolic or above or 90 diastolic or above) often become patients treated for serious cardiovascular problems. This includes about:

- 80% of those who experience a first stroke
- 70% of those who have a first heart attack
- 70% of those with chronic heart failure (CDC, 2016b).

Etiology and Pathogenesis of Hypertension

34.1 Failure to properly manage hypertension can lead to stroke, heart failure, or myocardial infarction.

Hypertension is a complex disease that is caused by a combination of genetic and environmental factors. Approximately 4% of HTN cases are believed to involve genetic factors. Scientists have discovered specific genes that appear to predispose a patient to HTN. These genes control critical activities such as renal sodium and water transport and the renin-angiotensin-aldosterone system. Environmental factors related to diet and exercise also play an important role in the development of HTN.

For the large majority of patients with HTN, no specific cause can be identified. HTN having no identifiable cause is called idiopathic, essential, or **primary hypertension** and accounts for 90% of all cases. Although patients with primary HTN cannot be cured with medication, the disease can be managed such that the risk of serious, long-term consequences can be reduced.

In some cases, a specific cause of the HTN can be identified. This type, called **secondary hypertension**, accounts for 10% of all patients with HTN. Certain diseases, such as Cushing's syndrome, hyperthyroidism, chronic kidney disease, pheochromocytoma, and arteriosclerosis, are associated with elevated blood pressure. Certain drugs are also associated with HTN, including alcohol, decongestants, caffeine, amphetamines, corticosteroids, oral contraceptives, estrogen, erythropoietin, and sibutramine. The therapeutic goal for secondary HTN is to treat or remove the underlying condition that is causing the blood pressure elevation. In many cases, correcting the comorbid condition will cure the associated HTN.

Research has clearly demonstrated that failure to control HTN can have serious consequences. Prolonged or improperly controlled HTN damages blood vessels, particularly small arteries and arterioles. As it progresses, the walls of the arteries gradually thicken in an attempt to protect the vessels against injury from the increased pressure. The injured vessel walls become inflamed, increasing the permeability of the vessels and causing additional thickening of their walls. Eventually, the lumen of the artery permanently narrows, reducing blood flow to vital tissues. HTN accelerates atherosclerosis and will worsen conditions such as coronary artery disease (CAD).

Hypertension may exist for years, indeed decades, before becoming symptomatic. As the disease progresses, however, the risk of target-organ damage increases. Because sustained HTN may affect any artery in the body, damage may be widespread and symptoms vary greatly according to which vessels are affected.

The heart is a primary organ damaged by chronic HTN. Hypertension increases afterload, forcing the heart to work harder to pump blood to the tissues. The heart is subjected to chronic pressure overload, resulting in left ventricular hypertrophy. If untreated, this excessive workload eventually causes the heart to fail and the lungs to fill with fluid, a condition known as heart failure (HF). Drug therapy for HF is covered in Chapter 36. Further damaging the heart is the effect of HTN on the coronary vessels. Hypertension accelerates the deposition of atherosclerotic

plaque, creating or worsening CAD. This places the patient at greater risk of dysrhythmias, angina pectoris, and myocardial infarction (MI). Heart failure and MI are the most common causes of death in patients with HTN.

The brain is also a major target organ for hypertensive damage. Occlusion of the small vessels supplying blood and oxygen to the brain can cause transient ischemic attacks and stroke. These neurologic events are common in patients with HTN and are a major cause of disability.

Because a large percentage of blood pumped per minute circulates through the kidneys, chronic HTN creates major stress on these organs. As the small arteries supplying the kidney become injured, inflamed, and atherosclerotic, the patient's renal function gradually declines. Poorly managed HTN is an important contributor to kidney failure and end-stage kidney disease.

Hypertension is a major cause of visual impairment, which can occur when vessels in the eye become atherosclerotic. Although patients may remain asymptomatic for many years, small hemorrhages that affect vision may occur. Symptoms of retinal damage range from subtle vision changes to blindness. Retinopathy is particularly serious in patients who present with diabetes mellitus (DM) as a comorbid condition with HTN.

The importance of treating this disorder in its early stage cannot be overstated. The long-term damage to target organs caused by HTN will become irreversible if the disease is allowed to progress unchecked. This is especially critical in people with DM and those with chronic kidney disease (CKD), as these patients are particularly susceptible to the long-term consequences of HTN.

Nonpharmacologic Management of Hypertension

34.2 Therapeutic lifestyle changes can reduce blood pressure and lessen the need for antihypertensive medications.

When a patient is first diagnosed with HTN, a comprehensive medical history is necessary to determine if the disease can be controlled by nonpharmacologic means. Therapeutic lifestyle changes should be recommended for all patients with HTN or at risk for the development of HTN. Of great importance is maintaining optimal weight, because obesity is closely associated with hyperlipidemia and HTN. A 5- to 9-kg (11- to 20-lb) weight loss often produces a measurable decrease in blood pressure, even in patients who are obese. Combining a medically supervised weight loss program with proper nutrition can delay the progression to HTN.

In some cases, implementing positive lifestyle changes may eliminate the need for pharmacotherapy altogether. Even if medication is required to manage the HTN, positive lifestyle changes may allow dosages to be minimized, thus lowering the potential for drug adverse effects. The nurse plays a vital role in educating patients about controlling their HTN. Because all blood pressure medications have potential adverse effects, it is important for patients to attempt to control their disease through nonpharmacologic means, to the greatest extent possible. Nonpharmacologic methods for controlling HTN include the following:

- Limit intake of alcohol.
- Restrict sodium consumption and increase potassium intake.
- Reduce intake of saturated fat and cholesterol, and increase consumption of fruits and vegetables.
- Increase aerobic physical activity.
- Discontinue use of all tobacco products.
- Explore measures for dealing with excessive stress.
- Maintain optimal weight.

Guidelines for the Management of Hypertension

34.3 Research-based guidelines have been developed to aid the healthcare provider in providing optimal treatment for patients with hypertension.

Hypertension (HTN) is defined as the consistent elevation of systemic arterial blood pressure. When most people use the word *hypertension*, they are referring to systemic HTN, that which is measured routinely by a conventional blood pressure cuff on the upper arm over the brachial artery. Systemic HTN is a general measurement of arterial blood pressure in the body. Localized HTN may also occur. For example, patients with cirrhosis of the liver often develop portal HTN, which occurs in the portal vein and its branches serving the liver. Pulmonary HTN occurs in the pulmonary artery and its branches and is most often observed in patients with left-sided HF. These localized types of HTN respond to many of the same antihypertensive drugs used for systemic HTN.

To develop guidelines for treatment, many attempts have been made to define HTN and to determine when medical intervention is beneficial in reducing mortality due to cardiovascular disease. In 2003, the National High Blood Pressure Education Program Coordinating Committee of the National Heart, Lung, and Blood Institute at the National Institutes of Health issued *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (JNC-7), which became the standard for treating HTN for the following decade. The JNC-7 defined HTN as a sustained systolic blood pressure of greater than 140 mmHg or diastolic pressure of greater than 90 to 99 mmHg.

In 2013, the Eighth Joint National Committee (JNC-8) significantly revised the HTN guidelines, based on newer research (James et al., 2014). The JNC-8 committee kept the same definition of hypertension as JNC-7: 140/90 mmHg. The primary difference is that research has shown that not

CONNECTIONS: Complementary and Alternative Therapies

Grape Seed Extract

Description

Grape seed extract is obtained from the seeds of grapes that are usually used in the process of winemaking.

History and Claims

Grapes and grape seeds have been used for medicinal purposes for thousands of years. The primary use of the extract has been to treat cardiovascular conditions such as venous insufficiency and to generally improve circulation. Some claim that it improves wound healing and reduces inflammation. The drug is also being examined for its effects on Alzheimer's disease.

Standardization

Grape seeds and skins contain antioxidant oligomeric proanthocyanidins (OPCs). The grape seeds are crushed and placed into tablet, capsule, or liquid forms. Typical doses are 50 to 300 mg/day. Standardization is based on percentage of polyphenols. The seeds also contain a high concentration of vitamin E, flavonoids, and linoleic acid. Grape skins contain resveratrol, another antioxidant that is being studied for its anti-inflammatory effects.

Evidence

Thousands of studies have been conducted on the polyphenols contained in this supplement. Grape seed extract has antioxidant properties (University of Maryland Medical Center, 2015). In general, antioxidants improve wound healing and repair cellular injury. Preliminary evidence suggests that grape seed extract may have some benefit in repairing blood vessel damage that could lead to atherosclerosis and HTN. It is also being studied in the treatment of Alzheimer's disease and in hereditary hemochromatosis (National Center for Complementary and Integrative Health, 2016). Controlled, long-term studies on the effects of grape seed extracts on HTN have not been conducted. It has few adverse effects. Caution should be used if taking anticoagulant drugs because increased bleeding may result.

all people with a blood pressure higher than 140/90 mmHg need pharmacotherapy. For example, it is now recommended that patients over age 60 who do not have CKD or diabetes should not receive pharmacotherapy until the 150/90 mmHg threshold. Furthermore, the classes of medications recommended as first-line therapy changed in JNC-8: Beta-adrenergic blockers are no longer considered first-line drugs, except for patients with angina.

The latest guideline, published in 2017 by the American College of Cardiology and the American Heart Association lowered the cut-off value that had previously defined HTN (Whelton et al., 2017). The new guideline for Stage 1 HTN is 130–139/80–89. It is estimated that the lower threshold will increase the percentage of individuals diagnosed with HTN from 31% to 48% of the population.

In the past decade, research has determined that there are racial differences in response to antihypertensive medications. To account for these differences, the JNC-8 guidelines made a distinction between drugs used for Black and non-Black patients. First-line drugs for non-Blacks without CKD include thiazide diuretics, calcium channel blockers (CCBs), angiotensin-converting enzyme (ACE) inhibitors, or angiotensin receptor blockers (ARBs). Blacks without CKD are more effectively treated with thiazide diuretics either alone or in combination with CCBs. The therapy for all patients with CKD is the same. These recommendations are summarized in Table 34.1.

Pharmacotherapy of Hypertension

34.4 The choice of antihypertensive medication is determined by the degree of hypertension and the presence of other medical conditions.

The goal of antihypertensive therapy is to reduce the morbidity and mortality associated with chronic HTN. Research has confirmed that keeping blood pressure within normal limits reduces the risk of hypertension-related target-organ damage.

The pharmacologic management of HTN is individualized to the patient's risk factors, comorbid medical conditions, and degree of blood pressure elevation. Patient responses to antihypertensive medications vary widely because of the many complex genetic and environmental factors affecting blood pressure.

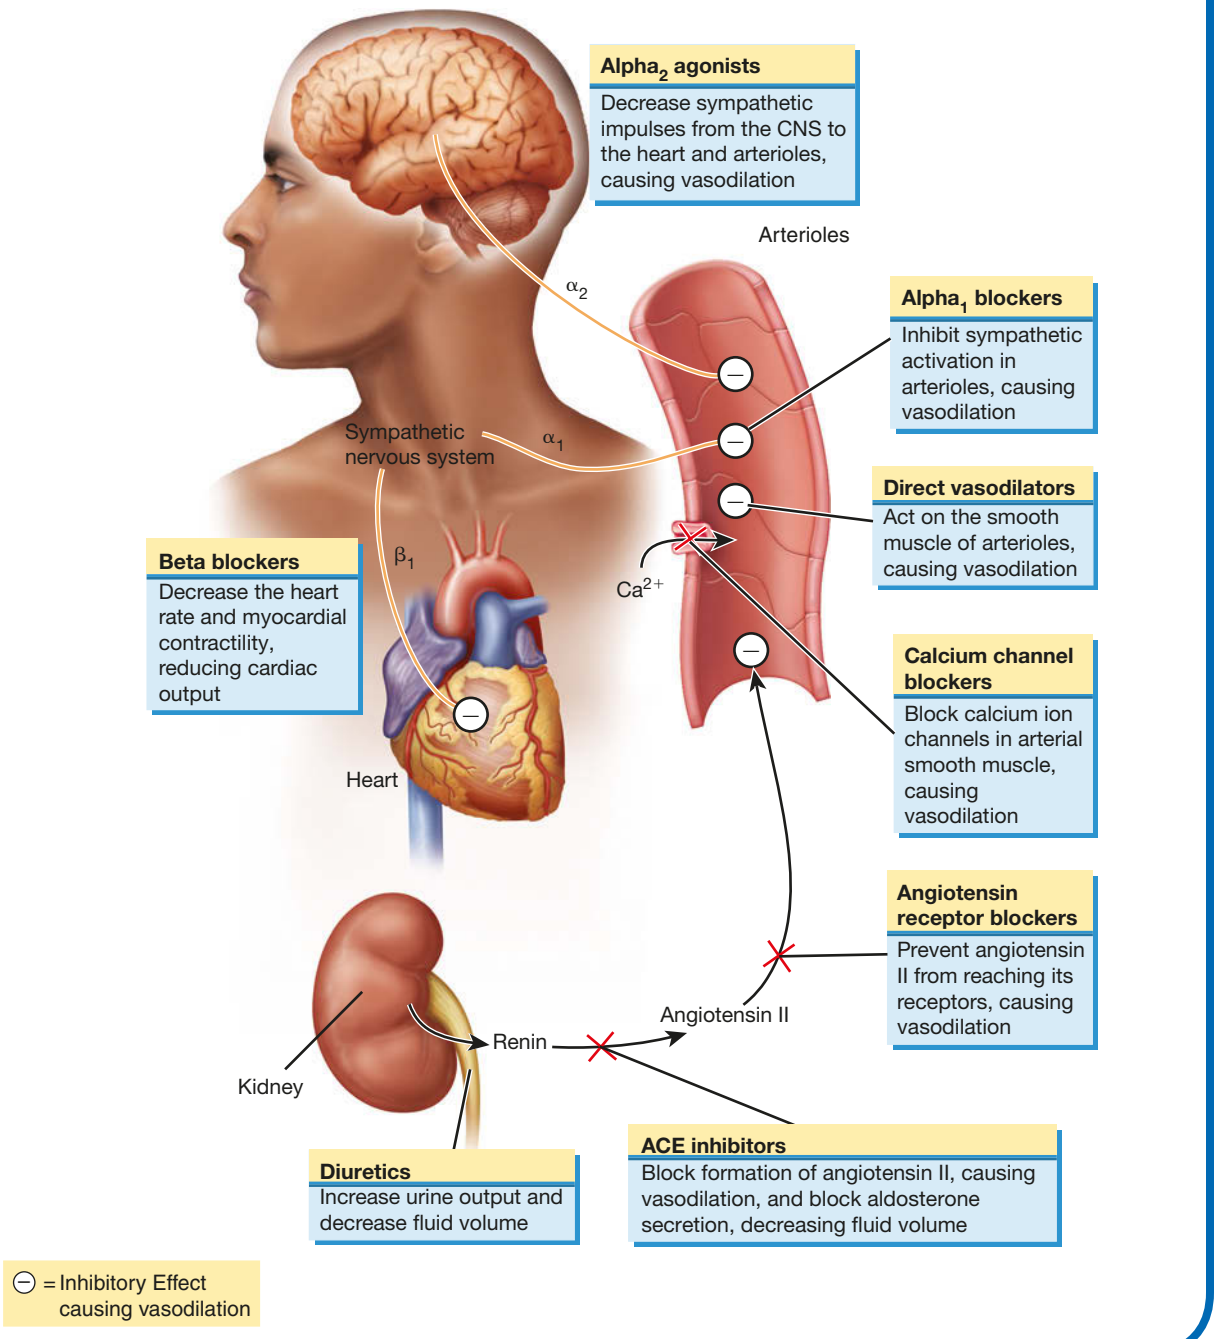

Table 34.1 Recommendations for Treating Hypertension

Group	Blood Pressure Goal	FIRST-LINE DRUGS (ALONE OR IN COMBINATION)	
		Non-Black	Black
Age 60 or greater without DM or CKD	Less than150/90 mmHg	Thiazide diuretic, ACEI, ARB, or CCB	Thiazide diuretic or CCB
Age 59 or lower without DM or CKD	Less than140/90 mmHg	Thiazide diuretic, ACEI, ARB, or CCB	Thiazide diuretic or CCB
All ages with DM present (no CKD)	Less than140/90 mmHg	Thiazide diuretic, ACEI, ARB, or CCB	Thiazide diuretic or CCB
All ages with CKD present (with or without DM)	Less than140/90 mmHg	ACEI or ARB	ACEI or ARB

DM = diabetes mellitus; CKD = chronic kidney disease; ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; CCB = calcium channel blocker.

Pharmacotherapy Illustrated 34.1

Mechanism of Action of Antihypertensive Drugs

Eleven different drug classes are used to treat HTN, as shown in Table 34.2. Each class has specific benefits and characteristic adverse effects. The mechanisms of action of the major classes of antihypertensive drugs are summarized in Pharmacotherapy Illustrated 34.1. Although many effective drugs are available, and the data supporting the benefits of therapy are strong, HTN remains a challenging disorder to treat successfully. Choice of therapy is often based on the clinician's experience. Although antihypertensive treatment varies, several principles guide pharmacotherapy.

Drugs for Initial Hypertension Therapy

The JNC-7 report recommended thiazide diuretics as initial drugs for the management of mild to moderate HTN. Although the thiazides are still preferred by some healthcare providers, the JNC-8 expanded this recommendation to also include ACE inhibitors, ARBs, or CCBs for most patients. Research has clearly demonstrated that these four primary drug classes reduce HTN-related morbidity and mortality.

Table 34.2 Drug Classes for Hypertension

Type	Class
First-line drugs	Angiotensin-converting enzyme (ACE) inhibitors Angiotensin receptor blockers (ARBs) Calcium channel blockers (CCBs) Thiazide diuretics
Second-line drugs	Alpha$_1$-adrenergic blockers Alpha$_2$-adrenergic agonists Beta-adrenergic blockers Centrally acting alpha and beta blockers Direct-acting vasodilators Direct renin inhibitors Peripherally acting adrenergic neuron blockers

In most cases, low doses of an initial drug are prescribed and the patient is reevaluated after an appropriate time period. As therapy continues, dosage is adjusted to maintain optimal blood pressure.

Adding Drugs to the Antihypertensive Regimen

If the patient does not respond to the initial medication, a drug from a different antihypertensive class may be added to the regimen. Prescribing two antihypertensives concurrently results in additive or synergistic blood pressure reduction and is common practice when managing resistant HTN. The use of two drugs allows lower doses, resulting in fewer adverse effects and better patient adherence. Drug manufacturers sometimes combine two drugs into a single pill or capsule for dosing convenience. The majority of these combinations include a thiazide diuretic, usually hydrochlorothiazide, sometimes abbreviated as HCTZ, combined with an ACE inhibitor or ARB. ACE inhibitors and ARBs are not used in combination with each other because they act by very similar mechanisms. Selected combination antihypertensives are shown in Table 34.3.

Certain antihypertensive classes cause a higher incidence of adverse effects and are generally prescribed when drugs from the four primary classes do not produce a satisfactory response. In some cases, research studies have not demonstrated a firm link between drug use and lowered morbidity or mortality. The alternative antihypertensive drug classes include the following:

- Alpha$_1$-adrenergic antagonists
- Alpha$_2$-adrenergic agonists
- Beta-adrenergic antagonists
- Direct-acting vasodilators
- Peripheral adrenergic antagonists.

Enhancing Patient Adherence

Because chronic HTN may produce no identifiable symptoms for as long as 10 to 20 years, many people are not aware of their condition. Convincing patients to change established lifestyle habits, spend money on medication, and take drugs on a regular basis when they are feeling healthy can be a challenging task for the nurse. Patients with limited income or who do not have health insurance are at high risk for not purchasing the drugs after receiving a prescription. The prescriber should consider generic forms of these drugs to reduce costs and increase adherence.

Table 34.3 Selected Combination Medications for Hypertension

Thiazide Diuretic with ACE Inhibitor	
Accuretic	HCTZ and quinapril
Lotensin HCT	HCTZ and benazepril
Vaseretic	HCTZ and enalapril
Zestoretic	HCTZ and lisinopril
Thiazide Diuretic with Angiotensin II Blocker	
Atacand HCT	HCTZ and candesartan
Avalide	HCTZ and irbesartan
Benicar HCT	HCTZ and olmesartan
Diovan HCT	HCTZ and valsartan
Edarbyclor	chlorthalidone and azilsartan
Hyzaar	HCTZ and losartan
Thiazide Diuretic with Autonomic Drug	
Corzide	HCTZ with bendroflumethiazide and nadolol (beta blocker)
Inderide	HCTZ and propranolol (beta blocker)
Lopressor HCT	HCTZ and metoprolol (beta blocker)
Minizide	polythiazide and prazosin (alpha blocker)
Tenoretic	chlorthalidone and atenolol (beta blocker)
Timolide	HCTZ and timolol (beta blocker)
Ziac	HCTZ and bisoprolol (beta blocker)
Thiazide Diuretic with Potassium-Sparing Diuretic	
Aldactazide	HCTZ and spironolactone
Dyazide	HCTZ and triamterene
Other Combinations	
Amturnide	HCTZ with amlodipine (CCB) and aliskiren (renin inhibitor)
Apresazide	HCTZ and hydralazine (direct vasodilator)
Azor	olmesartan and amlodipine
Byvalson	valsartan and nebivolol
Edarbyclor	azilsartan and chlorthalidone
Exforge	valsartan and amlodipine
Lexxel	enalapril and felodipine (CCB)
Lotrel	benazepril and amlodipine
Prestalia	perindopril and amlodipine
Tarka	trandolapril and verapamil (CCB)
Tekturna HCT	HCTZ and aliskiren
Tribenzor	HCTZ with olmesartan and amlodipine

Further reducing adherence to the regimen is the occurrence of adverse drug effects. Some of the antihypertensive drugs cause embarrassing adverse effects such as impotence, which may go unreported. Others cause fatigue and generally make patients feel sicker than they were before therapy was initiated. The nurse should teach the patient the importance of treating the disease to avoid serious long-term consequences. Furthermore, the nurse should teach patients to report adverse effects so that dosage can be adjusted, or the drug changed, so the treatment can continue without interruption. Simple adjustments to the dosage or changing the selected drug can often eliminate the causes of nonadherence.

Antihypertensives in African Americans

The incidence of HTN is significantly higher in African Americans than in other ethnic groups. As expected from this high incidence, African Americans experience greater target-organ damage than other populations. In an effort to reduce the high morbidity and mortality risks, aggressive antihypertensive therapy may be necessary to overcome resistant HTN.

Some research studies have suggested that certain antihypertensive drug classes are less effective in African Americans. Monotherapy with ACE inhibitors, ARBs, or beta-adrenergic antagonists does not reduce blood pressure as much in African Americans compared to other ethnic groups. Thiazide diuretics and CCBs seem to provide the greatest blood pressure reduction in this population. The JNC-8 report recommends initiating therapy with two drugs to ensure an adequate response.

Drug Classes for Hypertension

34.5 Diuretics are often preferred drugs for treating mild to moderate hypertension.

Diuretics were the first class of medications used to treat HTN in the 1950s. Despite the many advances in drug therapy, diuretics are still considered first-line drugs for this disease because they are very effective at controlling mild to moderate HTN with few serious adverse effects. Although sometimes used as monotherapy, diuretics are frequently prescribed with other antihypertensive medications to enhance their effectiveness. Because this class of drugs was presented in detail in Chapter 32, this section is a summary of their application to the treatment of HTN.

Although dozens of diuretics are available for the treatment of HTN, all produce a similar result: the reduction of blood volume through the urinary excretion of water and electrolytes. Reducing blood volume places less pressure on the arterial walls, thereby decreasing peripheral resistance and lowering systemic blood pressure. The mechanism by which diuretics increase the excretion of water and electrolytes, specifically where and how the kidney is affected, differs among the various classes of diuretics.

Whenever a medication changes urine flow or composition, dehydration and electrolyte depletion are possible. Dehydration may manifest as increased thirst or poor skin turgor. Excessive sodium loss (hyponatremia) is a concern for all diuretics. Potassium loss (hypokalemia) is of particular concern for loop and thiazide diuretics. The potassium-sparing diuretics such as triamterene (Dyrenium) have less tendency to cause hypokalemia.

CONNECTIONS: Community-Oriented Practice

Self-Monitoring Blood Pressure for Better Control

With the availability of small devices to self-monitor blood pressure that are easily used outside of the healthcare provider's office setting, better blood pressure control may be achieved. The U.S. Preventive Services Task Force (USPSTF, 2016) recommends that ambulatory blood pressure monitoring and home monitoring may be the best methods for detecting HTN, above and beyond a single value obtained in the healthcare provider's office. Values obtained in the provider's office may be affected by "white coat syndrome," that is, a higher than usual reading due to the stress or anxiety of the visit. It is estimated that up to 30% of the population may experience white coat syndrome (Piper et al., 2015). A corollary, "masked hypertension," where blood pressure appears normal in a provider's office but is higher throughout the day, is also estimated to occur in up to 30% of patients (Shimbo, Abdalla, Falzon, Townsend, & Muntner, 2015). Clearly, accurate blood pressure readings are necessary to treat HTN and to avoid unnecessary treatment (Piper et al., 2015).

The USPSTF recommendation for self-monitoring blood pressure included the use of ambulatory or home blood pressure monitoring. Ambulatory monitoring takes place throughout the day and night, and readings are commonly taken every 15 to 30 minutes. Home monitoring may be accomplished through brachial artery or wrist devices, although wrist readings may be less accurate. Recommended use may be two readings each in the morning and evening for up to 7 consecutive days (Shimbo et al., 2015). Cost, adequate calibration of the device, and the need for further information about the timing of the blood pressure measurement (e.g., at rest, after exercise) are also important items to consider (Cohen & Townsend, 2015). Patient use of the devices allows for a collaborative approach to treatment and, combined with office-based measurements, a fuller assessment of blood pressure fluctuations is possible, which allows the provider to make better decisions about drug therapy (Campos-Outcalt, 2016; Goldstein, Zullig, Bosworth, & Oddone, 2016).

Thiazide and thiazide-like diuretics: Thiazide and thiazide-like diuretics have been the mainstay for the pharmacotherapy of HTN for decades. The thiazide diuretics are inexpensive, and most are available in generic formulations. They are safe drugs, with excessive urinary potassium loss being the primary adverse effect. Because hypokalemia can induce serious dysrhythmias in susceptible patients, regular laboratory monitoring of serum potassium is necessary. Patients should increase their amount of dietary potassium, and potassium supplements may be prescribed. These diuretics may also cause hyperglycemia; therefore, blood glucose levels should be monitored in patients with diabetes. Because thiazides may increase blood lipids, these drugs should be used cautiously in patients with existing hyperlipidemia. Hydrochlorothiazide, or HCTZ (Microzide), is featured as the prototype drug in this class in Chapter 32. In addition to HCTZ, thiazides indicated for HTN include chlorothiazide (Diuril), chlorthalidone (Hygroton), indapamide (Lozol), methyclothiazide (Enduron), and metolazone (Zaroxolyn).

Potassium-sparing diuretics: Although potassium-sparing diuretics such as spironolactone (Aldactone) and triamterene (Dyrenium) produce only a modest diuresis, their primary advantage is they do not cause potassium depletion. They are especially beneficial when the patient is at risk of developing hypokalemia due to a medical condition or the use of thiazide or loop diuretics. The primary concern when using potassium-sparing diuretics is the possibility of retaining too much potassium, which can cause serious dysrhythmias. Patients with diabetes and those with CKD are particularly susceptible to hyperkalemia. Patients should be instructed to avoid excess potassium in their diet, including salt substitutes containing KCl, and not to use potassium supplements during therapy. Concurrent use with an ACE inhibitor or ARB significantly increases the potential for development of hyperkalemia. Spironolactone is presented as a prototype drug for this class in Chapter 32. In addition to spironolactone and triamterene, other potassium-sparing diuretics indicated for HTN are amiloride (Midamor) and eplerenone (Inspra).

Loop (high-ceiling) diuretics: The loop diuretics such as furosemide (Lasix) cause greater diuresis and have the potential to produce a higher reduction in blood pressure than the thiazides or potassium-sparing diuretics. Although this makes them very effective at reducing blood pressure, they are not ideal drugs for maintenance therapy. The risk of adverse effects such as hypokalemia and dehydration is great because of their ability to remove large amounts of fluid from the body in a short time period. Loop diuretics are ototoxic, an effect more likely to occur in patients with CKD or when high doses are administered. Because of their greater toxicity, loop diuretics are sometimes reserved for patients with resistant HTN. Furosemide, the only loop diuretic in widespread use, is presented as a prototype drug in Chapter 32. In addition to furosemide, other loop diuretics indicated for HTN include bumetanide (Bumex), ethacrynic acid (Edecrin), and torsemide (Demadex).

CONNECTION Checkpoint 34.1

From what you learned in Chapter 32, why must the thiazide diuretics be used with great caution in patients taking digoxin (Lanoxin)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

34.6 Calcium channel blockers have emerged as important drugs in the treatment of hypertension.

Calcium channel blockers (CCBs) are widely used in the treatment of HTN, angina pectoris, and dysrhythmias, as presented in Chapter 30. This section summarizes their application to the treatment of HTN.

CCBs exert beneficial effects on the heart and blood vessels by blocking calcium ion channels in cardiac and arteriolar smooth muscle. The flow of calcium ions into muscle cells is inhibited, limiting the degree of muscular contraction. At low doses, CCBs relax arterial smooth muscle, thus decreasing peripheral resistance and lowering blood pressure. Some CCBs such as nifedipine (Adalat CC, Procardia XL) are selective for arterioles, whereas others such as verapamil (Calan, Isoptin, Verelan) affect channels in both arterioles and the myocardium. CCBs vary in potency and in the frequency and types of adverse effects produced. Nifedipine and verapamil are highlighted as drug prototypes in Chapter 30.

Due to their potent vasodilating effects, CCBs can cause reflex tachycardia, especially with those CCBs that are selective for arterioles. Because CCBs can slow myocardial conduction, they are contraindicated in patients with certain types of heart conditions such as sick sinus syndrome or third-degree atrioventricular (AV) block without the presence of a pacemaker. The CCBs that reduce myocardial contractility can worsen HF.

CCBs are usually not used as monotherapy for chronic HTN. They are, however, useful in combination therapy for treating certain populations such as older adults and African Americans who are sometimes less responsive to drugs in other antihypertensive classes. In addition to nifedipine and verapamil, other CCBs indicated for HTN include amlodipine (Norvasc), clevidipine (Cleviprex), diltiazem (Cardizem, Dilacor, others), felodipine, isradipine (DynaCirc), nicardipine (Cardene), and nisoldipine (Sular).

CONNECTION Checkpoint 34.2

Verapamil and nifedipine are both calcium channel blockers used for HTN. From what you learned in Chapter 30, why would a beta blocker be used concurrently with nifedipine but be contraindicated with verapamil? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

34.7 Blocking the renin-angiotensin-aldosterone system leads to a decrease in blood pressure and improved kidney function.

As discussed in Chapter 31, the renin-angiotensin-aldosterone system (RAAS) is one of the primary homeostatic mechanisms controlling blood pressure and fluid balance. Drugs inhibiting the RAAS are widely used in the treatment of cardiovascular disease. Clinical research suggests ACE inhibitors are as effective as the diuretics in reducing HTN-related morbidity and mortality. The following section summarizes their applications to HTN pharmacotherapy.

Angiotensin-converting enzyme (ACE) inhibitors: **Angiotensin-converting enzyme (ACE) inhibitors** block the formation of angiotensin II, decreasing blood pressure through two mechanisms. First, ACE inhibitors block the intense vasoconstriction of arterioles caused by angiotensin II, which decreases blood pressure due to diminished peripheral resistance. Second, these drugs block the effects of angiotensin II on the secretion of aldosterone, which lowers blood pressure by decreasing blood volume. Through their inhibition of aldosterone secretion, ACE inhibitors enhance the effects of the thiazide diuretics; thus drugs from these two classes may be used concurrently in the management of HTN. Lisinopril (Prinivil, Zestril) is the prototype drug for the ACE inhibitors in Chapter 31. Other ACE inhibitors indicated for HTN include benazepril (Lotensin), captopril (Capoten), enalapril (Vasotec), fosinopril (Monopril), moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), and trandolapril (Mavik).

Adverse effects of ACE inhibitors are usually minor and include persistent cough and orthostatic hypotension, particularly following the first few doses of the drug. Hyperkalemia may occur and can be a major concern for patients with diabetes, those with CKD, and patients taking potassium-sparing diuretics. Though rare, the most serious adverse effect of ACE inhibitors is the development of angioedema. When it does occur, angioedema most often develops within days after beginning ACE inhibitor therapy. Cough and angioedema arise more frequently in African Americans than in other ethnic groups.

Angiotensin receptor blockers (ARBS) and direct renin inhibitors: The ARBs afford a second method for altering the RAAS pathway. ARBs such as losartan (Cozaar) block receptors for angiotensin II in arteriolar smooth muscle and in the adrenal gland, thus causing blood pressure to fall. Their actions are similar to those of the ACE inhibitors.

Angiotensin II receptor blockers have the lowest incidence of serious adverse effects of any of the antihypertensive classes. Most ARB adverse effects are related to hypotension. Unlike the ACE inhibitors, they do not cause cough, and angioedema is rare. Medications in this class are often combined with drugs from other classes in the management of HTN. A drug prototype feature for losartan (Cozaar) is included in Chapter 31. Other ARBs indicated for HTN include candesartan (Atacand), eprosartan (Teveten), irbesartan (Avapro), olmesartan (Benicar), telmisartan (Micardis), and valsartan (Diovan).

Aliskiren (Tekturna) was the first in a new class of antihypertensives called direct renin inhibitors approved for HTN. They act by interfering with part of the RAAS system. The combination of aliskiren with HCTZ (Tekturna ACT) is also approved for treating HTN. The most common adverse effects of aliskiren are diarrhea, cough, flulike symptoms, and rash. The direct renin inhibitors are not considered first-line medications for HTN.

34.8 Adrenergic antagonists are commonly used to treat hypertension.

The adrenergic antagonists, or blockers, are used for a wide variety of cardiovascular disorders, including HTN, angina pectoris, dysrhythmias, and MI prophylaxis. Blocking adrenergic receptors in the sympathetic nervous system has a number of beneficial effects on the heart and vessels. For example, by blocking the "fight-or-flight" responses, heart rate slows, blood pressure declines, and the bronchi dilate.

Adrenergic blockers affect the sympathetic division through a number of distinct mechanisms, although all have in common the effect of lowering blood pressure. These mechanisms include the following:

- Blockade of beta$_1$-adrenergic receptors
- Blockade of alpha$_1$-adrenergic receptors
- Nonselective blockade of both alpha$_1$- and beta-adrenergic receptors
- Stimulation of centrally acting alpha$_2$-adrenergic receptors in the brainstem
- Blockade of peripheral adrenergic neurons.

The earliest drugs for HTN were nonselective drugs that blocked nerve transmission at the ganglia or at both alpha- and beta-adrenergic receptors. Although the nonselective medications revolutionized the treatment of HTN, they caused a high incidence of adverse effects. These drugs are rarely used today because selective agents are more efficacious and better tolerated by patients. Of the five subclasses of adrenergic antagonists, the beta-adrenergic blockers are the most widely used group. All of the adrenergic inhibitors are considered second-line drugs for HTN.

Beta-adrenergic antagonists: In this section, the discussion of beta-adrenergic antagonists is limited to their use in treating HTN. The student should refer to Chapter 16 for a detailed discussion of the basic pharmacology of this drug class. Other important therapeutic applications of the beta blockers include angina pectoris and MI, dysrhythmias, HF, and migraines.

Beta-adrenergic antagonists may be cardioselective ($beta_1$) or nonspecific ($beta_1$ and $beta_2$). Cardioselective beta blockers decrease heart rate, myocardial contractility, and cardiac conduction velocity. Nonspecific beta blockers produce the same effects but also act on the respiratory system to cause bronchoconstriction. Decreasing the heart rate and contractility also reduces cardiac output and lowers systemic blood pressure. Some of their antihypertensive effect is also caused by the blockade of $beta_1$ receptors in the juxtaglomerular apparatus, which inhibits the secretion of renin and the formation of angiotensin II. Although they are not recommended by the JNC-8 report as first-line drugs for HTN, the beta-adrenergic antagonists are still widely used for this condition.

At low doses, beta blockers are well tolerated and serious adverse events are uncommon. As the dosage is increased, however, adverse effects can become numerous and potentially serious in certain patients. Because nonselective beta blockers will slow the heart rate and cause bronchoconstriction, they should be used with caution in patients with asthma or HF. Heart rate and rhythm should be regularly monitored during beta-blocker therapy. Many patients report fatigue and activity intolerance at higher doses because the reduction in heart rate causes the heart to become less responsive to exertion. When discontinuing a beta blocker, drug doses should be tapered over a several week period. Abrupt cessation of beta-blocker therapy can result in rebound HTN, angina, MI, and even death in patients with CAD.

Prototype features for beta-adrenergic antagonists can be found for propranolol (Inderal, InnoPran XL) and metoprolol (Lopressor, Toprol XL) in Chapter 16, atenolol (Tenormin) in Chapter 35, and timolol in Chapter 74. In addition to atenolol, metoprolol, propranolol, and timolol, other beta blockers approved for HTN include betaxolol (Kerlone), bisoprolol (Zebeta), nadolol (Corgard), and nebivolol (Bystolic).

CONNECTION Checkpoint 34.3

From what you learned in Chapter 16, should a patient with hypertension and asthma receive a selective $beta_1$ blocker or a nonselective beta blocker for HTN? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Alpha$_1$-adrenergic antagonists: The $alpha_1$-adrenergic antagonists have several clinical applications, which were presented in Chapter 16. In addition to their use in HTN, they are prescribed for benign prostatic hyperplasia (BPH) because their ability to relax smooth muscle in the prostate and bladder neck reduces urethral resistance. A prototype drug feature for prazosin (Minipress) is included in Chapter 16, and the use of tamsulosin (Flomax) in treating BPH is discussed in Chapter 71. Terazosin is another $alpha_1$-adrenergic antagonist used for HTN.

The $alpha_1$-adrenergic antagonists lower blood pressure directly by blocking sympathetic receptors in arterioles, causing the vessels to dilate. They also dilate veins, which lowers blood pressure indirectly by decreasing venous return to the heart and reducing cardiac output. The alpha blockers are not first-line drugs for HTN because long-term clinical trials have shown them to be less effective at reducing the incidence of serious HTN-related cardiovascular events than diuretics. When used to treat HTN, the alpha blockers are used concurrently with other classes of antihypertensives, such as diuretics.

The $alpha_1$-adrenergic blockers may cause significant orthostatic hypotension. It is particularly serious with the initial doses of these medications and is referred to as the first-dose phenomenon, although orthostatic hypotension may persist throughout treatment. In severe cases, syncope can occur. Blood pressure should be assessed regularly during therapy to maintain patient safety. Other common adverse effects include weakness, dizziness, dry mouth, headache, and gastrointestinal (GI) complaints such as nausea and vomiting. Less common, though sometimes a major cause for nonadherence, are adverse effects on male sexual function that include decreased libido and erectile dysfunction.

Nonselective alpha$_1$- and beta-adrenergic antagonists: Carvedilol (Coreg) and labetalol (Trandate) are unique in that they block both $alpha_1$- and beta-adrenergic receptors. These drugs act by a combination of effects: They reduce cardiac output, inhibit renin secretion, and block vasoconstriction of arterioles and veins. As expected, their adverse effects are a combination of alpha and beta blockade and include orthostatic hypotension, bradycardia, and bronchoconstriction. The applications of carvedilol in treating HF are presented in Chapter 36.

Alpha$_2$-adrenergic agonists: If an alpha antagonist such as prazosin lowers blood pressure, it might be predicted that the administration of an $alpha_2$-adrenergic agonist would raise blood pressure. This is not the case. The answer to this contradiction lies in the different locations of the two subtypes of alpha receptors. The $alpha_1$ receptors blocked by prazosin lie in the peripheral nervous system (PNS) at arterioles. The $alpha_2$ receptors reside in the central nervous system (CNS).

When $alpha_2$ receptors are activated, the outflow of sympathetic nerve impulses from the CNS to the heart and arterioles is inhibited. In effect, this produces the same responses as inhibition of the $alpha_1$ receptor: slowing the heart rate and conduction velocity and dilating the arterioles. Thus, activating $alpha_2$ receptors (in the CNS) produces similar actions as inhibiting $alpha_1$ receptors (in the PNS).

The centrally acting $alpha_2$ agonists are used less frequently than the $alpha_1$ antagonists. The $alpha_2$ agonists have a tendency to cause excessive sedation, dizziness, and orthostatic hypotension, which can be especially troublesome in

older adults. Extended use results in sodium and water retention, which increases blood volume and counteracts the antihypertensive action of these drugs. Alpha$_2$ agonists are usually reserved for treating resistant HTN that cannot be managed by safer medications. The two drugs in this class are methyldopa (Aldomet) and clonidine (Catapres, Duraclon, Kapvay, Nexiclon XR).

Methyldopa is an older drug approved in 1962. Its only indication is HTN that has not responded adequately to safer antihypertensives. The drug is normally administered by the oral (PO) route, although an intravenous (IV) form known as methyldopate is available for hypertensive crises. Compared to other antihypertensives given by the IV route, methyldopa has a relatively slow onset of action because it must first be metabolized inside neurons to an active metabolite, methyl norepinephrine. Methyldopa is sometimes used to treat HTN occurring during pregnancy because it maintains stable blood flow to the uterus, and its safety to the fetus has been demonstrated in long-term studies.

Because methyldopa is a centrally acting drug, CNS effects such as drowsiness, depression, headache, sedation, and bizarre dreams are relatively common. Orthostatic hypotension may occur, but it is less severe than that produced by the alpha$_1$ antagonists. Peripheral edema due to sodium retention may occur, which can be managed by administration of a thiazide diuretic. A significant number of patients develop a positive Coombs' test, which detects antibodies against the patient's own red blood cells. Because tolerance develops after 3 to 4 months of therapy, a dosage increase may be required to manage HTN. This drug is pregnancy category B.

Approved in 1974, clonidine (Catapres, Duraclon, Kapvay, Nexiclon XR) activates alpha$_2$-adrenergic receptors in the cardiovascular control centers in the brainstem. The reduced sympathetic outflow causes vasodilation and slows the heart rate. As an antihypertensive, it is available as regular oral tablets, extended release tablets or suspension (Nexiclon), or a transdermal patch (Catapres) that releases the drug at a constant rate over 7 days. A second approved indication for clonidine (Duraclon) is intractable pain in patients with cancer that is not relieved by opiates. Pain control is achieved by a continuous epidural infusion of the drug. To assist in pain management, transdermal clonidine may be used to provide some degree of analgesia so that the dose of opiate can be reduced. An extended release form of clonidine (Kapvay) is approved to treat attention-deficit/hyperactivity disorder.

Clonidine has many off-label indications. These include dysmenorrhea, menopausal flushing, migraine prophylaxis, smoking cessation, opiate and benzodiazepine withdrawal, and Tourette's syndrome.

The most common adverse effect of clonidine is dry mouth, which occurs in about 40% of the patients taking the drug. Like methyldopa, CNS adverse effects such as sedation, fatigue, drowsiness, and dizziness are common. Transdermal clonidine produces fewer serious adverse effects, although the patches can cause skin irritation and itching. The patient should be warned not to abruptly discontinue the drug, as severe rebound HTN, agitation, nervousness, and anxiety may result.

Adrenergic neuron blockers: The adrenergic neuron-blocker class consists of two drugs that inhibit the synthesis or release of norepinephrine (NE) in sympathetic neurons. With less NE available to cross the synapse, sympathetic activity is diminished at both alpha- and beta-adrenergic receptors. In effect, the actions of these drugs are the same as the nonselective alpha$_1$- and beta-adrenergic antagonists: reduced heart rate and cardiac output (beta effects) combined with dilation of arterioles (alpha effect).

The adrenergic neuron blockers have mostly historical interest, as they are rarely prescribed today due to the availability of safer medications. Reserpine (Serpalan), approved in 1952, was one of the earliest drugs used for HTN. Unfortunately, reserpine can cause profound depression and sedation, and cardiovascular adverse effects such as bradycardia and orthostatic hypotension can be severe. Reserpine is only prescribed when patients are unable to tolerate safer antihypertensives.

Guanethidine (Ismelin) is also an adrenergic neuron–blocking drug. The limiting adverse effects of guanethidine are severe diarrhea and orthostatic hypotension, which occur frequently and can be serious enough to cause syncope. Guanethidine is rarely prescribed due to the potential for serious adverse effects.

34.9 Direct-acting vasodilators lower blood pressure by relaxing arteriolar smooth muscle.

The ability to cause vasodilation is a property shared by many different classes of drugs, as shown earlier in Pharmacotherapy Illustrated 34.1. Most vasodilators are used to treat HTN, and some are also used for the pharmacotherapy of HF, angina pectoris, and MI. Some of the drugs presented in previous sections of this chapter produce vasodilation indirectly by affecting autonomic nerves or by influencing the renin-angiotensin-aldosterone pathway. The drugs presented in this section affect the vascular smooth muscle itself; thus, they are called direct vasodilators.

Direct relaxation of arteriolar smooth muscle is an effective way to reduce blood pressure. Indeed, the direct vasodilator sodium nitroprusside (Nitropress) is used in hypertensive emergencies to lower blood pressure almost instantaneously. Unfortunately, the medications in this class have the potential to produce serious adverse effects. In the pharmacotherapy of HTN, these drugs are generally reserved for hypertensive emergencies and for HTN that has not been successfully managed with medications from safer drug classes.

All direct vasodilators cause reflex tachycardia, a compensatory increase in heart rate due to the sudden decrease in blood pressure. The baroreceptor reflex is an essential component of the normal physiologic control of blood pressure. However, when reflex tachycardia occurs as the result of vasodilator drugs, the heart is forced to work harder and the resultant blood pressure increase counteracts the effect of the antihypertensive drug. Patients with CAD may experience an acute angina attack due to the sudden increase in cardiac workload. Fortunately, reflex tachycardia can be prevented by administering a beta-adrenergic blocker, such as propranolol (Inderal). Beta blockers are often administered concurrently with direct vasodilators for this reason.

A second potentially serious adverse effect of direct vasodilator therapy is salt and water retention. The reduction in blood pressure from the vasodilator causes a compensatory increase in aldosterone secretion by the adrenal gland. The increased aldosterone level signals the kidney to retain more sodium and water. Blood volume increases, thus raising blood pressure and canceling the antihypertensive action of the vasodilator. A diuretic may be administered concurrently with a direct vasodilator in order to prevent fluid retention.

Other adverse effects are drug specific. Hydralazine can induce a lupus-like syndrome characterized by myalgia, arthralgia, fever, and the presence of antinuclear antibodies. Although rare, symptoms may persist for 6 months or longer and antinuclear antibodies may be present for 9 years. The occurrence of this lupus-like syndrome is more common in Whites who are slow acetylators (see Chapter 11). Antinuclear antibody titers should be determined prior to initiating therapy and periodically thereafter to identify the development of this syndrome.

PROTOTYPE DRUG Hydralazine

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Direct vasodilator

Therapeutic Effects and Uses: In 1952, hydralazine was one of the first oral antihypertensive medications marketed in the United States. It is most commonly administered in tablet form for moderate to severe HTN, usually in combination with other antihypertensives. Apresazide is a fixed-dose combination of hydralazine with HCTZ. When given PO, hydralazine is administered 2 to 4 times per day, usually with food because this increases its bioavailability. Therapy is generally begun with low doses, which are gradually increased until the desired therapeutic response is obtained. After several months of therapy, tolerance to the drug develops and a dosage increase may be necessary. Although it produces an effective reduction in blood pressure, drugs in other antihypertensive classes have largely replaced hydralazine.

Hydralazine is also available by the intramuscular (IM) and IV routes for hypertensive emergencies, especially those associated with preeclampsia, although it is not a preferred drug for this indication. It is sometimes administered to patients with acute HF because the drug reduces the workload on the heart due to its antihypertensive action. ACE inhibitors have largely replaced hydralazine for patients with HF. A fixed-dose combination therapy of isosorbide dinitrate and hydralazine (BiDil) is available for the treatment of HF in African American patients.

Mechanism of Action: By causing peripheral vasodilation, hydralazine acts directly to relax arterial smooth muscle. The decreased peripheral resistance is accompanied by an increase in heart rate and cardiac output. The overall result is a reduction in afterload. Because the drug is selective for arterioles and does not cause dilation of veins, orthostatic hypotension is not a major adverse effect.

Pharmacokinetics:

Route(s)	PO, IM, IV
Absorption	Rapidly absorbed PO and well absorbed IM
Distribution	Widely distributed; crosses the placenta and is secreted in breast milk; 87% bound to plasma protein
Primary metabolism	GI mucosa and liver; extensive first-pass metabolism
Primary excretion	90% renal, 10% feces
Onset of action	PO: 20–30 min; IM: 10–30 min; IV: 5–20 min
Duration of action	3–8 h (PO); 1–4 h (IV)

Adverse Effects: Hydralazine may cause several adverse effects that have the potential to prompt discontinuation of therapy. Headache, tachycardia, palpitations, flushing, nausea, and diarrhea are common but may resolve as therapy progresses. Orthostatic hypotension, fluid retention, and peripheral edema may also occur. Patients who are slow acetylators and those with CKD or who are receiving high doses of hydralazine are susceptible to experiencing a lupus-like syndrome. Symptoms may include rash, urticaria, myalgia, fever, chills, and fatigue. Blood dyscrasias such as agranulocytosis and leukopenia are rare, though potentially serious, adverse effects.

Contraindications/Precautions: Patients with lupus should not receive hydralazine, as the drug can worsen symptoms. The drug is contraindicated in patients with cerebrovascular disease or rheumatic heart disease. Patients should discontinue hydralazine gradually because abrupt withdrawal may cause severe rebound HTN and anxiety. Because it is excreted primarily by the kidneys, the drug should be used with caution in patients with CKD. Caution

must be used when administering hydralazine to patients who are known slow acetylators because plasma drug levels will be significantly higher in these patients. Caution should be used when treating patients with CAD, because hydralazine can precipitate angina attacks and an acute MI.

Drug Interactions: Administering hydralazine with other antihypertensives or monoamine oxidase inhibitors (MAOIs) may cause severe hypotension. This includes all drug classes used as antihypertensives. Nonsteroidal anti-inflammatory drugs (NSAIDs) may decrease the antihypertensive action of hydralazine. Beta blockers are usually used concurrently with hydralazine to block reflex tachycardia, and heart rate should be carefully monitored to avoid bradycardia. Hydralazine may produce false-positive Coombs' tests. **Herbal/Food:** Hawthorn should be avoided because it may cause additive hypotensive effects.

Pregnancy: Category C.

Treatment of Overdose: Treatment includes gastric lavage, activated charcoal, and administration of a plasma volume expander to raise blood pressure. Tachycardia may require treatment with a beta blocker.

Nursing Responsibilities: Key nursing implications for patients receiving hydralazine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Direct Vasodilators.

Drugs Similar to Hydralazine

Other direct vasodilators used for HTN include minoxidil and nitroprusside. Nitroprusside is a drug for hypertensive emergencies and is presented in Section 34.10.

Minoxidil (Loniten): Minoxidil is a direct vasodilator with profound vasodilation activity that is selective for arterioles: It does not dilate veins. It is administered PO for severe HTN that is unresponsive to drugs from other classes. Because of its efficacy and the potential for serious effects on the cardiovascular system, initial doses are very low, and the amount is increased gradually. It is a pregnancy category C drug.

Minoxidil is considerably more toxic than hydralazine. The most serious adverse effects are cardiovascular in nature, including reflex tachycardia and plasma volume expansion due to sodium and water retention. Beta blockers are usually administered concurrently to minimize tachycardia, and diuretics to prevent fluid retention. Although rare, pericardial effusion has been reported with minoxidil use. Minoxidil causes **hypertrichosis**, the elongation, thickening, and increased pigmentation of body hair. This is normal and will reverse when the drug is discontinued. The drug's effect on hair growth is used to the patient's advantage in Rogaine, a topical form of minoxidil used to stimulate hair growth in patients with male-pattern baldness. The topical form of the drug is not absorbed into the systemic circulation; thus Rogaine produces none of the serious cardiovascular effects observed with Loniten.

Management of Hypertensive Emergency

34.10 Hypertensive crisis is a medical emergency that is treated by the intravenous administration of antihypertensive medications.

A **hypertensive emergency (HTN-E)**, also called hypertensive crisis, is defined as a diastolic pressure of greater than 120 mmHg, with evidence of target-organ system damage. HTN-E requires aggressive treatment, usually within minutes to hours, to prevent further organ damage. A related condition, **hypertensive urgency**, is when a patient presents with severe HTN but has no evidence of target-organ damage.

Target-organ damage from extreme HTN most often occurs in the cardiovascular system, the kidneys, or the CNS. In the cardiovascular system, the increased workload on the heart leads to acute left HF with pulmonary edema, sometimes accompanied by myocardial ischemia or infarction. Chest pain and dyspnea are the most common symptoms in patients with HTN-E. Renal function is diminished, as evidenced by oliguria, hematuria, and proteinuria. Acute renal failure may occur, or preexisting CKD may worsen. In the brain, thrombotic or hemorrhagic stroke may occur. The capillaries in the brain become leaky, producing hypertensive encephalopathy, with resulting headache, paralysis, seizures, or coma. In addition, retinal hemorrhages and edema of the retina (papilledema) are signs of severe HTN.

The most common cause of HTN-E is untreated or poorly controlled essential HTN. In some cases, the patient has abruptly discontinued use of the antihypertensive medication. There are, however, a large number of possible secondary causes of HTN-E, including the following conditions:

- Renovascular hypertension
- Pheochromocytoma
- Cocaine use
- Eclampsia or preeclampsia
- Head injuries
- Primary hyperaldosteronism
- Coarctation of the aorta
- Hyperthyroidism or thyroid storm.

In the management of HTN-E, the therapeutic goal is to rapidly lower blood pressure. Care must be taken, however, to not decrease blood pressure too quickly because rapid and intense vasodilation can result in serious hypoperfusion of the cerebral, coronary, or renal vascular

capillaries. This can cause ischemia or infarction, worsening target-organ damage to the brain, heart, kidneys, or retina. It is recommended that the pretreatment blood pressure be progressively reduced by 20% to 25%, over 30 to 60 minutes. Additional, gradual reductions are made over a 12- to 48-hour period until blood pressure is reduced to a value within the normal range. Parenteral antihypertensives are preferred over PO medications due to their rapid onset of action and because infusions offer more precise control during the gradual pressure reduction.

In patients with hypertensive urgencies, target-organ damage has not yet developed. These patients are treated more conservatively by increasing the dose of their current antihypertensive drug, or by adding a second drug to the regimen. Oral medications are used to lower blood pressure because these drugs are less toxic than parenteral antihypertensives. Oral drugs with a relatively rapid onset of action that may be used for hypertensive urgency include clonidine (Catapres), captopril (Capoten), or labetalol (Trandate). The patient should be monitored for several hours, and doses may be repeated at frequent intervals, as needed, to lower pressure to acceptable levels. All patients with hypertensive urgency should receive follow-up assessments after 1 to 3 days on the new regimen.

PROTOTYPE DRUG **Nitroprusside Sodium (Nitropress)**

Classification **Therapeutic:** Drug for hypertensive emergency
Pharmacologic: Direct vasodilator

Therapeutic Effects and Uses: Nitroprusside is a first-line drug for patients with aggressive, life-threatening HTN because it has the ability to lower blood pressure almost instantaneously upon IV administration. Indications include hypertensive crisis, acute HF, and promotion of controlled hypotension to reduce bleeding during surgery. The drug has a short half-life, and the hypotensive effects disappear approximately 3 minutes after the infusion is discontinued. Unlike most direct vasodilators, nitroprusside causes very little reflex tachycardia. Although discovered in 1850, the drug was not approved by the U.S. Food and Drug Administration (FDA) until 1974.

Patients must be continuously monitored while receiving nitroprusside to prevent hypotension due to overtreatment. Therapy is limited to 72 hours because the drug is metabolized to toxic thiocyanate and cyanide compounds. This is of special concern to patients with CKD who are unable to excrete the cyanide. If serum thiocyanate exceeds 12 mg/dL, the nitroprusside infusion should be discontinued. As a general rule, patients are switched from nitroprusside to an oral antihypertensive as soon as blood pressure has stabilized.

Mechanism of Action: Nitroprusside dilates both arteries and veins; therefore, the hypotensive action of nitroprusside is due to direct relaxation of arteriolar smooth muscle and to blood pooling in the veins. In most patients, heart rate is mildly increased, while cardiac output is decreased. In patients with severe left ventricular hypertrophy, however, cardiac output may increase.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Unknown
Primary metabolism	Metabolized to thiocyanates in erythrocytes and other tissues
Primary excretion	Renal
Onset of action	1–2 min
Duration of action	1–10 min

Adverse Effects: Signs and symptoms of vasodilation such as hypotension, headache, dizziness, and flushing of the skin are expected adverse effects. With extended therapy, thiocyanate toxicity may manifest. Thiocyanate poisoning is characterized by hypotension, lethargy, blurred vision, metabolic acidosis, faint heart sounds, and loss of consciousness. Irritation may occur at the infusion site. **Black Box Warning:** Nitroprusside requires dilution prior to infusion and is not suitable for direct injection. The drug can cause irreversible ischemic injury and death due to significant drops in blood pressure. Accumulation of cyanide ion may occur.

Contraindications/Precautions: Patients with inadequate cerebral circulation or who have compensatory HTN should not receive nitroprusside. Because the kidneys excrete the toxic thiocyanate metabolite of the drug, patients with serious CKD should be treated cautiously. Nitroprusside is contraindicated in patients with high intracranial pressure because the drug may worsen this condition.

Drug Interactions: Antihypertensive drugs, ethanol, general anesthetics, and ganglionic blockers should be used with caution with nitroprusside because additive hypotension could result. Sympathomimetics such as epinephrine will block the antihypertensive actions of nitroprusside. Dobutamine (Dobutrex) and nitroprusside are sometimes administered concurrently because this interaction results in a beneficial synergistic increase in cardiac output and decrease in pulmonary capillary wedge pressure. **Herbal/Food:** Hawthorn may cause additive hypotensive effects.

Pregnancy: Category C.

Treatment of Overdose: Extreme hypotension may be treated with a vasopressor. Cyanide toxicity caused by

the overdose may require the use of a cyanide antidote kit, which contains amyl nitrate, sodium nitrite, and sodium thiosulfate. The purpose of these drugs is to convert toxic cyanide into nontoxic thiocyanate.

Nursing Responsibilities: Key nursing implications for patients receiving nitroprusside are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Direct Vasodilators.

Drugs Similar to Nitroprusside Sodium (Nitropress)

Other vasodilators for HTN-E are shown in Table 34.4, which summarizes their applications to the pharmacotherapy of hypertensive crisis. Diazoxide is a rapid-acting vasodilator that is no longer marketed for blood pressure control. An oral form of diazoxide (Proglycem) is available to treat various hypoglycemic states, usually caused by the presence of excessive insulin (hyperinsulinism).

PharmFACT

Hypertensive crisis is a common condition, affecting 1% of the patients with primary HTN. The most common presentation, occurring in 25% of patients, is stroke. The 1-year survival rate for a patient presenting with a HTN crisis has improved from only 20% prior to 1950 to more than 90% with current medical treatment (Hopkins, 2017).

Table 34.4 Drugs for Hypertensive Emergency

Drug	Class	Applications
clevidipine (Cleviprex)	Calcium channel blocker	Onset of action is 2–4 min with a short duration, allowing for rapid blood pressure reduction
enalaprilat (Enalapril IV)	ACE inhibitor	Onset of action is 15–30 min; useful in HTN-E associated with HF or high plasma levels of angiotensin II
esmolol (Brevibloc)	Beta-adrenergic antagonist	Onset of action is 1–5 min; useful for patients with severe left ventricular dysfunction or with peripheral vascular disease
fenoldopam (Corlopam)	Dopamine agonist	Onset of action is 5 min; useful for patients with CKD because the drug increases renal blood flow
hydralazine	Direct vasodilator	Onset of action is 5–20 min; useful in HTN-E due to eclampsia and preeclampsia because it increases uterine blood flow
labetalol (Trandate)	Alpha- and beta-adrenergic antagonist	Onset of action is 2–5 min; reduces incidences of MI and death
nicardipine (Cardene IV)	Calcium channel blocker	Onset of action is 1 min; rapid and effective for most HTN-E, with fewer adverse effects than some other HTN-E drugs
nitroprusside sodium (Nitropress)	Direct vasodilator	Onset of action is 1 min; preferred drug for many HTN-E
phentolamine (Regitine)	Alpha-adrenergic antagonist	Onset of action is 1–5 min; rarely used due to high incidence of reflex tachycardia and myocardial ischemia; useful for HTN-E due to pheochromocytoma

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Direct Vasodilators

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular (including MI, HF), cerebrovascular and neurologic (including level of consciousness [LOC], history of stroke, head injury, increased intracranial pressure), respiratory, and the possibility of autoimmune diseases, especially systemic lupus erythematosus. Obtain a drug history including allergies, current prescription and over-the-counter drugs, and herbal preparations. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings: electrolytes, especially sodium and potassium levels, hepatic and renal function studies, and lipid profiles.
- Obtain baseline weight, vital signs, pulse oximetry, breath and heart sounds, and cardiac monitoring (e.g., electrocardiogram [ECG], cardiac output). Assess location and character of peripheral edema if present.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., lowered blood pressure within established limits).
- Continue frequent and careful monitoring of vital signs, pulse oximetry, urinary and cardiac output, and daily weight, especially if IV administration is used. Blood pressure and pulse must be monitored every 5 minutes or as ordered while on IV infusion of the drug. (Invasive monitoring, such as arterial lines, is often used for this purpose.)
- Continue periodic monitoring of electrolytes, especially potassium.
- Continue frequent physical assessments, particularly neurologic, cardiac, and respiratory systems.
- Assess for and promptly report adverse effects: excessive hypotension, dysrhythmias, reflex tachycardia (from too rapid decrease in blood pressure or significant hypotension), headache, decreased urinary output, peripheral edema, and priapism (prolonged erection in the absence of sexual stimulation). Severe hypotension, seizures, dysrhythmias, or palpitations may signal drug toxicity and are immediately reported.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. IV infusion of vasodilators may be titrated frequently to achieve desired effects. Vital signs, cardiac and urinary output, and daily weights should remain within the limits set by the healthcare provider. (Pulse, blood pressure, and respiratory rate should be within normal limits or acceptable parameters. An increase in weight of more than 1 kg [2 lb] per day may indicate excessive fluid gain, and may require judicious diuretic therapy.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring. • Teach the patient, family, or caregiver how to monitor pulse and blood pressure as appropriate if the patient is on oral therapy at home. Ensure proper use and functioning of any home equipment obtained. • Have the patient weigh self daily along with blood pressure and pulse measurements. Report a weight gain or loss of more than 1 kg (2 lb) in a 24-h period.
Minimizing adverse effects: • Continue to monitor vital signs frequently. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension, patients with a preexisting history of cardiac or cerebrovascular ischemia, which may be worsened by decreased blood pressure, patients with dehydration, and patients with lupus erythematosus. Immediately notify the healthcare provider if the blood pressure or pulse decrease beyond established parameters or if hypotension is accompanied by reflex tachycardia. (Direct-acting vasodilators cause significant vasodilation, resulting in the potential for dramatically and rapidly lowered blood pressure accompanied by reflex tachycardia. Reflex tachycardia may require treatment with beta-blocking drugs.)	• Instruct the patient, family, or caregiver to report angina-like symptoms (e.g., chest, arm, back, or neck pain), palpitations, faintness, dizziness, drowsiness, or headache.
• Continue cardiac monitoring (e.g., ECG) and invasive monitoring (e.g., cardiac output, arterial line pressures) as ordered in the hospitalized patient. (Monitoring devices assist in detecting early signs of adverse effects as well as monitoring for therapeutic effects. **Diverse Patients:** Hydralazine is known to metabolize in patients who are slow acetylators, and because this cannot always be predicted, ensure that frequent monitoring continues, especially in the early stages of drug therapy.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring.
• Continue frequent physical assessments, particularly neurologic, cardiac, and respiratory. Immediately report any changes in LOC, headache, or changes in heart or lung sounds. (Vasodilator therapy may worsen preexisting neurologic, cardiac, or respiratory conditions as blood pressure drops and perfusion to vital organs diminishes.)	• When on oral therapy at home, the patient, family, or caregiver should immediately report changes in mental status or LOC, palpitations, dizziness, dyspnea, increasing productive cough, especially if frothy sputum is present, and seek medical attention.
• Weigh the patient daily and report weight gain or loss of 1 kg (2 lb) or more in a 24-h period or significant peripheral edema. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may signal blood pressure has lowered too quickly, stimulating renin release, and may require judicious use of diuretic therapy to treat.)	• When on oral therapy at home, have the patient weigh self daily, ideally at the same time of day, and record weight along with blood pressure and pulse measurements. Have the patient report a weight gain or loss of more than 1 kg (2 lb) in a 24-h period, or peripheral edema, especially if increasing.
• Continue to monitor IV infusion sites frequently. (Direct-acting vasodilators may cause tissue damage if the drug extravasates.)	• Instruct the patient to report any burning or stinging pain, swelling, warmth, redness, or tenderness at the IV insertion site.
• Observe for signs and symptoms of lupus in patients taking vasodilators, particularly hydralazine. (Hydralazine has been linked to drug-induced or drug-related lupus. Other direct vasodilators are used with caution for this reason.)	• Instruct the patient to report symptoms such as a butterfly-shaped rash over the nose and cheeks, muscle aches, and fatigue when taking oral vasodilators, particularly hydralazine.
• Monitor for the development of priapism and notify the healthcare provider. (Priapism may result in tissue damage if unrelieved and is considered a medical emergency.)	• Instruct the patient to report a sustained erection that lasts more than 4 h if on vasodilator therapy at home and to seek immediate medical care.
• For oral drug therapy, give the first dose of the drug at bedtime. (A first-dose response may result in a greater initial drop in blood pressure than subsequent doses.)	• Instruct the patient to take the first dose of the medication at bedtime, immediately before going to bed, and to avoid driving or other substantial activities for 12–24 h after the first dose or when the dosage is increased until effects are known.
• Do not abruptly stop medication. (Rebound HTN and tachycardia may occur.)	• Teach the patient, family, or caregiver not to stop the medication abruptly and to call the healthcare provider if the patient is unable to take the medication for more than 1 day due to illness.
• Encourage appropriate lifestyle changes: lowered fat intake, gradual increase in exercise, limited alcohol intake, smoking cessation. (Healthy lifestyle changes will support and minimize the need for drug therapy. Direct vasodilators decrease blood pressure substantially, and concurrent beta-blocker use may decrease heart rate. Given alone or together, this may lead to exercise intolerance. Activity levels should be increased gradually to patient tolerance. If dizziness or shortness of breath occurs, decrease exercise levels to a comfortable level. Alcohol consumption may increase the risk of blood pressure–related adverse effects.)	• Encourage the patient, family, or caregiver to adopt a healthy lifestyle of low-fat food choices, reduced sodium intake, increased exercise, decreased alcohol consumption, and smoking cessation. • Provide for dietitian consultation as needed. • Caution the patient about sudden increases in activity level. Report dizziness, palpitations, or shortness of breath that occurs while exercising.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION *(continued)*

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration techniques, followed by return demonstration. • The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 34

Key Concepts Summary

34.1 Failure to properly manage hypertension can lead to stroke, heart failure, or myocardial infarction.

34.2 Therapeutic lifestyle changes can reduce blood pressure and lessen the need for antihypertensive medications.

34.3 Research-based guidelines have been developed to aid the healthcare provider in providing optimal treatment for patients with hypertension.

34.4 The choice of antihypertensive medication is determined by the degree of hypertension and the presence of other medical conditions.

34.5 Diuretics are often preferred drugs for treating mild to moderate hypertension.

34.6 Calcium channel blockers have emerged as important drugs in the treatment of hypertension.

34.7 Blocking the renin-angiotensin-aldosterone system leads to a decrease in blood pressure and improved kidney function.

34.8 Adrenergic antagonists are commonly used to treat hypertension.

34.9 Direct-acting vasodilators lower blood pressure by relaxing arteriolar smooth muscle.

34.10 Hypertensive crisis is a medical emergency that is treated by the intravenous administration of antihypertensive medications.

CASE STUDY: Making the Patient Connection

Remember the patient "Elmer Foley" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Elmer Foley is a 72-year-old White man with a 10-month history of uncontrolled HTN. Initially, Elmer was prescribed the thiazide diuretic HCTZ (Microzide). However, after 1 week of therapy, his blood pressure remained at 168/102 mmHg. Next, Elmer's healthcare provider added an ACE inhibitor, captopril (Capoten), to the regimen. Still, Elmer's blood pressure remained above normal limits. Lastly, the healthcare provider discontinued the captopril and started Elmer on PO hydralazine. With this visit, his blood pressure is 146/90 mmHg.

When Elmer was first told he had HTN, he began many of the suggested lifestyle changes encouraged by his healthcare provider. He has lost a total of 15 kg (33 lb) since starting his diet 10 months ago. Elmer started walking daily for exercise and can now walk up to 1 mile without fatigue. He avoids all salty foods and diligently checks food labels for fat and salt content. Elmer occasionally drinks a glass of wine, although never more than 1 to 2 glasses per month. Although it was difficult for Elmer to

stop smoking, he proudly claims he has been smokeless for 8 months.

Critical Thinking Questions

1. How would you respond to Elmer's question, "What else can I do?" Is there anything else he can do to reduce his blood pressure?
2. Elmer wants to know why the previous therapies were unsuccessful. What would you say as his nurse?
3. As the nurse, how can you support Elmer before he leaves the clinic?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Helen Edwards is a 44-year-old African American woman who presents to the emergency department (ED) with headache and shortness of breath. Helen has a long-standing history of HTN. She has never consistently adhered to any HTN management strategies and has been nonadherent with her medication regimen for the past 8 months. On arrival at the ED her blood pressure is 192/126 mmHg.

When you assess the patient, you note that she is approximately 1.7 m (5′6″) in height and the self-reported weight is 107 kg (235 lb). She is slightly lethargic and reports having left arm numbness and tingling. Other physical assessment parameters are normal.

Helen is started on an infusion of nitroprusside (Nitropress) 50 mg in 250 mL in D_5W. The dose will be titrated between 0.5 and 10 mcg/kg/min to maintain the patient's diastolic pressure at less than 100 mmHg.

1. Describe the mechanism of action related to nitroprusside (Nitropress).
2. For what adverse effects should you monitor in patients receiving this drug therapy?
3. What factors does this patient have that predispose her to hypertensive crises?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Methyldopa (Aldomet) is being initiated for a patient with hypertension. Which health teaching would be most appropriate for this drug?
   1. Avoid hot baths and showers and prolonged standing in one position.
   2. This drug may discolor the urine a pinkish-brown color.
   3. You may experience bloating and weight gain.
   4. The tablet should be taken only with food or milk.

2. A patient is receiving hydralazine for elevated blood pressure levels. The nurse would include in the care plan to monitor the patient for which adverse effects?
   1. Atelectasis
   2. Crystalluria
   3. Photosensitivity
   4. Orthostatic hypotension

3. The nurse is preparing to administer the first dose of enalapril (Vasotec). Identify the potential adverse effects of this medication. (Select all that apply.)
   1. Reflex hypertension
   2. Hyperkalemia
   3. Persistent cough
   4. Angioedema
   5. Hypotension

4. A patient with hypertensive crisis is started on nitroprusside (Nitropress) therapy. The nurse would perform what priority intervention during the course of this treatment?
   1. Monitor for the presence or absence of bowel sounds.
   2. Obtain urine samples for specific gravity measurements and glucose levels.
   3. Observe skin pressure points for turgor and integrity.
   4. Titrate intravenous infusion rate according to the blood pressure response.

5. A 65-year-old White patient has been newly diagnosed with hypertension, with an average blood pressure of 164/92 mmHg. Which of the following drug groups will potentially be ordered initially? (Select all that apply.)
   1. Beta blockers
   2. Calcium channel blockers
   3. Thiazide diuretics
   4. Angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs)
   5. Direct-acting vasodilators

6. A patient is receiving nitroprusside (Nitropress) and is being monitored in the intensive care unit. Because of toxic cyanide metabolites that develop, which of the following should the nurse evaluate in the patient? (Select all that apply.)
   1. Cardiac status and cardiac output
   2. Renal function and creatinine levels
   3. Past history of alcohol use
   4. Level of consciousness
   5. Skin color and turgor

See Answers to Chapter Review in Appendix A.

Chapter 35
Pharmacotherapy of Angina Pectoris and Myocardial Infarction

Chapter Outline

- Pathophysiology of Myocardial Ischemia
- Etiology of Coronary Artery Disease
- Pathophysiology of Angina Pectoris
- Nonpharmacologic Therapy of Coronary Artery Disease
- Pharmacologic Management of Angina Pectoris
- Drug Classes for Angina Pectoris
  - Organic Nitrates
    - **PROTOTYPE** *Nitroglycerin (Nitrostat, Nitro-Bid, Nitro-Dur, Others), p. 609*
  - Beta-Adrenergic Antagonists
    - **PROTOTYPE** *Atenolol (Tenormin), p. 611*
  - Calcium Channel Blockers
- Pathophysiology of Myocardial Infarction
- Pharmacologic Management of Myocardial Infarction
  - Thrombolytics and Adjunct Medications for Myocardial Infarction

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe factors that affect myocardial oxygen supply and demand.
2. Explain the relationship between atherosclerosis and coronary artery disease.
3. Explain the pathophysiology of angina pectoris and myocardial infarction.
4. Discuss the role of therapeutic lifestyle changes in the management of coronary artery disease.
5. Describe the pharmacologic management of the different types of angina.
6. Describe the pharmacologic management of myocardial infarction.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy for angina and myocardial infarction.

Key Terms

angina pectoris, 604
coronary artery disease (CAD), 604
myocardial infarctions (MIs), 612
myocardial ischemia, 603
nitric oxide, 607
partial fatty-acid oxidation inhibitors, 606
plaque, 604
silent ischemia, 605
stable angina, 605
unstable angina, 605
variant (Prinzmetal's) angina, 605

The tissues of the body depend on a continuous supply of oxygen and vital nutrients to support life and health. The heart is particularly demanding of a steady source of oxygen. Insufficient arterial blood supply to cardiac muscle may result in angina pectoris, acute myocardial infarction (heart attack), and possibly death. This chapter focuses on the pharmacologic interventions related to angina pectoris and myocardial infarction (MI).

Pathophysiology of Myocardial Ischemia

35.1 Myocardial ischemia develops when there is inadequate blood supply to meet the metabolic demands of cardiac muscle.

Myocardial ischemia is a condition in which the heart is receiving an insufficient amount of oxygen to meet its metabolic demands. This occurs when there is an imbalance between oxygen supply and oxygen demand in myocardial cells. Knowledge of factors affecting myocardial oxygen supply and demand is necessary for understanding the pharmacotherapy of the diseases associated with myocardial ischemia.

Myocardial Oxygen Supply

The heart, from the moment it begins to function *in utero* until death, works to distribute oxygen and nutrients by means of its nonstop pumping action. It is the hardest working organ in the body, functioning continuously during both activity and rest. Because the heart is a muscle, it needs a steady supply of nourishment to sustain itself and maintain the systemic circulation in a balanced state of equilibrium. Any disturbance in blood flow to the myocardium—even for brief episodes—can result in life-threatening consequences. A review of basic coronary circulation is provided in Chapter 28.

As with other arteries in the body, the amount of blood flow through the coronary arteries is dependent on a number of hemodynamic factors. Of these, blood pressure is the most important. When systolic blood pressure falls, the quantity of blood flowing to the coronary arteries is diminished. If this occurs suddenly, such as in acute shock, it could be life threatening. Immediate restoration of blood pressure is required to reestablish an adequate oxygen supply to the myocardium as well as to other vital tissues. Other hemodynamic factors contributing to the myocardial oxygen supply include changes in blood volume (e.g., hemorrhage) and disorders that reduce the oxygen content or carrying capacity of the blood (e.g., anemia).

The narrowing of a coronary artery resulting from atherosclerosis or coronary artery disease (CAD) deprives cells of needed oxygen and nutrients. If the narrowing develops over a long period of time, the heart compensates for its inadequate blood supply and the patient may be asymptomatic. Indeed, coronary arteries may be occluded as much as 50% or more and cause no symptoms.

Myocardial Oxygen Demand

As CAD progresses, cardiac muscle does not receive enough oxygen to meet the body's metabolic demands. The physiologic demands on the heart are highly variable and depend on a large number of hemodynamic and lifestyle factors.

Basically, anything that increases the workload of the heart will increase myocardial oxygen demand. It is not difficult to think of the many daily activities that increase cardiac workload. Exercise, for example, will cause the heart to beat faster in order to pump more blood to muscles. This physical activity need not be extreme: Simply walking at a normal pace will increase cardiac workload over resting levels.

In some patients, the increased cardiac workload can be the result of mental, rather than physical, stressors. Think of the first time (or last time) you had to give a speech in front of a group, or became angry with a child, spouse, or coworker. These activities resulted in your heart pumping harder or faster, even though there was no physical activity involved. What factors do physical exercise and mental stress have in common that produced the increased cardiac workload?

The answer is simple. Anything that increases heart rate, contractility, or tension on the ventricular walls causes the heart to work harder and affect cardiac oxygen consumption. For example, if heart rate increases due to

exercise or hyperthyroidism, it is easy to understand why the heart needs more oxygen because it must beat more times per minute. Similarly, the heart will need more oxygen if it beats more forcefully (increased contractility). A patient with heart failure (HF) has a thickened myocardium (increased tension) that will require more work to contract. The heart of a patient with hypertension will have to work harder to overcome resistance and eject blood. It is important to remember that anything that makes the heart beat faster or contract with more force will increase myocardial oxygen demand. Drugs that diminish these factors are of value in the treatment of angina, MI, and HF.

Etiology of Coronary Artery Disease

35.2 Coronary artery disease is the major cause of myocardial ischemia.

Coronary artery disease (CAD) is one of the leading causes of mortality in the United States. The primary defining characteristic of CAD is narrowing or occlusion of one or more coronary arteries. Narrowing can result in symptoms of angina pectoris, whereas occlusion results in MI. The two disorders are closely related, as most patients who experience an MI have narrowing of the coronary vessels.

The most common etiology of CAD in adults is atherosclerosis, the presence of **plaque**—a fatty, fibrous material—within the walls of the coronary arteries. Plaque develops progressively over time, producing varying degrees of intravascular narrowing that results in partial or total blockage of the vessel. During periods of rest, demands on the heart are reduced and a partially occluded artery may be able to provide adequate oxygen. During exercise (or a pharmacology test), however, workload on the heart increases, the cardiac muscle distal to the obstruction receives insufficient oxygen supply, and ischemia results.

A healthy heart responds to stress by changing the diameter of the coronary arteries. When the oxygen demands of the heart increase, the vessels will immediately dilate to bring more oxygen to the myocardium. Plaque impairs normal elasticity, and the coronary vessels are unable to dilate properly when the myocardium demands additional oxygen. Myocardial ischemia occurs when cardiac demands exceed the amount of oxygen that can be supplied through the narrowed, inelastic vessels characteristic of CAD.

Plaque accumulation occurs gradually, over periods of 40 to 50 years in some individuals, but actually begins to accrue very early in life. The development of atherosclerosis is illustrated in Figure 35.1.

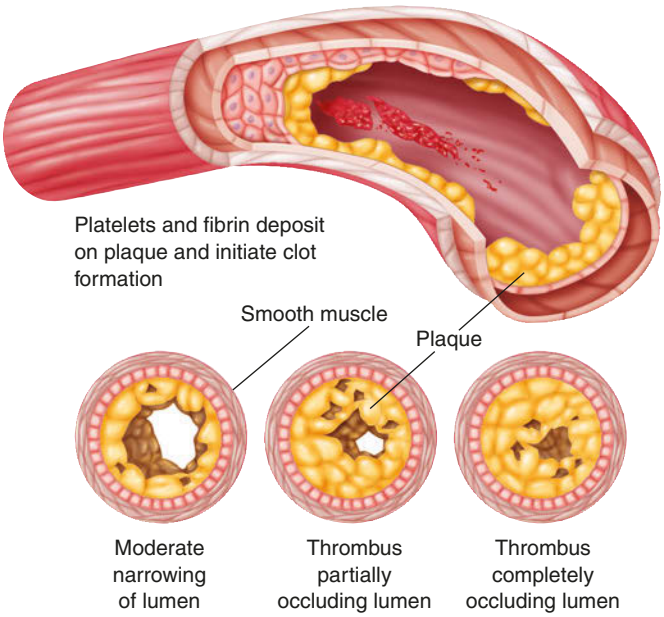

Figure 35.1 Atherosclerosis in the coronary arteries.

CONNECTION Checkpoint 35.1

From what you learned in Chapter 28, predict what would happen to the cardiac workload when plasma volume is increased by a rapid infusion of normal saline. What effect might this have on a patient with CAD? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pathophysiology of Angina Pectoris

35.3 Angina pectoris is characterized by severe chest pain brought on by physical exertion or emotional stress.

Angina pectoris is acute chest pain caused by myocardial ischemia. The classic presentation of angina pectoris is steady, intense pain, sometimes with a crushing sensation in the anterior chest. Typically, the discomfort radiates to the left shoulder and proceeds down the left arm. It may also extend to the posterior thoracic region or move upward to the jaw, and in some patients the pain is experienced in the epigastrium or abdominal area. Accompanying the discomfort is severe emotional distress—a feeling of panic with fear of impending death. There is usually pallor, dyspnea with cyanosis, diaphoresis, tachycardia, and elevated blood pressure.

Anginal pain is usually precipitated by physical exertion or emotional excitement—events associated with increased myocardial oxygen demand. Angina pectoris episodes are of short duration. With physical rest and mental relaxation, the workload demands on the heart diminish and the discomfort subsides within 5 to 10 minutes. Descriptions of the four basic types of angina follow.

When angina occurrences are fairly predictable in frequency, intensity, and duration, the condition is described as classic or **stable angina**. Rest usually relieves the pain associated with stable angina in about 5 minutes or less.

Variant (Prinzmetal's) angina occurs when the decreased myocardial blood flow is caused by spasms of the coronary arteries. This type is sometimes called vasospastic angina. The vessels undergoing spasms may or may not contain atherosclerotic plaque. Thus, the primary cause of the narrowing and subsequent angina pain is vasoconstriction of the artery, rather than plaque buildup. Variant angina pain occurs most often during periods of rest, although it may occur unpredictably, unrelated to rest or activity.

Although most people equate angina with chest pain, this is not always the case. When myocardial ischemia occurs in the absence of pain, it is called **silent ischemia**. Although one or more coronary arteries are partially occluded, the patient is asymptomatic. Some patients diagnosed with stable angina also experience silent ischemia. Although the mechanisms underlying silent ischemia are not completely understood, the condition is associated with a high risk for acute MI and sudden death.

Unstable angina occurs when episodes of angina happen suddenly, have added intensity, and occur during periods of rest. Unstable angina is a type of acute coronary syndrome in which an atherosclerotic plaque within a coronary artery ruptures. A thrombus quickly builds on the displaced plaque, and the artery becomes at serious risk of occlusion. This condition is a medical emergency requiring aggressive intervention because of the associated increased risk for MI.

Anginal pain often parallels the signs and symptomatology of MI. It is extremely important for the nurse to be able to accurately identify the characteristics that differentiate the two conditions, since the pharmacologic interventions related to angina differ considerably from those of MI. Angina, while aggravating and uncomfortable, rarely leads to a fatal outcome and the chest pain is usually immediately relieved by nitroglycerin. MI, however, carries with it a high mortality rate if appropriate treatment is delayed (see Section 35.9). In the event of MI, pharmacologic intervention must be initiated immediately and systematically maintained. When a patient presents with chest pain, the foremost objective for the healthcare provider is to quickly determine the cause of the pain so that proper, effective interventions can be delivered.

PharmFACT

About 9.8 million Americans experience angina each year. The risk of angina increases with age and is more common in women. Only 18% of coronary attacks are preceded by angina (Alaeddini, 2016).

Nonpharmacologic Therapy of Coronary Artery Disease

35.4 Therapeutic lifestyle changes can decrease the frequency of anginal episodes and reduce the risk of coronary artery disease.

A combination of variables influences the development and progression of angina, including dietary patterns and lifestyle choices. The nurse is instrumental in teaching patients the means of preventing CAD as well as how to lower the rate of recurrence of anginal episodes. Such support includes the formulation of a comprehensive plan of care that incorporates psychosocial support and an individualized teaching plan. The patient needs to understand the causes of angina, identify the conditions and situations that trigger it, and develop the motivation to modify behaviors associated with their disease.

Listing therapeutic lifestyle changes that modify the development and progression of cardiovascular disease (CVD) may seem repetitious, as these same factors have been included in chapters on hypertension (HTN) and heart disease. However, the importance of prevention and management of CVD through nonpharmacologic means cannot be overemphasized. Making healthy lifestyle choices can prevent CAD and slow the progression of the disease in those who have existing plaque. The following interventions have been shown to reduce the incidence of CAD:

- Limit alcohol consumption to small or moderate amounts.
- Eliminate foods high in cholesterol or saturated fats.
- Keep blood cholesterol and other lipid indicators within the normal ranges.
- Keep blood pressure within the normal range.
- Maintain blood glucose levels within the normal range.
- Exercise regularly and maintain optimal weight.
- Do not use tobacco.

When the patient is unable or unwilling to adopt healthy lifestyle choices, preventive drug therapy may be used to lower CAD risk factors. For example, antihypertensives are often used to manage blood pressure, statins to lower blood lipids, and insulin or oral hypoglycemics to keep blood glucose within the normal range. The nurse should teach patients that therapeutic lifestyle changes should be incorporated into their daily routine, even if medications are necessary to control major risk factors.

Pharmacologic Management of Angina Pectoris

35.5 The pharmacologic management of angina includes organic nitrates, beta-adrenergic antagonists, and calcium channel blockers.

There are several desired therapeutic goals for a patient receiving pharmacotherapy for angina. A primary goal is to reduce the frequency and intensity of angina episodes. Additionally, successful pharmacotherapy should improve exercise tolerance and allow the patient to actively participate in activities of daily living. Long-term goals include extending the patient's lifespan by preventing the serious consequences of ischemic heart disease such as dysrhythmias, HF, and MI. Pharmacotherapy alone, however, cannot usually achieve all these outcomes; the patient must be willing to implement therapeutic lifestyle changes that promote a healthy heart.

Medications for angina are sometimes placed into two categories: those that terminate an acute angina episode in progress, and those that decrease the frequency of angina episodes. The primary means by which antianginal medications act is by reducing the myocardial demand for oxygen. This may be accomplished by the following mechanisms:

- Slowing the heart rate
- Dilating veins so that the heart receives less blood (reduced preload)
- Causing the heart to contract with less force (reduced contractility)
- Lowering blood pressure (reduced afterload).

The pharmacotherapy of angina uses three primary classes of drugs: organic nitrates, beta-adrenergic antagonists, and calcium channel blockers (CCBs). Rapid-acting organic nitrates are preferred drugs for *terminating* an acute angina episode. Beta-adrenergic antagonists or blockers are first-line drugs for *prophylactic* treatment. CCBs are used when beta blockers are not tolerated well by a patient. Long-acting nitrates, given by the oral (PO) or transdermal routes, are alternatives for prophylaxis. Persistent angina requires drugs from two or more classes, such as a beta blocker combined with a long-acting nitrate or a CCB. Pharmacotherapy Illustrated 35.1 illustrates the mechanisms of action of medications used to prevent and treat angina.

Should the patient be unable to tolerate beta blockers or CCBs, ranolazine may be considered as another option. Approved in 2006, ranolazine (Ranexa) is the only medication in a class called **partial fatty-acid oxidation inhibitors**. Ranolazine reduces the flow of sodium and calcium ions into the myocardium, which decreases the metabolic rate and oxygen demands of myocardial cells. Thus, it is the only antianginal that acts through its metabolic effects, rather than hemodynamic effects; effects on heart rate and blood pressure are minimal. The drug is approved only for chronic angina that has not responded to other drugs.

CONNECTIONS: Complementary and Alternative Therapies

Omega-3 Fatty Acids

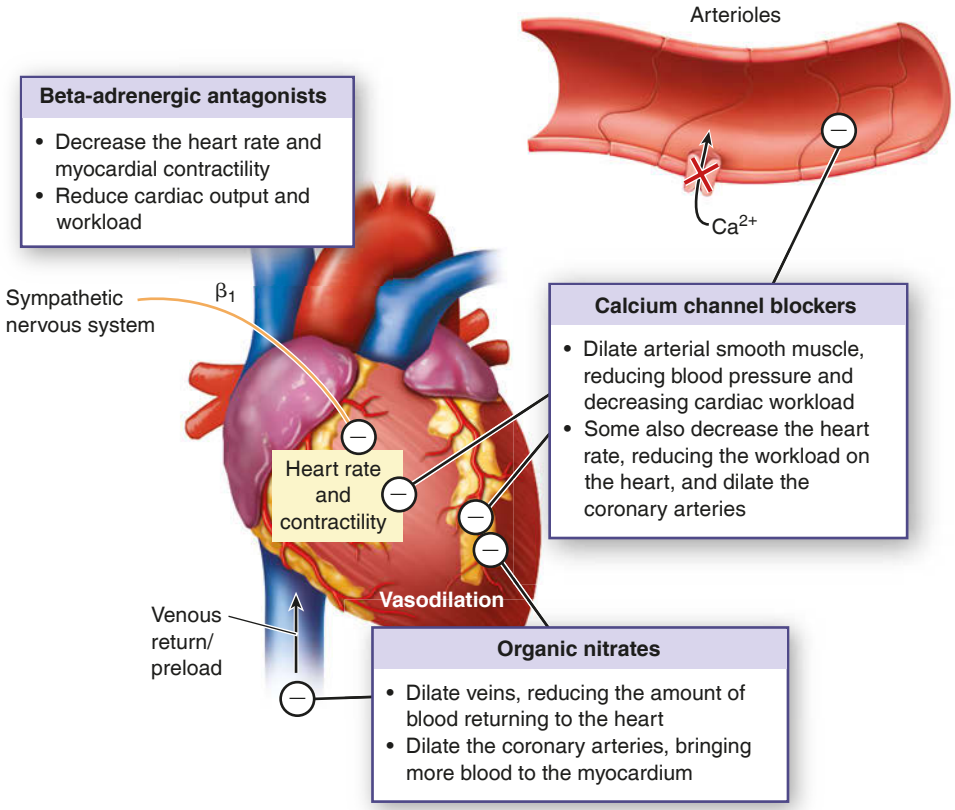
Description

Omega-3 fatty acids are unsaturated fats found in fatty fish such as salmon, mackerel, and tuna; vegetable oils such as canola and soybean; seeds such as flaxseed and flaxseed oil; and nuts, green leafy vegetables, and beans. Omega-3 fatty acids are essential to the body and necessary for regulating muscle function, blood clotting, digestion, cell growth, and other functions (National Center for Complementary and Integrative Health, 2015).

History and Claims

Claims have been made that omega-3 fatty acids can reduce inflammation and prevent or treat conditions such as heart disease, high blood pressure, rheumatoid arthritis, lupus, asthma, inflammatory bowel disease, and cancer.

Standardization



There are different types of omega-3 fatty acids: alpha-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). While a balance of omega-3 and omega-6 fatty acids in the diet is important, the average U.S. diet tends to contain as much as 10 to 25 times more omega-6 than omega-3, due in large part to the consumption of meats that are higher in omega-6. Doses of less than 3 g/day of omega-3 fatty acids are usually recommended to prevent GI side effects such as diarrhea. The recommended dose is up to 4 g/day for patients with high lipid levels and 1 g/day for patients with coronary artery disease (University of Maryland Medical Center, 2015).

Evidence

Research has shown that omega-3 fatty acids may reduce the incidence of cardiovascular disease. In some research studies, patients have shown improvement in lipid levels and in inflammatory conditions such as rheumatoid arthritis or inflammatory bowel disease. Larger studies need to be conducted, however, to determine the extent of such benefits. While obtaining omega-3 fatty acids through dietary means is highly recommended, concern about mercury and other toxic metals in fatty fish has been raised, and it is recommended that pregnant women and young children avoid eating more than one 2-ounce serving per week of fatty fish (mackerel, shark, swordfish, or tilefish), but may eat up to 12 ounces of other types (University of Maryland, 2015).

Pharmacotherapy Illustrated 35.1

Mechanisms of Action of Drugs Used to Treat Angina

CONNECTION Checkpoint 35.2

Many patients take HMG-CoA reductase inhibitors (statins) concurrently with antianginal medications. From what you learned in Chapter 29, what is the rationale for prescribing drugs from this class for a patient with CAD? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Drug Classes for Angina Pectoris

35.6 Organic nitrates may be used to terminate or prevent angina episodes.

After their medicinal properties were discovered in 1879, the organic nitrates became the mainstay for the treatment of angina for the next 100 years. The mechanism of action results from the formation of **nitric oxide** in vascular smooth muscle. Nitric oxide is an important cell-signaling molecule and a potent vasodilator, causing relaxation of both arterial and venous smooth muscle. Dilation of veins reduces the amount of blood returning to the heart (preload), and the chambers contain a smaller volume. With less blood for the ventricles to pump, cardiac output is reduced and the workload on the heart is decreased, thereby lowering myocardial oxygen demand. The therapeutic outcome is that chest pain is alleviated and episodes of angina become less frequent.

Organic nitrates also have the ability to dilate coronary arteries, which was once thought to be their primary mechanism of action. It seems logical that dilating a partially occluded coronary vessel would allow more oxygen to reach ischemic tissue. Although this effect does indeed occur, it is no longer considered the primary mechanism of nitrate action in the treatment of stable angina. Coronary artery vasodilation, however, is crucial in treating variant angina, in which the chest pain is caused by coronary artery spasm. The organic nitrates relax these spasms, allowing more oxygen to reach the myocardium, thereby terminating the pain.

Organic nitrates are classified by their onset and duration of action. The short-acting nitrates, such as nitroglycerin, may be taken sublingually (SL) or as an oral spray or buccal tablet to quickly terminate an acute anginal episode. Long-acting nitrates, such as isosorbide dinitrate (Isordil), are taken orally or are absorbed slowly through a

Table 35.1 Administration of Organic Nitrates

Route	Administration
Sublingual (SL) tablet	• Give 1 tablet. If pain is unrelieved, may give additional tablets at 5-min intervals up to 3 tablets in a 15-min period. • Moisture on SL tissue is necessary for the SL tablet to dissolve. A patient may be unresponsive to SL nitroglycerin, as the anxiety caused by chest pain typically leads to dry mouth.
Sustained release buccal tablet	• Place 1 tablet between lip and gum above incisors or between cheek and gum. Allow to slowly dissolve over 3–5 h. • Avoid touching tongue to tablet or drinking hot fluids, as these can increase dissolution of the tablet, decrease the duration of the medicinal effect, and lead to the onset of angina pain. • Avoid chewing, crushing, or swallowing the tablet.
Sustained release tablet or capsule	• Give on an empty stomach with a full glass of water 1 h before, or 2 h after, meals. The tablet should be swallowed whole. • Note that the sustained release form helps to prevent angina attacks but is not intended for immediate relief of angina. • Avoid chewing or crushing the tablet.
Translingual spray	• Avoid shaking medicine canister. Spray on or under the tongue. Never inhale spray. • Repeat spray every 5 min if needed for a maximum of 3 metered doses. • Teach the patient to avoid swallowing for at least 10 sec.
Transdermal ointment	• Avoid touching ointment with fingers. Squeeze the prescribed dosage onto the dose-determining applicator (paper application patch) in the medication package. Spread ointment in a thin, even layer to premarked 5.5- by 9-cm (2 1/4- by 3 1/2-in.) square. Place patch with ointment side down onto nonhairy skin surface such as the forearm, chest, abdomen, or anterior thigh. Cover with transparent wrap and secure with tape. • Rotate application sites to prevent skin inflammation and sensitization. Remove any residual ointment before reapplication. • Keep medication container closed and stored in a cool place.
Transdermal unit	• Apply transdermal patch at the same time each day to nonhairy or closely trimmed area without excessive movement. • Avoid application on irritated or scarred skin. • Rotate application site each time to prevent skin irritation and sensitization.
Intravenous (IV)	• Verify with healthcare provider the correct IV concentration and rate of infusion, and use the supplied IV tubing for administration. • Remove any existing transdermal unit or ointment in place on the patient before starting IV infusion to prevent overdosage. • Note that IV nitroglycerin can cause hypotension, so give with extreme caution to patients with preexisting hypotension or hypovolemia. • Monitor patient closely for any change in levels of consciousness and for dysrhythmias, because IV nitroglycerin contains a substantial amount of ethanol as a diluent. Ethanol intoxication with symptoms of nausea, vomiting, coma, lethargy, and alcohol breath can occur with high doses of IV nitroglycerin. Stop infusion if intoxication occurs. The patient should recover immediately when drug administration is discontinued.

transdermal patch to decrease the frequency and severity of angina episodes. Long-acting organic nitrates are occasionally used to treat symptoms of HF; their role in the treatment of that disease is presented in Chapter 36. The various routes of administration are listed in Table 35.1. Doses for the organic nitrates, along with other medications for treating angina and MI, are listed in Table 35.2.

Tolerance is a common and potentially serious problem with the long-acting organic nitrates. The magnitude of the tolerance depends on the dosage and frequency of drug administration. Although tolerance develops rapidly—as quickly as 24 hours after the initiation of therapy in some patients—it also disappears rapidly when the drug is withheld. Patients are often instructed to remove the transdermal patch for 6 to 12 hours each day or withhold a nighttime dose of the oral medications in order to delay the development of tolerance. Because the oxygen demands during sleep are diminished, the patient with stable angina experiences few angina episodes during this drug-free interval.

Most adverse effects of organic nitrates are extensions of their hypotensive action. Flushing of the face and headache are common effects, related to vasodilation. Orthostatic hypotension is a frequent adverse effect of this drug class, and patients should be advised to change positions gradually to prevent lightheadedness. Blood pressure should be carefully monitored, and the nurse should hold nitrates and remove topical forms if serious hypotension is discovered. Taking organic nitrates concurrently with alcohol may cause severe hypotension and even cardiovascular collapse.

An additional adverse effect that can be limiting in some patients is reflex tachycardia. When the organic nitrates dilate vessels and blood pressure falls, the baroreceptor reflex is triggered. Sympathetic stimulation of the heart increases heart rate and contractility, which are undesirable effects in a patient with angina. This adverse effect is often transient and asymptomatic. Patients who report significant palpitations may be administered a beta blocker, which will prevent the reflex cardiac stimulation.

Table 35.2 Selected Drugs for Angina and Myocardial Infarction

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Organic Nitrates		
isosorbide dinitrate (Dilatrate SR, Isordil)	PO (regular release): 2.5–30 mg qid (max: 480 mg/day) PO: (sustained release): 40 mg bid–qid (max: 160 mg/day) SL: 2.5–5 mg taken 15 min before exercise	*Headache, orthostatic hypotension, flushing of the face, dizziness, rash (transdermal patch), tolerance* Anaphylaxis, circulatory collapse due to hypotension, syncope due to orthostatic hypotension
isosorbide mononitrate (Imdur, Ismo, Monoket)	PO (regular release: Ismo, Monoket): 20 mg bid (max: 40 mg/day) PO (extended release: Imdur): 30–60 mg each morning (max: 240 mg/day)	
nitroglycerin (Nitrostat, Nitro-Bid, Nitro-Dur, others)	SL: 1 tablet (0.3–0.6 mg) or 1 spray (0.4–0.8 mg) every 3–5 min (max: 3 doses in 15 min)	
Beta-Adrenergic Antagonists		
atenolol (Tenormin)	PO: 25–50 mg daily (max: 100 mg/day)	*Fatigue, insomnia, drowsiness, impotence or decreased libido, depression, bradycardia, and confusion* Agranulocytosis, laryngospasm, Stevens–Johnson syndrome, anaphylaxis; if the drug is abruptly withdrawn, palpitations, rebound HTN, life-threatening dysrhythmias or myocardial ischemia may occur
metoprolol (Lopressor, Toprol XL)	PO (for HTN or angina): 100 mg/day (max: 400 mg/day)	
propranolol (Inderal, Inderal LA, InnoPran XL)	PO (immediate release): 40–420 mg bid (max: 640 mg/day) PO (extended release): 80–160 mg/day (max: 120 mg/day for InnoPran XL; 640 mg/day for Inderal LA)	
timolol	PO (for MI): 10 mg bid (max: 60 mg/day)	
Calcium Channel Blockers		
amlodipine (Norvasc)	PO: 5–10 mg daily (max: 10 mg/day)	*Flushed skin, headache, dizziness, peripheral edema, lightheadedness, nausea, constipation* Hepatotoxicity, MI, HF, confusion, mood changes
diltiazem (Cardizem, Cartia XT, Dilacor XR, others)	PO (regular release): 30 mg tid–qid (max: 360 mg/day) PO: (extended release): 120–240 mg bid (max: 540 mg/day)	
nicardipine (Cardene)	PO (regular release): 20–40 mg tid PO (sustained release): 30–60 mg bid (max: 120 mg/day)	
nifedipine (Adalat CC, Procardia XL, others)	PO (regular release): 10–20 mg tid (max: 180 mg/day) PO (extended release): 30–90 mg once daily	
verapamil (Calan, Covera-HS, Isoptin SR, Verelan)	PO (immediate release): 80–120 mg 3–4 times daily (max: 480 mg/day) PO (extended release): 180–540 mg/day	
Miscellaneous Drug		
ranolazine (Ranexa)	PO: 500–1000 mg bid (max: 2000 mg/day)	*Dizziness, constipation, headache, nausea* QT interval prolongation, bradycardia

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PROTOTYPE DRUG Nitroglycerin (Nitrostat, Nitro-Bid, Nitro-Dur, Others)

Classification **Therapeutic:** Antianginal drug
Pharmacologic: Organic nitrate, vasodilator

Therapeutic Effects and Uses: Nitroglycerin, the oldest and most widely used organic nitrate, can be delivered by a number of different routes: sublingual, lingual spray, PO, intravenous (IV), transmucosal, transdermal, topical, and extended release forms. The rapid-acting forms may be taken while an acute angina episode is in progress or just prior to physical activity. When given sublingually, it reaches peak plasma levels within minutes, thus quickly terminating angina pain. Chest pain that does not resolve within 5 minutes after a dose of SL nitroglycerin may indicate MI, and emergency medical services (EMS) should be contacted. The transdermal and oral sustained release forms are for prophylaxis only, since they have a relatively slow onset of action. The long-acting forms should be discontinued gradually because vasospasm may result if they are abruptly withheld.

Nitroglycerin is also used for indications other than angina. When administered by the IV route, the drug is approved for controlled hypotension induction during anesthesia and the treatment of HF, acute pulmonary edema, acute MI, severe HTN, or hypertensive emergency. Off-label indications include use as a uterine relaxant to aid in the extraction of a retained placenta and for pain associated with anal fissures or hemorrhoids.

Mechanism of Action: Upon reaching vascular smooth muscle, nitroglycerin forms nitric oxide, which triggers a cascade resulting in the release of calcium ions in smooth muscle. Nitroglycerin relaxes both arterial and

venous smooth muscle. The venous dilation decreases the amount of blood returning to the heart, reducing preload. With less blood for the ventricles to pump, myocardial oxygen demand is decreased. In addition, direct vasodilation of coronary arteries enhances the blood supply to the myocardium and is partially responsible for its therapeutic effects.

Pharmacokinetics:

Route(s)	PO: SL tablets, SL spray, buccal tablets; transdermal patch; topical ointment
Absorption	Rapid
Distribution	Widely distributed; 60% bound to plasma protein
Primary metabolism	Hepatic; extensive first-pass metabolism
Primary excretion	Renal
Onset of action	SL: 1–3 min; buccal: 2–5 min; transdermal patch: 40–60 min; topical ointment: 20–60 min
Duration of action	SL: 30–60 min; buccal: 2 h; transdermal patch: 18–24 h; topical ointment: 12 h

Adverse Effects: Most patients experience flushing of the face and a throbbing, transient headache, which result from the drug's vasodilation action. Orthostatic hypotension and syncope may occur. Stinging and rash may occur with ointments and transdermal patches. Methemoglobinemia is a rare adverse effect that can cause shock and coma. Anaphylaxis leading to circulatory collapse due to severe hypotension is rare. Tolerance develops with continuous therapy or large doses of the drug.

Contraindications/Precautions: Nitrates are contraindicated in patients with preexisting hypotension, shock, head injury with increased intracranial pressure, or head trauma because additive vasodilation would worsen these conditions. Drugs in this class are contraindicated in pericardial tamponade and constrictive pericarditis because the heart is unable to increase cardiac output to maintain blood pressure when the drug causes vasodilation. Sustained release forms of the medicine should not be given to patients with glaucoma because the drug may increase intraocular pressure. Nitroglycerin should be used cautiously in patients with severe liver or renal disease, as the drug could build to toxic levels. Dehydration or hypovolemia should be corrected before nitroglycerin is administered; otherwise serious hypotension may result.

Drug Interactions: Concurrent use with sildenafil (Viagra) or other phosphodiesterase-5 inhibitors may cause life-threatening hypotension and cardiovascular collapse. Nitrates should not be taken within 24 hours before or after taking these drugs. Concurrent use with ethanol, CCBs, antidepressants, phenothiazines, or antihypertensive drugs may cause additive hypotension. Sympathomimetics such as epinephrine will antagonize the vasodilation effects of nitroglycerin. **Herbal/Food:** Use with hawthorn may result in additive hypotension.

Pregnancy: Category C.

Treatment of Overdose: During overdose, hypotension may be reversed with the IV administration of normal saline. If methemoglobinemia is suspected, methylene blue may be administered.

Nursing Responsibilities: Key nursing implications for patients receiving nitroglycerin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Organic Nitrates for Angina and Myocardial Infarction.

Drugs Similar to Nitroglycerin (Nitrostat, Nitro-Bid, Nitro-Dur, Others)

Other organic nitrates include isosorbide dinitrate and isosorbide mononitrate.

Isosorbide dinitrate (Dilatrate SR, Isordil): Approved in 1961, isosorbide dinitrate is an organic nitrate used to terminate anginal attacks (SL) and for the prophylaxis of angina (extended release tablets). It is occasionally used to treat HF. The dosing schedule must allow for a drug-free period of at least 14 hours to prevent tolerance to the drug's effects. The PO forms of the drug should not be used to terminate angina attacks in progress because it takes as long as 60 minutes to reach therapeutic drug levels. The SL dosage forms may be taken 15 minutes prior to activities likely to precipitate angina. Adverse effects are similar to those of nitroglycerin. Like other nitrates, isosorbide dinitrate should not be administered within 24 hours of taking erectile dysfunction medications such as sildenafil. A fixed-dose combination of isosorbide dinitrate with hydralazine (BiDil) is available to reduce morbidity and mortality associated with HF. This drug is pregnancy category C.

Isosorbide mononitrate (Imdur, Ismo, Monoket): Approved in 1991, isosorbide mononitrate is an active, long-acting metabolite of isosorbide dinitrate. The mononitrate is only used for prophylaxis: Its 30- to 60-minute onset of action makes it unacceptable for termination of acute anginal pain. The dosing schedule must allow for a drug-free period of at least 7 hours to prevent the development of tolerance to the drug's effects. It is available as regular release or extended release tablets, which should be taken on an empty stomach at least 30 minutes before a meal. Imdur is an extended release form of the drug that permits once-daily dosing. Adverse effects are the same as the other organic nitrates. This drug is pregnancy category C.

35.7 Beta-adrenergic antagonists are sometimes preferred drugs for stable angina.

Beta-adrenergic antagonists decrease cardiac workload by lowering blood pressure, slowing heart rate, and reducing contractility. These actions on the heart are particularly beneficial during exercise. Beta blockers are as effective as the organic nitrates in decreasing the frequency and severity of anginal episodes caused by exertion. For the pharmacotherapy of CAD, cardioselective $beta_1$ antagonists are preferred over nonselective beta antagonists because they are less likely to cause bronchoconstriction (a $beta_2$ response). Beta-adrenergic antagonists are not effective for treating variant angina and may, in fact, worsen this condition.

Beta-adrenergic antagonists offer several advantages over the organic nitrates. Tolerance does not develop to the antianginal effects of the beta blockers during prolonged therapy. They possess antidysrhythmic properties, which help prevent cardiac conduction abnormalities that are common complications of patients with ischemic heart disease. Beta blockers are ideal for patients who have both HTN and CAD due to their antihypertensive action. They have also been shown to reduce the incidence of MI. Because of these cardioprotective actions, beta blockers are considered preferred drugs for the prophylaxis of chronic angina. The beta blockers used for angina are listed in Table 35.2. Beta blockers have a variety of indications and additional details may be found in chapters on adrenergic antagonists (see Chapter 16), HTN (see Chapter 34), HF (see Chapter 36), and dysrhythmias (see Chapter 37). A Nursing Practice Application for patients receiving beta blockers is included in Chapter 16.

Beta-adrenergic antagonists are well tolerated by most patients. In some patients, fatigue, lethargy, and depression are reasons for discontinuation of beta-blocker therapy. At high doses, drugs in this class can cause shortness of breath and respiratory distress due to bronchoconstriction, and they should be used cautiously in patients with asthma or chronic obstructive pulmonary disease (COPD). Because beta blockers slow the heart rate and myocardial conduction velocity, they are contraindicated in patients with bradycardia and greater than first-degree heart block. Heart rate should be closely monitored so that it does not fall below 50 to 60 beats/min at rest or 100 beats/min during exercise. Beta blockers are also contraindicated in cardiogenic shock and overt cardiac failure.

Patients with diabetes who are prescribed beta blockers should be aware that the actions of beta blockers can obscure the initial symptoms of hypoglycemia (palpitations, diaphoresis, and nervousness). Because of this, blood glucose levels should be monitored more frequently, and insulin doses may need to be adjusted accordingly.

Beta-adrenergic antagonists should never be abruptly discontinued. With long-term beta-blocker use, the heart becomes more sensitive to catecholamines, which are blocked by these medications. When withdrawn abruptly, adrenergic receptors are activated and rebound excitation occurs. In patients with CAD, this can exacerbate angina, precipitate tachycardia, or cause an MI.

PROTOTYPE DRUG Atenolol (Tenormin)

Classification **Therapeutic:** Antianginal drug
Pharmacologic: Beta-adrenergic antagonist

Therapeutic Effects and Uses: Atenolol is one of the most frequently prescribed drugs in the United States, due to its relative safety and effectiveness in treating a number of chronic disorders, including HF, HTN, stable angina, and post-acute MI. Approved in 1981, it is given by the PO route and has a long duration of action that allows for once-daily dosing. Off-label indications for atenolol include ethanol withdrawal, migraine prophylaxis, and unstable angina.

Mechanism of Action: Atenolol selectively blocks $beta_1$-adrenergic receptors in the heart. Its effectiveness in angina is attributed to its ability to slow the heart rate and reduce contractility, both of which lower myocardial oxygen demand.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	50% absorbed from the gastrointestinal (GI) tract
Distribution	Distributed to most tissues including the placenta; secreted in breast milk; does not readily cross the blood–brain barrier; 5–15% bound to protein
Primary metabolism	Not metabolized
Primary excretion	Renal (50%), feces (50%)
Onset of action	PO: 1 h; IV: immediate
Duration of action	PO/IV: 24 h; half-life: 6–7 h

Adverse Effects: Oral atenolol is well tolerated by most patients. Beta-blocking effects can result in bradycardia and hypotension. Fatigue, weakness, and dizziness are other potential adverse effects. Nausea and vomiting occur in some patients. **Black Box Warning:** Abrupt discontinuation should be avoided in patients with ischemic heart disease because this may worsen angina or cause an MI. Doses should be gradually reduced over a 1- to 2-week period if possible. If angina worsens during the withdrawal period, the drug should be reinstituted, at least temporarily.

Contraindications/Precautions: Because atenolol slows heart rate, it should not be used by patients with severe bradycardia, advanced atrioventricular (AV) heart block, cardiogenic shock, or decompensated HF. Due to its

vasodilation effects, it is contraindicated in patients with severe hypotension. Patients with severe chronic kidney disease (CKD) should receive reduced doses or have longer time intervals between doses to prevent drug accumulation. Because atenolol reduces cardiac output, patients with stroke or low cerebrovascular blood flow should not receive this drug. Patients with major depression should not receive beta blockers because these drugs can worsen this condition.

Drug Interactions: Anticholinergics may decrease the absorption of atenolol from the GI tract. Use with digoxin or other antidysrhythmic drugs that depress myocardial conduction may cause AV heart block. Concurrent use of atenolol with other antihypertensives may result in additive hypotension. Although CCBs are often used concurrently with beta blockers for their additive therapeutic actions, patients must be monitored carefully due to the possibility of excessive cardiac suppression. **Herbal/Food:** Use with hawthorn may result in additive hypotension.

Pregnancy: Category D.

Treatment of Overdose: The most serious symptoms of atenolol overdose are hypotension and bradycardia. Atropine or isoproterenol may be used to reverse bradycardia, or a cardiac pacemaker may be used to stabilize cardiac rhythm. Atenolol can be removed from the systemic circulation by hemodialysis.

Nursing Responsibilities: Key nursing implications for patients receiving atenolol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Antagonists in Chapter 16.

Drugs Similar to Atenolol (Tenormin)

Atenolol, metoprolol, propranolol, and timolol are equally effective in treating chronic angina. Information on these beta-adrenergic antagonists is presented in other chapters. The student should review the general information on beta blockers in Chapter 16. Several are featured as prototype drugs: metoprolol (Lopressor, Toprol XL) and propranolol (Inderal, InnoPran XL) in Chapter 16 and timolol is featured as an antiglaucoma medication in Chapter 74.

35.8 Calcium channel blockers are effective at reducing myocardial oxygen demand and treating stable and variant angina.

Blockade of calcium channels has a number of effects on the heart, most of which are similar to those of beta blockers. Although the first approved indication for CCBs was for the treatment of angina, these medications are also used for HTN and dysrhythmias. The mechanisms of calcium channel blockade by drugs in this class are presented in detail in Chapter 30. The actions of CCBs relevant to ischemic heart disease are discussed in this section. The CCBs used for angina are listed in Table 35.2.

CCBs have several actions on the cardiovascular system that benefit a patient with angina. Most importantly, CCBs relax arteriolar smooth muscle, thus reducing blood pressure. This reduction in afterload decreases myocardial oxygen demand. Some of the CCBs also slow cardiac conduction velocity through the AV node, thereby decreasing heart rate and contributing to the reduced cardiac workload. An additional effect of the CCBs is their ability to dilate the coronary arteries, bringing more oxygen to the myocardium. This vasodilation is especially important in patients with variant angina. CCBs are considered preferred drugs for that condition. For stable, exertional angina, they may be used as monotherapy in patients unable to tolerate beta blockers. In patients with persistent symptoms, CCBs may be administered concurrently with organic nitrates or beta blockers.

Adverse effects of CCBs are generally not serious and are related to vasodilation: headache, dizziness, and edema of the ankles and feet. CCBs should be used with caution in patients taking other cardiovascular medications that slow conduction through the AV node, particularly digoxin or beta-adrenergic antagonists. The combined effects of these drugs may cause partial or complete AV heart block, HF, or dysrhythmias. Some CCBs worsen HF by reducing myocardial contractility.

CONNECTION Checkpoint 35.3

For patients with asthma, calcium channel blockers are generally the preferred antianginal drugs, rather than beta-adrenergic antagonists. From what you learned in Chapter 16, why would calcium channel blockers be preferred for patients with this comorbid condition? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pathophysiology of Myocardial Infarction

35.9 Early diagnosis and pharmacotherapy of myocardial infarction increase chances of survival.

Myocardial infarctions (MIs), blood clots that block coronary arteries, are responsible for a substantial number of deaths each year. Many patients die before reaching a medical facility for treatment, or within 48 hours following the initial MI, due to complications of the disorder. Clearly, MI is a serious and frightening disease and one responsible for a large percentage of sudden deaths.

The primary cause of MI is advanced CAD: atherosclerotic plaque accumulation in the endothelial wall of one or more branches of the coronary arteries. Pieces of unstable

Table 35.3 Changes in Blood Test Values with Acute Myocardial Infarction

Blood Test	Initial Elevation After MI	Peak Elevation After MI	Duration of Elevation	Normal Range
CK: total creatine kinase (also called creatine phosphokinase)	3–8 h	12–24 h	2–4 days	Males: 5–35 mcg/L Females: 5–25 mcg/L
CK-MB	4–6 h	10–24 h	3–4 days	0–3% of CK
ESR (erythrocyte sedimentation rate)	2–3 days	4–5 days	Several weeks	Males: 15–20 mm/h Females: 20–30 mm/h
LDH: total (lactate dehydrogenase)	12–24 h	2–5 days	6–12 days	70–250 units/L
Myoglobin	2–6 h	8–12 h	1–2 days	12–90 ng/mL
Troponin I	1–3 h	24–36 h	5–9 days	0.1–0.5 mcg/L
Troponin T	1–3 h	24–36 h	10–14 days	less than 0.2 mcg/L

plaque in a coronary artery can ulcerate or rupture and lodge in a small vessel serving a portion of the myocardium. Exposed plaque activates the clotting cascade, resulting in platelet aggregation. A new clot quickly builds on the existing plaque, making obstruction of the vessel imminent. A detailed discussion of coagulation and clot formation is included in Chapter 38.

Deprived of adequate oxygen supply, the obstructed region of the myocardium becomes ischemic. The myocytes shift to anaerobic metabolism after only 8 to 10 seconds of oxygen loss. Anaerobic metabolism, however, is inefficient and cannot produce enough ATP to keep the heart beating efficiently for prolonged periods. Lactic acid accumulates, causing acidosis, which affects contractility and suppresses normal conduction across the myocardium. As contractility diminishes, the patient may experience HF. Myocytes will begin to die in about 20 minutes unless the blood supply is quickly restored. The necrosis of myocardial tissue, which may be irreversible, releases certain "marker" enzymes, such as creatine kinase (CK) or cardiac-specific troponin (cTn), which can be measured in the blood to confirm the patient has experienced an MI.

Extreme chest pain is often the first symptom of MI and the one that drives most patients to seek medical attention. An electrocardiogram (ECG) can give important clues as to the extent and location of the MI because the infarcted region of the myocardium is nonconducting, producing abnormal Q waves, T waves, and ST segments. Patients showing elevation of the ST segment on the ECG are at highest risk for death and require immediate treatment. Laboratory test results are used to aid in diagnosis and monitor progress after an MI. Table 35.3 describes some of these important laboratory values.

Early diagnosis and prompt pharmacotherapy of MI can significantly reduce the mortality and long-term disability associated with MI. Drugs used in the management of MI are shown in Table 35.2. The pharmacologic goals for treating a patient with an acute MI are as follows:

- If cardiac arrest has occurred, restart the heart and restore normal blood pressure with vasopressors.
- Restore blood supply (reperfusion) to the damaged myocardium as quickly as possible through the use of thrombolytics.
- Reduce myocardial oxygen demand with organic nitrates, beta blockers, or CCBs to lower the risk of additional infarctions.
- Control or prevent MI-associated dysrhythmias with amiodarone (Cordarone), beta blockers, or other antidysrhythmics.
- Reduce post-MI mortality with aspirin, beta blockers, and ACE inhibitors.
- Manage severe MI pain and associated anxiety with narcotic analgesics.

Pharmacologic Management of Myocardial Infarction

35.10 Thrombolytic drugs can restore perfusion to ischemic regions of the myocardium if administered soon after a myocardial infarction.

Thrombolytic therapy is administered to dissolve clots obstructing the coronary arteries in order to restore circulation to the ischemic region of the myocardium. Clinical research has confirmed that quick restoration of coronary circulation reduces mortality following an acute MI. After the clot is successfully dissolved, anticoagulant or antiplatelet therapy is initiated to prevent additional thrombus formation. Dosages and descriptions of the various thrombolytics are listed in Chapter 38 where alteplase (Activase) is presented as a drug prototype for this class. A Nursing Practice Application feature for thrombolytics is also included in Chapter 38.

Thrombolytics are most effective when administered from 20 minutes to 12 hours after the onset of MI symptoms. Ideally, the time from presentation in the emergency department (ED) to administration of the thrombolytic should be 30 minutes or less. Research has demonstrated little or no therapeutic benefit if the drugs are administered

24 hours or more after the MI onset. In addition, research suggests that patients over age 75 do not experience reduced mortality from these drugs. Because thrombolytic therapy is expensive and has the potential to produce serious adverse effects, it is important to identify circumstances that contribute to successful therapy. The development of clinical practice guidelines for thrombolytic therapy remains an area of active research. Pharmacotherapy Illustrated 35.2 illustrates this reperfusion process.

Thrombolytics exhibit a narrow margin of safety between dissolving clots and producing serious adverse effects. Although therapy is usually targeted to a single thrombus in a specific artery, once infused in the blood the drugs travel to all vessels and may cause adverse effects anywhere in the body. The primary risk of thrombolytics is excessive bleeding from interference with the clotting process. Vital signs must be monitored continuously and signs of bleeding call for discontinuation of therapy. Because these medications have a brief half-life and are rapidly destroyed in the blood, stopping the infusion normally results in the rapid termination of adverse effects. Physical and laboratory assessment for the possibility of abnormal bleeding should continue for 2 to 4 days after therapy is discontinued.

Thrombolytic therapy is contraindicated for many conditions, including recent trauma or surgery, internal bleeding (other than menses), active peptic ulcer, postpartum (within 10 days), history of intracranial hemorrhage, suspected ischemic stroke within the past 3 months, bleeding disorders, severe liver disease, or thrombocytopenia. Caution should be used when administering thrombolytics to patients taking anticoagulants or antiplatelet drugs.

35.11 Drugs are used to treat the symptoms and complications of acute myocardial infarction.

The most immediate needs of the patient with MI are to ensure that the heart continues to function adequately and that permanent damage from the infarction is minimized. In addition to restoring perfusion to the myocardium with thrombolytic therapy, drugs from several other classes are administered soon after the onset of symptoms to prevent reinfarction and to ultimately reduce mortality from the episode.

Aspirin

Unless contraindicated, 160 to 325 mg of aspirin is given as soon as an MI is suspected. Research has determined that aspirin use in the weeks following an acute MI dramatically reduces mortality. These effects from aspirin are believed to be due to several mechanisms. Clearly, aspirin has antiplatelet action that reduces platelet aggregation and thus the formation or enlargement of thrombi. Additionally, its anti-inflammatory properties decrease the formation of C-reactive protein, which is associated with an increased risk of MI.

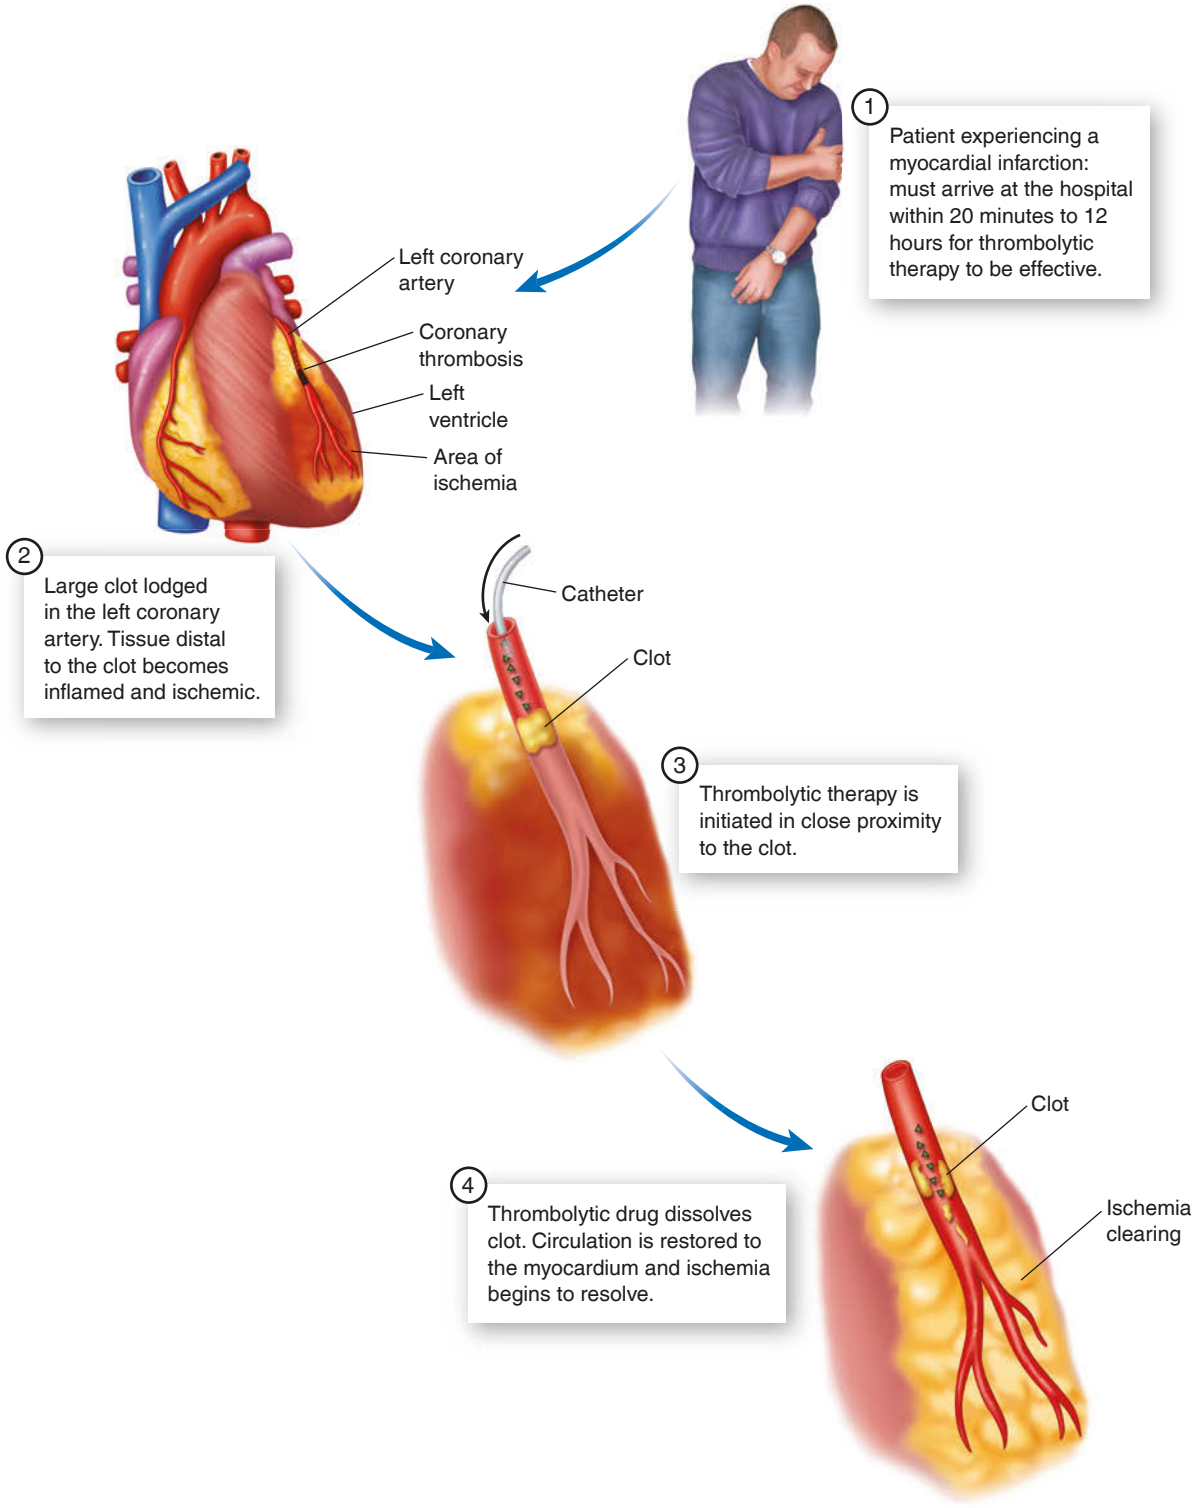
The major concern over aspirin use is its tendency to promote GI bleeding in some patients. This could be a serious adverse effect, given that some post-MI patients receive anticoagulants. However, the benefits of taking aspirin following an acute MI generally outweigh the risks for most patients. Aspirin maintenance therapy can cut the risk of death due to a subsequent MI by as much as 50% in some populations. Furthermore, the low doses used in maintenance therapy (75–150 mg/day) rarely cause GI bleeding. Additional discussion of aspirin may be found in Chapter 41, where it is featured as a prototype drug.

Anticoagulants and Antiplatelet Drugs

Drugs from several classes are routinely used to prevent MIs by altering the coagulation properties of the blood. The primary goal for using these coagulation modifiers is to prevent new thrombi from being formed or from enlarging.

CONNECTIONS: Treating the Diverse Patient

The Effect of the CYP2C19 Genotype on Therapeutic Treatment Outcomes for Cardiovascular Patients



Recall from Chapter 11 that genetic polymorphisms in the CYP450 enzyme system have an effect on the metabolism of drugs, potentially rendering them less useful due to slowed metabolism. Genetic CYP450 variations also have other effects, such as on platelet activity (Sun et al., 2016; Wang, Cai, Zhou, Zhang, & Liu, 2016). People of Asian descent and some African Americans are known to carry the CYP2C19 genotype variant.

In several recent studies, patients with the CYP2C19 genotype were found to have higher platelet activity and less response to clopidogrel and similar drugs after stenting procedures for coronary and carotid artery blockage (Arima et al., 2015; González et al., 2016; Sun et al., 2016; Tabata et al., 2016). The risk for additional cardiovascular events was noted to be higher in those with the variation, especially in the acute stage (Arima et al., 2015).

Further study is needed to determine whether patients with the CYP2C19 genotype would benefit from higher doses of clopidogrel or similar drugs, or whether combining those drugs with aspirin would be beneficial. At this time, routine screening for CYP2C19 is not recommended (Bhopalwala, Hong, Khan, Valentin, & Badawi, 2015), but at-risk patients who may be carriers of the genotype should be carefully assessed post-stent, especially in the acute phase, for suboptimal response to clopidogrel and for additional cardiovascular complications.

Pharmacotherapy Illustrated 35.2

Thrombolytic Pharmacotherapy

Anticoagulants: Upon diagnosis of MI in the ED, patients may be placed on the anticoagulant heparin to prevent the formation of additional thrombi. Unfractionated heparin therapy is sometimes continued for 48 hours, or until percutaneous coronary intervention (PCI) is completed, at which time the patients are switched to warfarin (Coumadin) or an antiplatelet drug. An alternative is to administer a low-molecular-weight heparin, such as enoxaparin (Lovenox). A comparison of these different anticoagulants is presented in Chapter 38, along with prototype drug features for heparin and warfarin.

Some patients may remain on anticoagulant therapy after hospital discharge. These include patients at high risk for thromboembolic disease and those with chronic atrial fibrillation. Research has not shown that the use of warfarin lowers mortality in post-MI patients; however, it does increase the risk of bleeding. For most patients, anticoagulation with aspirin or antiplatelet drugs is sufficient for protection from thromboembolic events. The long-term use of heparin in post-MI patients is limited unless other conditions are present that warrant the use of the drug.

Adenosine diphosphate receptor blockers: Clopidogrel (Plavix), ticlopidine (Ticlid), ticagrelor (Brilinta), and prasugrel (Effient) are antiplatelet drugs approved for the prevention of thrombotic stroke and MI. Research has demonstrated that these drugs reduce mortality associated with thromboembolic events. They are considered for antiplatelet therapy in patients who are allergic to aspirin or at high risk for GI bleeding from aspirin. Some protocols call for combination therapy with clopidogrel and aspirin. Clopidogrel is one of the most frequently used drugs for prevention of MI, and is featured as a prototype in Chapter 38.

Glycoprotein IIb/IIIa inhibitors: Glycoprotein IIb/IIIa is a receptor found on the surface of platelets. Glycoprotein IIb/IIIa inhibitors are sometimes indicated to prevent thrombi from forming in patients with unstable angina or MI or for those undergoing PCI procedures such as angioplasty. The most common drug in this class, abciximab (ReoPro), is infused at the time of PCI and continued for 12 hours after the procedure is completed to prevent reinfarction. These drugs may be used in combination therapy with aspirin and heparin, thus increasing the need for careful monitoring for bleeding. Doses for the glycoprotein IIb/IIIa inhibitors and a prototype feature for abciximab are found in Chapter 38.

Other antiplatelet drugs: In 2014 the Food and Drug Administration (FDA) approved the first in a new class of antiplatelet drugs called the protease-activated receptor-1 antagonists. Vorapaxar (Zontivity) is administered to reduce the incidence of thrombotic events in patients with a history of MI or other clotting disorders. It is usually given in combination with aspirin or clopidogrel.

Nitrates

The value of nitrates in treating myocardial ischemia was presented in Section 35.6. Nitrates have additional uses in the patient with a suspected MI. At the initial onset of chest pain, sublingual nitroglycerin is administered to assist in the diagnosis, and three doses may be taken 5 minutes apart. Pain that persists 5 to 10 minutes after the initial dose may indicate an MI, and the patient should seek medical assistance. Thus, nitrates serve a diagnostic role for MI patients.

Patients with persistent pain, HF, or severe HTN may receive IV nitroglycerin for 24 hours following the onset of pain. The arterial and venous dilation produced by the drug reduces myocardial oxygen demand. Organic nitrates also relieve coronary artery vasospasm, which may be present during the acute stage of MI. On patient discharge from the hospital, organic nitrates are discontinued, unless the patient needs them for relief of stable anginal pain.

Beta-Adrenergic Antagonists

Beta blockers have the ability to slow heart rate, decrease contractility, and reduce blood pressure. These three factors reduce myocardial oxygen demand, which is critical for patients experiencing a recent MI. In addition, they slow impulse conduction through the heart, suppressing dysrhythmias, which are serious and sometimes fatal complications following an MI. Research has clearly demonstrated that beta blockers can reduce MI-associated mortality if administered within 8 hours of MI onset. These drugs may be initially administered IV, and then switched to oral dosing for chronic therapy. Unless contraindicated, beta-blocker therapy continues for the remainder of the patient's life. For patients unable to tolerate beta blockers, CCBs are an alternative. The beta blockers most often used for MI are listed in Table 35.2.

Angiotensin-Converting Enzyme Inhibitors

Clinical research has demonstrated increased survival for patients administered the angiotensin-converting enzyme (ACE) inhibitors captopril (Capoten) or lisinopril (Prinivil, Zestoretic) following an acute MI. These drugs are most effective when therapy is started within 24 hours after the onset of symptoms. Oral doses are normally begun after thrombolytic therapy is completed and the patient's condition has stabilized. IV therapy may be used during the early stages of MI pharmacotherapy.

The benefit of ACE inhibitors is believed to be due to their ability to prevent cardiac remodeling and their ability to suppress dysrhythmias. Unless otherwise contraindicated, post-MI patients should receive an ACE inhibitor indefinitely to prevent HF and future ischemic development. The mechanisms of action and prototype features for several ACE inhibitors may be found in Chapter 31.

Pain Management

The pain associated with an MI can be debilitating and stressful, creating an increased workload for the myocardium. Pain control is essential in order to ensure patient comfort and to reduce stress. Narcotic analgesics such as morphine sulfate or meperidine (Demerol) are given to ease extreme pain, sedate the anxious patient, and decrease the workload of the heart. Pharmacology of the analgesics was presented in Chapter 25.

PharmFACT

About 1.5 million Americans experience a new or recurrent MI each year. About one third of the patients experiencing an MI will die within 24 hours of the onset of the attack (Zafari, 2017).

35.12 Vasopressors are used following cardiopulmonary arrest to reestablish coronary and cerebral blood flow.

Cardiopulmonary arrest is a complete stoppage of heart and lungs activity, usually resulting from a dysrhythmia such as ventricular fibrillation or pulseless ventricular tachycardia. Most patients who experience cardiopulmonary arrest have underlying CAD.

Cardiopulmonary resuscitation (CPR) must be initiated as quickly as possible to restore ventilation and blood circulation to avoid hypoxic injury to the tissues. Electrical defibrillation is used to restore normal cardiac rhythm.

Pharmacotherapy is an important component of CPR. The primary drugs used in the initial phase of resuscitation are sympathomimetics, and epinephrine is the preferred drug. Sympathomimetics cause vasoconstriction, immediately raising cerebral, coronary, and systemic blood pressure. Vasopressin, also called antidiuretic hormone, is an alternative therapy.

Following restoration of cardiac function and ventilation, it is critical that the heart maintain normal conduction in order to prevent the recurrence of ventricular fibrillation or the establishment of other serious dysrhythmias. Historically, lidocaine has been the preferred drug for ventricular dysrhythmias associated with MI. Clinical research, however, has shown that the administration of amiodarone (Cordarone) may result in improved patient survival. If the risk of dysrhythmia is high, a loading dose of amiodarone is given by infusion, and the patient is switched to oral forms after a therapeutic plasma level of the drug has been achieved. Amiodarone is featured as an antidysrhythmic drug prototype in Chapter 37.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Organic Nitrates for Angina and Myocardial Infarction

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular (including previous MI, HF, valvular disease), cerebrovascular and neurologic (including level of consciousness, history of stroke, head injury, increased intracranial pressure), renal or hepatic dysfunction, dysrhythmias, pregnancy, or lactation. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be aware that use of erectile dysfunction drugs (e.g., sildenafil [Viagra], vardenafil [Levitra], or tadalafil [Cialis]) within the past 24–48 h may cause profound and prolonged hypotension when nitrates are administered. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), and ECG. Assess for location and character of angina if currently present.
- Evaluate appropriate laboratory findings, electrolytes, renal function studies, and lipid profiles. Troponin and/or CK-MB laboratory values may be ordered to rule out MI.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., chest pain has subsided or has significantly lessened), heart rate and blood pressure remain within normal limits, ECG remains within normal limits without signs of ischemia or infarction.
- Continue periodic monitoring of ECG for ischemia or infarction.
- Continue frequent monitoring of blood pressure and pulse whenever IV nitrates are used or when giving rapid-acting (e.g., SL) nitrates. With SL nitrates, take blood pressure before and 5 min after giving dose and hold the drug if blood pressure is less than 90/60 mmHg, pulse over 100 beats/min, or parameters as ordered, and check with the healthcare provider before continuing to give the drug.
- Assess for and promptly report adverse effects: severe hypotension, dysrhythmias, reflex tachycardia (from too rapid decrease in blood pressure or severe hypotension), headache that does not subside within 15–20 min, or when accompanied by neurologic changes or decreased urinary output. Immediately report severe hypotension, seizures, dysrhythmias, or palpitations. Chest pain remaining present after three sublingual nitroglycerin tablets given 5 min apart should be reported immediately, even if pain has lessened, as this may be a sign of impending ischemia or infarction.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Because nitrates cause vasodilation, preload and afterload diminish, decreasing myocardial oxygenation needs, and chest pain diminishes.)	• Ask the patient to briefly describe the location and character of pain (use a pain rating scale for rapid assessment) prior to and after giving nitrates to assess for extent of relief. Correlate with objective assessment findings. **Lifespan and Diverse Patients:** Due to differences in reporting pain, use subjective and objective data in evaluating pain relief in ethnically diverse or older adult patients.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor ECG, blood pressure, and pulse. (Nitrates cause vasodilation and possible hypotension. Blood pressure assessment aids in determining drug frequency and dose. ECG monitoring helps detect adverse effects such as reflex tachycardia, ischemia, or infarction.)	• Teach the patient, family, or caregiver how to monitor pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained.
• Evaluate the need for adjunctive treatment with the healthcare provider for angina prevention and treatment (e.g., beta blockers, aspirin therapy) or further cardiac studies. (Patients with unstable angina may require adjunctive drug therapy or definitive cardiac studies to determine the need for other treatment options.)	• Encourage the patient to discuss any changes in character, severity, or frequency of angina episodes with the healthcare provider. • Instruct the patient not to take routine (daily) aspirin without discussing with the provider first, because the drug may be contraindicated depending on other conditions or medications.
• For patients on transdermal nitroglycerin patches, remove patch for 6–12 h at night, or as directed by the healthcare provider. (Removing the transdermal patch at night helps prevent or delay the development of tolerance to nitrates.)	• Instruct the patient on proper use of nitroglycerin and the rationale for removing transdermal patches. Also instruct patients using transdermal patches to always remove the old patch, to cleanse the skin underneath gently, and to rotate sites before applying a new patch.
• Encourage appropriate lifestyle changes: lowered fat intake, restricted sodium or fluid intake if ordered, gradually increased levels of exercise, limited alcohol intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support the benefits of drug therapy.)	• Encourage the patient, family, and caregivers to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation. Provide educational materials on low-fat, low-sodium food choices.
Minimizing adverse effects: • Continue to monitor vital signs frequently. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension, patients with a preexisting history of cardiac or cerebrovascular disease, or patients with a recent head injury, which may be worsened by vasodilation. Notify the healthcare provider immediately if angina remains unrelieved or if blood pressure or pulse decrease beyond established parameters, or if hypotension is accompanied by reflex tachycardia. (Nitrates may cause significant vasodilation, resulting in the potential for hypotension accompanied by reflex tachycardia. Reflex tachycardia increases myocardial oxygen demand, worsening angina.)	• Instruct the patient, family, or caregiver to report dizziness, faintness, palpitations, or headache unrelieved after taking nonnarcotic analgesics (e.g., acetaminophen). • Instruct the patient on nitrates to rise from lying to sitting or standing slowly to avoid dizziness or falls, especially if taking SL nitrates, or until drug effects are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes.
• Continue cardiac monitoring (e.g., ECG) as ordered if IV nitrates are administered. (Monitoring devices assist in detecting early signs of adverse effects of drug therapy and myocardial ischemia or infarction, as well as monitoring for therapeutic effects.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring.
• Continue frequent physical assessments, particularly neurologic, cardiac, and respiratory. Immediately report any changes in level of consciousness, headache, or changes in heart or lung sounds. (Nitrate therapy may worsen preexisting neurologic, cardiac, or respiratory conditions as blood pressure drops and perfusion to vital organs diminishes. Lung congestion may signal impending HF.)	• When on PO therapy at home, the patient, family, or caregiver should immediately report changes in mental status or level of consciousness, palpitations, dizziness, dyspnea, and increasing productive cough, especially if frothy sputum is present, and seek medical attention.
• Review the medications taken by the patient before sending the patient home, and review all prescription as well as OTC medications with the patient. Current use of erectile dysfunction drugs, as noted on medication history, is contraindicated with nitrates. (Erectile dysfunction drugs lower blood pressure and when combined with nitrates, can result in severe and prolonged hypotension.)	• Instruct the patient to not take sildenafil (Viagra), vardenafil (Levitra), or tadalafil (Cialis) while taking nitrates and to discuss treatment options for erectile dysfunction with the healthcare provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug; appropriate dose and scheduling; what adverse effects to observe for and when to report them; and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in the proper self-administration of drugs and when to contact the provider. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	The patient should be able to state how to use SL nitroglycerin at home: • Take one nitroglycerin tablet, under the tongue, for chest pain. Remain seated or lie down to avoid dizziness or falls. • If chest pain continues, repeat one nitroglycerin tablet, under the tongue, in 5 min. Remain seated or lying down. • If chest pain continues, repeat nitroglycerin, under the tongue, in 5 min. • If chest pain continues, even if reduced, do not take further nitroglycerin unless specifically directed by the healthcare provider. Call EMS (e.g., 911) for assistance. Do *not* drive self, or have family drive the patient, to the ED. • If blood pressure monitoring equipment is available at home, have the patient, family, or caregiver take blood pressure prior to the second and third nitroglycerin doses. Hold the drug and contact EMS if blood pressure is less than 90/60 mmHg.

Understanding Chapter 35

Key Concepts Summary

35.1 Myocardial ischemia develops when there is inadequate blood supply to meet the metabolic demands of cardiac muscle.

35.2 Coronary artery disease is the major cause of myocardial ischemia.

35.3 Angina pectoris is characterized by severe chest pain brought on by physical exertion or emotional stress.

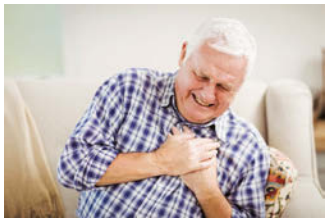
35.4 Therapeutic lifestyle changes can decrease the frequency of anginal episodes and reduce the risk of coronary artery disease.

35.5 The pharmacologic management of angina includes organic nitrates, beta-adrenergic antagonists, and calcium channel blockers.

35.6 Organic nitrates may be used to terminate or prevent angina episodes.

35.7 Beta-adrenergic antagonists are sometimes preferred drugs for stable angina.

35.8 Calcium channel blockers are effective at reducing myocardial oxygen demand and treating stable and variant angina.



35.9 Early diagnosis and pharmacotherapy of myocardial infarction increase chances of survival.

35.10 Thrombolytic drugs can restore perfusion to ischemic regions of the myocardium if administered soon after a myocardial infarction.

35.11 Drugs are used to treat the symptoms and complications of acute myocardial infarction.

35.12 Vasopressors are used following cardiopulmonary arrest to reestablish coronary and cerebral blood flow.

CASE STUDY: Making the Patient Connection

Remember the patient "Michael Graff" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Early one morning, 60-year-old Michael Graff began to feel severe anterior crushing chest pain that lasted for 35 minutes. He experienced dizziness, cold sweats, and nausea. Although he considered driving to the local ED, his family insisted on calling an ambulance for emergency transport to the hospital.

Michael, a general contractor, is a 2-pack-per-day smoker and consumes alcohol (beer) 2 to 3 times per week. He has a family history of CAD, diabetes mellitus, and hyperlipidemia. It has been at least 10 years since his last physical examination.

On arrival at the ED, he presents with symptoms of anxiety, moderate chest pain, and cold extremities. Auscultation of the thorax revealed tachycardia and clear lung fields. Blood pressure was slightly above normal at 156/90 mmHg. He had no neck venous distention. His white blood cell count was 7600/mm^3; hematocrit, 43.8%; platelets, 256,000/mm^3; CK, 87 international units/L; and troponin-I, less than 4.1 mcg/L. An ECG showed ST-segment elevation.

Once stabilized, Michael is transported to the coronary care unit with the admission diagnosis of unstable angina and to rule out MI. In the coronary care unit, he receives IV nitroglycerin 50 mg in D_5W 25 mL. The nurse begins the infusion at 10 mcg/min and titrates the rate based on his report of chest pain every 5 to 10 min (5–10 mcg/min).

Critical Thinking Questions

1. Michael and his family ask you to explain what is occurring with his heart. How would you describe the pathophysiology of Michael's condition to them?
2. Discuss the reason Michael is receiving nitroglycerin.
3. What adverse effects should the nurse monitor with patients receiving IV nitroglycerin?
4. How do nitroglycerin infusions differ from other IV infusions?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Bill Shackley, a 52-year-old man, is prescribed a daily nitroglycerin transdermal patch. While discussing his medications, Bill shares several of his concerns. How would you respond to the following questions?

1. "I heard that I can become 'tolerant' to this drug. What does this mean? How can it be avoided?"
2. "Sometimes, after applying the nitroglycerin patch, I get a throbbing headache. Is there anything I can do about this?"
3. "I was told to report episodes of dizziness when I stand up plus rapid heart rates. How does nitroglycerin cause these?"

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Nitroglycerin topical ointment is being initiated for a patient with angina. Which health teaching would be most appropriate?
    1. Keep the medication in the refrigerator.
    2. Take this medication only when chest pain is severe.
    3. Remove the old paste before applying the next dose.
    4. Apply the ointment on the chest wall only.

2. A patient with chest pain is receiving sublingual nitroglycerin. The nurse would include in the care plan to monitor the patient for which adverse effect?
    1. Photosensitivity
    2. Elevated blood pressure
    3. Vomiting and diarrhea
    4. Decreased blood pressure

3. The patient states, "I always put my nitroglycerin patch in the same place so I do not forget to take it off." The nurse's response would be based on which of the following physiologic concepts?
    1. Patients are more likely to remember to apply the patch if the same site is used daily.
    2. Repeated use of the same application site will enhance medication absorption.
    3. Rebound phenomenon is likely to occur when the same site is used more than once.
    4. Skin irritation due to the nitroglycerin ointment can occur if the same site is used repeatedly.

4. The nurse is caring for a patient with chronic angina pectoris. The patient is receiving isosorbide dinitrate (Isordil) oral tablets. Which patient manifestations would the nurse conclude are common adverse effects of this medication?
    1. Flushing and headache
    2. Tremors and anxiety
    3. Lightheadedness and dizziness
    4. Sleepiness and lethargy

5. The patient asks how atenolol (Tenormin) helps angina. The response provided by the nurse is based on which concept? This medication:
    1. Slows the heart rate and reduces contractility.
    2. Increases the heart rate and diminishes contractility.
    3. Blocks sodium channels and elevates depolarization.
    4. Decreases blood pressure and blocks the alpha$_2$ receptors.

6. Which of the following assessment findings, if discovered in a patient receiving verapamil (Calan) for angina, would be cause for the nurse to withhold the medication? (Select all that apply.)
    1. Bradycardia: heart rate of 40 beats/min
    2. Tachycardia: heart rate of 126 beats/min
    3. Hypotension: blood pressure 76/46 mmHg
    4. Tinnitus with hearing loss
    5. Hypertension: blood pressure 156/92 mmHg

Chapter 36
Pharmacotherapy of Heart Failure

Chapter Outline

- Etiology of Heart Failure
- Pathophysiology of Heart Failure
  - Ventricular Hypertrophy
- Pharmacologic Management of Heart Failure
- Drugs for Heart Failure
  - Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers
  - Diuretics
  - Beta-Adrenergic Antagonists
  - Vasodilators
  - Cardiac Glycosides
    - **PROTOTYPE** *Digoxin (Lanoxin, Lanoxicaps), p. 632*
  - Beta-Adrenergic Agonists
  - Phosphodiesterase III Inhibitors
    - **PROTOTYPE** *Milrinone (Primacor), p. 635*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the major diseases associated with heart failure.
2. Relate how the symptoms associated with heart failure may be caused by a weakened heart muscle and diminished cardiac output.
3. Identify compensatory mechanisms used by the body to maintain cardiac output in patients with heart failure.
4. Describe how heart failure is classified.
5. Describe the nurse's role in the pharmacologic management of heart failure.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy for heart failure.

Key Terms

cardiac remodeling, 624
digitalization, 632
diuretic resistance, 630
heart failure (HF), 623
natriuretic peptides, 625
phosphodiesterase III, 634
reverse remodeling, 630

Heart failure is one of the most common and fatal of the cardiovascular diseases, and its incidence is increasing as the population ages. Although improved treatment of myocardial infarction and hypertension has led to declines in mortality due to heart failure, approximately one in five patients still dies within a year of diagnosis of heart failure, and 50% die within 5 years. Historically, this condition was called *congestive heart failure*; however, because not all incidences of this disease are associated with congestion, the more appropriate name is *heart failure*.

PharmFACT

Each year, about 670,000 new cases of heart failure are diagnosed and about 277,000 deaths are attributed to HF in the United States. Although the incidence is equal in men and women, women develop HF later in life and survive longer with the disease (Dumitru, 2016).

Etiology of Heart Failure

36.1 Heart failure is closely associated with disorders such as chronic hypertension, coronary artery disease, and diabetes.

Heart failure (HF) is the inability of the heart to pump enough blood to meet the metabolic demands of the body. HF can be caused by any disorder that affects the heart's ability to receive or eject blood. While weakening of cardiac muscle is a natural consequence of aging, the process can be caused or accelerated by the following:

- Coronary artery disease (CAD)
- Mitral stenosis
- Myocardial infarction (MI)
- Chronic hypertension (HTN)
- Diabetes mellitus.

The student should detect a common theme throughout the chapters on cardiovascular pharmacology. That theme is the ability to prevent major causes of morbidity and mortality through control of healthy lifestyle choices. Controlling lipid levels, implementing a regular exercise program, maintaining optimal body weight, and keeping blood pressure within recommended limits reduce the incidences of CAD and MI. Maintaining blood glucose within the normal range reduces the consequences of uncontrolled diabetes. Thus, for many patients, HF is a preventable condition; controlling associated diseases will greatly reduce the risk of development and progression of HF.

Because there is no cure for HF, the treatment goals are to prevent, treat, or remove the underlying causes whenever possible and treat its symptoms, so that the patient's quality of life can be improved. Advances in understanding the pathophysiology of HF during the past two decades have led to a change in pharmacotherapeutic goals. No longer is therapy of HF focused on end stages of the disorder. Pharmacotherapy is now targeted at prevention and slowing the progression of HF. This change in emphasis has led to significant improvements in survival and quality of life in patients with HF.

Pathophysiology of Heart Failure

36.2 The body attempts to compensate for heart failure by increasing cardiac output.

Heart failure is a general term used to describe several different types of cardiac dysfunction. The dysfunction may occur on the left side, the right side, or on both sides of the heart.

Left-sided HF is sometimes called congestive heart failure (CHF) because it is characterized by an accumulation of fluid causing congestion in the pulmonary capillary beds. Although left-sided HF is more common, the right side of the heart can also become weak, either simultaneously with the left side or independently from the left side. In right-sided HF, the blood pools in the veins, resulting in peripheral edema and engorgement of organs such as the liver.

Left-sided HF is further subdivided into two types. Systolic HF occurs when cardiac output (CO) is diminished due to decreased contractility of the myocardium. Approximately 60% to 80% of left-sided HF is the systolic type. Diastolic HF occurs when the lungs become congested even though cardiac output is normal. Diastolic HF is caused by a restriction in ventricular filling, resulting in higher-than-normal pressure in the ventricle. Although cardiac output is normal, the increased pressure in the ventricle creates higher pressure in the pulmonary capillaries, resulting in pulmonary edema. A patient may have both systolic and diastolic HF. Pharmacotherapy of the two types differs somewhat. For example, inotropic drugs that increase contractility are more successful with systolic HF than diastolic HF.

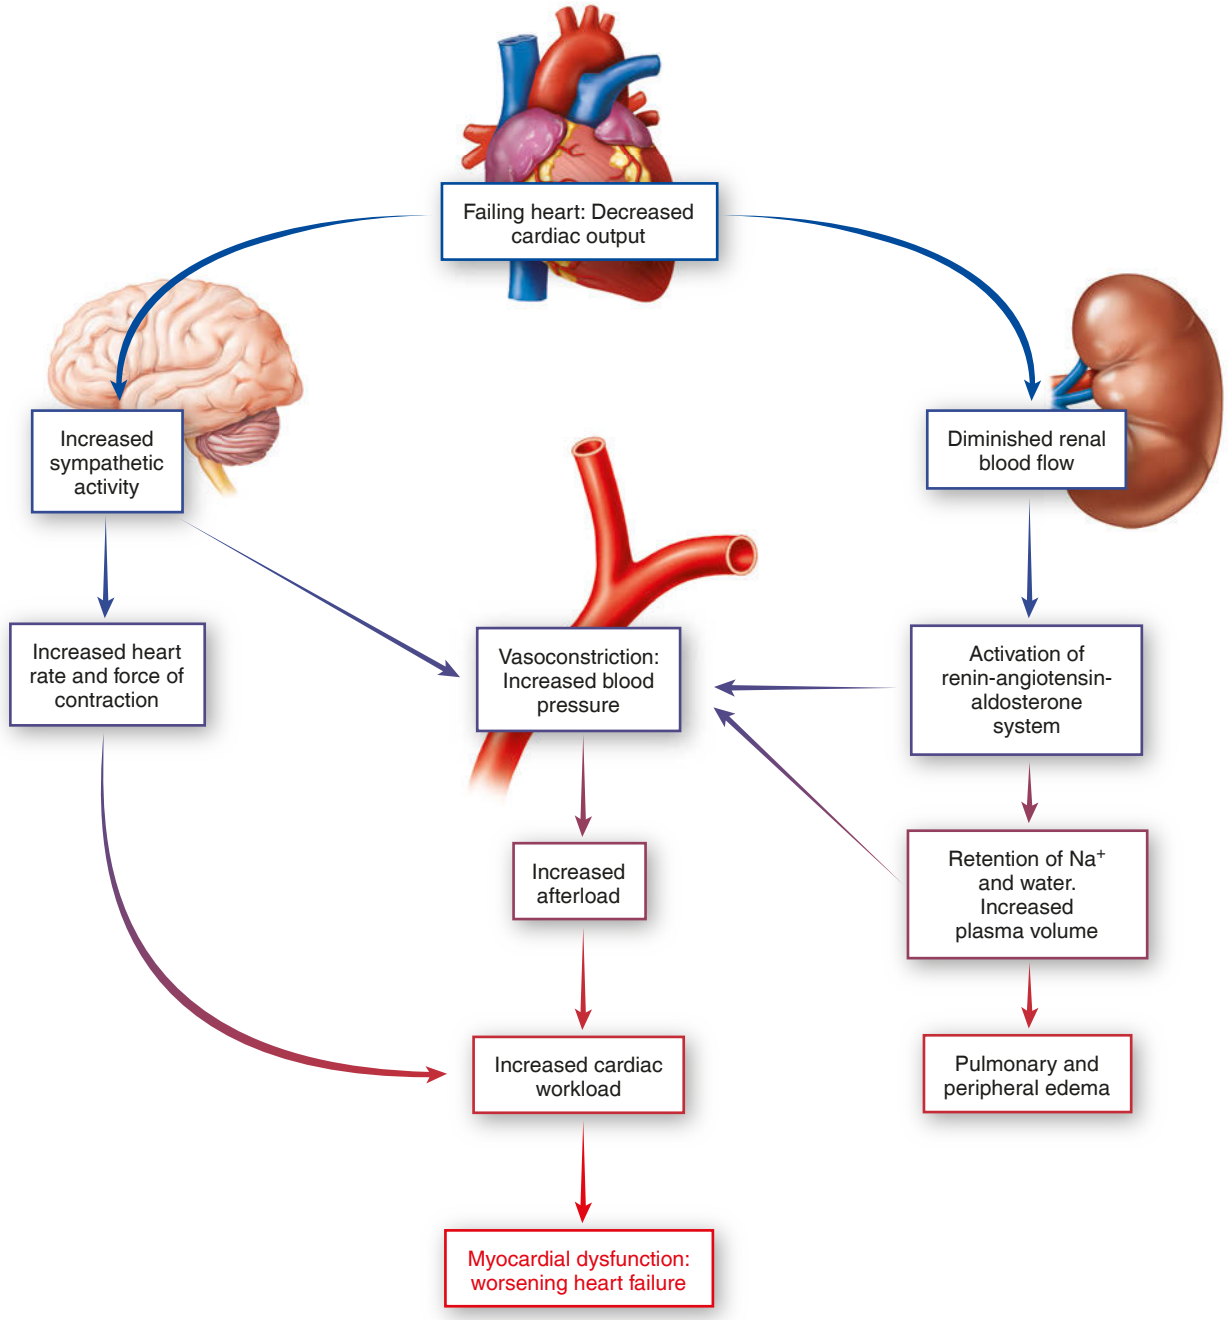

Figure 36.1 Pathophysiology of heart failure.

HF may progress slowly over many years, or it may have an acute onset. Once HF reaches the stage where cardiac output is affected, tissues receive inadequate perfusion and organ failure is possible. The body has developed a complex series of actions to compensate for HF. Knowledge of these compensatory mechanisms is important to understanding the pharmacotherapy of HF. Prior to continuing in this chapter, factors affecting cardiac output, stroke volume, afterload, and preload, discussed in Chapter 28, should be reviewed. The pathophysiology of HF is illustrated in Figure 36.1.

Ventricular Hypertrophy

In left HF, the left ventricle is forced to work harder due to the increased preload or afterload. Over time, the wall of the left ventricle thickens and enlarges (ventricular hypertrophy) in an attempt to compensate for the increased workload. Changes in the size, shape, and structure of the myocardial cells (myocytes) occur. These compensatory changes in structure benefit the heart by allowing it to better maintain adequate stroke volume and cardiac output. The term **cardiac remodeling** is

sometimes used to describe these changes to myocyte structure and function.

The benefits of cardiac remodeling as a compensatory mechanism, however, are limited. Myocytes continually die, likely due to workload injury, and fibrotic tissue fills the spaces between them. These tissue changes stiffen the myocardium, causing diminished contractility and reduced cardiac output. The heart responds with even more remodeling, continuing the destructive cycle. Without intervention, the abnormal structural changes can result in irreversible cardiac impairment.

Activation of the Sympathetic Nervous System

One of the fastest homeostatic responses to diminished cardiac output is activation of the sympathetic nervous system (SNS). The increased heart rate resulting from sympathetic activation is a normal compensatory mechanism that serves to increase cardiac output.

The SNS, however, also constricts arteries and activates the renin-angiotensin-aldosterone system (RAAS). Higher angiotensin II levels raise blood pressure and afterload, causing the heart to work harder. The stressed myocardium, which already has reduced contractility and is having difficulty maintaining cardiac output, is faced with even greater challenges by this additional workload. The diminished cardiac output caused by the high afterload produces an ongoing activation of the SNS. Patients with preexisting CAD may experience an anginal attack from the increased SNS activity. Again, although there are certain compensatory benefits to activating the SNS to maintain cardiac output, a destructive cycle is created that can lead to or worsen HF.

CONNECTION Checkpoint 36.1

Propranolol (Inderal) is an example of a negative inotropic drug. From what you learned in Chapter 16, explain why this type of drug should be administered with caution to a patient with heart failure who also has asthma. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Increased Plasma Volume and Preload

When cardiac output in a patient with HF is diminished, blood flow to the kidneys is reduced. The kidneys respond to the decreased perfusion by secreting renin and activating the RAAS. As a result of the action of angiotensin II, aldosterone secretion is increased, and the body retains sodium and water. This has the beneficial effects of increasing preload, stretching the myocardial fibers, and increasing contractility, thus returning cardiac output to normal levels. This is an important compensatory mechanism in normal hearts.

However, the heart has a limited ability to increase contractility. In a diseased heart, the increased preload leads to volume overload and pulmonary congestion. In addition, the increased plasma volume increases blood pressure, which further adds to afterload and to the burden of an already weak heart.

Research has discovered additional detrimental effects related to activation of the RAAS. Angiotensin II has been found to promote ventricular hypertrophy, myocyte death, and fibrosis formation in the myocardium. Aldosterone also has direct effects on the myocardium, promoting fibrosis and stiffening of the ventricular wall. Angiotensin-converting enzyme (ACE) inhibitors have become preferred drugs for HF, in part, because they are able to block these detrimental effects of angiotensin II and aldosterone on cardiac remodeling.

Natriuretic Peptides and Neurohumoral Factors

Natriuretic peptides are substances secreted in response to increased pressure in the heart. Three types have been identified:

1. Atrial natriuretic peptide (ANP) is secreted by the atria.
2. B-type natriuretic peptide (BNP) is secreted by the cardiac ventricles.
3. C-type natriuretic peptide (CNP) is secreted by the brain.

ANP and BNP are secreted in response to left ventricular volume overload and dysfunction. The physiologic functions of ANP and BNP are to cause diuresis and reverse the negative effects of SNS and RAAS activation on the heart. BNP is used as a biomarker to diagnose and establish the severity of HF. Nesiritide (Natrecor), a drug structurally identical to BNP, has a limited role in the treatment of HF, as discussed in Section 36.8.

Research has identified several other substances as potential mediators in the progression of HF. Two proinflammatory substances, tumor necrosis factor (TNF) and interleukin, are found in high levels in patients with HF and are associated with a poor prognosis. The hormone endothelin is a vasoconstrictor that also is associated with a poor prognosis in HF patients. Vasopressin (antidiuretic hormone), which is elevated in HF patients, causes fluid retention and worsens this condition. It is likely that research will identify additional mediators of HF, along with potential novel therapies for the disease.

36.3 Symptoms of heart failure occur when compensatory mechanisms fail to maintain adequate cardiac output.

The classic symptoms of HF are dyspnea on exertion, fatigue, pulmonary congestion, and peripheral edema.

Table 36.1 Drugs That May Worsen Heart Failure

Mechanism	Example Drugs and Classes
Negative inotropic effect: slow heart rate or reduce contractility	Antidysrhythmics Beta-adrenergic antagonists Calcium channel blockers Itraconazole (antifungal)
Cardiotoxicity: damage to the myocardium	Cyclophosphamide (antineoplastic) Daunomycin (antineoplastic) Doxorubicin (antineoplastic)
Increase blood volume: cause sodium and water retention and fluid overload	Androgens Estrogens Glucocorticoids NSAIDs Rosiglitazone and pioglitazone (antidiabetics)

Lung congestion causes a cough and orthopnea (difficulty breathing when recumbent). If pulmonary edema occurs, the patient feels as if he or she is suffocating and extreme anxiety may result. The condition often worsens at night.

Through pharmacotherapy and lifestyle modifications, many patients with HF can be maintained in a symptom-free, compensated state for years. The most common reason patients experience decompensation is fluid overload due to nonadherence to sodium and water restrictions. The second most common reason is nonadherence to the pharmacotherapeutic regimen. The nurse must stress to patients the importance of sodium restriction and treatment adherence to maintain a properly functioning heart. Cardiac events such as myocardial ischemia, MI, or dysrhythmias can also precipitate acute HF. Certain medications can worsen HF, and the nurse should use these drugs with caution. A list of selected drugs that may worsen HF is shown in Table 36.1.

Pharmacologic Management of Heart Failure

36.4 The specific therapy for heart failure depends on the clinical stage of the disease.

Several models are available to guide the pharmacologic management of HF. The New York Heart Association (NYHA) classification has been widely used in clinical practice for the staging of HF. This model classifies symptomatic HF into four functional classes:

- I: Patients with cardiac disease but with no symptoms during physical activity
- II: Patients with cardiac disease who have slight limitations on physical activity, with symptoms such as fatigue, palpitations, dyspnea, or angina
- III: Patients with cardiac disease who have marked limitations during physical activity
- IV: Patients with cardiac disease who are unable to perform physical activity and who have symptoms at rest.

A more recent model, proposed by the American College of Cardiology (ACC) and the American Heart Association (AHA), categorizes HF into four stages, as listed in Table 36.2. Although similar to the NYHA model, the ACC/AHA model better illustrates the progressive nature of the disease and the role of risk factor modification. In 2016, a focused review of the ACC/AHA recommendations considered new research evidence and added two additions to drug therapy for HF: ivabradine (Corlanor) and Entresto, a combination drug containing valsartan and sacubitril (Yancy et al., 2016). Sacubitril is the first in a new class of drugs called the neprilysin inhibitors.

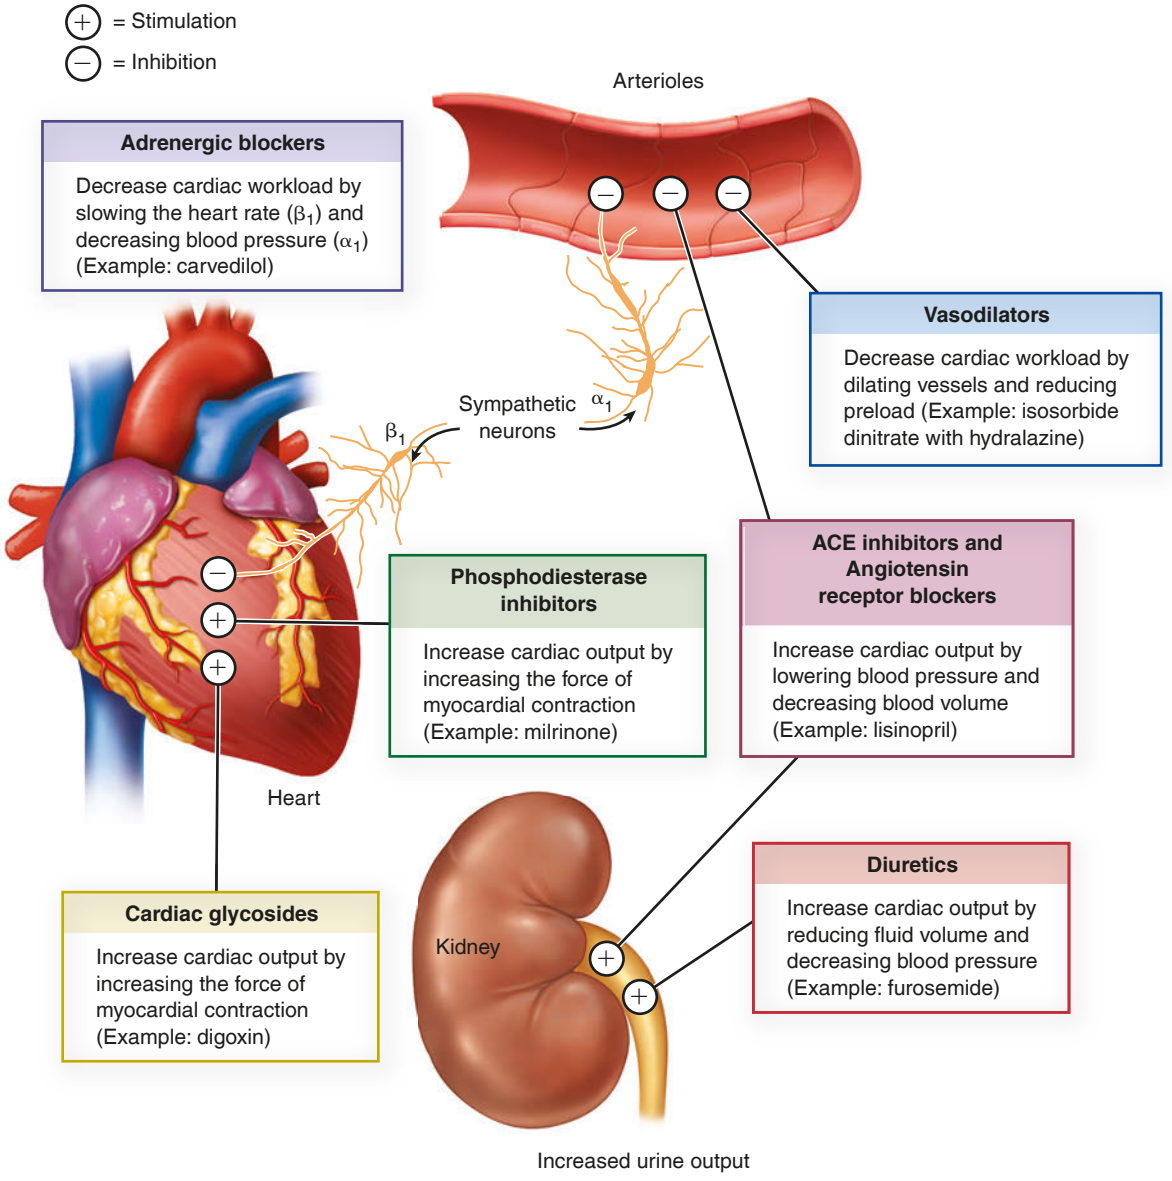

Table 36.2 Stages for Treating Heart Failure

Stage	Description	Treatment Examples
A	At high risk of developing HF but without structural heart disease or symptoms.	Make lifestyle modifications. Treat and control associated conditions: HTN, dyslipidemia, and diabetes. If hypertensive, use ACE inhibitor or angiotensin receptor blocker (ARB).
B	Structural evidence of heart disease, such as a previous MI or valvular disease, but no symptoms of HF. (Includes NYHA Class I patients.)	Continue treatments for stage A. Treat with ACE inhibitor or ARB. Beta blockers are added for those with prior HF symptoms or history of MI.
C	Structural evidence of heart disease with current symptoms of HF such as fatigue, fluid retention, or dyspnea. (Includes NYHA Class II and III patients.)	Continue lifestyle modifications and treatment with ACE inhibitor, ARB, or beta blocker. If needed to control symptoms, add digoxin or diuretic or combination of isosorbide dinitrate with hydralazine (in African Americans). In patients with a history of atrial fibrillation or thromboembolic event, implement anticoagulation with drugs such as warfarin, dabigatran, apixaban, or rivaroxaban. Consider supplementation with omega-3 fatty acids.
D	Symptoms at rest or minimal exertion despite optimal medical therapy. (Includes NYHA Class IV patients.)	Continue lifestyle modifications. Treatment may include IV diuretics, dopamine, dobutamine, IV nitroglycerin, nitroprusside, nesiritide, or phosphodiesterase inhibitors.

From "2013 ACCF/AHA Guideline for the Management of Heart Failure: A Report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines," by C. W. Yancy et al., 2013, *Circulation*, *128*, pp. e240–e327.

Pharmacotherapy Illustrated 36.1

Mechanisms of Action of Drugs Used for Heart Failure

Drugs for Heart Failure

Pharmacotherapy of HF focuses on three primary goals:

1. Reduction of preload
2. Reduction of systemic vascular resistance (afterload reduction)
3. Inhibition of both the RAAS and vasoconstrictor mechanisms of the sympathetic nervous system.

The first two goals provide symptomatic relief but do not reverse the progression of the disease. In addition to reducing symptoms, inhibition of the RAAS and vasoconstriction by the sympathetic nervous system also result in a significant reduction in morbidity and mortality from HF. These mechanisms are illustrated in Pharmacotherapy Illustrated 36.1.

36.5 Angiotensin-converting enzyme inhibitors are preferred drugs for heart failure.

Due to their effectiveness and relative safety, the angiotensin-converting enzyme (ACE) inhibitors have become first-line drugs for the treatment of chronic HF. Indeed, unless specifically contraindicated, all patients with HF and many patients at high risk of HF should receive an ACE inhibitor. The student should refer to Chapter 31 for details on the pharmacology of the drugs in this class. The following

CONNECTIONS: Patient Safety

Misunderstood Instructions

A patient has been taking enalapril (Vasotec) and carvedilol (Coreg CR) for stage B heart failure with history of prior MI. The patient is brought to the emergency department due to episodes of syncope at home whenever rising from lying or sitting to standing. When questioned, the patient reports taking "all medicines as directed" and that he has been "counting my pulse rate before I take the Coreg. I am not to take it if my heart beat is less than 60 in a minute." On assessing the patient's heart rate, the nurse notes a pulse of 42. When asked to demonstrate how he is taking his pulse, the patient requests the nurse's stethoscope and replies, "I've been using my daughter's stethoscope, she's a nurse. I count my heartbeats. It's easier than trying to find my pulse," and proceeds to demonstrate. He obtains a pulse rate of 84.

What is one possible underlying reason for the discrepancy in heart rate between the nurse's and the patient's values? What should the nurse do to correct the patient's technique?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

section focuses on the benefits of these drugs for patients with HF.

Clinical research has clearly demonstrated that ACE inhibitors slow the progression of HF and reduce mortality from this disease. Although this is probably true for all ACE inhibitors, the largest body of research has been conducted using captopril (Capoten) and lisinopril (Prinivil, Zestril). Doses for the ACE inhibitors indicated for HF are listed in Table 36.3.

The two primary actions of the ACE inhibitors are to lower peripheral resistance through the inhibition of angiotensin II formation and to reduce blood volume through inhibition of aldosterone secretion. The resultant reduction of arterial blood pressure diminishes afterload and increases cardiac output. An additional effect of the ACE inhibitors is dilation of veins. This action, which is probably not directly related to their inhibition of angiotensin, lowers preload and reduces pulmonary congestion and peripheral edema. The combined reductions in preload, afterload, and blood volume from the ACE inhibitors substantially decrease the workload on the heart and allow it to work more efficiently for patients with cardiac impairment. Patients taking ACE inhibitors experience fewer HF-related symptoms, hospitalizations, and treatment failures. Exercise tolerance is improved.

Research has also demonstrated that several ACE inhibitors are effective in preventing HF following an acute MI. Furthermore, post-MI therapy with ACE inhibitors reduces mortality and decreases reinfarction rates. Although these effects are most prominent when therapy is initiated within 36 hours after the onset of the MI, benefits are also obtained when therapy is begun later and continued for several years.

Therapy with ACE inhibitors is generally begun at low doses, and the amount is gradually increased until the desired therapeutic level is reached. Clinical research has not shown a significant difference in mortality between patients receiving low versus high doses. Because higher doses reduce HF symptoms more effectively, however, patients often receive doses in the higher range, as long as significant adverse effects do not interfere with therapy. Symptomatic relief from HF symptoms occurs within days of initiating therapy, but maximum benefits may take several weeks.

The ACE inhibitors are well tolerated by most patients with HF. Hypotension is the most common adverse effect, and the risk is increased when the patient is receiving other drugs that lower blood pressure such as diuretics and beta blockers. Hypotension is generally worse at the beginning of therapy or when the dosage is increased. Multidrug therapy is common in these patients, and the nurse serves a key role in teaching patients how to space drug administration times to minimize hypotensive adverse effects.

An additional concern during ACE inhibitor therapy is functional renal insufficiency. Patients with severe HF have high circulating levels of angiotensin II, which helps to maintain renal blood flow by constricting efferent arterioles in the kidney. When ACE inhibitors are administered, the level of angiotensin II declines rapidly, leading to reduced blood flow through the kidneys. During therapy with ACE inhibitors, renal insufficiency may also result from sodium depletion, often secondary to the concurrent use of diuretics. To avoid this potentially serious adverse effect, serum creatinine, serum electrolytes, and blood urea nitrogen (BUN) should be monitored during therapy. Should an assessment discover signs of renal impairment, the dose should be immediately decreased or the drug discontinued. Other adverse effects of ACE inhibitors are angioedema, cough, and hyperkalemia. The student should refer to Chapter 31 for additional information on the adverse effects of ACE inhibitors and for a drug prototype feature for lisinopril (Prinivil, Zestril).

Another class of drugs that blocks the effects of angiotensin II are the angiotensin receptor blockers (ARBs). Pharmacologically, the effects of the ARBs are very similar to those of the ACE inhibitors, as would be expected, because drugs from both classes inhibit the actions of angiotensin II. In patients with HF, ARBs show equivalent efficacy to the ACE inhibitors. Clinical research, however, has suggested that combining ARBs with ACE inhibitors does not improve patient survival but does increase the risk of adverse effects. Because they show no clear advantage over other HF

Table 36.3 Drugs for Early and Moderate Heart Failure

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
ACE Inhibitors and Angiotensin Receptor Blockers (ARBs)		
candesartan (Atacand)	PO: Start at 4 mg/day and increase gradually (max: 32 mg/day)	*Headache, dizziness, orthostatic hypotension, cough* Severe hypotension (first-dose phenomenon), syncope, angioedema, blood dyscrasias, fetal toxicity
captopril (Capoten)	PO: 6.25–12.5 mg tid (max: 450 mg/day)	
enalapril (Vasotec)	PO: 2.5 mg qid–bid (max: 40 mg/day)	
fosinopril (Monopril)	PO: 5–40 mg/day (max: 40 mg/day)	
lisinopril (Prinivil, Zestril)	PO: 10 mg/day (max: 80 mg/day)	
quinapril (Accupril)	PO: 10–20 mg/day (max: 40 mg/day)	
ramipril (Altace)	PO: 2.5–5 mg bid (max: 10 mg/day)	
valsartan (Diovan)	PO: 80 mg/day (max: 320 mg/day)	
Diuretics		
Loop or High-Ceiling		Loop and thiazides: *Electrolyte imbalances, fatigue, orthostatic hypotension* Severe hypotension, dehydration, serious hypokalemia, hyponatremia, hyperglycemia (thiazides), ototoxicity (loop diuretics) Potassium-sparing: *Hyperkalemia, gynecomastia in men, fatigue* Dysrhythmias due to hyperkalemia
bumetanide (Bumex)	PO: 0.5–2 mg/day (max: 10 mg/day)	
furosemide (Lasix)	PO: 20–80 mg in 1 or more divided doses (max: 600 mg/day)	
torsemide (Demadex)	PO/IV: 10–20 mg/day (max: 200 mg/day)	
Thiazide and Thiazide-Like		
hydrochlorothiazide (Microzide)	PO: 25–200 mg in 1–3 divided doses (max: 200 mg/day)	
Potassium-Sparing (Aldosterone Antagonist)		
eplerenone (Inspra)	PO: 25–50 mg once daily (max: 100 mg/day)	
spironolactone (Aldactone)	PO: 5–200 mg in divided doses	
Beta-Adrenergic Antagonists		
carvedilol (Coreg CR)	PO (extended release): 10–20 mg/day (max: 80 mg/day)	*Fatigue, insomnia, drowsiness, weight gain, bradycardia, dizziness* Agranulocytosis, laryngospasm, Stevens–Johnson syndrome, anaphylaxis; if the drug is abruptly withdrawn, palpitations, rebound HTN, life-threatening dysrhythmias, or myocardial ischemia may occur
metoprolol (Toprol XL)	PO (extended release): 12.5–25 mg/day initial dose (max: 200 mg/day)	
Miscellaneous drugs		
digoxin (Lanoxin, Lanoxicaps)	PO: 0.125–0.5 mg/day	*Nausea, vomiting, headache, and visual disturbances such as seeing halos, a yellow or green tinge, or blurring* Dysrhythmias, AV block
hydralazine with isosorbide dinitrate (BiDil)	PO: 1 tablet tid (max: 2 tablets tid); each tablet contains 37.5 mg of hydralazine and 20 mg of isosorbide dinitrate	*Headache, flushing of face, orthostatic hypotension, dizziness, reflex tachycardia* Fainting, severe headache, severe hypotension with overdose, lupus-like reaction (hydralazine)
ivabradine (Corlanor)	PO: 5 mg bid initial dose (max: 7.5 mg bid)	*Bradycardia, HTN* Atrial fibrillation, fetal toxicity
sacubitril with valsartan (Entresto)	PO: 97 mg (sacubitril)/103 mg (valsartan) bid maintenance dose	*Hypotension, hyperkalemia, cough, dizziness* Renal failure, fetal toxicity, angioedema

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

medications, the use of ARBs in the treatment of HF is usually reserved for patients who are unable to tolerate the adverse effects of ACE inhibitors. The ARB losartan (Cozaar) is featured as a prototype drug in Chapter 31.

In 2015, Entresto, a combination of sacubitril (a neprilysin inhibitor) and valsartan (an ARB), was approved. This drug represents a new class called angiotensin receptor neprilysin inhibitors (ARNIs). Neprilysin is an enzyme normally present in the body that breaks down natriuretic peptides and other substances that affect fluid balance. By blocking neprilysin, the concentration of natriuretic peptides in the blood increases and cardiac efficiency improves. The most significant finding of this new class of drugs is that they are able to reduce mortality and the number of hospitalizations in patients with HF. The neprilysin inhibitors are likely to lead to the discovery of other new approaches to treating angina, HTN, and HF. Indeed, it is possible that the ARNIs may replace monotherapy with ACE inhibitors as the first-line therapy for many patients with HF (Jhund & McMurray, 2016).

36.6 Diuretics relieve symptoms of heart failure by reducing fluid overload and decreasing blood pressure.

Diuretics are common medications for the treatment of patients with HF because they are effective at reducing peripheral edema and pulmonary congestion and produce few adverse effects. By reducing blood volume and lowering blood pressure, the workload on the heart is reduced, and cardiac output increases. Diuretics are rarely used alone for HF but are frequently prescribed in combination with other HF medications. Doses for selected diuretics are listed in Table 36.3. The student should refer to Chapter 32 for more detailed information on diuretics.

Although diuretics are effective at relieving HF symptoms, clinical research has not demonstrated their effectiveness in slowing the progression of HF or in decreasing the mortality rate associated with the disease. Indeed, some of the actions of the diuretics, particularly effects on potassium balance, may increase the risk of adverse effects from other HF drugs. Because of this, diuretics are only indicated when there is evidence of fluid retention. In patients presenting with fluid retention, especially with symptoms of severe pulmonary congestion or peripheral edema, diuretics are essential medications.

Of the diuretic classes, the loop diuretics are most commonly prescribed for HF, due to their effectiveness in removing fluid from the body. Loop diuretics are also able to function in patients with chronic kidney disease (CKD), an advantage for many patients with decompensated HF. Another major advantage in treating acute HF is that loop diuretics act quickly, within minutes for intravenous (IV) formulations. For chronic HF, therapy is begun with low doses and gradually increased until the desired volume reduction is obtained.

As therapy continues with loop diuretics, some patients become less responsive, a phenomenon known as **diuretic resistance**. The loop diuretics exhibit a ceiling effect; once the "ceiling dose" is reached, increases in dosage will not produce additional diuresis. To obtain additional diuresis and volume reduction, the loop diuretic may be administered more frequently, or a diuretic from a different class may be added to the regimen.

Thiazide diuretics are also used in the pharmacotherapy of HF, sometimes combined with loop diuretics to achieve a more effective diuresis in patients with acute HF. Because they are less effective than the loop diuretics, thiazides are generally reserved for patients with mild-to-moderate HF.

In addition to being a potassium-sparing diuretic, spironolactone is also classified as an aldosterone antagonist. As a diuretic, spironolactone has a limited role in HF, due to its low efficacy. Clinical research, however, has demonstrated that the drug is able to block the deleterious effects of aldosterone on the heart. High levels of aldosterone promote cardiac remodeling and the deposition of fibrotic tissue in the myocardium of patients with HF. By blocking these cardiac effects, spironolactone decreases mortality due to sudden death as well as progression to advanced HF.

Diuretic use in HF patients should be carefully monitored to avoid dehydration or electrolyte imbalances. These adverse effects are more likely to occur in HF patients who have CKD. During maintenance therapy, patients are urged to weigh themselves frequently and report significant changes to their healthcare provider. Frequent laboratory tests for blood electrolyte levels are obtained to prevent the development of hypokalemia during loop or thiazide diuretic therapy. This is especially important in patients who are also taking digoxin (Lanoxin), because hypokalemia may induce fatal dysrhythmias. Hydrochlorothiazide, furosemide, and spironolactone are featured as drug prototypes in Chapter 32.

CONNECTION Checkpoint 36.2

Conn's syndrome is characterized by excess secretion of aldosterone. From what you learned in Chapter 31, what effect would you predict this syndrome would have on the heart, and what medication might be a preferred drug? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

36.7 Beta-adrenergic antagonists can dramatically reduce hospitalizations and increase the survival of patients with heart failure.

Cardiac glycosides, beta-adrenergic agonists, and other medications that produce a positive inotropic effect serve important roles in reversing the diminished contractility that is the hallmark of HF. It may seem somewhat surprising, then, to find beta-adrenergic antagonists—drugs that exhibit a *negative* inotropic effect—prescribed for this disease. Even though this class of drugs has the potential to worsen HF, beta-adrenergic antagonists are standard therapy for many patients with this chronic disorder. Why is this the case?

In patients with HF, high levels of endogenous norepinephrine and other catecholamines cause excessive activation of the sympathetic nervous system and are associated with cardiac remodeling and progression of the disease. Beta-adrenergic antagonists block the actions of these catecholamines, slowing the heart rate and reducing blood pressure, thus decreasing the cardiac workload. After several months of therapy, heart size, shape, and function return to normal in some patients, in essence producing a **reverse remodeling** of the heart. Careful use of beta-adrenergic antagonists can reduce the number of HF-associated hospitalizations and deaths. They are effective in all stages of

symptomatic HF. Doses for selected beta-adrenergic antagonists are listed in Table 36.3.

To benefit patients with HF, however, beta-adrenergic antagonists must be administered in a very specific manner. Initial doses must be 1/10 to 1/20 of the target dose. Doses are doubled every 2 weeks until the target dose is reached. If therapy is begun with the target dose, or the dose is increased too rapidly, beta blockers can worsen HF. Carvedilol and metoprolol are the two beta-adrenergic antagonists approved for HF, although bisoprolol has also been shown to be effective. When treating HF, beta blockers are almost always combined with other HF drugs.

Adherence to beta-blocker therapy can be a major clinical challenge for some patients. The patient may not report symptomatic improvement with the drug and, in fact, may feel worse at the initiation of therapy. To achieve maximum patient adherence, the nurse must teach the patient the important long-term benefits of beta blockers.

Beta-adrenergic antagonists are contraindicated in patients with chronic obstructive pulmonary disease (COPD), severe bradycardia, or heart block. These medications should be used with caution in patients with diabetes, peripheral vascular disease, and hepatic impairment. Caution is needed with older adults because these patients often require a reduced dose. Hepatic function tests should be performed periodically and the prescriber notified if signs or symptoms of hepatotoxicity become apparent.

A new drug was introduced in 2015 for patients in whom beta blockers are contraindicated or when the maximum dose of the beta blocker fails to achieve therapeutic goals. Ivabradine (Corlanor) acts by a unique mechanism that slows ion (I_f) currents across the sinoatrial (SA) node, which slows the heart rate and reduces myocardial oxygen demand. The subscript *f* stands for "funny," so named because the original research determined this current had unusual properties, distinct from sodium, calcium, or potassium currents. Adverse effects include possible bradycardia, hypotension and atrial fibrillation.

The basic pharmacology of the beta-adrenergic antagonists is presented in Chapter 16, where metoprolol is featured as a prototype for this class. Other applications of the beta-adrenergic antagonists are discussed elsewhere in this text: HTN is discussed in Chapter 34, angina and MI in Chapter 35, and dysrhythmias in Chapter 37.

36.8 Vasodilators reduce symptoms of heart failure by reducing preload or afterload.

Vasodilators relax blood vessels and lower blood pressure, creating less workload on the heart. They serve a limited role in the pharmacotherapy of HF.

Hydralazine with isosorbide dinitrate (BiDil): Hydralazine combined with isosorbide dinitrate (BiDil) is approved as an adjunct to standard therapy for HF. The combination appears to be particularly effective in treating African Americans, who are sometimes resistant to therapy for HTN and HF.

Hydralazine acts on arterioles to decrease peripheral resistance, reduce afterload, and increase cardiac output. It is an effective antihypertensive drug, although it is not a preferred drug for this indication because hypotension and reflex tachycardia are common and may limit therapy. The drug must be taken 3 to 4 times daily, which places an extensive pill burden on patients with HF, who often are taking multiple drugs. Hydralazine is presented as a prototype vasodilator for HTN in Chapter 34.

Isosorbide dinitrate (Isordil) is a long-acting organic nitrate that reduces preload by directly dilating veins. The drug is not very effective as monotherapy, and tolerance develops to its actions with continued use. Isosorbide dinitrate is usually combined with hydralazine (BiDil) because the two drugs act synergistically when used in patients with HF. The high incidence of adverse effects, such as reflex tachycardia and orthostatic hypotension, limits their use in some patients. The use of isosorbide dinitrate in the pharmacotherapy of angina pectoris is presented in Chapter 35.

Nesiritide (Natrecor): A third vasodilator used for HF is very different from hydralazine or isosorbide dinitrate. Approved in 2001, nesiritide (Natrecor) is a small-peptide hormone produced through recombinant DNA technology that is structurally identical to human beta-type natriuretic peptide (hBNP). When HF occurs, the ventricles begin to secrete hBNP in response to the increased stretch on the ventricular walls. hBNP enhances diuresis and renal excretion of sodium.

In therapeutic doses, nesiritide causes vasodilation, which reduces preload. By lowering preload and afterload, the drug compensates for diminished cardiac function. The use of nesiritide is limited because it can rapidly cause severe hypotension, which can persist several hours after the infusion is discontinued. The drug is given by IV infusion, and patients require continuous monitoring. It is approved only for patients with acutely decompensated heart failure. The dosage for nesiritide is shown in Table 36.4. Nesiritide is pregnancy category C.

CONNECTION Checkpoint 36.3

Isosorbide dinitrate is also used for angina. From what you learned in Chapter 35, why is nitroglycerin a preferred drug for acute angina, rather than isosorbide dinitrate? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

36.9 Cardiac glycosides increase the force of myocardial contraction and were once preferred drugs for heart failure.

Once used as arrow poisons by African tribes and as medicines by the ancient Egyptians and Romans, the

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Beta-Adrenergic Agonists		
dobutamine (Dobutrex)	IV: Infused at a rate of 2.5–40 mcg/kg/min for a max of 72 h	*Headache, palpitations, nausea, vomiting, changes in blood pressure (hypo- or hypertension)* Dysrhythmias, gangrene, severe HTN
dopamine (Dopastat, Intropin)	IV: 2–5 mcg/kg/min initial dose; may be increased to 20–50 mcg/kg/min (max: 50 mcg/kg/min)	
epinephrine (Adrenalin)	Subcutaneous: 0.1–0.5 mL of 1:1000 every 10–15 min prn IV: 0.1–0.25 mL of 1:1000 every 10–15 min	
isoproterenol (Isuprel)	IV infusion: 0.5–5 mcg/min	
norepinephrine (Levophed)	IV: Initially, 0.5–1 mcg/min until pressure stabilizes, then 2–4 mcg/min for maintenance (max: 30 mcg/min)	
Phosphodiesterase Inhibitor		
milrinone (Primacor)	IV: 50 mcg/kg over 10 min; then 0.375–0.75 mcg/kg/min	*Headache, hypotension* Dysrhythmias
Vasodilator		
nesiritide (Natrecor)	IV: 2 mcg/kg bolus followed by continuous infusion at 0.1 mcg/kg/min	*Hypotension, increased serum creatinine* Dysrhythmias

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

value of the cardiac glycosides in treating heart disorders has been known for over 2000 years. Originally extracted from the beautiful flowering plants *Digitalis purpura* (purple foxglove) and *Digitalis lanata* (white foxglove), the cardiac glycosides were the mainstay of HF treatment until the discovery of the ACE inhibitors. During the past 20 years, the role of the cardiac glycosides in the pharmacotherapy of HF has become more limited. The dose for digoxin, the sole available drug in this class, is listed in Table 36.3.

Because of its long historical use, the effectiveness of digoxin in the pharmacotherapy of HF remained unquestioned until the late 1980s. Based on subsequent research and the development of safer and more effective drug classes, digoxin is now limited to late-stage HF, in combination with other drugs. Digoxin remains an important therapy in HF patients with supraventricular tachyarrhythmias because the drug has antidysrhythmic activity that can stabilize these types of cardiac conduction abnormalities.

The margin of safety between a therapeutic dose and a toxic dose of cardiac glycosides is very narrow, and severe adverse effects may result from poorly managed therapy. **Digitalization** refers to the procedure by which the dose of digoxin is gradually increased until tissues become saturated with the medication, and the symptoms of HF diminish. If the patient is critically ill, digitalization can be done rapidly with IV doses in a controlled clinical environment, where adverse effects may be carefully monitored. Using oral (PO) dosing digitalization may be completed over a period of 7 days. In either case, the goal is to determine the proper dose of medication to be administered, without undue adverse effects.

PROTOTYPE DRUG Digoxin (Lanoxin, Lanoxicaps)

Classification **Therapeutic:** Drug for heart failure
Pharmacologic: Cardiac glycoside, inotropic drug

Therapeutic Effects and Uses: The primary benefit of digoxin is its ability to increase the strength of myocardial contraction, a positive inotropic action. By increasing myocardial contractility, digoxin directly increases cardiac output, which alleviates symptoms of HF and improves exercise tolerance. The higher cardiac output increases urine production and results in a desirable reduction in blood volume, relieving the distressing symptoms of pulmonary congestion and peripheral edema. In current clinical practice, digoxin use is usually limited to patients who are not responding adequately to ACE inhibitor therapy or to HF patients with atrial fibrillation.

In addition to its positive inotropic effect, digoxin also affects the speed of myocardial conduction. Through a mechanism not fully understood, digoxin decreases SNS activity and increases parasympathetic activity. This helps attenuate the excessive sympathetic activation that causes tachycardia and worsens HF (see Section 36.2). Digoxin has the ability to suppress the SA node and slow electrical conduction through the atrioventricular node. The heart rate decreases, allowing greater diastolic filling of the ventricles. Because the heart rate may decline too much, healthcare providers establish parameters for each patient. As a general rule, if the apical pulse falls below 60 beats/min, the medication is withheld and the healthcare provider notified.

Digoxin is sometimes used to treat dysrhythmias, as discussed in Chapter 37.

Digoxin is available by the PO or IV route. Because differences in bioavailability of digoxin formulations can potentially affect drug action and the potential for adverse effects, patients are advised to continue with the same trade name, unless otherwise changed by the prescriber.

Mechanism of Action: Digoxin inhibits Na^+-K^+-ATPase, the critical enzyme responsible for pumping sodium ions out of the myocardial cells in exchange for potassium ions. As sodium ions accumulate in myocytes, calcium ions are released from their storage areas in the cell to activate contractile elements. The release of calcium ions produces a more forceful contraction of myocardial fibers.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	70–90% absorbed from the gastrointestinal (GI) tract
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 20–25% bound to protein
Primary metabolism	Hepatic, 14%
Primary excretion	Renal
Onset of action	PO: 30–90 min; IV: 5–30 min
Duration of action	Half-life: 3–4 days

Adverse Effects: Adverse effects of digoxin involve multiple body systems and can be severe. The most dangerous adverse effect is ventricular dysrhythmias, which may result in sudden cardiac death. The most common cause of digoxin-induced dysrhythmias is hypokalemia due to diuretic use. Other factors placing patients at risk for digoxin-induced dysrhythmias include hypomagnesemia, hypercalcemia, and impaired renal function. Additional serious adverse cardiac effects include atrioventricular (AV) block, atrial dysrhythmias, and sinus bradycardia. Frequent electrocardiograms (ECGs) should be obtained to assess for cardiotoxicity.

Noncardiac adverse effects include general malaise, dizziness, headache, anorexia, nausea, and vomiting. The drug may produce unusual visual effects such as halos, changes in color perception, and photophobia.

Frequent serum digoxin levels should be obtained during therapy, and the dosage adjusted based on the laboratory results and the patient's clinical response. Digoxin levels from 0.5 to 2 ng/mL give the most therapeutic benefit, with an acceptable risk of adverse effects for most patients. For each patient, the healthcare provider should establish acceptable parameters for serum digoxin levels, and the drug should be discontinued should the level rise above the maximum. Digoxin levels greater than 2.0 ng/mL are considered toxic. However, the nurse should remember that toxicity should be based on patient symptoms rather than serum level.

Contraindications/Precautions: Patients with AV block or ventricular dysrhythmias unrelated to HF should not receive digoxin, because the drug may worsen these conditions. Digoxin should be administered with caution to older adults because these patients experience a higher incidence of adverse effects. Patients with CKD should receive lower doses of digoxin, because the drug is excreted by this route. The drug should be used with caution in patients with MI, cor pulmonale, or hypothyroidism.

Drug Interactions: Digoxin interacts with many drugs. Concurrent use of digoxin with diuretics must be carefully monitored, since diuretics can cause hypokalemia and increase the risk of dysrhythmias. Use with ACE inhibitors, spironolactone, or potassium supplements can lead to hyperkalemia and reduce the therapeutic action of digoxin. Administration of digoxin with other positive inotropic drugs can cause additive effects on myocardial contractility. Concurrent use with beta blockers may result in additive bradycardia. Antacids and cholesterol-lowering drugs can decrease the absorption of digoxin. If calcium is administered intravenously together with digoxin, it can increase the risk of dysrhythmias. Quinidine, verapamil, amiodarone, and alprazolam will decrease the distribution and excretion of digoxin, thus increasing the risk of digoxin toxicity. **Herbal/Food:** The drug should be used with caution with ginseng, which may increase the risk of digoxin toxicity.

Pregnancy: Category C.

Treatment of Overdose: Digoxin overdose can be fatal and the nurse should be prepared to administer digoxin immune Fab (Digibind). Digoxin immune Fab consists of digoxin-specific antibodies, which form a complex with digoxin that prevents the drug from reaching the tissues, and is removed through renal excretion. Reversal of adverse effects occurs quickly: 90% of patients respond within an hour after IV administration. As digoxin is removed from the body, the inotropic effects of the drug will diminish, and the patient may be at risk of HF. The patient must be monitored continuously during the infusion.

Nursing Responsibilities: Key nursing implications for patients receiving digoxin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Heart Failure.

Drugs Similar to Digoxin (Lanoxin, Lanoxicaps)

Digoxin is the only cardiac glycoside available in the United States.

CONNECTION Checkpoint 36.4

Cholestyramine reduces the bioavailability of digoxin, thus potentially decreasing the actions of the cardiac glycoside. From what you learned in Chapter 29, what is the primary indication for cholestyramine and what is the likely reason this drug causes a decrease in digoxin bioavailability? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: Treating the Diverse Patient

The Impact of Health Literacy on Heart Failure Outcomes

The treatment of HF involves complex diet routines, fluid and salt restrictions, drug therapy including titration of medications, exercise prescriptions, and follow-up reassessment visits. The patient must manage these routines and also monitor weight, vital signs, and responses to medications. Low health literacy levels can have significant impact on the outcome of HF management.

Health literacy has been defined as an individual's ability to obtain, communicate, process, and understand basic health information and services and then make appropriate health decisions (Centers for Disease Control and Prevention, 2016). Low health literacy has been associated with increased risk of mortality, the inability to self-manage the disease adequately, and a lower quality of life for HF patients (Cajita, Cajita, & Han, 2016; McNaughton et al., 2015). Particularly for patients in acute HF, low health literacy has been associated with an increased risk of death (McNaughton et al., 2015).

Because of the significant impact health literacy has on the outcome of HF treatment, an assessment of a patient's ability to understand the disorder and its treatment is essential to include during initial and subsequent nurse–patient interactions. In addition to assessing the patient's ability to understand and use the information provided during patient education, assessing the patient's skills as to when and how to search for additional appropriate and credible information and when to seek assistance with finding information is also needed (Champlin, Mackert, Glowacki, & Donovan, 2016).

Patient education has always been a major focus for nurses, and it is especially crucial when caring for patients with HF. Assessing the level of health literacy, and helping patients improve their knowledge of their disease, can have a significant impact on the overall success of treatment.

36.10 Phosphodiesterase III inhibitors and other positive inotropic drugs are used for acute advanced heart failure.

Advanced or decompensated HF can be a medical emergency, and prompt, effective treatment is necessary to avoid organ failure or death. In addition to high doses of loop diuretics, positive inotropic drugs may be necessary. The two primary classes of inotropic drugs used for acute advanced HF are beta-adrenergic agonists and phosphodiesterase inhibitors. Doses for these drugs are listed in Table 36.4.

Beta-Adrenergic Agonists (Sympathomimetics): Beta-adrenergic agonists used for HF include isoproterenol (Isuprel), epinephrine, norepinephrine, dopamine, and dobutamine. Dobutamine has been a traditional preferred drug in this class because it has the ability to rapidly increase myocardial contractility, with minimal changes to heart rate or blood pressure. This is important because increases in heart rate or blood pressure will create greater oxygen demands on the heart and possibly worsen HF. Therapy with dobutamine is usually limited to 72 hours, as continuous infusion of the drug causes the heart to become tolerant to beta-adrenergic activation, making the drug less effective. The two most common adverse effects with beta agonists are tachycardia and dysrhythmias.

Patients who have both HF and hypotension benefit from dopamine, which not only increases myocardial contractility but also activates alpha-adrenergic receptors to increase blood pressure. However, tachycardia is more prominent with dopamine than with dobutamine. Patients who have been receiving a beta-adrenergic antagonist for their HF may require a higher initial dose of beta agonist. The basic pharmacology of the beta-adrenergic agonists was presented in Chapter 15, where epinephrine and isoproterenol were featured as prototypes for this drug class.

Phosphodiesterase III Inhibitors: In the 1980s, two medications became available that block the enzyme **phosphodiesterase III** in cardiac and smooth muscle, which leads to increases in the amount of calcium available for myocardial contraction. The enzyme inhibition results in two main actions that benefit patients with HF: a positive inotropic action and vasodilation. Cardiac output is increased due to the increase in contractility and the decrease in left ventricular afterload. There is little effect on heart rate. Arterial pressure is either decreased or, in some patients, it remains unchanged. Inamrinone was discontinued in 2011, leaving milrinone the only drug in this class.

Although the actions of milrinone are very similar to those of dobutamine, it has a much longer half-life. This makes it more difficult to make rapid changes in dose when controlling acute HF. In addition, if adverse effects do occur, they are more prolonged than with dobutamine.

Milrinone has serious toxicity that limits its use in patients with resistant HF who have not responded to ACE inhibitors, digoxin, or other therapies. Therapy is limited to 2 to 3 days and the patient is continuously monitored for ventricular dysrhythmias, including ectopic beats, supraventricular dysrhythmias, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. If the patient presents with hypokalemia, this should be corrected before administering milrinone because this can increase the likelihood of dysrhythmias.

PROTOTYPE DRUG **Milrinone (Primacor)**

Classification **Therapeutic:** Drug for heart failure
Pharmacologic: Phosphodiesterase III inhibitor; inotropic drug

Therapeutic Effects and Uses: Approved in 1987, milrinone is indicated for the short-term treatment of patients with acute advanced heart failure. It is only given intravenously, and peak effects occur in 2 minutes. Immediate effects of milrinone include an increased force of contraction (positive inotropic effect) and a resulting increase in cardiac output. Research has not demonstrated any decrease in mortality or morbidity with the use of milrinone infusions. Drug therapy with milrinone is generally limited to 48 hours.

Mechanism of Action: Milrinone inhibits phosphodiesterase III, the enzyme responsible for the breakdown of cAMP to AMP, in cardiac and vascular smooth muscle. The rise in cAMP levels increases intracellular calcium, resulting in greater contractility. Cardiac output is increased and pulmonary capillary wedge pressure is decreased.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Unknown; 70% bound to plasma protein
Primary metabolism	83% is excreted unchanged; small amounts metabolized by liver
Primary excretion	Renal
Onset of action	2–10 min
Duration of action	Half-life: 3–6 h

Adverse Effects: The most serious adverse effect of milrinone is ventricular dysrhythmia, which can occur in more than 10% of patients taking the drug. The ECG is monitored continuously during infusion of the drug to prevent serious dysrhythmias. Blood pressure is also continuously monitored during the infusion to prevent hypotension. Patients with NYHA Class IV HF are at high risk for life-threatening cardiovascular reactions. Less serious adverse effects include headache, nausea, and vomiting.

Contraindications/Precautions: Milrinone is contraindicated in patients with severe obstructive valvular heart disease. The drug should be used with caution in patients with preexisting dysrhythmias. Hypovolemia or electrolyte imbalances should be corrected before starting the infusion, and the dose should be reduced in patients with CKD.

Drug Interactions: Caution should be used when administering milrinone with digoxin, dobutamine, or other inotropic drugs, since their cardiac effects may be additive. Use with antihypertensive drugs may cause additive hypotension. **Herbal/Food:** Ginger may contribute to the cardiac actions of milrinone.

Pregnancy: Category C.

Treatment of Overdose: Overdose of milrinone causes hypotension, which may be treated with the administration of normal saline or a vasopressor.

Nursing Responsibilities: Key nursing implications for patients receiving milrinone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Heart Failure.

Drugs Similar to Milrinone (Primacor)

Milrinone is the only drug in the phosphodiesterase inhibitor class.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Heart Failure

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular (including previous MI, HF, valvular disease, dysrhythmias [especially heart block]), renal dysfunction, pregnancy, or lactation. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs (especially pulse and blood pressure), breath sounds, and ECG. Assess for location and character of edema if present.
- Evaluate appropriate laboratory findings, electrolytes, especially potassium level, renal function studies, and lipid profiles.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., heart rate and blood pressure return to, or remain within, normal limits; urine output returns to, or is within, normal limits; respiratory congestion [if present] is improved; peripheral edema [if present] is improved; level of consciousness, skin color, capillary refill, and other signs of adequate perfusion are within normal limits; fatigue lessens).
- Continue periodic monitoring of electrolytes, especially potassium, renal function, and drug levels.
- Assess for adverse effects: hypotension, fatigue, dizziness, or drowsiness. Bradycardia, nausea, vomiting, anorexia, and visual changes (e.g., halos around lights, yellow or yellowish-green tint to colors) may also occur with digoxin. A pulse rate below 60 or above 100 beats/min, palpitations, significant dizziness or syncope, dyspnea, persistent anorexia or vomiting, or visual changes should be reported to the provider immediately.
- **Lifespan:** Exercise extra caution when giving the drug to older adults, pediatric patients, or patients with CKD. Immature renal function or declines in renal function make these populations more susceptible to adverse effects.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (As the heart contracts more forcefully, blood pressure and pulse should return to within normal limits or within the parameters set by the healthcare provider; urine output returns to within normal limits, peripheral edema decreases, and lung sounds are clear.)	• Teach the patient, family, or caregiver how to monitor the pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained.
• Encourage appropriate lifestyle changes: lowered fat intake, restricted sodium or fluid intake if ordered, gradually increased levels of exercise, limited alcohol intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support the benefits of drug therapy.)	• Encourage the patient, family, or caregiver to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation. Provide educational materials on low-fat, low-sodium food choices.
Minimizing adverse effects: • Continue to monitor vital signs. Take an apical pulse for 1 full minute before giving the drug. Hold the drug and notify the healthcare provider if heart rate is below 60 or above 100 beats/min. Monitor ECG during infusion of milrinone (Primacor) and during the digitalization period for dysrhythmias or bradycardia. (Drugs that are positive inotropes increase myocardial contractility but may affect cardiac conduction. Milrinone is associated with serious and potentially life-threatening dysrhythmias. Digoxin slows the heart rate and may cause bradycardia.)	• Teach the patient, family, or caregiver how to take a peripheral pulse for 1 full minute before taking the drug. Assist the patient to find the most convenient and easily felt pulse area. Record daily pulse rates and bring the record to each healthcare visit. Instruct the patient to not take the drug if pulse is below 60 or above 100 beats/min, and to contact the provider for further direction. If the patient, family, or caregiver chooses to buy a stethoscope to take pulse, ensure proper understanding of heart sounds (i.e., the "lub-dub" sound of a heartbeat is one heartbeat) and appropriate stethoscope placement. Have the patient, family, or caregiver return demonstrate. (With easier accessibility to OTC medical equipment such as stethoscopes, patients, family, or caregivers may try to emulate the healthcare provider. Ensure proper use before the patient goes home.) • Instruct patients receiving milrinone by infusion to immediately report any chest pain.
• Continue to monitor electrolyte levels periodically, especially potassium, renal function laboratory values, drug levels, and ECG. (Hypokalemia increases the risk of dysrhythmias from drugs used to treat HF.)	• Instruct the patient on the need to return periodically for laboratory work. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating drug therapy for HF.
• Weigh the patient daily and report a weight gain or loss of 1 kg (2 lb) or more in a 24-h period. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may signal impending HF with reduced organ perfusion, stimulating renin release.)	• Have the patient weigh self daily, ideally at the same time of day, and record weight along with pulse measurements. Instruct the patient to report a weight loss or gain of more than 1 kg (2 lb) in a 24-h period.
• Monitor for signs of worsening HF (e.g., increasing dyspnea or postural nocturnal dyspnea, rales or crackles in lungs, frothy pink-tinged sputum) and report immediately. (Positive inotropic drugs such as digoxin or phosphodiesterase inhibitors are usually reserved for patients with more advanced stages of HF. If signs and symptoms worsen, other treatment options may need to be considered.)	• Instruct the patient to immediately report any severe shortness of breath, frothy sputum, profound fatigue, or swelling of extremities as possible signs of HF.
• For patients taking digoxin, report signs of possible toxicity immediately to the provider and obtain a drug level. Digoxin levels should remain less than 1.8 mg/mL. Signs and symptoms such as bradycardia, nausea and vomiting, anorexia, visual changes, depression, changes in level of consciousness, fatigue, dizziness, or syncope should be reported. **Lifespan:** Digoxin is on the Beers list of potentially inappropriate drugs for the older adult and warrants careful monitoring. (Decreased excretion of digoxin and phosphodiesterase inhibitors due to age-related changes may increase the risk of adverse effects.)	• Instruct the patient, family, or caregiver on signs to report to the healthcare provider. Encourage the patient to report any significant change in overall health or mental activity promptly.
• **Lifespan:** Use extra caution when measuring the precise dose of medication ordered, and use extreme caution when measuring liquid doses, especially for pediatric patients. (For drugs such as digoxin with a long half-life and duration, toxic levels may result with only small amounts of additional drug.)	• Caution the patient, family, or caregiver on taking the precise dose of medication ordered, not doubling the dose if a dose is missed, and to use extreme caution when measuring liquid doses, especially for pediatric patients.
• **Lifespan:** Assess for the possibility of pregnancy before beginning the drug. (Many drugs for HF are pregnancy category C drugs and should be used with caution during pregnancy or breastfeeding.)	• Instruct female patients who may be considering pregnancy, or are pregnant or breastfeeding, to notify their provider before starting the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in the proper self-administration techniques. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs. • The drug should be taken at the same time each day, and doses should not be skipped or doubled. • The brand of the drug prescribed should not be switched without consultation with the provider to ensure consistent effects.

Understanding Chapter 36

Key Concepts Summary

36.1 Heart failure is closely associated with disorders such as chronic hypertension, coronary artery disease, and diabetes.

36.2 The body attempts to compensate for heart failure by increasing cardiac output.

36.3 Symptoms of heart failure occur when compensatory mechanisms fail to maintain adequate cardiac output.

36.4 The specific therapy for heart failure depends on the clinical stage of the disease.

36.5 Angiotensin-converting enzyme inhibitors are preferred drugs for heart failure.

36.6 Diuretics relieve symptoms of heart failure by reducing fluid overload and decreasing blood pressure.

36.7 Beta-adrenergic antagonists can dramatically reduce hospitalizations and increase the survival of patients with heart failure.

36.8 Vasodilators reduce symptoms of heart failure by reducing preload or afterload.

36.9 Cardiac glycosides increase the force of myocardial contraction and were once preferred drugs for heart failure.

36.10 Phosphodiesterase III inhibitors and other positive inotropic drugs are used for acute advanced heart failure.

CASE STUDY: Making the Patient Connection

Remember the patient "Thelma Walters" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Thelma Walters is a 77-year-old woman who arrives via EMS at the emergency department (ED) after experiencing increasing dyspnea for the past 2 days. She has also noticed swelling in her feet and ankles. Due to her onset of shortness of breath, she has had to sleep in a recliner and is unable to lie flat in bed at night. Her past medical history includes a mild stroke occurring 8 years ago with mild residual weakness on her right side, MI 3 years ago, and an episode of HF 1 year ago. The HF was treated with captopril (Capoten) and furosemide (Lasix), which she has been taking since that time. Her surgical history includes a hysterectomy 20 years ago. She has never used tobacco or alcohol.

As the nurse performs the initial physical assessment, the following relevant findings are discovered. The patient is 1.7 m (5′6″) tall and weighs 82 kg (180 lb). She uses a walker or a cane to feel more secure and avoid falls, due to the mild residual weakness on her right side. The patient's blood pressure is 162/92 mmHg, her heart rate is 148 beats/min and irregular, and her respiratory rate is 38 breaths/min and labored. The neck veins of the

patient are distended when she is placed at a 45-degree incline. She is orthopneic and cannot tolerate the head of the bed being lowered below 45 degrees. The nurse notes scattered crackles bilaterally throughout the lung fields. The patient has a productive cough with frothy, pink-tinged sputum; 4+ pitting edema of both hands and legs is noted with the nail beds moderately cyanotic. Circumoral cyanosis is also noted.

Immediately upon arrival at the ED, the patient received oxygen therapy and an IV line was started. Blood was collected for initial laboratory data with the following results: serum sodium 136 mEq/L (normal: 135–147 mEq/L), serum potassium 3.1 mEq/L (normal 3.5–5.2 mEq/L), and arterial blood gases on room air: pH 7.32, PaO_2 54, $PaCO_2$ 48, SpO_2 68%, indicating overall hypoxemia. Thelma is in acute distress and admitted to the intensive care unit (ICU) with a diagnosis of HF. She is given a dose of furosemide (Lasix) 20 mg IV and she will receive milrinone (Primacor) by IV infusion after admission to the ICU.

Critical Thinking Questions

1. Describe how milrinone (Primacor) aids in treating HF.
2. During the infusion of milrinone (Primacor), Thelma's ECG and blood pressure will be monitored closely. What adverse effects does milrinone have on the heart rhythm and blood pressure?
3. Because Thelma has been taking furosemide (Lasix) at home and has received another dose in the ED, what will the nurse assess prior to starting the milrinone (Primacor)? What electrolyte imbalance must be corrected before Thelma receives the milrinone (Primacor)?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Jim Mabry, a 77-year-old man, currently takes the following medications daily: digoxin (Lanoxin) 0.125 mg; furosemide (Lasix) 20 mg daily; and potassium supplementation (K-Dur) 20 mEq. As his nurse, you will be discussing Jim's medication regimen and his next healthcare provider office visit after discharge from the hospital.

1. Discuss the relationship among the three medications.
2. Jim will have a digoxin serum level collected during the healthcare provider office visit. What does he need to know about this procedure?
3. Prepare a list of foods that are rich in potassium as requested by Jim.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient newly diagnosed with heart failure following an acute myocardial infarction has a prescription for enalapril (Vasotec). This drug class is frequently used in early heart failure because of what clinical improvement?
   1. It strengthens the force of myocardial contraction to improve cardiac output.
   2. It decreases peripheral resistance, increasing cardiac output.
   3. It slows the heart rate, improving filling time and increasing cardiac output.
   4. It has diuretic effects, decreasing peripheral edema and pulmonary congestion.
2. In providing the patient with heart failure information prior to discharge, the nurse will discuss digoxin (Lanoxin) therapy. Which point would the nurse include in the patient's teaching?
   1. Take the drug in the morning before rising.
   2. Monitor the pulse daily prior to taking the drug.
   3. Discontinue the drug if the pulse rate is 70 beats per minute.
   4. Eat a diet high in bran fiber and calcium.
3. The nurse is evaluating the therapeutic effects of milrinone (Primacor). The nurse knows that this drug is given to:
   1. Increase the force of cardiac contractions and improve cardiac output.
   2. Decrease the volume of the cardiac output to reduce hypertension.

3. Relax the myocardial muscle, decreasing myocardial oxygen requirements.
4. Inhibit cardiac irregularities, decreasing the sensation of palpitations.

4. The patient is receiving hydralazine with isosorbide (BiDil) for heart failure. The nurse should monitor this patient for:
   1. Confusion and agitation.
   2. Bleeding.
   3. Tingling or cramping in the legs.
   4. Dizziness and rapid heart rate.

5. A patient will begin taking carvedilol (Coreg) for heart failure. Before teaching the patient about this drug, the nurse will discuss the strategy for drug dosage with the healthcare provider because of which recommended routine for beta-adrenergic antagonists in heart failure?
   1. Significantly lower dosages are used first and gradually increased to a target dose.
   2. A loading dose that is higher than the subsequent daily dose must be given.
   3. The beta-adrenergic antagonist dosage must be lowered if the patient is also on ACE inhibitors.
   4. Beta-adrenergic antagonists are almost never used in HF and the order must be confirmed.

6. When planning patient education, the nurse knows that patient adherence to beta-adrenergic antagonist therapy in heart failure may be difficult to achieve despite the usefulness of these drugs. What will the nurse need to address in the teaching plan? (Select all that apply.)
   1. The dosage must be gradually adjusted over time to a beneficial dose.
   2. The patient may not notice significant improvement during early therapy.
   3. The drug may require changes to many other medications the patient is taking.
   4. The drug has significant benefit in reducing mortality from heart failure.
   5. The drug will require extensive lifestyle changes.

Chapter 37
Pharmacotherapy of Dysrhythmias

Chapter Outline

- Etiology of Dysrhythmias
- Phases and Measurement of the Cardiac Action Potential
- Classification of Dysrhythmias
- General Principles of Dysrhythmia Management
- Drugs for Dysrhythmias

Sodium Channel Blockers: Class I

PROTOTYPE *Procainamide, p. 649*

Beta-Adrenergic Antagonists: Class II

Potassium Channel Blockers: Class III

PROTOTYPE *Amiodarone (Pacerone), p. 653*

Calcium Channel Blockers: Class IV

Miscellaneous Antidysrhythmics

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify disorders associated with an increased risk of dysrhythmias.
2. Explain how rhythm abnormalities can affect cardiac function.
3. Sketch a typical cardiac action potential and label the flow of potassium, sodium, and calcium ions during each phase.
4. Design a table that indicates the classification of dysrhythmias and the types of drugs used to treat them.
5. Describe general principles guiding the management of dysrhythmias.
6. Identify the primary mechanisms of action of antidysrhythmic drugs.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy for dysrhythmias.

Key Terms

bradydysrhythmias, 645
cardioversion, 646
cinchonism, 651
defibrillation, 646
depolarization, 643
dysrhythmias, 642
electrocardiogram (ECG), 644
paroxysmal supraventricular tachycardia (PSVT), 645
polarized, 643
prodysrhythmics, 642
refractory period, 643
repolarization, 643
tachydysrhythmias, 645
threshold potential, 643
torsades de pointes, 645

Dysrhythmias are disorders of cardiac rhythm characterized by abnormal heart rate or irregular contractions. Also called arrhythmias, they encompass a number of different disorders that range from harmless to life threatening. Dysrhythmias are diagnosed based on medical and family histories, a physical exam, and the results from tests and procedures. To diagnose the exact type of rhythm disorder, patients must be connected to an electrocardiogram (ECG) when they are experiencing symptoms. Proper diagnosis and optimal pharmacotherapy can significantly affect the frequency of dysrhythmias and their consequences.

Etiology of Dysrhythmias

37.1 Some dysrhythmias produce no patient symptoms, whereas others may be life threatening.

Some dysrhythmias are asymptomatic and have no effect on cardiac function, whereas others require immediate treatment. Typical symptoms of dysrhythmias include dizziness, weakness, fatigue, decreased exercise tolerance, palpitations, dyspnea, and syncope. It is difficult to estimate the frequency of the disease, although it is likely that dysrhythmias are quite common in the population. Patients often wait until these symptoms occur more frequently or become acute before seeking medical intervention.

Dysrhythmias occur in all age groups and in both healthy and diseased hearts. While the actual cause of most dysrhythmias is elusive, the majority are closely associated with certain conditions, primarily heart disease and myocardial infarction (MI): 90% of patients experiencing an MI will develop a dysrhythmia. Persistent dysrhythmias are associated with increased risk of stroke and heart failure (HF), and severe dysrhythmias may result in sudden death. Conditions that promote the formation of cardiac rhythm abnormalities are called **prodysrhythmics**. Some of the diseases and conditions associated with dysrhythmias are as follows:

- Hypertension (HTN)
- Cardiac valve disease such as mitral stenosis
- Coronary artery disease (CAD)
- Low or high potassium levels in the blood
- Myocardial infarction (MI)
- Stroke
- Diabetes mellitus
- Heart failure.

In addition to the preceding list, a number of medications have been found to *cause* new dysrhythmias or *worsen* existing ones. Caution must be used when administering prodysrhythmic drugs to patients with preexisting cardiac impairment or who may have any of the above conditions. Table 37.1 lists selected drugs known to have prodysrhythmic properties.

Table 37.1 Selected Prodysrhythmic Drugs

Class of Medication	Example Drugs
Antidysrhythmic drugs	amiodarone, disopyramide, dofetilide, flecainide, ibutilide, procainamide, propafenone, quinidine, sotalol
Autonomic drugs	atenolol, clonidine, methyldopa, nadolol, propranolol
Calcium channel blockers	diltiazem, nifedipine, verapamil
Cardiac glycosides	digoxin
Miscellaneous drugs	amitriptyline, chloroquine, cimetidine, haloperidol, lithium carbonate, phenothiazines

Phases and Measurement of the Cardiac Action Potential

37.2 The phases of cardiac action potential include rapid depolarization, a long plateau, and repolarization.

Dysrhythmias are alterations in the normal generation or conduction of electrical impulses, or action potentials, across the myocardium. Because antidysrhythmic drugs act by correcting or modifying impulse conduction, a firm grasp of cardiac electrical properties is essential to understanding drug mechanisms. Before proceeding, the student should review the normal pathway of impulse conduction in the heart presented in Chapter 28.

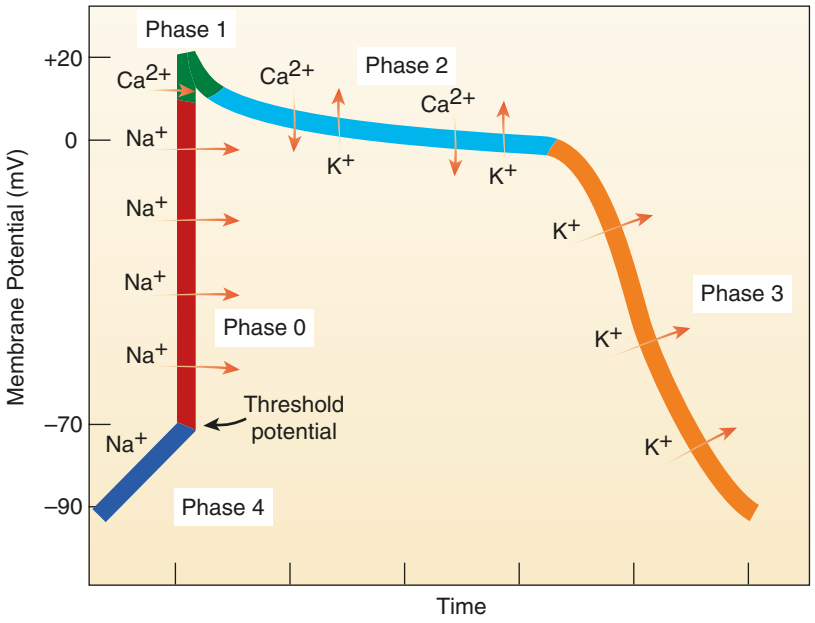

Figure 37.1 Phases of the myocardial action potential. Ion movements during each phase are shown.

Action potentials occur in neurons and cardiac muscle cells (myocytes) due to the changes in the concentration of specific ions found inside and outside the cell. Under resting conditions, sodium ions (Na^+) and calcium ions (Ca^{2+}) are in higher concentrations *outside* of myocytes, whereas potassium ions (K^+) are found in higher concentration *inside* these cells. These imbalances are, in part, responsible for the inside of a myocyte plasma membrane having a slightly negative charge (80–90 mV), relative to the outside of the membrane. A cell having this negative membrane potential is **polarized**.

An action potential illustrating the steps in electrical conduction is shown in Figure 37.1. The changes in ions, or fluxes, occurring during an action potential may be grouped into five phases.

Phase 4: It is easiest to begin with phase 4 because this is the period during which the myocyte is "resting" and the action potential has not yet occurred. Note in Figure 37.1, however, that during phase 4 the membrane potential is slowly increasing toward a potential that will trigger an action potential: the **threshold potential**. Sodium is slowly "leaking" into the cell during this period, causing the change in potential, which gives certain regions such as the sinoatrial (SA) node the property of automaticity, the ability to depolarize spontaneously, without input from the nervous system.

Phase 0: An action potential begins when the threshold potential is reached and gated sodium ion channels located in the plasma membrane become activated and open. Sodium ions rush into the cell, producing a rapid **depolarization**, or loss of membrane potential. Because they open and close rapidly, these sodium channels are sometimes referred to as "fast" channels. During this period, Ca^{2+} also enters the cell through calcium ion channels, although the influx is slower than that of sodium. In myocytes located in the SA and atrioventricular (AV) nodes, it is the influx of Ca^{2+}, rather than Na^+, that generates the rapid depolarization of the membrane.

Phase 1: During depolarization, the inside of the plasma membrane temporarily reverses its charge, becoming positive. This is a brief, transient phase.

Phase 2: During phase 2, a plateau is reached in which depolarization is maintained. The entry of Ca^{2+} into the cells signals the release of additional calcium ions that had been held in storage inside the sarcoplasmic reticula. This large and sudden increase in intracellular Ca^{2+} is responsible for the contraction of cardiac muscle. Gated potassium ion channels open, causing an efflux of K^+ from the cells. The plateau is maintained as long as the positive calcium ions entering the myocytes are balanced by the positive potassium ions leaving the cell. Action potentials in skeletal muscle lack this plateau phase.

Phase 3: During phase 3, the calcium channels close and additional potassium channels open, thus causing a net loss of positive ions from the cell. This **repolarization** returns the negative resting membrane potential to the cell.

The synchronized pumping action of the heart requires alternating periods of contraction and relaxation. There is a brief period of time following depolarization and most of repolarization during which the cell cannot initiate a subsequent action potential. This **refractory period** ensures that the myocardial cell finishes contracting before a second action potential begins.

Although learning about the different ions involved in an action potential may seem complicated, they are very important to cardiac pharmacology. Blocking potassium, sodium, or calcium ion channels is a pharmacologic strategy used to terminate or prevent dysrhythmias. In addition, the therapeutic effect of some antidysrhythmic drugs is due to their prolongation of the refractory period. It is not possible to understand drug mechanisms without adequate knowledge of the normal electrical conduction properties of the heart. In general, most cardiac drugs:

- Increase impulse formation (or automaticity).
- Increase conduction velocity.
- Increase both impulse formation and conduction velocity.

OR

- Decrease impulse formation or automaticity.
- Decrease conduction velocity.
- Decrease both impulse formation or automaticity and conduction.

CONNECTION Checkpoint 37.1

From what you learned in Chapter 30, what are the three types of calcium channels? Which type is blocked by calcium channel blocker medications? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

37.3 The electrocardiogram is used to measure electrical conduction across the myocardium.

The **electrocardiogram (ECG)** is a graphic recording of the wave of electrical conduction across the myocardium. The ECG is a primary tool in the diagnosis of dysrhythmias and other heart diseases. A normal ECG and its relationship to impulse conduction in the heart are shown in Figure 37.2.

Three distinct waves are produced by a normal ECG: the P wave, the QRS complex, and the T wave. Changes to the wave patterns or in their timing are associated with certain pathologies. The different classes of antidysrhythmic drugs also affect the ECG in characteristic manners. A summary of the different waves, segments, and intervals, and their importance to cardiac physiology is given in Table 37.2.

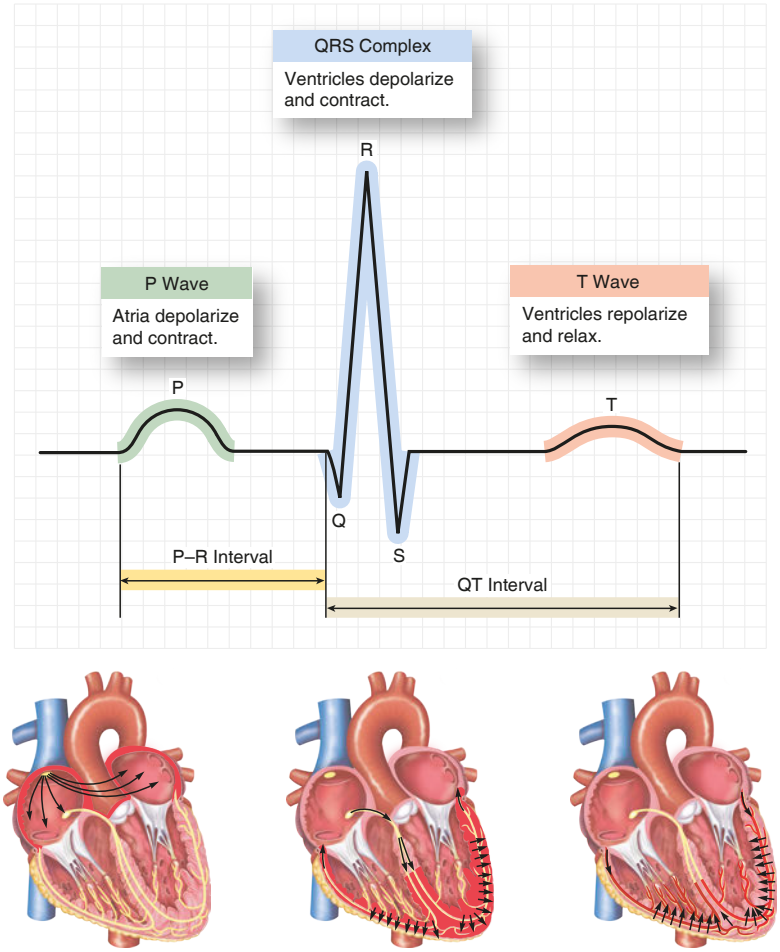

Figure 37.2 Relationship of the electrocardiogram to electrical conduction in the heart.

Table 37.2 ECG Waves and Intervals

Wave or Interval	Physiologic Significance	Importance
P wave	Represents atrial depolarization.	A large P wave (voltage greater than 2.5 mm) suggests the atria may be enlarged.
PQ segment	Represents the delay at the AV node; sometimes referred to as the PR segment.	This delay is vital so the ventricles can fill with blood. Prolonged PQ segments suggest slow or nonconducting fibrotic areas in the myocardium.
PQ interval	Represents all electrical activity prior to the impulse reaching the ventricles and contains the P wave and the PQ segment; sometimes referred to as the PR interval.	Normal measurements range between 0.12 and 0.20 sec. Slightly prolonged PQ intervals are common and considered harmless. More prolonged PQ intervals suggest a first-degree heart block.
QRS complex	Represents ventricular depolarization and atrial repolarization.	An exaggerated R wave suggests enlargement of the ventricles. The QRS should not be longer than 0.10 sec. Patients experiencing an MI may show QRS complexes that are abnormally high or that have extended durations.
T wave	Represents ventricular repolarization.	A flat T wave suggests ischemia to the myocardium; an elevated T wave indicates hyperkalemia.
ST segment	Represents the plateau phase of the action potential when the ventricles are depolarized.	Elevated ST segments are used to guide the pharmacotherapy of MI.
QT interval	Represents the time from the start of ventricular depolarization to the completion of ventricular repolarization.	Drugs that lengthen the QT interval have been linked to cardiac dysrhythmias, cardiac arrest, and sudden death. At the same time, prolongation of the action potential duration is a primary antidysrhythmic mechanism.

PharmFACT

Inherited long QT syndrome (LQTS) is a dysrhythmia that causes about 4000 sudden deaths in children and young adults each year. It is usually diagnosed during childhood and is more common in females than males. LQTS is usually treated with beta-adrenergic blockers (Sovari, 2015).

Classification of Dysrhythmias

37.4 Dysrhythmias are classified by the impulse origin and type of rhythm abnormality produced.

There are many types of dysrhythmias and they are classified by a number of different methods. The two broad categories of rhythm abnormalities are those that affect impulse formation and those that affect impulse conduction. Although a correct diagnosis of the type of dysrhythmia is sometimes difficult, it is essential for effective treatment.

Bradydysrhythmias are disorders characterized by a heart rate of less than 60 beats/min. Bradydysrhythmias are very common in older adults because the number of cells in the SA node declines progressively such that by age 75 about 90% of the cells are nonfunctional. Similar age-related changes occur in the AV node, where normal cells progressively die and are replaced by fibrotic tissue. Bradydysrhythmias are the major indication for pacemaker implantation. Common bradydysrhythmias include the following:

- **Sinus bradycardia.** This is the most common slow heart rhythm. Sinus bradycardia generally does not require treatment unless the patient is experiencing syncope or dizziness due to lack of sufficient blood flow to the brain, or if the heart rate fails to increase during periods of exertion.
- **Sinoatrial node dysfunction (sick sinus syndrome).** The SA node fails to generate or transmit sufficient electrical impulses. Patients with this condition may experience severe bradycardia (less than 40 beats/min resting), failure of the heart rate to increase with exercise, or significant sinus "pauses." Severe episodes of bradycardia may alternate with periods of abnormally rapid heart rates.
- **Atrioventricular conduction block.** The AV node fails to conduct impulses to the rest of the myocardium. AV blocks are classified by degree. In first-degree AV block, the AV node conducts the impulse slowly, and conduction is delayed. In second-degree AV block, some, but not all, impulses are prevented (blocked) from leaving the AV node. Second-degree AV block results in nonconducted P waves. A third-degree AV block results in total stoppage of impulses through the AV node. None of the impulses originating in the atria can make their way through the block into the ventricles. Second- and third-degree blocks require pharmacotherapy or the insertion of a temporary or permanent pacemaker. Some AV blocks are temporary in origin and can be due to cardiac drug toxicity. Any drug that slows AV conduction can cause a temporary form of AV block.

Tachydysrhythmias are disorders exhibiting a heart rate greater than 100 beats/min. The incidence of tachydysrhythmias increases in older adults and in patients with preexisting cardiovascular disease. The simplest method for categorizing tachydysrhythmias is according to the type of rhythm abnormality produced and its location. Dysrhythmias that originate in the atria are sometimes referred to as supraventricular. Those that originate in the ventricles are generally more serious because they are more likely to interfere with the normal function of the heart.

- **Atrial tachycardia.** This may be caused by a rapidly firing SA node or by an ectopic focus in the atria that suppresses the SA node and establishes a rapid heart rate, often between 160 and 200 beats/min. When these episodes alternate with periods of normal rhythm, it is called paroxysmal atrial tachycardia (PAT), or **paroxysmal supraventricular tachycardia (PSVT)**.
- **Atrial flutter.** This is a rapid, regular heartbeat in which the atria may beat 250 to 350 times per minute. During atrial flutter, the job of the AV node is to selectively block some of the impulses coming from the atria, so the ventricular rate (pulse) is 125 to 175 beats/min (usually two, three, or four atrial beats for each ventricular beat).
- **Atrial fibrillation.** A complete disorganization of rhythm, this is the most common type of dysrhythmia. It is caused by multiple sites of impulse formation in the atria, all firing in a chaotic fashion. The atrial rate can range from 300 to 600 beats/min, causing an irregular ventricular rate ranging from 50 to 200 beats/min. The rapid atrial rate causes a loss of organized atrial contraction and results in quivering (fibrillation). This lack of contraction causes blood to lie dormant in parts of the atria and may give rise to clots. Because of the potential for clot formation, atrial fibrillation is a leading risk factor for stroke.
- **Ventricular tachycardia.** This is usually recognized by regular, rapid, wide beats with a ventricular rate of 100 to 200 beats/min. Patients with sustained or symptomatic ventricular tachycardia must be treated immediately because this condition is associated with a high risk of sudden death. **Torsades de pointes** is a specific type of ventricular tachycardia that is characterized by rates between 200 and 250 beats/min and

"twisting of the points" of the QRS complex on the ECG.

- **Ventricular fibrillation.** This is a complete disorganization of rhythm in which the ventricles pump little or no blood, quickly starving the tissues of oxygen. Ventricular fibrillation is now considered cardiac arrest.

General Principles of Dysrhythmia Management

37.5 Antidysrhythmic drugs are only used when there is a clear benefit to the patient.

Most antidysrhythmic drugs have the potential to produce serious adverse effects. The very drugs used to treat dysrhythmias may actually worsen or create new dysrhythmias. Furthermore, research suggests that mortality may actually increase when some of these drugs are used to treat or prevent dysrhythmias. The following guidelines are used in the management of the patient with dysrhythmias.

Asymptomatic dysrhythmias: Research has shown little or no benefit to the patient in treating asymptomatic dysrhythmias with medications. Antidysrhythmic drugs are normally reserved for patients experiencing overt symptoms or for those whose condition cannot be controlled by other means.

Acute dysrhythmias: Some types of dysrhythmias are serious and may be life threatening. In these cases, pharmacotherapy or cardioversion is warranted. For example, ventricular dysrhythmias often interfere with cardiac output and have greater potential for harm than atrial dysrhythmias. Dysrhythmias that are sustained may worsen and affect cardiac function. Several antidysrhythmics available by the intravenous (IV) route have an immediate onset of action to terminate life-threatening dysrhythmias.

Prophylaxis of dysrhythmias: Patients who are afflicted with recurring dysrhythmias or who have a comorbid condition, such as preexisting heart disease, may benefit from prophylactic therapy with antidysrhythmics. These patients should be monitored regularly to assess for prodysrhythmic effects from the drugs. Drug combinations that have the potential to prolong the QT interval are avoided and doses are kept as low as possible to minimize risk. Prophylactic therapy should be initiated only for high-risk patients.

Nonpharmacologic treatment: Serious types of dysrhythmias are corrected through electrical stimulation of the heart, a treatment called **cardioversion** or **defibrillation**. The electrical shock momentarily stops all electrical impulses in the heart, both normal and abnormal. Under ideal conditions, the temporary cessation of electrical activity will allow the SA node to automatically return conduction to a normal sinus rhythm.

Other types of nonpharmacologic treatment include identification and destruction of the myocardial cells responsible for the abnormal conduction through a surgical procedure called catheter ablation. Cardiac pacemakers are sometimes inserted to correct the types of dysrhythmias that cause the heart to beat too slowly. Implantable cardioverter defibrillators (ICDs) are placed in a patient to restore normal rhythm by either pacing the heart or giving it an electric shock when dysrhythmias occur. In addition, the ICD is capable of storing information regarding the heart rhythm for the healthcare provider to evaluate.

CONNECTIONS: Lifespan Considerations

Dental Health and Dysrhythmias in the Older Adult

Atrial fibrillation is the most common sustained cardiac dysrhythmia in the older adult and is a known risk factor for strokes and MIs. Evidence suggests that inflammation may play an important role in the development of atrial fibrillation, and dental caries (tooth decay) have been shown to increase inflammatory chemicals in the body (Vedin, 2014).

Aging is often associated with increasing dental concerns and tooth loss, and nurses should continue to encourage the older adult to maintain adequate dental hygiene. Hygiene is not only a method for preserving teeth and dental function, it is also a possible preventive measure against other more serious conditions such as coronary heart disease and dysrhythmias.

Drugs for Dysrhythmias

37.6 Antidysrhythmic drugs are classified by their mechanism of action.

The therapeutic goals of antidysrhythmic pharmacotherapy are to terminate existing dysrhythmias or to prevent abnormal rhythms for the purpose of reducing the risks of sudden death, stroke, or other complications resulting from the disease. Antidysrhythmic drugs act by altering specific electrophysiologic properties of the heart. They do this through two basic mechanisms: blocking flow through ion channels (conduction) or altering autonomic activity (automaticity).

In use since 1985, the most common method of classifying antidysrhythmic drugs is the Vaughan Williams classification. This classification scheme groups drugs as Classes I, II, III, and IV based on the stage at which they affect the action potential. A fifth group includes miscellaneous drugs not acting by one of the first four mechanisms. Although widely used, the Vaughan Williams classification

Table 37.3 Classification of Antidysrhythmics

Class	Actions	Primary Indications
I: Sodium Channel Blockers		
IA	Delays repolarization; slows conduction velocity; increases duration of the action potential.	Atrial fibrillation, premature atrial contractions, premature ventricular contractions, tachycardia
IB	Accelerates repolarization; slows conduction velocity; decreases duration of action potential.	Severe ventricular dysrhythmias
IC	No significant effect on repolarization; slows conduction velocity.	Severe ventricular dysrhythmias
II: Beta-Adrenergic Antagonists	Slows conduction velocity; decreases automaticity; prolongs refractory period.	Atrial flutter and fibrillation, tachydysrhythmias, ventricular dysrhythmias
III: Potassium Channel Blockers	Slows repolarization; increases duration of action potential; prolongs refractory period.	Severe atrial and ventricular dysrhythmias
IV: Calcium Channel Blockers	Slows conduction velocity; decreases contractility; prolongs refractory period.	Paroxysmal supraventricular tachycardia, supraventricular tachydysrhythmias

method is simplistic because some of these drugs act by more than one mechanism, and the drugs within each class have unique properties that distinguish them from each other. For example, the Class I drugs have three subclasses. The categories of antidysrhythmics and their mechanisms are shown in Table 37.3.

The use of antidysrhythmic drugs has significantly declined in recent years. The reason for this decline is that research studies determined that the use of antidysrhythmic medications for prophylaxis can actually increase patient mortality. Drugs affecting cardiac electrophysiology have a narrow margin of safety between a therapeutic effect and a toxic effect. While they have the ability to correct dysrhythmias, they can also worsen or even create new dysrhythmias. These prodysrhythmic effects have resulted in less use of these drugs, especially those medications in Class I.

Another reason for the decline in antidysrhythmic drug use is the success of nonpharmacologic techniques. Catheter ablation and implantable defibrillators are more successful in managing many types of dysrhythmias than is the prophylactic use of medications.

Sodium Channel Blockers: Class I

37.7 Class I antidysrhythmics act by blocking ion channels in myocardial cells.

Sodium channel blockers, the Class I drugs, are the largest group of antidysrhythmics. They are further divided into three subgroups (IA, IB, and IC) based on subtle differences in their mechanisms of action. Because initiation of the action potential is dependent on the opening of gated sodium ion channels, a blockade of these channels will prevent depolarization of the myocardium. The spread of the action potential will slow, and areas of ectopic pacemaker activity will be suppressed. The sodium channel blockers are shown in Table 37.4 and Figure 37.3.

The sodium channel blockers are similar in structure and action to local anesthetics. In fact, the Class I antidysrhythmic lidocaine is a prototype local anesthetic in Chapter 26. This anesthetic-like action slows impulse conduction across the heart. Some, such as quinidine and procainamide, are effective against many types of dysrhythmias. The remaining Class I drugs are more specific and indicated only for life-threatening ventricular dysrhythmias.

The adverse effects of the sodium blockers vary with each individual drug. All these medications can cause new dysrhythmias or worsen existing ones. The slowing of the heart rate can cause hypotension, dizziness, and fainting. During pharmacotherapy, the ECG should be monitored for signs of cardiotoxicity, such as increases in the PR and QT intervals and widening of the QRS complex. Some Class I drugs have significant anticholinergic adverse effects such as dry mouth, constipation, and urinary retention. Special precautions should be taken with older adults, because anticholinergic adverse effects may worsen urinary hesitancy in men with prostate enlargement.

Class IA: The Class IA antidysrhythmics include quinidine, disopyramide (Norpace), and procainamide. Although quinidine is the oldest and best known Class IA drug, procainamide is the prototype because it has been more widely used than quinidine in recent decades. All are available by the oral (PO) route and act by blocking sodium ion channels during phase 0 of the action potential.

The primary action responsible for the antidysrhythmic effects of the Class IA drugs is a slowing of conduction velocity. These drugs also inhibit potassium channels, which delays repolarization and increases the refractory period. Subsequent action potentials must wait slightly longer before triggering the next electrical impulse. These actions allow the Class IA drugs to inhibit the formation of ectopic foci in both the atria and ventricles.

Table 37.4 Antidysrhythmic Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Class IA: Sodium Channel Blockers		
disopyramide (Norpace)	PO (immediate release): 400–800 mg in divided doses PO (extended release): 300 mg bid	*Nausea, vomiting, diarrhea, dry mouth, urinary retention, cinchonism (quinidine), anorexia, rash, photosensitivity* May produce new dysrhythmias or worsen existing ones; hypotension, torsades de pointes, blood dyscrasias, hepatotoxicity (quinidine), lupus (procainamide)
procainamide	IV: 100 mg q5min at a rate of 25–50 mg/min (max: 1 g)	
quinidine gluconate	PO: 324–648 mg tid–qid (max: 3–4 g/day) IV: 0.25 mg/kg/min (max: 5–10 mg/kg)	
quinidine sulfate	PO: 200–400 mg tid–qid (max: 3–4 g/day); therapeutic serum drug level is 2–5 mcg/mL	
Class IB: Sodium Channel Blockers		
lidocaine (Xylocaine)	IV: 1–4 mg/min infusion (max: 3 mg/kg per 5–10 min)	*Nausea, vomiting, drowsiness, dizziness, lethargy, confusion (phenytoin)* May produce new dysrhythmias or worsen existing ones; hypotension, bradycardia, central nervous system (CNS) toxicity (lidocaine), malignant hyperthermia (lidocaine), cardiac arrest (lidocaine), blood dyscrasias (phenytoin)
mexiletine (Mexitil)	PO: 200–300 mg tid (max: 1200 mg/day)	
phenytoin (Dilantin)	IV: 50–100 mg q10–15min until dysrhythmia is terminated (max: 1 g/day)	
Class IC: Sodium Channel Blockers		
flecainide (Tambocor)	PO: 50 mg bid (max: 400 mg/day)	*Nausea, vomiting, fatigue, dizziness, headache, visual disturbances (flecainide)* May produce new dysrhythmias or worsen existing ones; hypotension, bradycardia, cardiac arrest (flecainide), blood dyscrasias, lupus (propafenone), HF (propafenone), acute liver injury (propafenone)
propafenone (Rythmol)	PO (extended release): 225 mg bid (max: 425 mg q12h)	
Class II: Beta-Adrenergic Antagonists		
acebutolol (Sectral)	PO: 200–600 mg bid–tid (max: 1200 mg/day)	*Fatigue, insomnia, drowsiness, impotence, decreased libido, dizziness, bradycardia, confusion* Agranulocytosis, HF, bronchospasm, hypotension, Stevens–Johnson syndrome, anaphylaxis; if the drug is abruptly withdrawn, palpitations, rebound HTN, life-threatening dysrhythmias, or myocardial ischemia may occur.
esmolol (Brevibloc)	IV: 50–300 mcg/kg/min (maintenance dose)	
propranolol (Inderal, InnoPran XL)	PO: 10–30 mg tid–qid (max: 480 mg/day) IV: 0.5–3.1 mg q4h or prn	
Class III: Potassium Channel Blockers		
amiodarone (Pacerone)	PO: 400–600 mg/day in 1–2 divided doses (max: 1600 mg/day as loading dose)	*Blurred vision (amiodarone), photosensitivity, nausea, vomiting, anorexia* May produce new dysrhythmias or worsen existing ones; hypotension, HF, heart block, bradycardia, pneumonia-like syndrome (amiodarone, dronedarone), angioedema (dofetilide), CNS toxicity (ibutilide)
dofetilide (Tikosyn)	PO: 125–500 mcg bid based on creatinine clearance	
dronedarone (Multaq)	PO: 400 mg bid	
ibutilide (Corvert)	IV: 1 mg infused over 10 min (for patients over 60 kg); (max: 2 mg infused over at least 20 min)	
sotalol* (Betapace, Betapace AF, Sorine)	PO: 80 mg bid (max: 320 mg/day)	
Class IV: Calcium Channel Blockers		
diltiazem (Cardizem, Dilacor, Taztia XR, Tiazac)	IV: 5–10 mg/h continuous infusion for a maximum of 24 h (max: 15 mg/h)	*Flushed skin, headache, dizziness, peripheral edema, lightheadedness, nausea, diarrhea, syncope* Hepatotoxicity, MI, HF, confusion, mood changes, hypotension
verapamil (Calan, Isoptin SR, Verelan)	PO: 240–480 mg/day in divided doses IV: 5–10 mg direct; may repeat in 15–30 min	
Miscellaneous Antidysrhythmics		
adenosine (Adenocard, Adenoscan)	IV: 6–12 mg given as a bolus injection every 1–2 min as needed (max: 12 mg/dose)	*Facial flushing, dyspnea, headache* May produce new dysrhythmias or worsen existing ones, AV block
digoxin (Lanoxin, Lanoxicaps)	PO: 0.125–0.5 mg qid Therapeutic serum drug level: 0.8–2 ng/mL	*Nausea, vomiting, headache, diarrhea, visual disturbances* May produce new dysrhythmias or worsen existing ones

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

*Sotalol is a beta blocker, but because its cardiac effects are more similar to amiodarone, it is in Class III. Adverse effects are those of Class II and Class III.

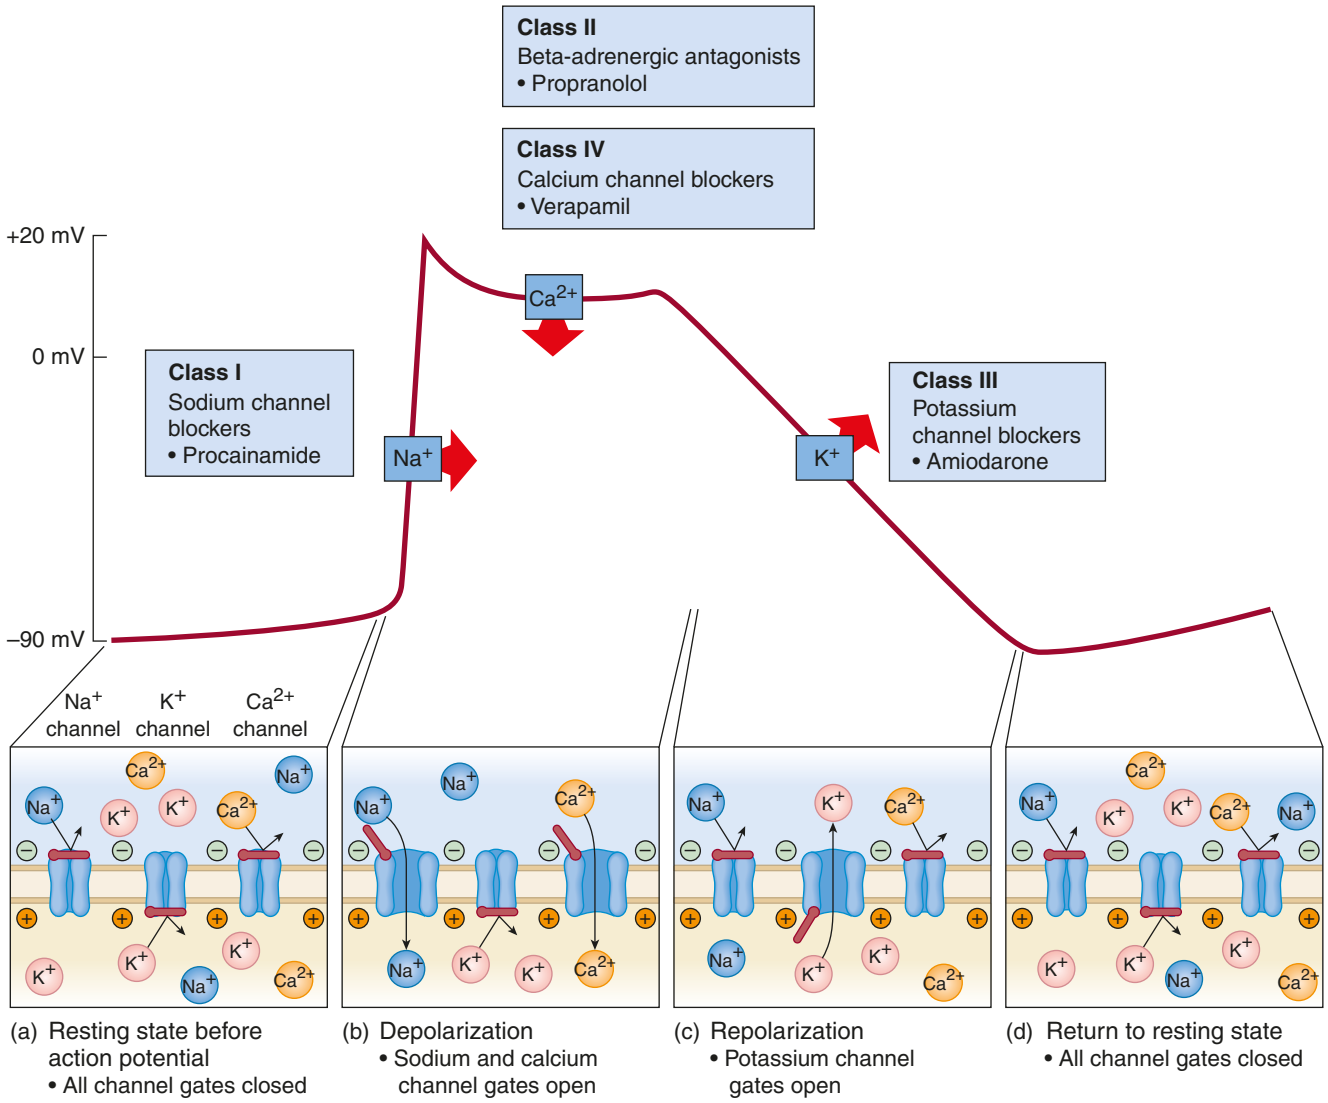

Figure 37.3 Ion channels in myocardial cells: (a) resting state before action potential (all channel gates closed); (b) depolarization (sodium and calcium channel gates open); (c) repolarization (potassium channel gates open); (d) return to resting state (all channel gates closed).

The effects of the Class IA drugs can be recognized on the ECG. The QRS complex widens, owing to the slowed depolarization of the ventricles. The QT interval is increased due to the delay in repolarization of the ventricles.

PROTOTYPE DRUG Procainamide

Classification **Therapeutic:** Antidysrhythmic, Class IA
Pharmacologic: Sodium channel blocker

Therapeutic Effects and Uses: Approved in 1950, procainamide is a broad-spectrum antidysrhythmic chemically related to the local anesthetic procaine that has the ability to correct many different types of atrial and ventricular dysrhythmias. Indications include ventricular tachycardia during cardiopulmonary resuscitation (CPR); refractory ventricular fibrillation or pulseless ventricular tachycardia during CPR; conversion to sinus rhythm in patients with paroxysmal atrial tachycardia, atrial flutter, or atrial fibrillation; and treatment or prophylaxis of PSVT. Procainamide is now considered a drug of last choice for advanced cardiac life support due to its toxicity; it is used when other drugs have failed to reverse a severe dysrhythmia. The major hepatic metabolite of the drug, N-acetyl procainamide, also has antidysrhythmic activity. Because the rate of acetylation to the active metabolite is genetically determined, "slow acetylators" and "fast acetylators" will require adjustments in dosages to obtain optimal therapeutic results.

Procainamide is available in IV and intramuscular (IM) formulations: PO forms of procainamide have been discontinued. Dosage is guided by periodic serum drug levels, which are maintained between 4 and 8 mcg/mL. The supine position should be used during IV administration because severe hypotension may occur during the infusion. Use of procainamide must be terminated if the QRS widens more than 50% of its original width.

Mechanism of Action: Procainamide blocks sodium ion channels in myocardial cells, thus reducing automaticity and slowing the velocity of the action potential across the myocardium. This slight delay in conduction velocity prolongs the refractory period and can suppress dysrhythmias.

Pharmacokinetics:

Route(s)	IV, IM
Absorption	Readily absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 15% bound to plasma protein
Primary metabolism	Hepatic; metabolized to active metabolite
Primary excretion	Renal, 50–70% unchanged
Onset of action	IV: immediate; IM: 10–30 min
Duration of action	IM/IV: 3–4 h

Adverse Effects: Procainamide has a narrow therapeutic index and dosage must be monitored carefully to avoid serious adverse effects. Nausea, vomiting, abdominal pain, and headache are common during therapy. The drug can cause fever, accompanied by anorexia, weakness, nausea, and vomiting. High doses may produce central nervous system (CNS) effects such as confusion or psychosis. Rapid IV administration of procainamide can cause severe hypotension. **Black Box Warnings:** Chronic administration may result in an increased titer of antinuclear antibodies (ANAs). A lupus-like syndrome may occur in 30% to 50% of patients taking the drug for more than a year. Procainamide should be reserved for life-threatening dysrhythmias because it has the ability to produce new dysrhythmias or worsen existing ones. Agranulocytosis, bone marrow depression, neutropenia, hypoplastic anemia, and thrombocytopenia have been reported, usually within the first 3 months of therapy. Complete blood counts should be monitored carefully and the drug discontinued at the first sign of potential blood dyscrasia.

Contraindications/Precautions: Procainamide is contraindicated in patients with second- or third-degree AV block (unless controlled by a pacemaker), severe HF, peripheral neuropathy, and myasthenia gravis. Because procainamide may activate or worsen lupus, the drug is only used in these patients when there is no safer alternative. Doses must be lowered in patients with chronic kidney disease (CKD) due to possible accumulation of the drug. Patients in shock or with severe hypotension should not receive this drug due to additive hypotension. Procainamide may worsen blood dyscrasias; thus, it should be used with caution in patients with preexisting bone marrow suppression.

Drug Interactions: Additive cardiac depressant effects may occur if procainamide is administered with other antidysrhythmics. Additive anticholinergic adverse effects will occur if procainamide is used concurrently with anticholinergic drugs. Procainamide may increase plasma levels of amiodarone or quinidine. Use with antihypertensives may result in hypotension. **Herbal/Food:** Although no interactions have been well documented, the use of all herbal products or supplements should be avoided unless approved by the healthcare provider due to the toxicity of the drug.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available for overdose. Supportive treatment is targeted to reversing hypotension with vasopressors and preventing or treating procainamide-induced dysrhythmias.

Nursing Responsibilities: Key nursing implications for patients receiving procainamide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Dysrhythmias.

Drugs Similar to Procainamide

There are similar Class IA, IB, and IC antidysrhythmics. Other Class IA antidysrhythmics include disopyramide and quinidine. Moricizine, a unique oral antidysrhythmic that possessed some properties attributed to all three Class I subclasses, was discontinued in 2007 due to lack of market demand.

Disopyramide (Norpace): Approved in 1977, disopyramide has actions and indications similar to those of other Class IA drugs. Available only by the PO route, the drug is used infrequently due to a high incidence of anticholinergic effects such as xerostomia (dry mouth) and urinary retention in patients with benign prostatic hyperplasia. The anticholinergic effects cause an increase in heart rate, which may directly cancel out the therapeutic cardiac depressant effects of the drug. Off-label uses include maintenance of, or conversion to, sinus rhythm in patients with atrial flutter or atrial fibrillation. Disopyramide has a black box warning that the drug should be restricted to patients with life-threatening ventricular dysrhythmias. This drug is pregnancy category C.

Quinidine: Approved in 1938, quinidine is the oldest antidysrhythmic drug, originally obtained as a natural substance from the bark of the South American cinchona tree. Like procainamide, quinidine is a broad-spectrum drug having the ability to correct many different types of atrial and ventricular dysrhythmias. The two salts of quinidine are sulfate, which is given PO, and gluconate, which is given PO and IV. Like other drugs in this class, quinidine blocks sodium ion channels in myocardial

cells, thus reducing automaticity and slowing the velocity of the action potential across the myocardium. In addition to dysrhythmias, quinidine gluconate may be used to treat malaria and persistent hiccups. The most common adverse effect of quinidine is diarrhea, which occurs in about one third of patients and may be intense. The drug can induce various types of dysrhythmias when serum levels rise above normal. High doses result in a syndrome called **cinchonism** with symptoms such as tinnitus, headache, blurred vision, hearing loss, and dysrhythmias. These symptoms are reversible once the drug is discontinued. Quinidine is contraindicated in patients with incomplete AV block because it can induce total blockage of conduction. Quinidine carries a black box warning that the drug has resulted in increased mortality when used for non–life-threatening dysrhythmias. This drug is pregnancy category C.

Class IB: The Class IB antidysrhythmics include lidocaine, mexiletine, and phenytoin. Like other Class I drugs, these agents act by blocking gated sodium ion channels in cardiac muscle cells. Unlike the Class IA drugs, the Class IB agents shorten the refractory period and have little effect on conduction velocity. The Class IB drugs have minimal effects on the ECG and their primary indication is ventricular dysrhythmias.

Lidocaine (Xylocaine): Lidocaine, the most frequently prescribed Class IB antidysrhythmic, was featured as a prototype local anesthetic in Chapter 26. It is an important treatment for life-threatening ventricular dysrhythmia, although amiodarone is considered a preferred drug for this indication. It is not effective in preventing or treating atrial dysrhythmias. Lidocaine decreases the refractory period of the action potential, especially in ischemic myocardial tissue. For acute conditions, lidocaine is administered by IV bolus or infusion; it is rarely given by the IM or subcutaneous routes. Serum lidocaine levels may be monitored and should be between 2 and 6 mcg/mL. The first signs of lidocaine toxicity usually involve the CNS and include confusion, anxiety, tremors, and paresthesias. As doses increase, the patient may become comatose and experience seizures or respiratory arrest. The correct lidocaine formulation must be used for IV infusions: Local anesthetic lidocaine preparations may contain preservatives and epinephrine and should not be given IV. This drug is pregnancy category B.

Mexiletine (Mexitil): Approved in 1985, mexiletine is chemically similar to lidocaine, has local anesthetic properties, and is used only for serious ventricular dysrhythmias. Mexiletine is well absorbed orally and may be used off-label for the treatment of neuropathic pain. The most common adverse effects are nausea and vomiting. CNS effects such as dizziness, tremor, and ataxia are common. Less common, though potentially serious, adverse effects include blood dyscrasias, pulmonary fibrosis, and worsening of HF. A black box warning has been issued regarding the possibility of acute liver damage in patients taking mexiletine. The target range for serum mexiletine concentration is 0.5 to 2 mcg/mL. This drug is pregnancy category C.

Phenytoin (Dilantin): The primary use for phenytoin is to treat seizures, and it was presented in Chapter 22 as a prototype antiseizure medication. Phenytoin is rarely used for its antidysrhythmic properties and is not approved by the U.S. Food and Drug Administration (FDA) for this purpose. Historically, it has been used off-label to treat dysrhythmias secondary to digoxin (Lanoxin) toxicity. This drug is pregnancy category D.

Class IC: The Class IC antidysrhythmics include two drugs: flecainide and propafenone. Like other Class I drugs, these medications block gated sodium ion channels in cardiac muscle cells. The Class IC antidysrhythmics profoundly decrease conduction velocity. Thus the PR, QRS, and QT intervals are often prolonged. The refractory period may be shortened slightly but is mostly unchanged by the Class IC drugs. Their primary indication is for life-threatening atrial dysrhythmias, although they can also prevent ventricular dysrhythmias. Research has shown these drugs to have a pronounced prodysrhythmic effect that has the potential to increase mortality in patients who have experienced a recent MI.

Flecainide (Tambocor): Flecainide is an oral drug used primarily to treat or prevent paroxysmal atrial fibrillation or atrial flutter due to its ability to markedly decrease conduction velocity. It is indicated for the prophylaxis of life-threatening ventricular dysrhythmias, although it is rarely used for this purpose. The FDA has issued several black box warnings regarding flecainide. The prodysrhythmic effects of the drug may generate new ventricular dysrhythmias in about 10% of the patients. Due to an excessive mortality rate, the drug is contraindicated in patients with left ventricular dysfunction who have experienced a recent MI. Serum flecainide levels should be monitored, especially in patients with CKD or hepatic impairment, and maintained between 0.2 and 1 mcg/mL. Pulmonary fibrosis and bone marrow suppression are potentially serious adverse effects. Other adverse effects include dizziness, headache, asthenia, tremor, and malaise. This drug is pregnancy category C.

Propafenone (Rythmol): Approved in 1989, propafenone is an oral drug similar to flecainide that is used primarily for atrial fibrillation and the prophylaxis of PSVT. Its prodysrhythmic activity limits its use in treating ventricular dysrhythmias. Unlike flecainide, propafenone exhibits clinically significant beta-adrenergic antagonist activity. This

beta-blocker action may cause a negative inotropic effect that can worsen symptoms of HF. Furthermore, the beta-blocking actions may cause bronchospasm in patients with asthma or chronic obstructive pulmonary disease (COPD). An extended release formulation (Rythmol SR) allows for twice-daily dosing. Propafenone is metabolized to active metabolites, which account for much of the drug's effects. In addition to exacerbating or creating new dysrhythmias, propafenone may cause dizziness and dysgeusia (altered sense of taste). Like some of the other antidysrhythmics, propafenone has a black box warning that it should be restricted to patients with life-threatening ventricular dysrhythmias. This drug is pregnancy category C.

Beta-Adrenergic Antagonists: Class II

37.8 Beta-adrenergic antagonists reduce automaticity and slow conduction velocity in the heart.

Beta-adrenergic antagonists, or blockers, are used to treat HTN, MI, HF, and dysrhythmias. The basic pharmacology of beta-adrenergic antagonists was explained in Chapter 16; the student should refer to that chapter for nursing responsibilities and patient and family education related to this drug class. Only the actions of these drugs that relate to dysrhythmias are discussed in this section.

As expected from their effects on the autonomic nervous system, beta-adrenergic antagonists slow the heart rate (negative chronotropic effect) and decrease conduction velocity. These effects are primarily caused by the blockade of calcium ion channels in the SA and AV nodes, although these drugs also block gated sodium ion channels in the atria and ventricles. The reduction in myocardial automaticity stabilizes many types of dysrhythmias. The main value of beta blockers as antidysrhythmic drugs is to treat atrial dysrhythmias associated with HF. When administered to post-MI patients, beta blockers decrease the likelihood of sudden death due to fatal dysrhythmias. Tachydysrhythmias respond well to beta blockers, including those that are induced by exercise.

Only a few beta blockers are approved for dysrhythmias, due to potential adverse effects, and these are listed in Table 37.4. Unless a functioning pacemaker is present, these drugs are contraindicated in patients with severe bradycardia, sick sinus syndrome, or advanced AV block because they depress conduction through the AV node. Blockade of beta-adrenergic receptors in the heart causes bradycardia, which may not be well tolerated in patients with preexisting cardiac disease, and hypotension may cause dizziness and possible fainting. Nonselective beta blockers may affect $beta_2$ receptors in the lung, causing bronchospasm in patients with asthma or COPD. Higher doses may produce depression, as well as hallucinations and psychosis, especially in older adults. Abrupt discontinuation of beta blockers can lead to dysrhythmias and HTN.

Acebutolol (Sectral): Approved in 1984, acebutolol is a cardioselective $beta_1$-adrenergic antagonist available only by the oral route. Like other beta blockers, acebutolol reduces sympathetic activity to the heart, thus lowering heart rate. It also has a negative inotropic effect. As an antidysrhythmic, it is used to treat premature ventricular contractions and reduce exercise-induced tachycardia. Other indications include chronic, stable angina and HTN. Adverse effects such as hypotension and bradycardia are extensions of its beta-blocking action. At high doses, the selectivity for $beta_1$ receptors diminishes and the drug may cause bronchoconstriction ($beta_2$ receptors). Because the negative inotropic effects of the drug may worsen symptoms of HF, it is usually contraindicated in patients with HF. This drug is pregnancy category B.

Esmolol (Brevibloc): Approved in 1986, esmolol differs from the other antidysrhythmic beta blockers in that it has a very short half-life of 9 minutes and is only given by IV infusion. As an antidysrhythmic, esmolol is used for the immediate termination of atrial tachyarrhythmias and noncompensatory sinus tachycardia and to control ventricular rate in patients with atrial flutter or fibrillation. When a loading dose is administered, peak plasma levels can be reached in 5 minutes. Off-label indications include treatment of hypertensive emergencies, acute MI, and unstable angina. Hypotension and bradycardia are common adverse effects but they quickly resolve once the infusion is discontinued. At therapeutic doses, the drug is selective for $beta_1$-adrenergic receptors. This drug is pregnancy category C.

Propranolol (Inderal, InnoPran XL): Propranolol is a nonselective beta-adrenergic antagonist. Because it slows automaticity, propranolol is indicated for many types of

CONNECTIONS: Treating the Diverse Patient

Sensitivity of Asian Patients to Propranolol

Growing evidence from research studies has shown a differential drug response to propranolol among Asians and Asian Americans. These individuals typically lack a specific enzyme (mephenytoin hydroxylase) that is needed to metabolize propranolol. Because of this sensitivity, propranolol has a significantly greater effect on heart rate. In other words, individuals of Asian descent will develop signs of toxicity more quickly than non-Asians. The nurse should assess this population for signs and symptoms of early drug toxicity, possible overdosage, and adverse reactions due to high drug levels. Assessing for unique cultural sensitivity to drug therapies is necessary for safe drug administration.

dysrhythmias including suppression of exercise-induced tachycardia, atrial dysrhythmias, ventricular dysrhythmias, premature ventricular contractions, and digoxin-induced tachydysrhythmias. Propranolol exhibits few serious adverse effects at therapeutic doses. At high doses, patients may experience bradycardia, hypotension, HF, and bronchospasm. Propranolol is featured as a prototype beta-adrenergic antagonist in Chapter 16. This drug is pregnancy category C.

CONNECTION Checkpoint 37.2

Both alpha$_1$ blockers and beta$_1$ blockers are used to treat HTN but only the beta$_1$ blockers are antidysrhythmics. From what you learned in Chapter 16, explain why the selective alpha$_1$ blockers are not used to treat dysrhythmias. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Potassium Channel Blockers: Class III

37.9 Potassium channel blockers prolong the refractory period of the heart.

The potassium channel blockers are a small but diverse class of drugs that have very important applications to the treatment of dysrhythmias. After the action potential has passed and the myocardial cell is in a depolarized state, repolarization depends on removal of potassium from the cell. The drugs in Class III exert their actions by blocking potassium ion channels in myocardial cells. Although there are significant differences among the drugs, all have in common the ability to delay repolarization and prolong the refractory period. This action is reflected by an increase in the QT interval on the ECG. Automaticity is also reduced.

Most drugs in this class have multiple actions on the heart and also affect adrenergic receptors or sodium channels. For example, in addition to blocking potassium channels, sotalol (Betapace) is considered a beta-adrenergic antagonist. The potassium channel blockers are listed in Table 37.4.

Drugs in this class have limited uses due to potentially serious toxicity. Like other antidysrhythmics, potassium channel blockers slow the heart rate, resulting in bradycardia and possible hypotension in a significant percentage of patients. These drugs can create or worsen dysrhythmias, especially during the first few doses. Older adults with preexisting HF must be carefully monitored because these patients are at higher risk for the cardiac adverse effects of potassium channel blockers.

PROTOTYPE DRUG **Amiodarone (Pacerone)**

Classification **Therapeutic:** Antidysrhythmic, Class III
Pharmacologic: Potassium channel blocker

Therapeutic Effects and Uses: Approved in 1985, amiodarone is the most frequently prescribed Class III antidysrhythmic. It is considered a broad-spectrum antidysrhythmic because it is effective in terminating both atrial and ventricular dysrhythmias. It is approved for the treatment of resistant ventricular tachycardia and recurrent fibrillation that may prove life threatening, and it has become a preferred medication for the treatment of atrial dysrhythmias in patients with HF.

Amiodarone is available as PO tablets and as an IV infusion. IV infusions are limited to short-term therapy (2–4 days). Although its onset of action may take several weeks when the medication is given PO, its effects can last 4 to 8 weeks after the drug is discontinued because it has an extended half-life that may exceed 100 days. Amiodarone is a structural analog of thyroid hormone. The therapeutic serum level for amiodarone is 1 to 2.5 mcg/mL.

Mechanism of Action: Amiodarone exerts multiple, complex actions on the heart and its exact mechanism of action is not completely known. In addition to blocking potassium ion channels, some of this drug's actions relate to its blockade of sodium ion channels and inhibiting sympathetic activity to the heart. Repolarization is delayed, the refractory period prolonged, and automaticity reduced. In addition to prolonging the QT interval, amiodarone increases the PR interval and widens the QRS complex on the ECG.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Completely absorbed by the gastrointestinal (GI) tract
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; concentrated in the lung, kidneys, spleen, and adipose tissue
Primary metabolism	Hepatic to active metabolites; some enterohepatic recirculation; inhibits some CYP450 enzymes
Primary excretion	Primarily biliary; some feces
Onset of action	PO: 2–3 days; IV: 2 h
Duration of action	PO/IV; 10–150 days

Adverse Effects: Potentially serious adverse effects limit the use of amiodarone. Amiodarone may cause nausea, vomiting, anorexia, fatigue, dizziness, and hypotension. Visual disturbances are common in patients taking this drug for extended periods and include blurred vision due to cornea deposits, photophobia, xerostomia, cataracts, and macular degeneration. Rashes, photosensitivity, and other skin reactions occur in 10% to 15% of patients taking the drug. Certain tissues concentrate this medication; thus, adverse effects may be slow to resolve,

persisting long after the drug has been discontinued. **Black Box Warning (oral form only):** Amiodarone causes a pneumonia-like syndrome in the lungs. Because the pulmonary toxicity may be fatal, baseline and periodic assessments of lung function are essential. Amiodarone has prodysrhythmic action and may cause bradycardia, cardiogenic shock, or AV block. Mild liver injury is frequent with amiodarone.

Contraindications/Precautions: Amiodarone is contraindicated in patients with severe bradycardia, cardiogenic shock, sick sinus syndrome, severe sinus node dysfunction, or third-degree AV block. Because amiodarone contains iodine in its chemical structure, patients who have hypersensitivity to this element should not receive the drug. It should be used with caution in patients with HF because it has a negative inotropic effect that can worsen symptoms. Electrolyte imbalances, especially hypokalemia and hypomagnesemia, should be corrected before administering amiodarone because these conditions predispose the patient to the development of dysrhythmias. Due to the drug's pulmonary toxicity, it is contraindicated in patients with COPD or respiratory insufficiency. Breastfeeding during amiodarone therapy may cause infant hypothyroidism; thus, the drug is contraindicated during lactation.

Drug Interactions: Amiodarone is metabolized by the cytochrome CYP450 enzymes and markedly inhibits the metabolism of many other drugs. This can raise the serum levels of these drugs and cause toxicity. For example, amiodarone can increase serum digoxin levels by as much as 70%. Amiodarone greatly enhances the actions of anticoagulants; thus the dose of warfarin must be cut by as much as half. Use with beta-adrenergic antagonists or calcium channel blockers (CCBs) may potentiate sinus bradycardia, sinus arrest, or AV block. Amiodarone may increase phenytoin levels two- to threefold. Caution must be used during therapy with loop diuretics because hypokalemia can enhance the prodysrhythmic properties of amiodarone. Because of the large number of potential drug interactions, the nurse should regularly check current reference sources when patients are taking amiodarone concurrently with other medications. **Herbal/Food:** Use with echinacea may increase the risk of hepatotoxicity. Aloe may increase the effect of amiodarone. When the drug is administered PO, grapefruit juice can increase serum amiodarone levels by over 80%.

Pregnancy: Category D.

Treatment of Overdose: Overdose will cause bradycardia, hypotension, and life-threatening dysrhythmias. Supportive treatment is targeted to reversing hypotension with vasopressors and bradycardia with atropine or isoproterenol.

Nursing Responsibilities: Key nursing implications for patients receiving amiodarone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Dysrhythmias.

Drugs Similar to Amiodarone (Pacerone)

Other Class III antidysrhythmics include dofetilide, dronedarone, ibutilide, and sotalol.

Dofetilide (Tikosyn): Approved in 1999, dofetilide is an oral drug indicated for conversion of symptomatic atrial flutter or fibrillation to normal sinus rhythm. Like other potassium channel blockers, dofetilide prolongs the refractory period and action potential duration, thus increasing the QT interval. Dofetilide does not exhibit a negative inotropic effect, as do amiodarone and sotalol. The drug has no effect on the PR interval and it does not widen the QRS complex. Dofetilide has many potentially serious adverse effects, and a black box warning states that therapy should begin in a clinical setting under continuous monitoring for a minimum of 3 days. The drug exhibits significant dose-related prodysrhythmic effects, including heart block, ventricular tachycardia, and torsades de pointes. The risk for drug-induced dysrhythmias is increased when dofetilide is administered concurrently with other medications that prolong the QT interval, including Class I and Class III antidysrhythmics. Dofetilide may accumulate to toxic levels in patients with CKD. Therefore, serum creatinine levels are monitored frequently during therapy. Electrolyte imbalances, especially hypokalemia or hypomagnesemia, should be corrected before administering dofetilide because these conditions predispose the patient to developing dysrhythmias. This drug is pregnancy category C.

Dronedarone (Multaq): Approved in 2009, dronedarone is given PO to reduce the risk of hospitalization in patients with atrial dysrhythmias and associated cardiovascular risk factors such as HTN, diabetes, or previous stroke. The drug has a black box warning that it is contraindicated in patients with advanced HF with recent decompensation. It is also contraindicated in patients with bradycardia (less than 50 beats/min), prolonged QT interval, and severe hepatic impairment. The most common adverse effects are diarrhea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone inhibits CYP450 enzymes and can participate in multiple drug–drug interactions with other cardiovascular medications. Dronedarone is a category X drug and should not be taken during pregnancy or lactation.

Ibutilide (Corvert): Approved in 1995, ibutilide is only administered as an IV infusion. Continuous ECG monitoring should be conducted for at least 4 hours following the infusion to identify the potential development of new or worsening dysrhythmias. Administered over 10 minutes,

ibutilide is a preferred drug for rapidly converting atrial flutter or fibrillation to normal sinus rhythm. The drug prolongs the duration of the cardiac action potential without affecting the PR interval or QRS complex. The infusion is stopped as soon as the dysrhythmia is terminated. Ibutilide is generally well tolerated, although it does have prodysrhythmic effects, including induction of ventricular tachycardia and torsades de pointes. Like other Class III drugs, precautions must be taken when administering this drug concurrently with other medications that prolong the QT interval or if given to patients with hypokalemia or hypomagnesemia, as these conditions increase the risk of dysrhythmias. This drug is pregnancy category C.

Sotalol (Betapace, Betapace AF, Sorine): Approved in 1992, sotalol is unique in that the medication has both Class II and Class III antidysrhythmic properties. As a Class II drug, it is a nonselective beta blocker that slows conduction through the AV node. Its Class III actions delay repolarization and prolong the refractory period, thus widening the QT interval. Its mixed mechanisms are reflected in the diversity of indications for the drug.

Betapace and its generic equivalents are indicated for sustained ventricular fibrillation that is deemed to be life threatening. Betapace AF converts atrial fibrillation to normal sinus rhythm and is indicated for highly symptomatic atrial dysrhythmias. The drugs contain a black box warning stating that they are not interchangeable.

Because of its prodysrhythmic activity, the first 3 days of therapy with sotalol are usually conducted in a controlled clinical setting with continuous monitoring. The drug should be used with caution when taken concurrently with other medications that prolong the QT interval or if given to patients with hypokalemia or hypomagnesemia, as these conditions increase the risk of dysrhythmias. Other adverse effects and contraindications for beta-adrenergic antagonists are given in Chapter 16. This drug is pregnancy category B.

Calcium Channel Blockers: Class IV

37.10 Calcium channel blockers are used to treat atrial dysrhythmias.

Although about 10 CCBs are available to treat cardiovascular disease, only a limited number are approved for dysrhythmias. Review Chapter 30 for details regarding the mechanism of actions, indications, and nursing responsibilities for this drug class. Only actions relevant to dysrhythmias are discussed in this section. The antidysrhythmic CCBs are listed in Table 37.4.

Blockade of calcium ion channels has a number of effects on the heart that are very similar to those of beta-adrenergic antagonists. Effects include reduced automaticity in the SA node and slowed impulse conduction through the AV node. These effects are predictable, because nodal tissues are more dependent on calcium channels than other areas of the myocardium. This slows the heart rate and prolongs the refractory period. On an ECG, the most prominent effect of CCBs is prolongation of the PR interval. Indications include the control of ventricular rate in cases of atrial flutter or fibrillation, and prophylaxis of PSVT. CCBs are effective only against atrial dysrhythmias.

CCBs are well tolerated by most patients. As with many other antidysrhythmics, patients should be carefully monitored for bradycardia and hypotension. Because their cardiac effects are almost identical to those of beta-adrenergic antagonists, patients concurrently taking drugs from both classes are especially at risk for bradycardia and possible HF. Because older adults often have multiple cardiovascular disorders, such as HTN, HF, and dysrhythmias, it is not unusual to find older patients taking drugs from multiple classes.

Diltiazem (Cardizem, Dilacor, Taztia XR, Tiazac): Like other CCBs, diltiazem inhibits the transport of calcium into myocardial cells. The actions and indications for diltiazem are the same as those of verapamil. The IV form of the drug is indicated for the management of acute atrial dysrhythmias, including paroxysmal supraventricular tachycardia. In addition to its use in treating and preventing atrial dysrhythmias, the oral forms are indicated for HTN as well as stable and vasospastic angina. Adverse effects of diltiazem are generally not serious and are related to vasodilation: headache, dizziness, and edema of the ankles and feet. Because of its profound depressant effects on nodal tissue, diltiazem is contraindicated in patients with severe bradycardia, AV block, or sick sinus syndrome. Concurrent use of diltiazem with digoxin or beta-adrenergic antagonists may cause partial or complete heart block, HF, or dysrhythmias.

Verapamil (Calan, Isoptin SR, Verelan): Verapamil was the first CCB approved by the FDA. In the heart, verapamil slows conduction velocity and stabilizes dysrhythmias. The IV form of the drug is indicated for the rapid control of acute atrial dysrhythmias. Because verapamil can cause bradycardia and AV block, patients with HF should be carefully monitored. Because the drug may produce profound bradycardia, patients should notify their healthcare provider if their heart rate falls below 60 beats/min or if systolic blood pressure falls below 90 mmHg. The therapeutic serum level is 0.08 to 0.3 mcg/mL. A prototype drug feature that describes other indications for verapamil is presented in Chapter 30.

CONNECTION Checkpoint 37.3

Nifedipine (Procardia) is a prototype CCB discussed in Chapter 30. From what you learned in Chapter 30, why is this drug (and other dihydropyridines) not effective in treating dysrhythmias? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

Sudden cardiac arrest (SCA) occasionally occurs in young athletes. About half of the athlete SCAs occurred in high school students and 82% occurred during competition or training. Only 11% occurred in females (Mozaffarian et al., 2015).

Miscellaneous Antidysrhythmics

37.11 Adenosine and digoxin are used for specific dysrhythmias.

Two other medications, adenosine and digoxin, are occasionally used to treat specific dysrhythmias, but they do not act by the mechanisms described above. Doses for these miscellaneous drugs are listed in Table 37.4.

Adenosine (Adenocard, Adenoscan): Adenosine is a naturally occurring nucleoside that activates potassium channels in the SA and AV nodes, causing the potassium to leave cardiac muscle cells. When given as a rapid 1- to 2-second IV bolus, adenosine blocks reentry pathways in the AV node and terminates the tachycardia. It is usually followed by a 1- to 5-second period of asystole. Patients should be laid supine prior to adenosine use and warned that they may feel faint. The IV site used to give adenosine should be antecubital or above, and an 18-gauge angiocatheter or larger should be used. A rapid saline flush immediately after instillation of the medication is necessary due to its short half-life. Immediate medical assistance must be nearby during the procedure. If the tachycardia has not been eliminated in 1 to 2 minutes, a second rapid bolus may be given. The primary indication for adenosine is PSVT, for which adenosine is a preferred drug. It is also used to assist in the diagnosis of coronary artery disease of dysrhythmias in patients who are unable to undergo a cardiac exercise stress test. It is not effective in treating ventricular dysrhythmias. Although the drug has prodysrhythmic effects and dyspnea is common, adverse effects are generally self-limiting because of its 10-second half-life. In 2013, the FDA issued a safety alert that the use of adenosine may be associated with an increased risk of heart attack and death. This drug is pregnancy category C.

Digoxin (Lanoxin, Lanoxicaps): Although digoxin is primarily used to treat HF, it is also prescribed for atrial flutter or fibrillation and PSVT because of its ability to decrease automaticity of the SA node and slow conduction through the AV node. The drug is not effective against ventricular dysrhythmias. Because excessive levels of digoxin can produce serious dysrhythmias, and interactions with other medications are common, patients must be carefully monitored during therapy. Additional information on the mechanism of action, adverse effects, and nursing responsibilities for digoxin may be found in Chapter 36, where the drug is featured as a prototype.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Dysrhythmias

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular (including previous dysrhythmias, HTN, MI, HF) and the possibility of pregnancy. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), ECG (rate and rhythm), cardiac monitoring (such as cardiac output if appropriate), and breath sounds. Assess for location, character, and amount of edema, if present.
- Evaluate appropriate laboratory findings: electrolytes, especially potassium, calcium, and magnesium levels; renal and liver function studies; and lipid profiles.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., control or elimination of dysrhythmia, blood pressure and pulse within established limits).
- Continue frequent monitoring of ECG (continuous if hospitalized). Check pulse quality, volume, and regularity, along with ECG. Assess for complaints of palpitations and correlate symptoms with ECG findings. Assess for changes in level of consciousness (LOC).
- Continue periodic monitoring of electrolytes, especially potassium and magnesium.
- Assess for adverse effects: lightheadedness or dizziness, hypotension, nausea, vomiting, headache, fatigue or weakness, flushing, sexual dysfunction, or impotence. Immediately report bradycardia, tachycardia, or new or different dysrhythmias to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Dysrhythmias have diminished or are eliminated. Blood pressure and pulse should be within normal limits or within parameters set by the healthcare provider.)	• To alleviate possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring.
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, limited caffeine intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient, family, or caregiver to adopt a healthy lifestyle of low-fat food choices, increased exercise, reduced caffeine intake, decreased alcohol consumption, and smoking cessation.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Continue to monitor ECG and pulse for quality and volume. Take the pulse for 1 full minute to assess for regularity. Continue to assess for complaints of palpitations and correlate palpitations or pulse irregularities with the ECG. (Not all dysrhythmias are symptomatic. Correlating symptoms with an ECG may help determine the need for further symptom management. **Diverse Patients:** Because of differences in acetylation and because some antidysrhythmics metabolize through the CYP450 pathways, monitor ethnically diverse patients more frequently to ensure optimal therapeutic effects and to minimize adverse effects.)	• Teach the patient, family, or caregiver how to take a peripheral pulse for 1 full minute before taking the drug. Assist the patient to find the pulse area most convenient and easily felt. Record daily pulse rates and regularity, and bring the record to each healthcare visit. Instruct the patient to notify the provider if the pulse is below 60 or above 100 beats/min, there is a noticeable change in regularity from previously felt pulse rate, or if palpitations develop or worsen.
• Take the blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with the first few doses of the drug and with the older adult who is at increased risk for hypotension. (Antidysrhythmic drugs may cause hypotension. A first-dose effect may occur with a significant drop in blood pressure with the first few doses. Orthostatic hypotension may increase the risk of falls and injury.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Instruct the patient to take the first dose of the new prescription in the evening before bed if possible, and to be cautious during the next few doses until the drug effects are known. • Teach the patient, family, or caregiver how to monitor blood pressure if required. Ensure proper use and functioning of any home equipment obtained. • Instruct the patient to notify the healthcare provider if blood pressure is 90/60 mmHg or below, or below the parameters set by the healthcare provider.
• Continue to monitor periodic electrolyte levels, especially potassium, calcium, and magnesium; renal function laboratory values; and drug levels as needed. (Hypokalemia, hypocalcemia, and hypomagnesemia increase the risk of dysrhythmias. Inadequate or high levels of antidysrhythmic drugs may lead to increased or more lethal dysrhythmias.)	• Instruct the patient on the need to return periodically for laboratory work. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating antidysrhythmic therapy.
• Weigh the patient daily and report weight gain or loss of 1 kg (2 lb) or more in a 24-h period. Continue to assess for edema, noting location and character. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may indicate adverse drug effects or worsening cardiovascular disease processes.)	• Have the patient weigh self daily, ideally at the same time of day, and record weight along with pulse measurements. Have the patient report weight loss or gain of more than 1 kg (2 lb) in a 24-h period.
• Monitor for breath sounds and heart sounds (e.g., increasing dyspnea or postural nocturnal dyspnea, rales or crackles in lungs, frothy pink-tinged sputum, murmurs, or extra heart sounds) and report immediately. (Increasing lung congestion or new or worsening heart murmurs may indicate impending HF. Potassium channel blockers are associated with pulmonary toxicity.)	• Instruct the patient to immediately report any severe shortness of breath, frothy sputum, profound fatigue, or swelling of extremities as possible signs of HF or pulmonary toxicity.
• Report any visual changes, skin rashes, or unusual sunburn to the healthcare provider. (Potassium channel blockers may cause photosensitivity, skin rashes, and blurred vision.)	• Teach the patient to report any visual changes promptly and to maintain regular eye examinations. • Teach the patient about the importance of wearing protective clothing and applying sunscreen regularly during periods of sun exposure.
• **Lifespan:** Assess for the possibility of pregnancy before beginning the drug. (Some antidysrhythmics such as amiodarone are pregnancy category D drugs and should not be used during pregnancy.)	• Instruct female patients who may be considering pregnancy, or are pregnant or breastfeeding, to notify their provider before starting the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, equipment needed as appropriate and how to use that equipment, and the required length of medication therapy needed, with any special instructions regarding renewing or continuing the prescription as appropriate.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Teach the patient to take drugs as evenly spaced apart as possible and not to double dose if a dose is missed. • Teach the patient, family, or caregiver not to stop the medication abruptly, and to call the healthcare provider if the patient is unable to take the medication for more than 1 day due to illness.

Understanding Chapter 37

Key Concepts Summary

37.1 Some dysrhythmias produce no patient symptoms, whereas others may be life threatening.

37.2 The phases of cardiac action potential include rapid depolarization, a long plateau, and repolarization.

37.3 The electrocardiogram is used to measure electrical conduction across the myocardium.

37.4 Dysrhythmias are classified by the impulse origin and type of rhythm abnormality produced.

37.5 Antidysrhythmic drugs are only used when there is a clear benefit to the patient.

37.6 Antidysrhythmic drugs are classified by their mechanism of action.

37.7 Class I antidysrhythmics act by blocking ion channels in myocardial cells.

37.8 Beta-adrenergic antagonists reduce automaticity and slow conduction velocity in the heart.

37.9 Potassium channel blockers prolong the refractory period of the heart.

37.10 Calcium channel blockers are used to treat atrial dysrhythmias.

37.11 Adenosine and digoxin are used for specific dysrhythmias.

CASE STUDY: Making the Patient Connection

Remember the patient "Jada Chinn Nguyen" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

The day had been busy as Jada prepared for her daughter's upcoming wedding. There were so many arrangements to be made, and Jada felt overwhelmed. During the day she experienced heaviness in her chest, but she attributed it to the stress of the wedding and perhaps a touch of bronchitis. Nonetheless, she knew there was no time to stop and rest; there was too much to do.

Later that afternoon, she realized that she had to take it easy. Then she experienced that strange sensation once again. As she sat in a chair, Jada suddenly felt dizzy with extreme weakness and difficulty breathing. Her family members report that she became pale and unexpectedly collapsed. Emergency personnel were called to the scene, and Jada was taken to the nearest hospital.

In the emergency department, Jada's physical examination revealed the following findings: weak, middle-aged Asian woman; vital signs: blood pressure, 102/68 mmHg; heart rate, 116 beats/min; respiratory rate, 18 breaths/min; afebrile; weight 53 kg (116 lb). She has clear bilateral breath sounds and active bowel sounds heard in all four quadrants. Her ECG reveals atrial fibrillation with a ventricular rate of 116 beats/min. She is admitted to the coronary care unit for further testing and observation.

Critical Thinking Questions

1. Jada's ECG shows atrial fibrillation. Trace the electrical conduction system through the heart. What part of the ECG complex would be most affected by this patient's medical diagnosis?
2. While in the coronary care unit, Jada will receive amiodarone IV infusion. She wants to know how long she will need to receive the IV medication and how it works. How would you respond to this patient's questions?
3. The patient is being discharged on amiodarone 400 mg twice daily. What instructions should this patient receive?
4. List any drug–food interaction concerns you should discuss with Jada.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Malcolm Hibbert is a 56-year-old man who was diagnosed with a rapid atrial dysrhythmia and placed on diltiazem (Cardizem) to control the condition. He has been surfing the internet to find out more about his condition and drug therapy. When he returns to the clinic, he has multiple questions to ask you. How would you respond to each of the following?

1. "My neighbor had a fast heartbeat and now he's on something called digoxin. Why didn't they use that for me?"
2. "If I'm on a calcium channel blocker, does that mean my bones might get weak?"
3. "Might any of my medications cause an increase in dysrhythmias?"

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A healthcare provider has ordered procainamide for each of four patients. A nurse should question the order for a patient with which condition?
    1. Ventricular tachycardia
    2. Paroxysmal atrial tachycardia
    3. Atrial fibrillation
    4. Severe heart failure

2. A patient is receiving intravenous lidocaine for ventricular dysrhythmias. Which nursing intervention is appropriate for this therapy?
    1. Monitor the patient for decreased platelet levels.
    2. Place the patient in a supine position during administration.
    3. Monitor for paresthesias, drowsiness, or confusion.
    4. Encourage coughing and deep breathing to remove secretions.

3. The patient with a rapid atrial dysrhythmia is being treated with verapamil (Calan). The nurse would monitor for therapeutic effectiveness by noting which of the following?
    1. Change in the blood pressure
    2. Increase in the serum potassium level
    3. Changes in the cardiac rhythm
    4. Reduction in the urine output

4. A patient is to receive adenosine (Adenocard) for rapid supraventricular tachycardia. This drug must be administered:
    1. Over a 24-hour period by IV drip.
    2. Along with potassium chloride to prevent electrolyte imbalance.
    3. Over 20 to 30 minutes IV.
    4. By a rapid IV bolus injection over 1 to 2 seconds.

5. The patient is prescribed propranolol (Inderal) for the treatment of atrial dysrhythmias associated with heart failure. The nurse knows this drug is used cautiously in patients with heart failure because of which effect?
    1. It causes sodium retention, worsening congestion.
    2. Its adverse effects include hypertension, worsening heart failure.
    3. It is a negative inotropic drug and will decrease myocardial contractility and cardiac output.
    4. It may cause bronchoconstriction.

6. A patient is being discharged with a diagnosis of dysrhythmias. The nurse is teaching the patient about amiodarone. What patient teaching is needed related to this medication?
    1. Avoid crowds while taking this medication.
    2. Avoid birth control pills and use an alternate form of birth control.
    3. Wear protective clothing and adequate sunscreen.
    4. Use an electric razor to shave.

See Answers to Chapter Review in Appendix A.

Chapter 38
Pharmacotherapy of Coagulation Disorders

Chapter Outline

- Disorders of Hemostasis
- Overview of Coagulation Modifiers
- Anticoagulants
  PROTOTYPE *Heparin, p. 666*
  PROTOTYPE *Warfarin (Coumadin), p. 669*
  Direct Thrombin Inhibitors
  PROTOTYPE *Dabigatran (Pradaxa), p. 671*
- Antiplatelet Drugs
  Aspirin
  Adenosine Diphosphate Receptor Blockers
  PROTOTYPE *Clopidogrel (Plavix), p. 675*
  Glycoprotein IIb/IIIa Receptor Inhibitors
  PROTOTYPE *Abciximab (ReoPro), p. 677*
- Drugs for Intermittent Claudication
- Thrombolytics
  PROTOTYPE *Alteplase (Activase), p. 681*
- Hemostatics
  PROTOTYPE *Aminocaproic Acid (Amicar), p. 684*
- Drugs for Hemophilia

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe primary risk factors for thromboembolic disorders.
2. Explain the etiology and symptoms of coagulation disorders.
3. Identify the primary mechanisms by which coagulation-modifying drugs act.
4. Explain how laboratory testing of coagulation parameters is used to monitor anticoagulant pharmacotherapy.
5. Describe the nurse's role in the pharmacologic management of patients with coagulation disorders.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy for coagulation disorders.

Key Terms

activated partial thromboplastin time (aPTT), 664
anticoagulants, 662
antithrombin III (AT-III), 666
deep vein thrombosis (DVT), 662
fibrinolysis, 680
hemophilia, 663
intermittent claudication (IC), 679
plasminogen, 680
procoagulants, 662
prothrombin time (PT), 664
pulmonary embolism, 663
thrombocytopenia, 663
thromboembolic disorder, 662
venous thromboembolism (VTE), 662
von Willebrand's disease (vWD), 687

Everyone is familiar with the bleeding associated with simple cuts and scrapes, and we take for granted that bleeding will stop in a few minutes. The stoppage of blood flow, or hemostasis, is complex and essential to our well-being. The underlying mechanisms of hemostasis promote blood clotting that protects us from injuries that could lead to shock and perhaps death. Too much clotting, however, can be just as dangerous. The physiologic processes of hemostasis must maintain a delicate balance between blood fluidity and coagulation.

Many common diseases and conditions affect hemostasis, including myocardial infarction (MI), stroke, venous or arterial thrombosis, sepsis, and cancer. Because these conditions are prevalent in clinical practice, nurses will have frequent occasions to administer and monitor the effects of coagulation-modifying medications. Drugs may be used to enhance coagulation, inhibit coagulation, or dissolve existing clots to restore blood flow.

Disorders of Hemostasis

38.1 Thromboembolic disorders are abnormalities of hemostasis that include deep vein thrombosis and pulmonary embolism.

Coagulation is regulated by a large number of natural substances circulating in the blood. Some of these are **procoagulants**, which favor the formation of clots, while others are **anticoagulants**, which inhibit clot formation. Coagulation, then, can be thought of as a delicate balance between procoagulants and anticoagulants. For example, injuries to blood vessels release procoagulants that tip the balance in favor of initiating coagulation. The student should review the coagulation cascade presented in Chapter 28 before proceeding.

Once a stationary clot, or thrombus, forms in a vessel, it often grows larger as more fibrin is added. Pieces of the thrombus may break off and travel in the bloodstream to block other vessels. A traveling clot is called an *embolus*. Because these two conditions often occur concurrently in patients, the term **thromboembolic disorder** is used to describe conditions in which the body forms undesirable clots. Thromboembolic disorders may be classified as either venous or arterial.

Venous thromboembolism (VTE) is a common condition that occurs when blood flow through a vein is very slow (stasis). Venous stasis allows procoagulation factors to accumulate and overcome the natural anticoagulant substances in the blood. There are two manifestations of VTE: deep vein thrombosis and pulmonary embolism.

When thrombosis occurs in the legs it is called **deep vein thrombosis (DVT)**. Because blood flow is slowest in the deep veins of the lower limbs, these vessels are the most common sites for VTE. Conditions associated with venous stasis and DVT include the following:

- **Extended immobility.** During major illness or following surgery, patients may be supine or otherwise immobile for extended periods. Because the movement of blood through the deep veins is entirely dependent on the squeezing action from skeletal muscular contraction, blood in the deep veins of these patients has difficulty returning to the heart.
- **Major trauma.** Trauma often causes serious bleeding that activates procoagulation factors. In addition, stasis will likely occur surrounding the injured area, promoting the development of DVT. Trauma involving the lower extremities places the patient at high risk for DVT.
- **Major surgery.** Surgery of the lower extremities, especially knee and hip replacements, are common causes of DVT for the same reasons as trauma; bleeding activates procoagulation factors and stasis occurs around the surgical site.
- **Hypercoagulability states.** Malignancy, lupus, and pregnancy are examples of conditions associated with an increased risk of coagulation and DVT. Certain genetic disorders also produce hypercoagulability, the most common being a genetic deficiency of protein C, a natural anticoagulant.
- **Drug therapy.** High amounts of estrogen, prescribed as replacement therapy or as a component of oral

contraceptives, have been associated with DVT in numerous studies. Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), are also associated with a higher risk of DVT.

The second primary thromboembolic disorder is **pulmonary embolism**, which occurs when a venous clot dislodges, migrates to the pulmonary vessels, and blocks arterial circulation to the lungs. Pulmonary emboli are the most serious consequence of VTE because death may occur within minutes after the onset of symptoms. The factors associated with an increased risk of pulmonary embolism are the same as those for patients with DVT: prolonged immobility, major trauma, lower extremity surgery, hypercoagulability states, and estrogen therapy. Prevention of pulmonary embolism is a primary goal for all patients with VTE and a major indication for pharmacotherapy.

Patients with DVT are sometimes asymptomatic, or report nonspecific symptoms such as pain, swelling, or warmth of the legs. The disorder may be present for years, causing progressive damage to venous valves, thus worsening blood flow in the region and increasing the risk of an acute episode. A pulmonary embolism, however, produces a sudden onset of cough, chest pain, tachypnea, dyspnea, tachycardia, and hemoptysis. Symptoms of pulmonary embolism resemble an MI, and rapid diagnosis and treatment are essential.

PharmFACT

Up to 30% of patients presenting with DVT have a malignancy. This is because about 90% of patients with cancer have some abnormal clotting factors (Patel, 2016).

Arterial thromboembolism may deprive an area of blood flow and is a medical emergency because tissue hypoxia and cellular death will result soon after blood stoppage. The most serious arterial thromboembolism disorders are MI and stroke.

Arterial thrombi and emboli commonly result from procedures involving arterial punctures such as angiography and stent placement. They may also originate from the heart. Emboli are common complications of mitral valve disease, prosthetic heart valves, and atrial dysrhythmias. Emboli originating from the left side of the heart may lodge in any organ in the body.

CONNECTION Checkpoint 38.1

Coagulation occurs by intrinsic and extrinsic pathways. From what you learned in Chapter 28, which pathway is activated when blood leaks from a vessel? Which is more complex and takes several minutes? Which results in the formation of fibrin? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

38.2 Coagulation disorders are caused by decreased numbers of platelets or by deficiencies in specific clotting factors.

Whereas thromboembolic disorders are caused by too much clotting, coagulation disorders result from too little clotting. Serious consequences result if the body does not form clots in a timely manner. The two most common etiologies of coagulation disorders are decreased numbers of platelets and deficiencies in one or more clotting factors.

Platelets are central to the process of coagulation. Recognizing a site of vessel injury, activated platelets release von Willebrand's factor, which causes platelets to become "sticky" and adhere to the site. Following adhesion, platelets secrete substances such as adenosine diphosphate (ADP) and thromboxane A_2 that promote platelet aggregation and the formation of a platelet plug at the site. Procoagulation factors become activated on the platelets and a fibrin mesh clot results. Nearly every step of this pathway requires sufficient numbers of properly functioning platelets.

The most common coagulation disorder is a deficiency of platelets, or **thrombocytopenia**, which occurs when platelet counts fall below 150,000 mm^3. Thrombocytopenia is the result of either decreased platelet production or increased platelet destruction. Any condition or disease that suppresses bone marrow function has the potential to cause decreased platelet production. Other common causes of decreased platelet production are folic acid or vitamin B_{12} deficiencies and decreased production of thrombopoietin by the liver during hepatic failure. Increased destruction of platelets may occur in patients with thrombocytopenic purpura, disseminated intravascular coagulation (DIC), or lupus.

Of special concern is thrombocytopenia caused by drug therapy. A significant number of drugs have the potential to increase platelet destruction, either by direct toxic effects on bone marrow or by inducing the immune system to destroy them. When caring for patients receiving these drugs, the nurse must be vigilant in assessing the results of blood laboratory tests and observing for signs of thrombocytopenia such as bleeding gums, nosebleeds, and extensive bruising. Selected drugs that cause thrombocytopenia are listed in Table 38.1. Heparin-induced thrombocytopenia, a particularly serious form of this disorder, is discussed in Section 38.4.

Deficiencies in specific clotting factors may prolong coagulation and lead to excess bleeding. Deficiencies in multiple coagulation factors occur frequently in patients with serious hepatic impairment, because the liver synthesizes most clotting factors. Deficiency in a single coagulation factor suggests **hemophilia**, a series of coagulation disorders caused by genetic deficiencies in specific clotting factors. Hemophilia disorders are typified by prolonged coagulation times, resulting in persistent bleeding that can

Table 38.1 Selected Drugs That Cause Thrombocytopenia

Class	Examples
Analgesics	acetaminophen, aspirin, diclofenac, ibuprofen, indomethacin, morphine, naproxen
Anticoagulants and antiplatelets	clopidogrel, glycoprotein IIb/IIIa inhibitors, heparin
Anti-infectives	acyclovir, amphotericin B, ampicillin, clarithromycin, ethambutol, fluconazole, indinavir, isoniazid, itraconazole, linezolid, oxacillin, piperacillin, rifampin, sulfonamides, trimethoprim, vancomycin
Antineoplastic and immunotherapy drugs	carboplatin, interferon-alfa, methotrexate
Cardiovascular drugs	atorvastatin, captopril, digoxin, hydrochlorothiazide, inamrinone, nitroglycerin, procainamide, quinidine, simvastatin
Central nervous system drugs	carbamazepine, chlorpromazine, diazepam, haloperidol, lithium, phenobarbital, phenytoin, valproic acid
Other drug classes	cimetidine, isotretinoin, MMR vaccine, octreotide, ranitidine, sirolimus

be acute or chronic. Patients may experience various forms of the disease, with symptoms ranging from mild to severe. Approximately two thirds of patients with hemophilia will report a family history of the disease. The pharmacotherapy of hemophilia is described in Section 38.14.

To diagnose coagulation and thromboembolic disorders, a thorough medical history and physical examination are necessary. Laboratory tests measuring coagulation must be obtained. These usually include a whole-blood clotting time, **prothrombin time (PT)**, thrombin time, **activated partial thromboplastin time (aPTT)**, liver function tests, platelet count, and, in some instances, a bleeding time. Another test frequently ordered to assess hemostatic function is the D-dimer. D-dimer tests are used to help rule out the presence of a thrombus, DVT, and pulmonary embolisms. Additional tests, such as serum levels of specific clotting factors, may be indicated.

Overview of Coagulation Modifiers

38.3 The normal coagulation process can be modified by a number of different mechanisms.

Medications can be used to modify hemostasis in a number of ways. An overview of the basic mechanisms of coagulation-modifying drugs is presented in Table 38.2. These mechanisms are illustrated in Figure 38.1.

The most commonly prescribed coagulation modifiers are the anticoagulants and antiplatelet drugs. Although they work by different mechanisms, both of these drug classes have the ability to prevent clot formation or enlargement. Some basic differences between the two are as follows:

- **Anticoagulants** inhibit specific clotting factors in the coagulation cascade. Patients usually call these drugs "blood thinners," but that is an inaccurate description because they do not change the viscosity or thickness of the blood. Examples include heparin and warfarin (Coumadin).

Table 38.2 Overview of Coagulation Modifiers

Type of Modification	Mechanism	Drug Classification
Prevention of clot formation	Inhibition of specific clotting factors	Anticoagulants
	Inhibition of platelet actions	Antiplatelet drugs
Removal of an existing clot	Clot dissolved by the drug	Thrombolytics
Promotion of clot formation	Inhibition of fibrin destruction	Hemostatics
	Administration of missing clotting factors	Clotting factor concentrates

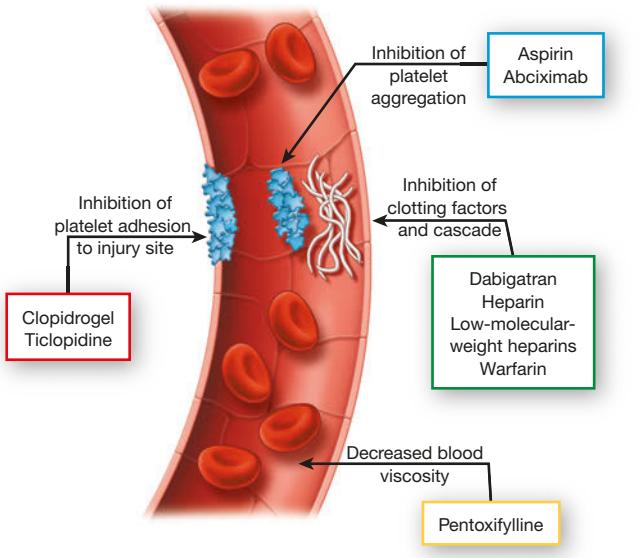

Figure 38.1 Mechanisms of action of coagulation modifiers.

- **Antiplatelet drugs** inhibit the clotting action of platelets. Examples include aspirin and clopidogrel (Plavix).

Compared to antiplatelets, anticoagulants are considered more aggressive therapy for those at high risk for strokes. Anticoagulants carry a higher risk of serious

adverse effects, participate in more drug interactions, and require more extensive follow-up (American Stroke Association, 2014). Anticoagulants and antiplatelets are widely used for thromboembolic disease and are discussed in Sections 38.4 through 38.6.

Once an abnormal clot has formed, it may block blood vessels that serve critical tissues and it must be quickly removed to restore normal function. This is particularly important for vessels serving the heart, lungs, and brain. A specific class of drugs, the thrombolytics, has been developed to dissolve life-threatening clots. These drugs are presented in Section 38.12.

Coagulation modifiers are also used to promote the formation of clots. Drugs called hemostatics inhibit the normal removal of fibrin, thus keeping the clot in place for a longer period of time. These drugs are primarily used to speed clot formation to limit bleeding from a surgical site; they are discussed in Section 38.13. For patients with hemophilia, clotting factors may be administered to promote clotting by providing a missing or deficient component in the coagulation cascade, as presented in Section 38.14.

Because hemostasis involves a fine balance of factors favoring clotting versus those inhibiting clotting, pharmacotherapy with coagulation modifiers is individualized to each patient. Serious adverse effects may occur if the drugs are not used properly; therefore, these patients will require frequent assessment and monitoring to ensure that the goal of normal coagulation is being achieved, without serious adverse events.

Anticoagulants

38.4 Heparin is the traditional drug for rapid anticoagulation.

Extensively used in the treatment of thromboembolic disease, anticoagulants lengthen clotting time and prevent thrombi from forming or growing larger. Since thromboembolic disease can be life threatening, therapy is often begun by administering anticoagulants parenterally to achieve the most rapid onset of action. As the disease stabilizes and the desired degree of anticoagulation has been achieved, the patient is gradually switched to oral anticoagulants, with careful monitoring of appropriate coagulation laboratory values. Traditionally, the most frequently prescribed parenteral anticoagulant has been heparin; warfarin is the most common oral anticoagulant (see Section 38.5). The anticoagulants are listed in Table 38.3.

Table 38.3 Anticoagulants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
antithrombin, recombinant (ATryn)	IV infusion: Dose is individualized based on pretreatment antithrombin level and body weight	*Minor bleeding, nausea, vomiting, transient thrombocytopenia (heparin), anemia (fondaparinux)* Hemorrhage, anaphylaxis, heparin-induced thrombocytopenia
fondaparinux (Arixtra)	Subcutaneous: 2.5 mg/day starting at least 6 h postop for 5–9 days (max: 10 mg/day)	
heparin	IV: 5000-unit bolus dose, then 20,000–40,000 units infused over 24 h (use agency-specific heparin nomogram) Subcutaneous: 10,000–20,000 units followed by 8000–20,000 units q8–12h	
warfarin (Coumadin)	PO: Dose varies based on target international normalized ratio (INR), which is usually within the range of 2–3	
Low-Molecular-Weight Heparins (LMWHs)		
dalteparin (Fragmin)	Subcutaneous (DVT prophylaxis): 2500–5000 units/day for 5–10 days (max: 18,000 international units/day) Subcutaneous (DVT treatment): 120 international units/kg bid	*Minor bleeding, nausea, vomiting, hematoma, local pain, fever* Hemorrhage, thrombocytopenia, pancytopenia, anaphylaxis, local site reactions
enoxaparin (Lovenox)	Subcutaneous (DVT prophylaxis): 30 mg bid Subcutaneous (DVT treatment): 1 mg/kg q12h or 1.5 mg/kg/day IV (acute STEMI): 30-mg bolus followed by subcutaneous doses	
Direct Thrombin Inhibitors		
argatroban (Acova, Novastan)	IV: 2 mcg/kg/min (max: 10 mcg/kg/min)	*Fever, nausea, allergic skin reactions, hepatic impairment, pneumonia, fever, minor bleeding, back pain (bivalirudin)* Serious internal hemorrhage, hemoptysis, hematuria, sepsis, heart failure
bivalirudin (Angiomax)	IV: 0.75 mg/kg initial bolus followed by 1.75 mg/kg/h for 4 h	
dabigatran (Pradaxa)	PO: 75–150 mg bid	
desirudin (Iprivask)	Subcutaneous: 15 mg bid for 9–12 days (max: 80 mg/day)	
Factor Xa Inhibitors		
apixaban (Eliquis)	PO: 5 mg bid	*Minor bleeding, rash* Major bleeding, including stroke; anemia; hypersensitivity reactions
betrixaban (Bevyxxa)	PO: Single dose of 160 mg followed by 80 mg once daily	
edoxaban (Savaysa)	PO: 30–60 mg once daily	
rivaroxaban (Xarelto)	PO: 10–20 mg once daily	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Heparin is a natural chemical found in the liver and the lining of blood vessels. As a drug, heparin has been used for many decades and is one of the few drugs still obtained from animal tissue, usually beef lung or pig intestine. Chemically, heparin is a special type of carbohydrate called a glycosaminoglycan that consists of repeated disaccharide units of differing lengths. Thus, heparin is actually a mixture of different molecules, varying in size. This drug is also called unfractionated heparin because it contains a mixture of different molecular pieces or "fractions." This mixture affects protein binding and drug bioavailability and is partially responsible for the wide variation in patient responses to heparin.

Heparin produces its anticoagulant effects by binding to **antithrombin III (AT-III)**. As its name implies, antithrombin inactivates thrombin (as well as several other clotting factors). The binding to heparin produces a structural change in AT-III that makes it 1000 times more active in inhibiting thrombin, Factor Xa, Factor IXa, and other substances involved in coagulation. Within minutes after intravenous (IV) administration, the loss of these activated clotting factors prevents the formation of fibrin clots.

Because responses to heparin anticoagulation vary considerably among patients, regular monitoring of laboratory values during heparin therapy is essential to patient safety. The aPTT value is the conventional measurement that guides heparin therapy, with normal values ranging from 25 to 40 seconds. For therapeutic anticoagulation, the aPTT should be between 1.5 and 2 times the patient's baseline, or 60 to 80 seconds. Elevated aPTT values indicate the patient is at high risk for bleeding and that a reduction in heparin dose is necessary. aPTT values of less than 60 seconds indicate the need for higher heparin doses. During continuous IV heparin therapy, the aPTT is measured daily and 6 to 8 hours after any changes in dosage.

Low-molecular-weight heparins: The heparin molecule has been shortened and modified to create a new class of drugs called low-molecular-weight heparins (LMWHs). Given subcutaneously, the mechanism of action of these drugs is very similar to that of heparin, except the shorter heparin molecules are unable to bind thrombin, making them more selective for Factor Xa inhibition. For some applications, the LMWHs have begun to replace traditional heparin anticoagulation.

LMWHs possess the same anticoagulant activity as heparin but have several advantages. They produce a more predictable anticoagulant response than heparin because there is less binding of the drug to proteins and macrophages; therefore, less frequent laboratory monitoring is required. They are about 10 times less likely to cause thrombocytopenia, a potentially serious adverse effect of heparin. They also exhibit a half-life that is 2 to 4 times longer than heparin that permits once-daily dosing, and family members or the patient can be trained to give the necessary subcutaneous injections at home. Like heparin, the LMWHs do not cross the placenta. LMWHs have become preferred drugs for a number of clotting disorders, including the prevention of DVT following surgery. One disadvantage is that LMWHs are more expensive than heparin.

When using LMWHs, the aPTT laboratory value does not reflect the anticoagulant effects of the drugs because aPTT is insensitive to changes in Factor Xa. Instead, dosage calculations with LMWHs are fixed and based on the patient's weight. A given amount of subcutaneous LMWH results in a predictable plasma drug level. This is a major advantage over heparin, for which levels continually fluctuate and doses must be adjusted based on aPTT levels. In highly unstable patients or those with chronic kidney disease (CKD), measurement of antifactor Xa activity may be used to gauge therapeutic response. Acceptable target values for antifactor Xa range from 0.5 to 1 unit/mL.

PROTOTYPE DRUG Heparin

Classification **Therapeutic:** Anticoagulant
Pharmacologic: Indirect thrombin inhibitor

Therapeutic Effects and Uses: Heparin is the traditional standard to which other parenteral anticoagulants are compared. Because it has an immediate onset of action when administered IV, heparin is a first-line drug for acute thromboembolic disorders where rapid anticoagulation is necessary. Subcutaneous heparin is injected into the deep fatty layers of the abdomen and may take up to 1 hour to achieve a therapeutic effect. A continuous IV infusion allows for better titration and finer management of aPTT values. Indications include DVT, pulmonary embolism, unstable angina, evolving MI, and prevention of thrombosis in high-risk patients. Heparin and LMWHs are preferred anticoagulants during pregnancy because heparin molecules are too large to cross the placenta. Heparin is also used to maintain the patency of peripheral catheters (heparin locks) and arterial lines.

Heparin prolongs coagulation time, thereby inhibiting excessive clotting within blood vessels. As a result, it prevents the enlargement of existing clots and the formation of new ones. It has no ability to dissolve existing clots. Clotting time is prolonged, although bleeding time is only affected at high doses.

Mechanism of Action: Heparin activates the enzyme antithrombin III, which in turn inhibits thrombin. To a lesser extent, and by a separate mechanism, heparin also inactivates Factor Xa. Other clotting factors are affected by heparin, but these have less clinical significance. High doses interfere with platelet aggregation.

Pharmacokinetics:

Route(s)	Subcutaneous, IV bolus injection, or continuous infusion
Absorption	Heparin is poorly absorbed by the gastrointestinal (GI) mucosa because of rapid metabolism by the hepatic enzyme, heparinase
Distribution	Unknown; does not cross the placenta and is not secreted in breast milk
Primary metabolism	Hepatic and by reticuloendothelial system
Primary excretion	Reticuloendothelial system
Onset of action	Subcutaneous: 30–60 min; IV: immediate
Duration of action	8–12 h; half-life: 90 min

Adverse Effects: Abnormal bleeding occurs in about 10% of patients, and is the most serious adverse effect. Bleeding may be major or minor and may involve any system in the body. The risk of bleeding is dose dependent; the higher the dose, the greater the risk. Should the aPTT become excessively prolonged or bleeding be observed, discontinuation of the drug will result in loss of anticoagulant activity within hours. **Black Box Warning:** Epidural or spinal hematomas may occur when heparin or LMWHs are used in patients receiving spinal anesthesia or lumbar puncture. Because these can result in long-term or permanent paralysis, frequent monitoring for neurologic impairment is essential.

Heparin-induced thrombocytopenia (HIT) is a serious complication that occurs in up to 30% of patients taking the drug. Symptoms range from mild to severe. More severe symptoms usually appear after 5 to 10 days of therapy; thus, frequent blood laboratory testing should be conducted during this period. Although thrombocytopenia usually leads to excessive bleeding, HIT causes the opposite effect: an increase in adverse thrombotic events. HIT markedly increases platelet aggregation and the patient may experience serious and even life-threatening thrombosis. Although the half-life of heparin is brief, it may take a week after the drug is discontinued for platelets to recover. In addition, HIT may not even become evident until several weeks after the drug is discontinued.

Because heparin is derived from animal sources, hypersensitivity reactions are possible. Mild allergic symptoms include fever, chills, and urticaria. Anaphylaxis is rare. Osteoporosis has been reported in patients taking the drug longer than 30 days and may be severe enough to cause bone fractures. Skin lesions may develop, especially at the site of parenteral injections.

Contraindications/Precautions: Heparin should not be administered to patients with active internal bleeding, serious bleeding pathologies, severe hypertension (HTN), recent trauma, intracranial hemorrhage, or bacterial endocarditis. Some heparin products may contain sulfites and should not be administered to patients with sulfite sensitivity. Patients with severe thrombocytopenia or HIT should not be given heparin. Whenever possible, intramuscular (IM) injections of other medications should be avoided because they may cause serious bruising, bleeding, or hematomas. Although relatively safe during pregnancy, the drug should be used with caution during the peripartum period due to the risk of maternal hemorrhage. Caution must be used when administering heparin to patients with serious CKD or hepatic impairment because the drug may rise to toxic levels.

Drug Interactions: Oral anticoagulants, including warfarin, potentiate heparin activity. Drugs that inhibit platelet aggregation (such as aspirin, indomethacin, and ibuprofen) may induce bleeding. Nicotine, digoxin, tetracyclines, or antihistamines may inhibit anticoagulation. **Herbal/Food:** Herbal supplements that may affect coagulation such as ginger, garlic, green tea, feverfew, or ginkgo should be avoided because they may increase the risk of bleeding.

Pregnancy: Category C.

Treatment of Overdose: If serious hemorrhage occurs, a specific antagonist, protamine sulfate, may be administered IV (1 mg for every 100 units of heparin) to neutralize the anticoagulant activity of heparin. Protamine sulfate has an onset of action of 5 minutes and a duration of 2 hours. Multiple doses may be necessary to control extensive hemorrhaging. Protamine is also an antagonist to the LMWHs.

Nursing Responsibilities: Key nursing implications for patients receiving heparin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Anticoagulants.

Drugs Similar to Heparin

The LMWHs include dalteparin and enoxaparin. A third LMWH, tinzaparin, is no longer marketed in the United States. Antithrombin (recombinant) and fondaparinux are parenteral anticoagulants that act by unique mechanisms.

Antithrombin, recombinant (ATryn): ATryn is a unique coagulation modifier approved in 2009 to treat patients who have a congenital deficiency of antithrombin III. These patients have a high incidence of blood clots, especially DVT. The drug is indicated for the prevention of perioperative and peripartum thromboembolic events in hereditary antithrombin-deficient patients. Antithrombin (ATryn) is unusual because it is obtained from genetically engineered goats. The goats are engineered through recombinant

deoxyribonucleic acid (DNA) technology to secrete human antithrombin in their milk. The drug is then purified and powdered for reconstitution as an IV infusion.

Levels of antithrombin activity in the blood must be monitored before, during, and immediately following therapy. The initial and subsequent drug doses are based on the level of antithrombin activity. The most common adverse effects are hemorrhage and infusion site reaction. ATryn enhances the anticoagulant effect of heparin and LMWHs. This drug is pregnancy category C.

Dalteparin (Fragmin): As an LMWH, dalteparin has smaller glycosaminoglycan chains than unfractionated heparin. Approved in 1994, dalteparin is given by the subcutaneous route for the treatment and prophylaxis of DVT or pulmonary embolism. Other approved indications include thrombosis prophylaxis in patients at increased risk due to unstable angina, an acute MI, or cancer. It has a longer half-life than heparin, which allows for less frequent dosing. Like other LMWHs, bleeding is the most serious adverse effect and the drug should not be administered to patients with active bleeding. This drug is pregnancy category B.

Enoxaparin (Lovenox): Enoxaparin was the first LMWH approved by the U.S. Food and Drug Administration (FDA) in 1993. Indications include treatment and prophylaxis of DVT and pulmonary embolism. Following hip or lower extremity surgery, enoxaparin may be administered once daily for 7 to 10 days. Some orthopedic procedures such as repair of hip fractures require more prolonged therapy. Enoxaparin may also be administered for the prophylaxis of coronary artery thrombosis and the prevention of ischemic complications in patients with acute coronary syndrome, for patients with unstable angina, and patients having percutaneous coronary intervention (PCI). Bleeding is the most serious adverse effect and the drug should not be administered to patients with active bleeding. This drug is pregnancy category B.

Fondaparinux (Arixtra): Approved in 2001, fondaparinux is an anticoagulant used for many of the same indications as heparin and the LMWHs, but it has certain differences that make it unique. Fondaparinux is a synthetic drug that consists of only five saccharide units (a pentasaccharide) that is structurally identical to the region of the heparin molecule that binds AT-III. The pentasaccharide unit is able to selectively inhibit Factor Xa without directly affecting thrombin. Fondaparinux is only given by the subcutaneous route and is approved for the prophylaxis of VTE following orthopedic surgery and the treatment of DVT or pulmonary embolism. Like the LMWHs, fondaparinux is administered as fixed doses based on the patient's weight, and routine laboratory monitoring is not required because aPTT and PT are not accurate measures of drug activity. Doses of fondaparinux are not interchangeable with heparin or the LMWHs. There is no specific antidote for overdose; administration of protamine is ineffective. This drug is pregnancy category B.

38.5 Warfarin is a widely used drug for oral anticoagulant therapy.

Although parenteral anticoagulants have the advantage of an almost immediate onset of action, drugs given by this route require close medical supervision because adverse effects such as bleeding can rapidly ensue. When the patient's condition allows, oral anticoagulants are used due to their convenience and greater safety.

Warfarin (Coumadin) has been available as an anticoagulant for over 50 years and is the historical prototype for oral anticoagulants. In acute situations, patients begin anticoagulation therapy with heparin and are switched to warfarin when their condition stabilizes. When transitioning, the two drugs must be administered concurrently for 2 to 3 days. This is because heparin has a brief half-life (90 minutes), and aPTT returns to normal within 2 to 3 hours following discontinuation of heparin. Warfarin, on the other hand, takes 1 to 3 days of therapy to achieve optimal anticoagulation. Thus, concomitant pharmacotherapy is necessary to ensure continuous anticoagulation. During this transition, risk of bleeding increases, due to the additive anticoagulant action of the two drugs.

CONNECTIONS: Lifespan Considerations

Miscarriage Prevention with Anticoagulants

Miscarriage in pregnancy is devastating, and recurrent miscarriage even more so. Autoimmune diseases are related to poorer obstetric outcomes than that of the general population, especially in mothers with undiagnosed thrombophilias (genetic hypercoagulability disorders) such as antiphospholipid syndrome (APS). Antiphospholipid antibodies are present in 15% of women with recurrent miscarriage, and there is a potential 90% risk of future fetal loss in those women if left untreated (Chetty & Duncan, 2015). Other obstetric and neonatal complications related to APS include preeclampsia; eclampsia; hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; early delivery and subsequent prematurity; intrauterine growth restriction (IUGR); and placental insufficiency (Begum, Ganguly, & Islam, 2015; de Jesús, Rodrigues, de Jesús, & Levy, 2014).

Due to discrepancies in the research on treatment recommendations for the use of heparin, LMWH, or aspirin for recurrent spontaneous abortion before 10 weeks of pregnancy, it is recommended that a woman experiencing such loss discuss the situation with her provider and whether genetic testing should be conducted. If genetic coagulation abnormalities are found, heparin or LMWH may be considered as an option (Andreoli et al., 2013).

Whereas heparin is monitored with aPTT values, the standard laboratory test used to monitor the effectiveness of warfarin is the PT value. The normal PT range is 12 to 15 seconds. During therapeutic anticoagulation, PT should increase to 1.5 to 2 times the patient's baseline. Because laboratory testing methods for PT vary, however, PT time is also reported as an international normalized ratio (INR) value; INR values averaging 2.5 are considered therapeutic for most indications. PT is measured daily until the desired level of therapeutic anticoagulation is achieved. Then, the frequency of laboratory testing is decreased to weekly or monthly as the patient's condition stabilizes. Home monitoring devices are available to provide convenient and reliable INR values, which can guide the patients to adjust their own medication amounts. Self-monitoring has its limitations, however. The devices are expensive and the patient or their caregiver must be capable of understanding how to properly adjust the dosage.

Several newer drugs have emerged as significant alternatives to warfarin for stroke prevention. While warfarin affects coagulation *indirectly* by inhibiting vitamin K, these newer drugs *directly* inhibit an aspect of the coagulation cascade. Thus, these drugs are referred to as direct oral anticoagulants (DOACs). The DOACs include three drugs that directly inhibit Factor Xa and one that directly inhibits thrombin. The Factor Xa inhibitors include rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). The fourth DOAC is dabigatran (Pradaxa), which is a prototype thrombin inhibitor discussed in Section 38.6.

PROTOTYPE DRUG Warfarin (Coumadin)

Classification **Therapeutic:** Anticoagulant
Pharmacologic: Vitamin K antagonist

Therapeutic Effects and Uses: Indications for warfarin therapy include the long-term prophylaxis of arterial thromboembolism, including prevention of stroke and MI. Other uses include the prophylaxis and treatment of DVT or pulmonary embolism in patients undergoing hip or knee surgery, or in those with long-term indwelling central venous catheters or prosthetic heart valves. The drug may be given to prevent thromboembolic events in high-risk patients following an MI or an atrial fibrillation episode.

Warfarin is well absorbed after PO administration but takes several days to produce an optimal therapeutic effect. Ninety-nine percent of absorbed warfarin is bound to plasma proteins and is not immediately available to produce its effect. This high level of protein binding is also responsible for some of the many drug–drug interactions that occur with warfarin.

Patient responses to warfarin therapy vary widely. Dosage levels must be determined individually for each patient and carefully monitored. Patients stabilized on warfarin should not switch brands of the drug unless recommended by the healthcare provider, due to differences in bioavailability. For most indications, the therapeutic range of serum warfarin levels varies from 1 to 10 mcg/mL to achieve a target INR value of 2 to 3.

Mechanism of Action: Warfarin inhibits two enzymes involved in the formation of activated vitamin K, which is required for the synthesis of clotting Factors II, VII, IX, and X. Warfarin inhibits the synthesis of new clotting factors but does not affect clotting factors that are already circulating in the blood. It takes 3 to 4 days for the plasma levels of existing clotting factors to fall and for the anticoagulant effect of warfarin to appear. After discontinuing the drug, 3 to 4 days are needed for the body to make new clotting factors and return coagulation to baseline levels.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Widely distributed; crosses the placenta but is not secreted in breast milk; 99% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal; small amounts in bile
Onset of action	2–7 days
Duration of action	3–5 days; half-life: 0.5–3 days

Adverse Effects: Like all anticoagulants, the most serious adverse effect of warfarin is abnormal bleeding, which may occur in any body system. Warfarin may release pieces of atheromatous plaque from vessel walls, resulting in systemic cholesterol microembolization that may occlude small vessels. For example, "purple-toe syndrome" is caused by cholesterol microembolization and severe cases may lead to gangrene or amputation. Long-term use of warfarin may increase the risk of osteoporosis and bone fractures. **Black Box Warning:** Warfarin can cause major or fatal bleeding, and regular monitoring of INR is required. Patients should be instructed about prevention measures to minimize bleeding risk and to immediately notify healthcare providers of signs and symptoms of bleeding.

Contraindications/Precautions: Patients with recent trauma, active internal bleeding, serious bleeding disorders, intracranial hemorrhage, severe HTN, bacterial endocarditis, severe CKD, or hepatic impairment should not take warfarin. When possible, warfarin should be discontinued or the dosage lowered before dental or elective surgical procedures. Patients with heart failure may exhibit excessive anticoagulation with warfarin, which requires lower doses. Whenever possible, IM injections of other medications should be avoided because they may cause

Table 38.4 Drug–Drug Interactions with Warfarin

Interaction	Drug or Drug Class
Increased anticoagulant effect	acetaminophen, amiodarone, anabolic steroids, aspirin, azole antifungals, cephalosporins, cimetidine, clopidogrel, danazol, disulfiram, heparin, isoniazid, macrolides, metronidazole, nalidixic acid, NSAIDs, omeprazole, paroxetine, penicillin, propafenone, quinidine, statins, tamoxifen, tetracyclines, thyroid hormone, trimethoprim-sulfisoxazole
Decreased anticoagulant effect	barbiturates, bile-acid sequestrants, carbamazepine, cyclosporine, dicloxacillin, oral contraceptives, rifampin
Mixed effect	allopurinol, corticosteroids, ethanol, phenytoin
Supplements and food	American ginseng, cranberry, feverfew, ginkgo, green tea, vitamin E, vitamin K

bruising, bleeding, or hematomas. Warfarin should not be taken during pregnancy because the drug has been shown to produce numerous fetal abnormalities, induce fatal bleeding, and can cause fetal death. Warfarin is believed to be safe for lactating women who are at risk for postpartum DVT because very little of the drug enters breast milk. Studies have shown no change in the INR values of lactating infants whose mothers are receiving warfarin.

Drug Interactions: Drug–drug interactions with warfarin are numerous. Because the therapeutic index of warfarin is very low, drugs that interact with warfarin have the potential to affect coagulation time and cause harm. Concurrent use with other drugs with anticoagulant activity, including aspirin, heparin, and antiplatelet drugs, may produce additive effects and excessive bleeding. Extensive protein binding is responsible for numerous drug–drug interactions, some of which include nonsteroidal anti-inflammatory drugs (NSAIDs), diuretics, selective serotonin reuptake inhibitors (SSRIs) and other antidepressants, steroids, antibiotics, vaccines, and vitamins (e.g., vitamin K). NSAIDs increase bleeding risk. During warfarin therapy, the patient should not take any other prescription or over-the-counter (OTC) drugs or herbal products unless approved by the healthcare provider. A listing of selected drugs and supplements affecting warfarin therapy is given in Table 38.4. **Herbal/Food:** Herbal supplements such as green tea, ginkgo, feverfew, garlic, cranberry, chamomile, and ginger may increase the risk of bleeding.

Pregnancy: Category X.

Treatment of Overdose: The specific treatment for warfarin overdose is PO or parenteral administration of vitamin K_1. When administered IV, vitamin K_1 can reverse the anticoagulant effects of warfarin within 6 hours.

Nursing Responsibilities: Key nursing implications for patients receiving warfarin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Anticoagulants.

Drugs Similar to Warfarin (Coumadin)

Apixaban, edoxaban, and rivaroxaban are DOACs that serve as alternatives to warfarin for providing anticoagulation. These drugs will be considered as a group because they have identical mechanisms and very similar actions.

All three drugs in this class are oral medications that act by inhibiting Factor Xa, resulting in prolonged clotting time. Initial approvals were granted for rivaroxaban (Xarelto) in 2011, apixaban (Eliquis) in 2012, and edoxaban (Savaysa) in 2015. Indications for the Factor Xa inhibitors include the following.

- Reduction in the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation (all three drugs)
- Treatment of DVT and pulmonary embolism (all three drugs)
- Prophylaxis of DVT in patients who have undergone knee or hip replacement surgery (apixaban and rivaroxaban).

The most serious adverse reaction is excessive bleeding. Unlike warfarin, there is no antidote for Factor Xa inhibitor overdose. The three drugs carry a black box warning that abrupt discontinuation can increase the risk of thromboembolism. Unless discontinued for a pathologic reason (excessive bleeding), another drug should be immediately substituted so that continuous anticoagulation is obtained. A second black box warning is that spinal or epidural hematomas may occur in anticoagulated patients receiving epidural or spinal anesthesia or who are undergoing spinal puncture.

The Factor Xa inhibitors offer significant advantages over warfarin. The Factor Xa inhibitors require no monitoring to determine their anticoagulant effect—the same dose is used for most patients. They exhibit fewer drug–drug and drug–food interactions than warfarin. Their anticoagulant effect clears in 1–2 days after discontinuation, versus 5–7 days for warfarin.

38.6 The direct thrombin inhibitors and Factor Xa inhibitors have become important drugs in the prevention and treatment of venous thromboembolism.

The direct thrombin inhibitors and Factor Xa inhibitors, listed in Table 38.3, are relatively new drugs in the prevention and treatment of venous thromboembolism and pulmonary emboli. They offer several advantages over warfarin and heparin.

The direct thrombin inhibitors have an interesting history; they were originally derived from chemicals found in

leeches. Leeches are wormlike animals that survive by sucking and digesting blood from mammals. Medical leeches are an ancient treatment that dates back to early Egyptian and Greek civilizations. They were applied to the skin as a type of bloodletting, which was thought to remove harmful substances from the body. Known as hirudotherapy, the use of leeches was largely discontinued with the advent of modern medicine in the early 1900s. However, leeches are still an approved therapy for relieving venous congestion in transplanted or reattached fingers or limbs. While studying leeches, scientists isolated a potent chemical called hirudin, which prevented blood from coagulating in the leech.

The direct thrombin inhibitors bind reversibly to thrombin, preventing the formation of fibrin. They are highly specific for thrombin and do not require AT-III as an intermediate in promoting anticoagulation as does heparin. They bind to circulating thrombin as well as thrombin attached to fibrin clots. These drugs exhibit typical anticoagulant actions and are used for the same types of indications as heparin and the LMWHs. The only drug in this class given by the PO route is dabigatran.

The Factor Xa inhibitors bind to activated Factor Xa, which blocks the formation of thrombin from both the intrinsic and extrinsic pathways of the coagulation cascade. They block Factor Xa in both plasma and in clots, and have no effects on platelets. They are well absorbed by the PO route and do not require routine monitoring. The number of adverse bleeding events is the same, or less, than that of warfarin. Peak concentrations can be reached in 3 hours. The American College of Chest Physicians (ACCP) now recommends 3 months of therapy with dabigatran (Pradaxa), rivaroxaban (Xarelto), apixaban (Eliquis), or edoxaban (Savaysa) as initial choices for DVT or pulmonary embolus prevention (Kearon et al., 2016).

PROTOTYPE DRUG **Dabigatran (Pradaxa)**

Classification **Therapeutic:** Anticoagulant
Pharmacologic: Direct thrombin inhibitor

Therapeutic Effects and Uses: Dabigatran is a direct thrombin inhibitor that was approved in 2010 for stroke prophylaxis in patients with nonvalvular atrial fibrillation. Indications have been extended to include treatment of DVT and pulmonary embolus in patients who have been treated with a parenteral anticoagulant for 5 to 10 days, and prophylaxis of DVT and PE in patients who have undergone hip replacement surgery. Because it is administered PO, dabigatran is an alternative to both heparin and warfarin. Although more expensive, dabigatran has equal efficacy to warfarin and does not require the same high degree of laboratory monitoring as does warfarin or heparin.

Mechanism of Action: Dabigatran directly inhibits the action of thrombin without requiring the intermediate step of AT-III inhibition.

Pharmacokinetics:

Route(s)	PO
Absorption	3–7% absorbed
Distribution	35% bound to plasma proteins; unknown if it crosses the placenta or is secreted in breast milk
Primary metabolism	Hepatic to active metabolites
Primary excretion	Renal 80%
Onset of action	30–90 min
Duration of action	Half-life: 12–17 h

Adverse Effects: Like other anticoagulants, the most serious adverse effect of dabigatran is bleeding. Symptoms may include bleeding from puncture or wound sites, epistaxis, hematuria, vaginal bleeding, or GI bleeding. Hypersensitivity reactions, including anaphylaxis, have been reported. Dyspepsia and gastritis are common during therapy. **Black Box Warnings:** Premature discontinuation of dabigatran increases the risk of thrombotic events. Epidural or spinal hematomas may occur when administering this drug to patients who are receiving neuraxial anesthesia or spinal puncture.

Contraindications/Precautions: Dabigatran should not be administered to patients with active bleeding or those with impaired hemostasis. Patients with mechanical heart valves should not receive this drug due to an increased risk of thrombotic events. Patients with severe CKD or on hemodialysis should not receive dabigatran. The drug should be used with caution in patients with recent hemorrhage, recent surgery, intracranial hemorrhage, ulcerative GI disease, or symptoms of gastritis.

Drug Interactions: Additive risk for bleeding may occur if dabigatran is administered concurrently with other coagulation modifiers, including warfarin, heparin, aspirin, and fibrinolytic drugs. **Herbal/Food:** Herbal supplements that affect coagulation such as ginger, garlic, green tea, feverfew, St. John's wort, or ginkgo should be avoided because they may increase the risk of bleeding.

Pregnancy: Category C.

Treatment of Overdose: Administration of protamine and vitamin K are not effective. In 2015, idarucizumab (Praxbind) was approved for emergency use to reverse the anticoagulant action of dabigatran. When given IV, idarucizumab binds to free dabigatran and fully reverses anticoagulation after 4 hours in most patients.

Nursing Responsibilities: Key nursing implications for patients receiving dabigatran are included in the

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Anticoagulants

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular (including HTN, MI, heart failure) and peripheral vascular disease (including thrombophlebitis), respiratory (including previous pulmonary embolism), neurologic (including recent head injury or stroke), hepatic disease, CKD, diabetes, peptic ulcer disease, hypercholesterolemia, and the possibility of alcoholism or pregnancy. **Lifespan:** Ask women of menstrual age about length and heaviness of usual menstrual flow. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight; vital signs; electrocardiogram (ECG), if appropriate; and breath sounds. Assess for presence, quality, location of angina, and for presence of dyspnea or chest pain. Assess extremities for symptoms of thrombophlebitis (e.g., warmth, swelling, tenderness in calf, positive Homans' sign), and for location, character, and amount of edema, if present.
- Evaluate appropriate laboratory findings (e.g., aPTT, PT/INR), complete blood count (CBC), renal and liver function studies, arterial blood gases (ABGs) as appropriate, and lipid profiles.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., existing area of phlebitis exhibits signs of improvement with no symptoms of thrombosis formation; signs and symptoms of existing thrombosis show gradual improvement: e.g., previous anginal or peripheral extremity pain has diminished or is eliminated; peripheral pulses are improving in quality and volume).
- Continue periodic monitoring of appropriate laboratory values (e.g., aPTT, PT/INR).
- Assess for adverse effects: bleeding at IV sites, wounds, excessive ecchymosis, petechiae, hematuria, black or tarry stools, rectal bleeding, coffee-ground emesis, epistaxis, bleeding from gums, hemoptysis, prolonged or heavy menstrual flow; and assess for occult bleeding: pallor, dizziness, hypotension, tachycardia, abdominal pain, areas of abdominal wall swelling or firmness, lumbar pain, or decreased level of consciousness (LOC).

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects, e.g., existing area of phlebitis exhibits signs of improvement with no symptoms of thrombosis formation; signs and symptoms of existing thrombosis show gradual improvement: e.g., previous anginal or peripheral extremity pain has diminished or is eliminated; peripheral pulses are improving in quality and volume. (Anticoagulants help prevent the formation of thrombi or prevent existing thrombi from increasing in size. As the body's own thrombolysis factors activate, existing thrombi will gradually reduce in size.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used (e.g., antiembolic stockings, intermittent pneumatic sequential compression devices) and the need for frequent monitoring.
• Encourage early ambulation postoperatively in the hospitalized patient and active range of motion (ROM) if the patient is on bed rest or has limited mobility. Perform passive ROM for patients unable to perform active ROM. (Early ambulation and ROM prevent venous stasis and thrombosis formation, lessening the need for anticoagulant therapy.)	• Assist the patient with ambulation postoperatively, and teach active ROM. Teach the patient, family, or caregiver how to perform passive ROM exercises for patients unable to perform active ROM.
• Assess the patient's lifestyle and occasions of travel over extended lengths of time (e.g., air travel, lengthy driving trips) and the frequency of such trips. (Prolonged sitting during air or car travel may limit blood flow to lower extremities and venous return, promoting the formation of thrombi. Frequent stretching, ambulating when possible, and increasing fluids to maintain normal osmolarity and viscosity may decrease thrombosis formation and lessen the need for anticoagulant therapy.)	• Educate patients and consumers about thrombosis prevention during travel: stretch periodically, ambulate for short periods, avoid sitting for prolonged periods, and increase fluid intake.
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, limited caffeine intake, and smoking cessation. Provide for dietitian consultation as needed. (Smoking increases platelet aggregation and promotes the formation of thrombi. Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation. Provide for appropriate consultation (e.g., dietitian) as needed.
Minimizing adverse effects: • Monitor for signs and symptoms of excessive visible bleeding and for occult bleeding. (Bleeding is the most common adverse effect of anticoagulant therapy. Frequent assessment for both visible and occult bleeding is necessary to prevent hemorrhage and to start early corrective treatment as appropriate. **Diverse Patients:** Because some drugs such as clopidogrel [Plavix] metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Anticoagulant use is a high-risk safety concern and is included in The Joint Commission's National Patient Safety Goals. • Teach the patient, family, or caregiver the signs and symptoms of excessive bleeding, including occult. If external bleeding occurs, pressure over the site should be held up to 15 min. If bleeding continues, is severe, or is accompanied by dizziness or syncope, immediate medical attention (e.g., 911) should be obtained. • **Lifespan:** Women of menstrual age should report excessively heavy or prolonged menstrual bleeding and should keep a pad count and report to the healthcare provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor frequent laboratory tests (aPTT, PT/INR), CBC, and platelets. (Therapeutic aPTT levels are usually 1.5–2.5 times the normal control value. INR is usually 2–3.5 or 4. Learn own laboratory provider's values. Values below the norm indicate less than optimal therapeutic levels of the drug; values above the norm indicate a high potential for bleeding and hemorrhage. CBC, especially red blood cell [RBC], hemoglobin [Hgb], hematocrit [Hct], and platelet levels should remain within normal limits. Decreasing values on CBC may indicate excessive bleeding and the need to assess for location. **Lifespan:** Be especially cautious with the older adult as age-related hepatic changes may increase the risk of bleeding.)	• Instruct the patient on the need to return periodically for laboratory work and to alert laboratory personnel that anticoagulant therapy is being used. • Instruct the patient to carry a wallet identification card or wear medical identification jewelry indicating anticoagulant therapy.
• Continue to monitor peripheral pulses for quality and volume, complaints of angina or chest pain, especially if new or of sudden onset or accompanied by dyspnea. (Anticoagulants prevent thrombus formation or extension; they do not prevent emboli from occurring. Monitoring for new or sudden onset of pain is necessary to ensure prompt treatment of possible emboli.)	• Teach the patient, family, or caregiver to report immediately any sudden pain in the chest, legs or calves, dyspnea, or new-onset anginal pain.
• Minimize opportunities for injury or bleeding where possible: Avoid IM injections, provide a soft toothbrush, and be cautious when providing care, especially with older adults who have more fragile skin. (Anticoagulants raise the risk of bleeding, and causes of even minor bleeding should be avoided when possible. If minor bleeding occurs, prolonged pressure, longer than expected, will be necessary to stop it, and the site should be assessed frequently for oozing. Warfarin and antiplatelet drugs may continue to have effects after the drug is stopped.)	Instruct the patient on ways to minimize opportunities for injury or bleeding: • Switch to a soft toothbrush and inspect gums after brushing. • Use an electric razor, or be extra cautious with a safety razor, holding prolonged pressure over small nicks. • Be cautious with food preparation, especially when cutting food. • Avoid contact sports, amusement park rides, or other physical activities that may cause intense or violent bumping, jostling, or injury. • **Lifespan:** Frequently assess older adult family members on anticoagulant therapy who have more fragile skin and may experience skin tears or ecchymosis more frequently.
• Closely evaluate all new prescriptions or use of OTC medications for drug interactions. (Many drugs interact with anticoagulants, enhancing the action and increasing the chance for bleeding. All OTC medications containing salicylates, e.g., aspirin, and NSAIDs are contraindicated.)	• Instruct the patient to consult the healthcare provider before taking any new prescription or OTC medication, including herbal preparations.
• Maintain a normal diet, avoiding increases or decreases in vitamin K–rich foods (e.g., asparagus, broccoli, cabbage, cauliflower, kale), and limit or eliminate alcohol intake. (Vitamin K is necessary for synthesis of clotting agents in the liver. Sudden increases or decreases in dietary intake of vitamin K–rich foods may increase or decrease the effectiveness of anticoagulants, particularly oral anticoagulant therapy. Excessive intake of alcohol, more than two drinks in men or one in women per day, may alter the effectiveness of oral anticoagulants.)	• Teach the patient to maintain a normal diet, avoiding increases or decreases in vitamin K–rich foods and limit or eliminate alcohol intake. Vitamin K supplements and protein supplement drinks (e.g., Ensure or Boost), which often have vitamin K added, should also be avoided. • Advise patients to avoid excessive intake of alcohol while on oral anticoagulants.
• Assess for any symptoms of hepatitis (e.g., darkening urine, light or clay-colored stools, itchy skin, jaundice of sclera or skin, abdominal pain, especially in the right upper quadrant [RUQ]) in patients receiving oral anticoagulant therapy. (Drug-induced hepatitis is a possible adverse effect of oral anticoagulant therapy.)	• Instruct the patient, family, or caregiver to report any signs of possible hepatitis immediately, especially abdominal discomfort that localizes in the RUQ.
• **Lifespan:** Assess for the possibility of pregnancy before beginning the drug. (Women on anticoagulant therapy will be monitored closely for labor and the possibility of excessive bleeding. Warfarin is a pregnancy category X drug.)	• Instruct female patients who may be considering pregnancy, or are pregnant, to notify their provider before starting the drug. Women taking warfarin should use extra precautions during sex, such as barrier contraceptive measures, to prevent pregnancy.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, equipment needed as appropriate and how to use that equipment, and the required length of medication therapy needed, with any special instructions regarding renewing or continuing the prescription as appropriate.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by return demonstration. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	Teach the patient, family, or caregiver proper self-administration techniques: • Injections of heparin or LMWHs should be administered in the fatty layers of the abdomen or just above the iliac crest, avoiding the periumbilical area by 5 cm (2 in.). • Skin is drawn up (pinched), and the needle is inserted at a 90-degree angle. • Injection is given without aspirating for blood return. • Release the skin and hold slight pressure to the site, but do not massage the area. • Have the patient, family, or caregiver return demonstrate until the proper technique is used and they are comfortable giving the injection. • Teach the patient on oral anticoagulants to take the medication at the same time each day.

Nursing Practice Application for Patients Receiving Pharmacotherapy with Anticoagulants.

Drugs Similar to Dabigatran (Pradaxa)

Other direct thrombin inhibitors include argatroban, bivalirudin, and desirudin. Lepirudin (Refludan) was withdrawn from the market in 2012.

Argatroban (Acova, Novastan): Approved in 2000, argatroban is a synthetic thrombin inhibitor that is given by the IV route for prophylaxis of thrombosis in patients with HIT and to treat or prevent thrombotic events associated with PCI. Unlike dabigatran, which is excreted by the kidneys, argatroban is metabolized and eliminated by the liver and therefore may be used in patients with CKD. Caution must be observed, however, when administering the drug to patients with hepatic impairment. Allergic reactions occur in up to 10% of patients receiving argatroban. Bleeding is the most serious adverse effect and the drug should not be administered to patients with active bleeding. This drug is pregnancy category C.

Bivalirudin (Angiomax): Approved in 2000, bivalirudin is a direct thrombin inhibitor that is available only by the IV route. Bivalirudin is given concurrently with aspirin to reduce the incidence of thromboembolic events associated with HIT and to provide anticoagulation in patients undergoing PCI. Back pain is a common adverse effect of the drug, occurring in about 40% of patients. Nausea, vomiting, hypotension, and headache also occur in a significant number of patients. Bleeding is the most serious adverse effect and the drug should not be administered to patients with active bleeding. Bivalirudin is as effective as heparin and produces a lower incidence of serious bleeding, although it is very expensive. This drug is pregnancy category B.

Desirudin (Iprivask): Made through recombinant DNA technology, desirudin is nearly identical to hirudin and is the only direct thrombin inhibitor administered by the subcutaneous route. It acts by the same mechanism and has the same adverse effects and contraindications as bivalirudin. The drug was approved in 2003 for DVT prophylaxis in patients undergoing hip replacement surgery. Off-label uses include prevention of thromboembolic events in patients with unstable angina and those undergoing PCI. Allergic reactions, including anaphylaxis, are rare. Bleeding is the most serious adverse effect and the drug should not be administered to patients with active bleeding. This drug is pregnancy category C.

Factor Xa inhibitors: Factor Xa inhibitors include betrixaban (Bevyxxa), rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). The four differ somewhat in their pharmacokinetics, but have similar actions and adverse effects. They are approved to treat DVT and pulmonary emboli, as well as to reduce the risk of stroke or embolism in patients with nonvalvular atrial fibrillation. The drugs are well tolerated, with the most common adverse effects being diarrhea, dizziness, and peripheral edema. As with all anticoagulants, abnormal bleeding is a potentially serious adverse effect.

The Factor Xa inhibitors contain a black box warning that epidermal or spinal hematomas may occur in anticoagulated patients receiving neuroaxial anesthesia or spinal puncture. The black box warning also cautions against premature discontinuation of anticoagulants because this places the patient at risk for adverse events. Apixaban is pregnancy category B. Rivaroxaban and edoxaban are category C.

Antiplatelet Drugs

38.7 Antiplatelet drugs provide anticoagulation by reducing the aggregation properties of platelets.

Antiplatelet drugs modify coagulation primarily by interfering with platelet aggregation. Unlike the anticoagulants, which are used primarily to prevent thrombosis in veins, the primary indications for antiplatelet drugs are to prevent clot formation in arteries. The antiplatelet medications are listed in Table 38.5.

Because platelets are a central component of blood hemostasis, reducing the number of platelets or their function can profoundly increase bleeding time. Three groups of drugs are classified as antiplatelet drugs:

- Aspirin
- Adenosine diphosphate (ADP) receptor blockers
- Glycoprotein IIb/IIIa receptor blockers.

Aspirin deserves special mention as an antiplatelet drug. Because it is available OTC, patients may not consider aspirin a potent medication; however, its anticoagulant activity is well documented. Aspirin acts by binding irreversibly to the enzyme cyclooxygenase (COX) in platelets. This binding inhibits the formation of thromboxane A_2, a powerful inducer of platelet aggregation. The anticoagulant effect of a single dose of aspirin may persist for as long as 1 week. Concurrent use of aspirin with other coagulation modifiers should be avoided, unless medically approved. Nursing responsibilities and a prototype feature for aspirin are given in Chapter 41.

38.8 The adenosine diphosphate receptor blockers are antiplatelet drugs prescribed for the prevention and treatment of arterial thrombosis.

Although platelets are simply fragments of cells that have no nucleus, they contain many receptors on their plasma

Table 38.5 Antiplatelet Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
anagrelide (Agrylin)	PO: 0.5 mg qid or 1 mg bid (max: 10 mg/day)	*Nausea, vomiting, diarrhea, abdominal pain, dizziness, headache* Increased bleeding, central nervous system (CNS) effects (dipyridamole), anaphylaxis (aspirin), interstitial lung disease (anagrelide)
aspirin (ASA, acetylsalicylic acid)	PO: 80 mg daily to 650 mg bid	
dipyridamole (Persantine)	PO: 75–100 mg qid as adjunct to warfarin therapy	
vorapaxar (Zontivity)	PO: 2.08 mg/day	
ADP Receptor Blockers		
clopidogrel (Plavix)	PO: 75 mg/day (max: 300 mg/day for life-threatening cases)	*Minor bleeding, dyspepsia, abdominal pain, headache, rash, diarrhea* Increased clotting time, GI bleeding, blood dyscrasias, angina
prasugrel (Effient)	PO: 60-mg loading dose followed by 10 mg/day	
ticagrelor (Brilinta)	PO: 180-mg loading dose followed by 90 mg bid	
Glycoprotein IIb/IIIa Receptor Antagonists		
abciximab (ReoPro)	IV: 0.25 mg/kg initial bolus over 5 min, then 0.125 mcg/kg/min for 12 h (max: 10 mcg/min)	*Dyspepsia, dizziness, pain at injection site, hypotension, bradycardia, minor bleeding* Major hemorrhage, thrombocytopenia
eptifibatide (Integrilin)	IV: 180 mcg/kg initial bolus over 1–2 min, then 2 mcg/kg/min for 24–72 h (max: 180 mcg/kg bolus, 2 mcg/kg/min infusion)	
tirofiban (Aggrastat)	IV: 0.4 mcg/kg/min for 30 min, then 0.1 mcg/kg/min for 12–24 h	
Drugs for Intermittent Claudication		
cilostazol (Pletal)	PO: 100 mg bid	*Dyspepsia, nausea, vomiting, dizziness, myalgia, headache* Tachycardia and palpitations (cilostazol), CNS effects (pentoxifylline), heart failure, MI
pentoxifylline (Trental)	PO: 400 mg tid (max: 1200 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

membranes and their functions are complex. Chemicals such as epinephrine, thromboxane A_2, thrombin, serotonin, and fibrinogen can bind to these receptors and modify coagulation through their interaction with the platelets.

Following vessel injury, platelets become "sticky," bind to exposed collagen, and release substances that recruit additional platelets to the site. One of these chemicals is ADP, whose function is to promote platelet aggregation. The ADP receptor blockers comprise a small group of drugs that irreversibly alter the plasma membrane of platelets. For the remainder of their lifespan, the affected platelets are unable to recognize the chemical signals required for them to aggregate.

Ticagrelor (Brilinta), clopidogrel (Plavix), and prasugrel (Effient) are ADP receptor blockers given PO to prevent thrombi formation in patients who have experienced a recent thromboembolic event such as stroke or MI. The newer drugs in this class, ticagrelor and prasugrel, act more rapidly than clopidogrel and achieve a more consistent and effective antithrombotic effect. Adverse effects among the three drugs are similar.

Drugs affecting platelet aggregation increase the risk of bleeding should the patient sustain trauma or undergo dental or surgical procedures. These drugs are sometimes given concurrently with anticoagulants, which can further increase bleeding risk. Prolonged direct pressure over injection or venipuncture sites may be required to control bleeding. Bleeding lasting more than 10 minutes may require special medical or nursing interventions, such as suturing or applying a sandbag to a venipuncture site that does not stop bleeding.

PROTOTYPE DRUG Clopidogrel (Plavix)

Classification **Therapeutic:** Antiplatelet drug
Pharmacologic: ADP receptor blocker

Therapeutic Effects and Uses: Approved in 1997, clopidogrel is used for the prophylaxis of arterial thromboembolism to reduce the risk of stroke, MI, and death in patients with acute coronary syndrome. For patients with ST-elevation MI, this drug has been shown to reduce the risk of death, reinfarction, or stroke. Clopidogrel has similar anticoagulant activity to aspirin but is more expensive.

Clopidogrel is given PO and has the advantage of once-daily dosing. Inhibition of platelet function may persist for 7 to 10 days after the drug is discontinued. When possible, clopidogrel should be discontinued at least 5 days prior to surgery to avoid excessive bleeding.

Mechanism of Action: Clopidogrel inhibits ADP receptors on platelets and prolongs bleeding time by irreversibly inhibiting platelet aggregation. Clopidogrel itself has little activity; however, it is changed to a highly active metabolite in the liver through extensive first-pass metabolism.

CONNECTIONS: Complementary and Alternative Therapies

Garlic

Description:

Garlic (*Allium sativum*) is a perennial plant in the onion family that can be grown and cultivated worldwide.

History and Claims:

Garlic has been used for centuries by most cultures as a flavoring and as a medicine. Historical uses have included curing deafness and earaches, and treating leprosy and scurvy. Modern claims have focused on cardiovascular uses: treatment of high blood lipid levels, atherosclerosis, and HTN. Other modern claims are that garlic reduces blood glucose levels and has antibacterial and antineoplastic activity.

Standardization:

Substances called alliaceous oils have been isolated from garlic and shown to have pharmacologic activity. Dosage forms include eating prepared garlic oil or the fresh bulbs (cloves) from the plant. In tablet or capsule form, doses range from 1 to 4 g/day. Extracts may be standardized by percent allicin.

Evidence:

Garlic is one of the best-studied herbs. Like most other herbal products, garlic likely has some health benefits, but controlled, scientific studies are lacking and the results are mixed. One of the more rigorous studies, a meta-analysis of 11 randomized controlled trials, found that on the whole, taking garlic daily reduced blood pressure and decreases the aggregation or "stickiness" of platelets, thus producing an anticoagulant effect (Ried, Frank, Stocks, Fakler, & Sullivan, 2008). Subsequent research has found associations between garlic consumption and a reduced incidence of cancer, but that correlation has not been proven in controlled studies (National Center for Complementary and Integrative Health, 2016; University of Maryland Medical Center, 2015).

Garlic is safe for consumption in small and moderate amounts. Patients taking anticoagulant medications should limit their intake of garlic to avoid bleeding complications. Patients with diabetes should monitor their blood glucose levels closely if taking high doses of garlic.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Unknown; unknown if it crosses the placenta or is secreted in breast milk; 94–98% bound to plasma protein
Primary metabolism	Hepatic; metabolized to active metabolite
Primary excretion	Renal 50%; feces 50%
Onset of action	1–2 h
Duration of action	5 days

Adverse Effects: Clopidogrel has approximately the same tolerability as aspirin and adverse effects are rarely severe enough to cause discontinuation of therapy. Although excessive bleeding is a potential adverse effect, it occurs in only about 1% of patients. Older adults are more susceptible to bleeding during therapy and should be carefully monitored. The incidence of GI bleeding is less than that of aspirin. Common adverse effects are flulike syndrome, headache, diarrhea, dizziness, bruising, upper respiratory tract infection, and rash or pruritus. **Black Box Warning:** Because the effectiveness of clopidogrel is dependent on its metabolic activation by CYP450 enzymes, poor metabolizers will exhibit less therapeutic effect and more adverse cardiovascular events.

Contraindications/Precautions: Clopidogrel is contraindicated in patients with active bleeding and should be used with caution in patients at high risk for bleeding, including those with peptic ulcer disease. Severe hepatic disease may impair the ability of the liver to convert the drug to its active metabolite. The drug should be discontinued at least 5 days prior to elective surgery

Drug Interactions: Use with anticoagulants, other antiplatelet drugs, thrombolytics, or NSAIDs, including aspirin, will increase the risk of bleeding. Drugs that inhibit hepatic metabolic enzymes—such as the azole antifungals, protease inhibitors, erythromycin, verapamil, or zafirlukast—may diminish the antiplatelet actions of clopidogrel. Drugs that increase hepatic metabolic enzyme activity, such as barbiturates, rifampin, or carbamazepine, may increase the anticoagulant activity of clopidogrel. **Herbal/Food:** Herbal supplements that affect coagulation such as feverfew, green tea, ginkgo, fish oil, ginger, or garlic may increase the risk of bleeding.

Treatment of Overdose: There is no specific therapy for clopidogrel overdose. Platelet transfusions may be beneficial in preventing hemorrhage.

Pregnancy: Category B.

Nursing Responsibilities: Key nursing implications for patients receiving clopidogrel are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Anticoagulants. Although nursing responsibilities are similar to those for the anticoagulant drugs, bleeding risk is lessened with the antiplatelet drugs.

Drugs Similar to Clopidogrel (Plavix)

Other antiplatelet drugs include anagrelide, dipyridamole, prasugrel, ticagrelor, and vorapaxar. Aspirin also provides anticoagulation by this mechanism and is discussed in Section 38.7. The first ADP receptor blocker approved, ticlopidine (Ticlid), is no longer available in the United States.

Anagrelide (Agrylin): Approved in 1977, anagrelide is an antiplatelet medication used for a very specific indication: to control elevated platelet counts in patients with myeloproliferative neoplasms. Elevated platelet levels in patients with these disorders can increase the risk of thrombosis. Unlike other antiplatelet drugs that reduce platelet aggregation, anagrelide reduces the production of platelets. Use with other antiplatelet drugs such as aspirin increases the risk of bleeding. This drug is pregnancy category C.

Dipyridamole (Persantine): Approved in 1961, the only approved use of dipyridamole is in combination with warfarin for postoperative prophylaxis of thromboembolism in patients following cardiac valve replacement. By itself, dipyridamole provides little antithrombotic protection, but it may be combined with aspirin or warfarin to produce an anticoagulant effect. Dipyridamole acts by a different mechanism than clopidogrel. Rather than blocking ADP receptors, dipyridamole elevates levels of cyclic AMP (cAMP), which is a potent inhibitor of platelet aggregation. Dizziness, abdominal pain, and headache are the most common adverse effects. This drug is pregnancy category B.

Prasugrel (Effient): Prasugrel is an ADP receptor blocker that was approved in 2009 to reduce the risk for thrombotic events in patients with acute coronary syndrome who undergo PCI. Prasugrel is a prodrug that is rapidly metabolized to its active form as it crosses the intestinal mucosa. Antiplatelet effects begin to occur within 30 minutes. Compared to clopidogrel, prasugrel is associated with a reduced risk of adverse cardiovascular events, such as stroke and MI, and it is less prone to interact with other medications. Prasugrel carries a black box warning that it can cause serious and life-threatening bleeding. It should not be used in patients with active bleeding or a history of transient ischemic attack or stroke. Prasugrel should be discontinued at least 7 days prior to expected surgery. This drug is pregnancy category B.

Ticagrelor (Brilinta): Approved in 2011, ticagrelor is a newer coagulation modifier indicated to reduce the risk of thromboembolic events in patients with acute coronary syndrome. In patients with PCI, the drug reduces the risk of stent thrombosis. Like clopidogrel and prasugrel, ticagrelor acts by blocking the ADP receptor on platelets. The most frequent adverse effects are dyspnea and bleeding. Ticagrelor carries a black box warning that the drug can cause serious or fatal bleeding, that it is contraindicated in patients with a history of intracranial hemorrhage or pathologic bleeding, and that it should be discontinued at least 5 days prior to surgery. The black box warning also states that maintenance doses of aspirin should not exceed 100 mg/day because aspirin decreases the effectiveness of ticagrelor. This drug is pregnancy category C.

Vorapaxar (Zontivity): In 2014 the FDA approved vorapaxar, a new type of antiplatelet drug, to reduce the risk for blood clots in patients with a history of MI or other thromboembolic disorders. Given PO, it is the first drug to cause anticoagulation by blocking the protease-activated receptor (PAR-1) on platelets. Like other anticoagulants, its primary adverse effect is increased bleeding risk. Vorapaxar carries a black box warning that it should not be administered to patients with a history of stroke, transient ischemic attack, or intracranial hemorrhage. This drug is pregnancy category B.

38.9 The glycoprotein IIb/IIIa receptor inhibitors are effective antiplatelet drugs for preventing coagulation.

Glycoprotein IIb/IIIa is a receptor found on the surface of platelets. The receptor contains two distinct protein chains, designated IIb and IIIa. Platelets contain a huge number of glycoprotein IIb/IIIa receptors: approximately 50,000 to 80,000 per cell. These receptors serve as docking stations, waiting for signals from chemical messengers that indicate injury may have occurred.

Substances that normally bind to and activate glycoprotein IIb/IIIa receptors include thrombin, von Willebrand's factor (vWF), ADP, and thromboxane A_2. Following activation of the surface glycoprotein, the platelets change shape, bind fibrinogen, and become sticky. Essentially, the platelets develop an enhanced ability to bind to each other, to fibrinogen, and to the exposed collagen of damaged vessels. This process is illustrated in Figure 38.2.

Inhibition of the glycoprotein IIb/IIIa receptor prevents platelet activation and thrombus formation in patients with a recent MI, stroke, and PCI, with or without stent placement. Although these medications are effective antiplatelet drugs, they are very expensive. Another major disadvantage is that they are given only by the IV route. PO forms of these drugs recently entered clinical trials but proved less effective than aspirin in reducing thromboembolic events.

PROTOTYPE DRUG **Abciximab (ReoPro)**

Classification **Therapeutic:** Antiplatelet drug
Pharmacologic: Glycoprotein IIb/IIIa inhibitor

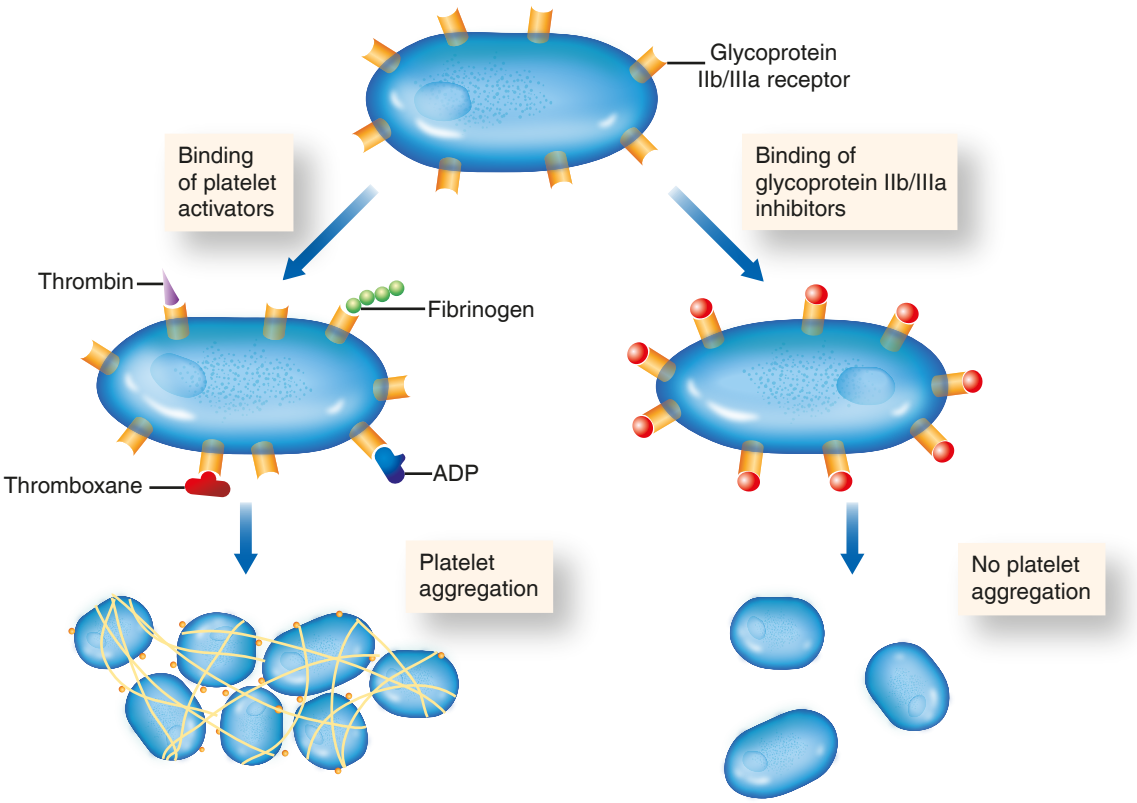

Figure 38.2 Glycoprotein IIb/IIIa receptor activation of platelet function.

Therapeutic Effects and Uses: Abciximab was the first glycoprotein IIb/IIIa inhibitor approved by the FDA in 1994. It is of value in decreasing the incidence of thromboembolic events in patients with acute coronary syndrome, and in conjunction with PCI, both before and after the procedure. Abciximab is only available by IV bolus injection and infusion. It is often given concurrently with aspirin, clopidogrel, or heparin to achieve optimal therapeutic results.

Glycoprotein IIb/IIIa receptor inhibitors act very rapidly: Platelet function is reduced by as much as 90% in just 2 hours. Effects may persist for more than 10 days following discontinuation of the drug.

Mechanism of Action: Abciximab is an antibody fragment that binds to glycoprotein IIb/IIIa receptors on platelets, thus preventing fibrinogen, vWF, and other procoagulants from activating platelets.

Pharmacokinetics:

Route(s)	IV
Absorption	NA
Distribution	Mostly bound to platelets, with very little circulating free; unknown if the drug crosses the placenta or is secreted in breast milk
Primary metabolism	Rapidly destroyed by proteases in plasma
Primary excretion	Unknown
Onset of action	10 min
Duration of action	72 h; half-life: 10–30 min

Adverse Effects: The most common adverse effect of abciximab is abnormal bleeding, which may occur in any body system. Major bleeding occurs in about 10% of patients, with the most common bleeding occurring at the arterial access site. Hypotension may occur secondary to loss of blood. Thrombocytopenia occurs in more than 5% of the patients; thus, blood counts must be periodically monitored during therapy. Anaphylaxis is rare. Back pain and chest pain occur in 11% to 18% of patients taking the drug.

Contraindications/Precautions: Abciximab is contraindicated in patients with active bleeding, recent trauma or surgery, or serious bleeding disorders, or in patients who have conditions that place them at high risk for bleeding. Patients with thrombocytopenia (less than 100,000 cells/mL) should not receive this drug. Patients who have received previous abciximab therapy have a higher risk of anaphylaxis and thrombocytopenia upon reexposure to the drug.

Drug Interactions: Concurrent administration of abciximab with heparin, other anticoagulants, or thrombolytics

increases the risk of bleeding. Abciximab is contraindicated when IV dextran has been used before or during PCI because bleeding risk is increased. Oral anticoagulants should be discontinued at least 7 days prior to abciximab use, unless the PT is less than 1.2 times control. **Herbal/Food:** Herbal supplements, such as white willow, that contain salicylates may create an additive effect with antiplatelet drugs. Ginkgo and feverfew should also be avoided.

Pregnancy: Category C.

Treatment of Overdose: There is no specific therapy for abciximab overdose. Platelet transfusions may be beneficial in preventing hemorrhage.

Nursing Responsibilities: Key nursing implications for patients receiving abciximab are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Anticoagulants. Although nursing responsibilities are similar to those for the anticoagulant drugs, bleeding risk is lessened with the antiplatelet medications.

Drugs Similar to Abciximab (ReoPro)

The two other glycoprotein IIb/IIIa inhibitors are eptifibatide and tirofiban.

Eptifibatide (Integrilin): Approved in 1998, eptifibatide is a synthetic drug administered by the IV route that is highly specific to binding the glycoprotein IIa/IIIb receptor. Unlike abciximab, the binding of eptifibatide is rapidly reversible and a large amount of unbound drug may circulate in the plasma. In overdose situations, platelet infusions may be of little benefit because the unbound drug will quickly occupy glycoprotein IIb/IIIa receptors on the new platelets to prevent their activation by procoagulants. The drug is indicated for the prevention of thromboembolic events in patients with acute coronary syndrome and those undergoing PCI. Aspirin or heparin is usually administered concurrently with eptifibatide. Should platelet count decrease to less than 100,000/mm^3, the aspirin or heparin is discontinued. The kidneys primarily excrete the drug; thus, caution should be used in patients with CKD. Bleeding at the arterial access site is the most common adverse effect. This drug is pregnancy category B.

Tirofiban (Aggrastat): Like eptifibatide, tirofiban is an IV synthetic drug highly selective for binding the glycoprotein IIb/IIIa receptor in a rapid, reversible manner. The drug is indicated for the prevention of thromboembolic events in patients with acute coronary syndrome and those undergoing PCI. Aspirin or heparin is usually administered concurrently. Its duration of action (4–8 hours) is longer than that of eptifibatide but still considerably less than abciximab's duration. The kidneys primarily excrete the drug; thus, caution should be used in patients with CKD. Tirofiban is contraindicated in patients with platelet counts less than 100,000/mm^3. Bleeding secondary to the drug's antiplatelet effect is the most common adverse effect. This drug is pregnancy category B.

Drugs for Intermittent Claudication

38.10 Coagulation modifiers can be used to treat symptoms of intermittent claudication.

Intermittent claudication (IC) is pain or cramping in the lower legs that worsens with walking or exercise. IC is the primary symptom of peripheral vascular disease (PVD), in which progressive atherosclerosis of vessels causes a lack of oxygen to major muscles of the leg. Factors that cause angina pectoris are those that also worsen PVD: diabetes, smoking, and HTN. Exercise, smoking cessation, reduction of blood pressure, and blood glucose management are important nonpharmacologic therapies for IC. Medications are used to reduce symptoms and increase pain-free walking time, although none are able to reverse the underlying cause of PVD.

Pentoxifylline (Trental) and cilostazol (Pletal) are specifically approved for IC, although statins, aspirin, and clopidogrel may also be used in managing the condition. Pentoxifylline is a unique drug with anticoagulation properties that acts on red blood cells to reduce their viscosity and increase their flexibility, allowing them to enter vessels that are partially occluded and prevent thrombi formation. It also inhibits platelet aggregation. It is given PO to increase the microcirculation in patients with IC. Two to three months of therapy with pentoxifylline may be necessary before improvement in IC symptoms is noted.

Cilostazol is indicated to improve walking distance before the onset of IC pain. Given PO, the drug has antiplatelet and antithrombotic activity. Cilostazol should be used with care in patients with cardiac disease because it may cause palpitations and tachycardia.

38.11 Fibrinolysis is a process that removes thrombi.

The goal of hemostasis has been achieved once a blood clot is formed and the body is protected from excessive hemorrhage. The process of hemostasis, however, is a positive feedback mechanism in which small amounts of clotting lead to additional clotting. Without an effective means of controlling the process, clotting would spread far beyond the zone of injury and, indeed, occur throughout the vascular system until existing clotting factors were used up. Furthermore, fibrin clots can prevent blood flow to the

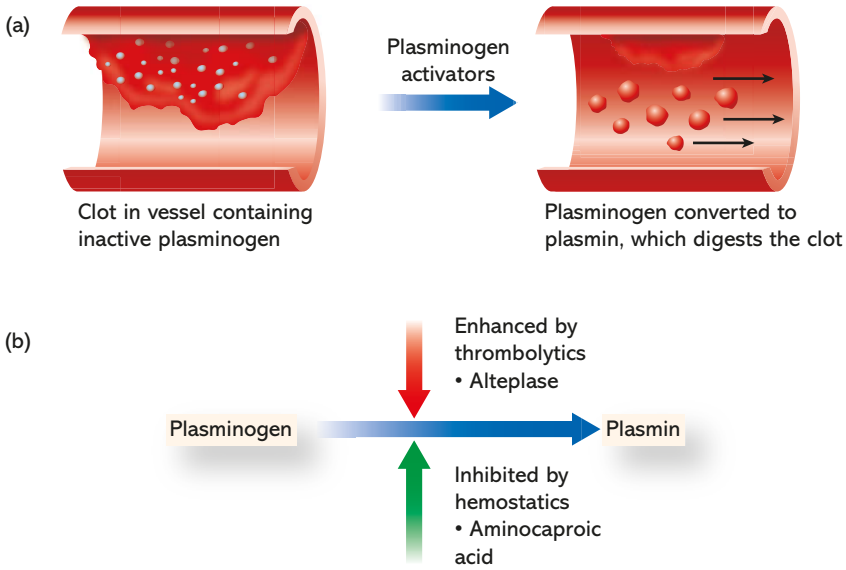

Figure 38.3 Steps in fibrinolysis: (a) Clot dissolves when plasminogen is converted to plasmin. (b) Thrombolytics enhance fibrinolysis; hemostatics inhibit fibrinolysis.

surrounding area. Circulation must eventually be restored so that the tissue can resume normal activities.

Fibrinolysis is the physiologic process that limits clot formation and removes existing clots. During the time a fibrin clot is forming, the surrounding damaged tissue secretes anticoagulant chemicals that limit the spread of the clot to the area of injury. Removal of the clot begins about 24 to 48 hours following clot formation and continues until it is dissolved.

Like hemostasis, fibrinolysis involves several cascading steps. The process is initiated by plasminogen activators. The two best studied plasminogen activators are tissue-plasminogen activator (tPA), which is secreted by the endothelium of blood vessels, and urokinase-plasminogen activator (uPA), secreted by the kidney. The function of tPA and uPA is to convert the inactive protein **plasminogen**, which is present in the fibrin clot, to its active form called plasmin. Plasmin is an enzyme that attacks the fibrin strands, breaking them into small fragments that are soluble and no longer able to hold the clot together. The procoagulation factors fibrinogen, prothrombin, and clotting Factors V and XII are also inactivated by plasmin. The body normally regulates fibrinolysis such that unwanted fibrin clots are removed, while fibrin present in wounds is left to maintain hemostasis. The steps of fibrinolysis are shown in Figure 38.3.

Thrombolytics

38.12 Thrombolytics are used to dissolve existing intravascular clots in patients with myocardial infarction and stroke.

It is often mistakenly believed that the purpose of anticoagulants such as heparin or warfarin is to digest clots. This is not the case. A totally different type of drug is needed for this goal. The thrombolytics, listed in Table 38.6, are administered very differently from the anticoagulants and antiplatelet drugs, and they produce their effects by different mechanisms. Thrombolytics are prescribed for disorders in which an intravascular clot has already formed, such as acute MI, pulmonary embolism, acute ischemic stroke, and DVT.

Thrombolytics promote fibrinolysis by converting plasminogen to plasmin. The enzyme plasmin then digests fibrin, breaking it into small soluble fragments. In essence, the thrombolytics simply accelerate the normal process of clot removal in the body. The thrombolytics are also called fibrinolytics, owing to their destructive effects on fibrin. The therapeutic outcomes of thrombolytic therapy are strongly dependent on the time frame in which they are administered. They are considerably more effective when given as soon as possible after the clot has formed—preferably within 4 hours. The mechanism of action of the thrombolytics is shown in a Pharmacotherapy Illustrated feature in Chapter 35.

Thrombolytics are nonspecific and have a very narrow margin of safety between dissolving "normal" and "abnormal" clots. Vital signs must be monitored continuously and any signs of bleeding may call for discontinuation of

Table 38.6 Thrombolytics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
alteplase (Activase)	IV: Begin with 60 mg and then infuse 20 mg/h over next 2 h	*Superficial bleeding at injection sites, allergic reactions* Serious internal bleeding, intracranial hemorrhage, HTN
reteplase (Retavase)	IV: 10 units over 2 min; repeat dose in 30 min	
streptokinase (Streptase)	IV: 250,000–1.5 million units over 60 min	
tenecteplase (TNKase)	IV: 30–50 mg infused over 5 sec	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

therapy. Patients with recent trauma, active bleeding, or surgery may have "fresh" clots that could be disrupted by the action of these drugs. Thus, they may not be candidates for thrombolytic therapy due to the risk of bleeding.

The use of thrombolytics in older patients is controversial. Research has shown that thrombolytic therapy in patients older than age 75 does not decrease mortality from the MI or stroke the patient has experienced. The risks of serious bleeding following drug administration may outweigh the therapeutic benefits. Patients older than age 75 must be carefully screened for contraindicated conditions, such as uncontrolled HTN, recent ischemic stroke, or current use of anticoagulants.

Because these medications are rapidly destroyed in the bloodstream, discontinuing the infusion quickly terminates their thrombolytic activity. After the clot is successfully dissolved with the thrombolytic, anticoagulant therapy is initiated to prevent the reformation of clots. Since the discovery of streptokinase, the first drug in this class, there have been several subsequent generations of thrombolytics. The newer drugs such as tenecteplase (TNKase) are more fibrin specific and are reported to have fewer adverse effects than streptokinase.

The FDA recommends that TNK and tPA not be used as abbreviations for thrombolytics because this has led to numerous medication errors. Instead, the full generic or trade name should be used on all prescriptions (FDA, 2015).

PROTOTYPE DRUG Alteplase (Activase)

Classification **Therapeutic:** None
Pharmacologic: Thrombolytic, fibrinolytic

Therapeutic Effects and Uses: Produced through recombinant DNA technology, alteplase is identical to human tPA. Approved in 1987, alteplase is a preferred drug for the treatment of thrombotic stroke, acute MI, and acute massive pulmonary embolism. Activase (Cathflo Activase) is approved to restore function to central venous access devices. Although not routinely indicated for treating venous clots, the drug may be used in cases where a limb is at risk of gangrene and possible amputation due to vessel occlusion. Like other drugs in this class, it is administered by the IV route.

To achieve maximum effect, alteplase therapy should begin within 6 hours of onset of MI symptoms and within 3 hours of thrombotic stroke. Therapy should be initiated only after intracranial hemorrhage has been ruled out. Alteplase elicits fewer allergic reactions than streptokinase.

Mechanism of Action: The primary action of alteplase is to convert plasminogen to plasmin, which then dissolves fibrin clots. Alteplase is more fibrin specific than streptokinase but less so than some of the other thrombolytics. The drug also degrades the procoagulant Factors V and VIII and lowers the circulating amounts of fibrinogen and plasminogen.

Pharmacokinetics:

Route(s)	IV
Absorption	NA
Distribution	Unknown; unknown if the drug crosses the placenta or is secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Immediate
Duration of action	3 h; half-life: less than 10 min

Adverse Effects: The most common adverse effect of alteplase is bleeding, which may occur superficially at catheter access or needle puncture sites, or internally. Signs of bleeding such as spontaneous ecchymoses, hematomas, or epistaxis should be reported to the healthcare provider immediately. Fibrinolysis of clots in the coronary arteries may cause transient dysrhythmias. Angioedema and intracranial bleeding are rare, though serious, adverse effects.

Contraindications/Precautions: History of stroke within the past 3 months, recent trauma or surgery, active bleeding, severe uncontrolled HTN, intracranial neoplasm, and arteriovenous malformation are contraindications to the use of alteplase. Whenever possible, parenteral injections of other drugs should be avoided during alteplase therapy to avoid an increased risk of bleeding at the injection site. Alteplase should not be administered if the patient is on warfarin and INR is greater than 1.7 or PT is greater than 15 seconds.

Drug Interactions: Concurrent use with anticoagulants, antiplatelet drugs, or NSAIDs, including aspirin, will increase the risk of bleeding. Intravenous nitroglycerin enhances the hepatic degradation of alteplase, reducing its ability to dissolve clots. **Herbal/Food:** Use with supplements that affect coagulation such as feverfew, green tea, ginkgo, fish oil, ginger, or garlic should be avoided, because they may increase the risk of bleeding.

Pregnancy: Category C.

Treatment of Overdose: There is no specific treatment for overdose. Excessive bleeding may require the administration of blood, blood products, or hemostatics.

Nursing Responsibilities: Key nursing implications for patients receiving alteplase are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Thrombolytics.

Drugs Similar to Alteplase (Activase)

Other thrombolytics include reteplase, streptokinase, and tenecteplase.

Reteplase (Retavase): Approved in 1996, reteplase is used to treat acute MI with ST elevation due to coronary artery thrombosis and also acute peripheral arterial thromboembolism. The drug is a modified form of human tPA produced through recombinant DNA technology. Reteplase has the same adverse effects and contraindications as alteplase. It has a more rapid onset of action than alteplase, perhaps because reteplase is better able to reach the inside of clots. Like alteplase, it is selective for lysing fibrin and the most serious adverse effect is bleeding. This drug is pregnancy category C.

Streptokinase (Streptase): Streptokinase, the first approved thrombolytic, is indicated for the treatment of acute MI with ST elevation due to coronary artery thrombosis, acute pulmonary embolism, DVT, or arterial thromboembolism. Streptokinase is obtained from beta-hemolytic streptococci and is less fibrin specific than the other drugs in this class; the drug also breaks down fibrinogen and other clotting factors. The drug may be administered by IV infusion into the general circulation or introduced via catheter directly at a site of occlusion.

Although it is much less expensive than other thrombolytics, streptokinase is considered a second-line drug because it is less effective at opening arteries. Allergic reactions such as urticaria, flushing, and headache occur in 1% to 4% of patients, although anaphylaxis is rare. The body develops antistreptokinase antibodies, which can cause resistance to the effects of the drug. Streptokinase shares the same contraindications and adverse effects with the other thrombolytics. The most common adverse effect is abnormal bleeding. Fever occurs in many patients and is managed by administering acetaminophen. This drug is pregnancy category C.

Tenecteplase (TNKase): Approved in 2000 for the treatment of acute MI with ST elevation with coronary artery thrombosis, tenecteplase is a modified form of human tPA. The drug has similar indications, contraindications, and adverse effects to alteplase but has greater fibrin specificity and a longer half-life. This may be responsible for a slightly lower incidence of noncerebral bleeding with tenecteplase. Another advantage is that it can be administered using a single, 5-second bolus injection. Allergic reactions are rare. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Thrombolytics

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular, peripheral vascular disease, respiratory, neurologic (including recent head injury), recent surgeries or injuries, hepatic disease, CKD, diabetes, peptic ulcer disease, recent childbirth (within 10 days), or the possibility of pregnancy. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs, ECG, and breath sounds. Assess presence, quality, location of angina, and for presence of dyspnea or chest pain. Assess neurologic status.
- Evaluate laboratory findings (aPTT, PT/INR, bleeding time), CBC and platelets, renal and liver function studies, ABGs as appropriate, and lipid profiles. Support the patient during other required tests (e.g., CT or MRI prior to thrombolytic therapy for stroke).
- Establish all monitoring equipment and necessary lines, or arrange for their insertion (e.g., ECG monitoring, IV, Foley catheter, arterial line).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Continue frequent assessments for therapeutic effects (e.g., angina has diminished significantly or is eliminated, ECG findings within normal limits, respiratory effort and ABGs significantly improved).
- Continue frequent monitoring of appropriate laboratory values (e.g., Hgb, Hct, platelets, RBC, urinalysis, ABGs).
- Monitor vital signs and ECG every 15 min during the first hour of infusion, and then every 30 min during the remainder of the infusion. Continue to monitor vital signs every 30 min to 1 h for the first 8 h following the infusion.
- Assess for adverse effects: bleeding at IV sites, wounds, excessive ecchymosis, petechiae, hematuria, black or tarry stools, rectal bleeding, coffee-ground emesis, epistaxis, bleeding from gums, hemoptysis, dysrhythmias, and signs of occult bleeding: pallor, dizziness, hypotension, tachycardia, abdominal pain, areas of abdominal wall swelling or firmness, lumbar pain, or decreased LOC.
- Monitor neurologic status frequently, especially if thrombolytics are used for stroke.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects, e.g., previous angina has diminished significantly or is eliminated and ECG findings show decrease in ischemia. (Thrombolytics rapidly dissolve existing clots to allow reperfusion of the affected area.)	• Teach the patient, family, or caregiver about all procedures and their necessity prior to beginning thrombolytic therapy. • To allay anxiety, teach the patient, family, or caregiver the rationale for all equipment used.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Post-therapy, encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol and caffeine intake, and smoking cessation. Provide for dietitian consultation as needed. (Smoking increases platelet aggregation and promotes the formation of thrombi. Healthy lifestyle changes will support and minimize the need for future drug therapy.)	• Encourage the patient to adopt a healthy lifestyle of low-fat food choices, increased exercise, decreased alcohol consumption, and smoking cessation. Provide for appropriate consultation (e.g., dietitian) as needed.
Minimizing adverse effects: • Monitor frequently for signs and symptoms of excessive visible bleeding: bleeding at IV sites, wounds, hematuria, rectal bleeding, coffee-ground emesis, bleeding from gums, hemoptysis, bleeding at previous recent incisional sites; and assess for occult bleeding: pallor, hypotension, tachycardia, dizziness, sudden severe headache, lumbar pain, and decreased LOC. (Bleeding is the most common adverse effect of thrombolytic therapy. Frequent assessment for both visible and occult bleeding is necessary to prevent extensive hemorrhage and to start early corrective treatment as appropriate. Bleeding risk is elevated up to 2–4 days post-treatment and if the patient is maintained on anticoagulant or antiplatelet therapy post-thrombolytics.)	• Allay anxiety by reassuring the patient and explaining the rationale for frequent monitoring. Provide adequate pain relief as appropriate.
• Monitor vital signs and ECG every 15 min during first hour of infusion, and then every 30 min during remainder of the infusion. Continue to monitor vital signs every 30 min to 1 h for the first 8 h following the infusion. Report any dysrhythmias immediately. (Frequent monitoring of vital signs assesses for adverse effects of the drug, including hypotension and tachycardia associated with bleeding, and for dysrhythmias. Dysrhythmias may occur postperfusion of the coronary arteries or may be associated with adverse effects. Further treatment may be necessary.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring. • Teach the patient to report any palpitations, dyspnea, or angina postinfusion.
• Maintain the patient on bed rest and with limited activity during the infusion. (Limited physical activity and bed rest decrease the chance for bruising, injury, and bleeding.)	• Provide explanation and rationale that activity will be limited during the infusion and for up to 8 h post-treatment.
• Monitor neurologic status frequently, especially if thrombolytics are used for stroke. (A sudden change in neurologic status or sudden severe headache is a possible sign of an intracranial bleed with increased intracranial pressure.)	• To allay possible anxiety, teach the patient, family, or caregiver the rationale for the frequent assessments and provide reassurance. • Instruct the family to report immediately any change in the patient's mental status or LOC during the postinfusion period.
• Avoid invasive procedures during infusion and up to 8 h postinfusion when possible. (Any puncture site or site of invasive procedure will create an additional site for bleeding. Whenever an invasive procedure must be used, e.g., ABGs, the site must be maintained under pressure for 30 min or longer to prevent hemorrhage.)	• Teach the patient that after any required procedures, pressure will be maintained on the site for a prolonged period of time.
• Continue to monitor laboratory work (Hgb, Hct, platelet counts, and bleeding time) frequently post-treatment. Periodic CBC and ABGs may also be monitored. Risk of bleeding remains high for 2–4 days postinfusion.	• Provide explanation for the need for activity restriction and frequent monitoring during this time.
Patient understanding of drug therapy: • Use opportunities during administration of thrombolytic therapy to explain the rationale for drug therapy, desired therapeutic outcomes, required monitoring for adverse effects, and precautions that will be taken during the infusion and during the immediate postinfusion time period. (Using time during nursing care helps to reassure the patient and allay anxiety.) • Provide support and reassurance to family and caregivers during the time of treatment. (Thrombolytics are used to treat potentially life-threatening conditions. Providing support, reassurance, and appropriate referrals, e.g., pastoral care or social service support, assists family members in a stressful situation.)	• The patient, family, or caregiver should have an understanding of the rationale behind thrombolytic therapy, equipment, and monitoring that will be used, and the care required in the postinfusion period. • Allow family members time to discuss fears and concerns, and provide referral to support and ancillary providers as appropriate.
Patient self-administration of drug therapy: • Provide education during the postinfusion period about required medical care follow-up, postinfusion drug therapy (e.g., anticoagulants or antiplatelet drugs), and lifestyle changes. (Using time during nursing care helps to reinforce teaching and assess for any questions or concerns the patient or family may have.)	• Teach the patient, family, or caregiver in the proper self-administration techniques of anticoagulants or antiplatelet drugs as appropriate.

Hemostatics

38.13 Hemostatics are used to promote the formation of clots.

The hemostatics, or antifibrinolytics, have an action opposite to that of anticoagulants: to shorten bleeding time. Although their mechanisms differ, all drugs in this class prevent fibrin from dissolving, thus enhancing the stability of the clot and preventing excessive bleeding. The hemostatics, listed in Table 38.7, have very specific indications, and none are commonly prescribed.

Aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron, Lysteda) are hemostatics that are administered IV. Injection sites should be monitored frequently for thrombophlebitis and extravasation. These drugs may affect muscles, causing wasting and weakness. High doses can promote the formation of abnormal clots. Chest pain and shortness of breath may indicate pulmonary thrombus or embolus. Use is contraindicated in patients with DIC or severe CKD.

PROTOTYPE DRUG Aminocaproic Acid (Amicar)

Classification **Therapeutic:** Drug for shortening bleeding time
Pharmacologic: Hemostatic, antifibrinolytic

Therapeutic Effects and Uses: Approved in 1982, aminocaproic acid is prescribed for conditions where there is excessive hemorrhage due to clots being dissolved rapidly or prematurely. Excessive fibrinolysis is associated with conditions such as aplastic anemia, hepatic cirrhosis, postoperative cardiac surgery, and in certain carcinomas. It is most commonly prescribed following surgery to reduce postoperative bleeding. Patients with hemophilia A (see Section 38.14) may receive aminocaproic acid immediately following dental procedures to control bleeding. The combination of aminocaproic acid with desmopressin (DDAVP) has been used to reduce postoperative bleeding in patients undergoing cardiopulmonary bypass.

During acute hemorrhage, aminocaproic acid can be given IV to reduce bleeding in 1 to 2 hours. It is also available in tablet form. The therapeutic serum level is 100 to 400 mcg/mL.

Mechanism of Action: Aminocaproic acid occupies binding sites on plasminogen and plasmin. This effectively prevents digestion of the fibrin clot by plasmin.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Rapidly absorbed from GI tract
Distribution	Widely distributed; unknown if it crosses the placenta or is secreted in breast milk
Primary metabolism	Unknown
Primary excretion	Renal
Onset of action	1–2 h
Duration of action	3–4 h

Adverse Effects: Aminocaproic acid is well tolerated and adverse effects are generally mild. By inhibiting fibrinolysis, the incidence of thrombosis may increase. Myopathy is an uncommon adverse effect that requires monitoring because the drug may lead to rhabdomyolysis. Rapid IV administration may cause hypotension or bradycardia.

Contraindications/Precautions: Since aminocaproic acid tends to stabilize clots, it should be used cautiously in patients with a recent history of thromboembolic disease, including those with DIC. Aminocaproic acid is contraindicated in patients with urinary tract bleeding because the drug promotes the formation of clots in the renal pelvis or ureters that may cause obstruction. Caution

Table 38.7 Hemostatics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aminocaproic acid (Amicar)	IV: 4–5 g for 1 h, then 1–1.25 g/h until bleeding is controlled	*Allergic skin reactions, nausea, sinus and nasal symptoms, headache* Anaphylaxis, thrombosis, bronchospasm, nephrotoxicity
desmopressin (DDAVP, Stimate)	IV: 0.3 mcg/kg infused over 15–30 min Intranasal: 300 mg (1 spray per nostril)	*Headache, dizziness, flushing, nosebleed, mild abdominal pain* Hyponatremia, thrombosis
thrombin (Evithrom, Recothrom, Thrombinar)	Topical: Amount varies based on the size of the treated area	*Incision-site complications, pruritus, nausea* Antibody development, anaphylaxis, atrial fibrillation
tranexamic acid (Cyklokapron, Lysteda)	PO: Two 650-mg tablets tid for a maximum of 5 days IV: 10 mg/kg, tid or qid, for 2–8 days	*Headache, nasal and sinus symptoms, back and abdominal pain* Anaphylaxis, thromboembolic events

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

must be used when administering the drug to patients with serious CKD because the drug may accumulate to toxic serum levels.

Drug Interactions: Aminocaproic acid antagonizes the action of thrombolytic drugs. Hypercoagulation may occur with concurrent use of estrogens and oral contraceptives. In individuals with hemophilia, concurrent administration of aminocaproic acid with Factor IX increases the risk of thrombosis and acute MI. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose may lead to hypotension and renal failure. No treatment for overdose is known, although hemodialysis or peritoneal dialysis may be used to remove the drug.

Nursing Responsibilities:

- Check IV site frequently for extravasation or thrombophlebitis and immediately change the site if this occurs.
- Monitor laboratory tests for creatine phosphokinase (CPK) activity, and obtain urinalyses for early detection of myopathy. Report fever, myalgia, reddish-brown urine, or decrease in urine output to the healthcare provider.
- Observe for signs of thrombophlebitis or embolism. If signs develop, immediately discontinue the drug and notify the provider.
- Monitor vital signs and urine output throughout therapy and for up to 24 hours post-therapy.

Lifespan and Diversity Considerations:

- Monitor renal function laboratory tests more frequently with the older adult because normal changes related to aging or the development of myopathy or rhabdomyolysis may increase the risk of renal failure.

Patient and Family Education:

- Immediately report any of the following to the healthcare provider: difficulty urinating, reddish-brown urine, arm or leg pain, chest pain, difficulty breathing, bleeding, clotting, dizziness, drowsiness, confusion, or convulsions.
- Make position changes slowly when moving from a lying to a standing position to prevent dizziness and possible fainting.
- Observe for increased toxicity with oral contraceptives and estrogen.
- Immediately notify the healthcare provider of any known or suspected pregnancy.
- Do not breastfeed while taking this drug without approval of the healthcare provider.

Drugs Similar to Aminocaproic Acid (Amicar)

Other hemostatics include desmopressin, thrombin (recombinant), and tranexamic acid.

Desmopressin (DDAVP, Stimate): Approved in 1978, DDAVP differs from other hemostatics in being a hormone similar to vasopressin (antidiuretic hormone [ADH]), a drug that promotes the renal conservation of water. As a hemostatic, it is approved for the treatment of spontaneous bleeding, trauma-induced hemorrhage or bleeding prophylaxis in patients with hemophilia A, or von Willebrand's disease type 1 with Factor VIII activity. The drug may be given parenterally in acute care scenarios, or by the nasal route (Stimate) for prophylaxis. Because desmopressin inhibits diuresis, caution must be used to prevent water intoxication. Headache and facial flushing are common adverse effects of the intranasal formulation. Tolerance rapidly develops to the actions of desmopressin, although this is usually not a problem when the drug is used to treat hemorrhage because only one to two doses are needed. Desmopressin has uses beyond hemostasis that include the control of excessive or nocturnal urination (enuresis) and polydipsia in patients with diabetes insipidus. This drug is pregnancy category B.

Thrombin, topical (Evithrom, Recothrom, Thrombinar): Topical thrombin is applied with a spray or gelatin sponge to areas that are oozing blood and for minor bleeding from capillaries. The drug is not to be used for serious arterial bleeding or bleeding over large areas. Care must be taken not to inject this drug or to allow systemic absorption due to the risk of thrombi formation.

Thrombin-JMI is an older form of thrombin prepared from cow blood. Allergic reactions may occur in patients hypersensitive to cow products. Approved by the FDA in 2007, human thrombin (Evithrom) is prepared from human plasma. Although screened and treated to inactivate viruses, products obtained from human plasma carry a small risk for transmission of infectious agents, such as viruses and the Creutzfeldt–Jakob disease agent. In 2008 the FDA approved thrombin (recombinant) (Recothrom), the first recombinant formulation of thrombin. The topical thrombins are pregnancy category C drugs.

Tranexamic acid (Cyklokapron, Lysteda): Like aminocaproic acid, tranexamic acid produces an antifibrinolytic effect by inhibiting plasminogen and plasmin activity. The drug was first approved in 1986 as an IV medication to reduce or prevent bleeding in patients with hemophilia who are undergoing dental procedures. In 2009, the PO form of the drug (Lysteda) was approved for the treatment of excessive menstrual bleeding. Because the drug inhibits clot removal, patients must be monitored carefully for signs and symptoms of thromboembolism. Taking Lysteda

concurrently with hormonal contraceptives increases the risk of thromboembolic adverse effects. The drug is 8 to 10 times more potent and has a longer half-life than aminocaproic acid. Adverse effects are similar to those of aminocaproic acid. Tranexamic acid is pregnancy category B.

Drugs for Hemophilia

38.14 Hemophilia is treated by replacing the missing clotting factor(s) or by inhibiting coagulation.

Hereditary disorders of coagulation are relatively rare and may be caused by deficiency in any blood factor in the coagulation cascade. Symptoms of congenital coagulation disorders manifest as bleeding in muscles or weight-bearing joints, ecchymoses, epistaxis, gingival bleeding, and abnormally long bleeding times following trauma or surgery. Joint bleeding causes chronic inflammation and may result in permanent deformity and loss of mobility.

Some patients have mild forms of hemophilia, exhibiting no symptoms of excessive bleeding until they experience major trauma or surgery. The most severe forms of these disorders, however, are diagnosed shortly after birth and require a lifetime of lifestyle adjustment and pharmacotherapy. Because symptoms associated with the different clotting disorders are nonspecific, diagnosis requires laboratory assays for each of the clotting factors to determine which deficiency is causing the disorder.

The pharmacotherapy of hereditary coagulation disorders has resulted in a remarkable change in the lifespans of afflicted patients. Prior to 1960, the average lifespan of a male with severe hemophilia A was 11 years; the lifespan is now 50 to 60 years.

PharmFACT

Hemophilia A is the most common X-linked genetic disease. Of the 20,000 people with hemophilia A in the United States, about 50% to 60% have the most severe form of the disease (Zaiden, 2016).

Hemophilia A: Lack of clotting Factor VIII results in hemophilia A, which accounts for approximately 80% of all hemophilia. Adequate amounts of Factor VIII are necessary to activate Factor X in the intrinsic coagulation pathway. Because the gene for Factor VIII is carried on the X chromosome, hemophilia A is a sex-linked disease with nearly all cases occurring in males. Females are asymptomatic carriers. Remarkably, patients may have a 75% reduction in the amount of Factor VIII in the blood and yet have no major symptoms. Those with 1% or less of Factor VIII have severe forms of the disease.

The traditional treatment for hemophilia A is administration of fresh frozen plasma. Plasma obtained from blood donors contains all the necessary components to replace the missing clotting factor(s). Unfortunately, contamination of blood products with the human immunodeficiency virus (HIV), hepatitis B, and hepatitis C in the early 1980s infected most patients with hemophilia and resulted in a significant percentage of deaths in transfusion recipients. Although all donated blood is screened for viral pathogens, fresh frozen plasma is now rarely used to treat hemophilia due to a small risk of viral contamination.

Hemophilia A is now treated with the administration of a concentrated solution of Factor VIII. A large number of products are available, and trade names include Advate, Alphanate, Bioclate, Helixate, Humate, Hyate, Koate, Kogenate, Kovaltry, Monarc, Monoclate, NovoEight, Nuwiq, Recombinate, ReFacto, Xuriden, and Xyntha. Factor VIII products differ in purity and whether they are derived from plasma or through recombinant DNA technology. Factor concentrates were once obtained by pooling the plasma from human donors, but this has been replaced by creating ultra-high-purity factors through recombinant DNA technology to lower the risk of viral contamination. There is still a very small risk of viral contamination and allergic reaction because human cells and albumin are used to prepare some of the recombinant DNA products. Most factor concentrates are subjected to dry heat, vapor heat, solvent detergent, or a monoclonal antibody to remove any viruses that may remain.

Factor VIII therapy in people with hemophilia is indicated for acute bleeding due to trauma and to prevent perioperative bleeding associated with medical and surgical procedures. Prompt and early therapy is required for acute bleeding events. A typical regimen for a bleeding episode includes an initial bolus dose followed 8 hours later by a second dose. Subsequent doses are administered every 12 hours until a target blood level of Factor VIII is reached: 30% to 50% of normal level for minor bleeding episodes and 100% for major bleeding. Some regimens substitute a continuous infusion of the drug, rather than bolus doses.

Patients with severe hemophilia A may receive prophylactic therapy with Factor VIII with the goal of preventing chronic joint damage and disability. For prophylaxis, a typical regimen is 10 to 20 international units/kg of Factor VIII given 3 times per week. The target level for Factor VIII prophylaxis ranges from 1% to 5% of normal. To be most effective, therapy should begin before joint damage has occurred, usually prior to age 2. Prophylactic therapy is very expensive and must be continued throughout the patient's lifespan. A central venous access device may be installed to allow more convenient dosing.

Adverse reactions to Factor VIII administration are uncommon. Flushing, headache, dyspnea, and urticaria may signal an allergic reaction. Anaphylaxis is possible, though rare. About 30% of patients will develop antibodies (called inhibitors) to Factor VIII that can significantly

decrease the therapeutic effect of the drug. Patients who experience this inhibition may receive higher doses of Factor VIII or they may receive activated Factor VIIIa. Factor VIIIa is very expensive and is used only when medically necessary.

Desmopressin is an alternative therapy for treating minor bleeding episodes in patients with mild hemophilia A. Available by infusion or intranasal spray, desmopressin causes the release of Factor VIII and vWF from storage sites within the body. The drug can cause a two- to fourfold increase in Factor VIII levels. Desmopressin therapy is usually limited to 2 to 3 days because repeated administration results in a diminished response. If desmopressin is used for a minor surgical procedure, a test dose is usually administered 1 week prior to surgery to determine if the patient is responsive to the drug. In adults with hemophilia, 10% to 20% of patients will not respond to desmopressin therapy. Those with severe forms of the disease have no internal storage depots of Factor VIII or vWF; thus, the drug will be ineffective in these patients.

Other therapies for hemophilia A include the hemostatic drugs aminocaproic acid and tranexamic acid. These drugs are primarily used for short-term therapy to reduce bleeding related to dental procedures.

Hemophilia B: Hemophilia B, or Christmas disease, is caused by a deficiency of Factor IX, and comprises about 20% of those with hemophilia. Factor IX, in conjunction with activated Factor VIII, is required for the activation of Factor X in the coagulation cascade. Like Factor VIII, the gene for Factor IX is on the X chromosome. Thus symptomatic disease occurs predominantly in males. The disease is much less common than hemophilia A, but symptoms of excessive bleeding are the same. Laboratory testing is necessary to distinguish between the two diagnoses.

Treatment of hemophilia B is through replacement therapy with Factor IX. Like Factor VIII, fresh frozen plasma and pooled factor concentrates were historically used to supply the missing clotting factor. The development of a recombinant form of Factor IX in 1996, however, removed the risk of viral contamination and has become the therapy of choice for this disorder. The drug is administered for treating and preventing excessive bleeding events such as acute trauma or surgery. Products containing recombinant Factor IX include Alprolix, BeneFIX, Idelvion, Rebinyn, and Rixubis. A typical regimen for acute bleeding includes an initial dose of 20 to 80 international units/kg, followed by repeat doses every 24 hours until the target level of Factor IX is obtained. Target levels can sometimes be achieved after a single dose and maintained with lower doses. Factor IX is also administered prophylactically to reduce the incidence of spontaneous bleeding. Hemostatic drugs such as aminocaproic acid and tranexamic acid may be used for short-term therapy to reduce bleeding related to dental procedures in patients with hemophilia B.

Hemophilia C: Factor XI deficiency, or hemophilia C, occurs in equal numbers of males and females and is a mild form of hemophilia. In the general population, hemophilia C occurs at a rate of 1 per million births, but it affects up to 13% of those with Ashkenazi Jewish heritage. No therapy is generally indicated unless the patient is undergoing a medical, surgical, or dental procedure. Administration of fresh frozen plasma supplies adequate amounts of Factor XI to prevent or slow bleeding during these procedures.

von Willebrand's Disease The most common inherited coagulation disorder, **von Willebrand's disease (vWD)**, affects 1 in every 100 to 500 people. This disorder results in a decrease in quantity or quality of vWF, which is required for platelet adhesion to injured blood vessel endothelium. vWF is also a carrier molecule for Factor VIII, protecting it from destruction as it circulates through the blood. Thus, a deficiency in vWF will decrease levels of Factor VIII and affect coagulation. Like hemophilia, the disease has mild and severe forms, both characterized by abnormal bleeding. The disease affects males and females equally, and life expectancy is usually normal.

This type of bleeding disorder is treated with Factor VIII concentrate as well as desmopressin, which promotes the release of stored vWF. For the most severely affected patients, plasma products containing vWF may be required.

Understanding Chapter 38

Key Concepts Summary

38.1 Thromboembolic disorders are abnormalities of hemostasis that include deep vein thrombosis and pulmonary embolism.

38.2 Coagulation disorders are caused by decreased numbers of platelets or by deficiencies in specific clotting factors.

38.3 The normal coagulation process can be modified by a number of different mechanisms.

38.4 Heparin is the traditional drug for rapid anticoagulation.

38.5 Warfarin is a widely used drug for oral anticoagulant therapy.

38.6 The direct thrombin inhibitors and Factor Xa inhibitors have become important drugs in the prevention and treatment of venous thromboembolism.

38.7 Antiplatelet drugs provide anticoagulation by reducing the aggregation properties of platelets.

38.8 The adenosine diphosphate receptor blockers are antiplatelet drugs prescribed for the prevention and treatment of arterial thrombosis.

38.9 The glycoprotein IIb/IIIa receptor inhibitors are effective antiplatelet drugs for preventing coagulation.

38.10 Coagulation modifiers can be used to treat symptoms of intermittent claudication.

38.11 Fibrinolysis is a process that removes thrombi.

38.12 Thrombolytics are used to dissolve existing intravascular clots in patients with myocardial infarction and stroke.

38.13 Hemostatics are used to promote the formation of clots.

38.14 Hemophilia is treated by replacing the missing clotting factor(s) or by inhibiting coagulation.

CASE STUDY: Making the Patient Connection

Remember the patient "Jihyo Yun" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Jihyo Yun had looked forward to the trip and was anxious to see her grandchildren. When her son accepted an executive position with his company, she had no idea that he would be relocated to Bangkok. The trip would be long but certainly worth the effort. She never dreamed in her 74 years that she would be flying out of the United States, much less to Thailand. When the opportunity came to see her son and his family, she jumped at the chance. After all, it had been 5 years since he had left their home in Chicago.

When she returned from her trip, she noticed some pain in her right leg. Although she sees herself as a healthy older woman, she does experience occasional arthritis pain. Considering that she was on a commercial airliner for more than 20 hours, she did not think much about the leg discomfort. However, after a few days, her leg became increasingly more painful and swollen. She could not imagine what was causing this problem. Finally, after 3 days, Jihyo became worried about what seemed to be increasing leg swelling and pain.

She is seen in her healthcare provider's office. The following health information is documented in her medical record:

> Jihyo Yun, 74-year-old Asian American woman. Her physical examination revealed the following findings: alert, oriented 74-year-old woman with chief complaint of swelling, painful right lower extremity × 3 days. Cardio: Heart rate regular without murmurs; blood pressure, 118/74 mmHg; all pulses present equal and strong in all extremities; no respiratory distress—regular, clear, breath sounds; audible bowel sounds in all four quadrants. Her right mid-calf area has 3–4+ pitting edema, and is hot and painful to touch and she has a moderate amount of varicosities in lower extremities bilaterally.
>
> Jihyo had a hysterectomy 15 years ago, and does not drink alcohol or use tobacco. She takes occasional aspirin for muscle aches, and has no known allergies. Her family history indicates that her father died from a stroke and her mother died of "old age." She has one sister who has diabetes.

Jihyo was diagnosed with DVT in her right leg. The treatment plan was to admit her into the hospital for anticoagulant therapy and pain control. In the hospital setting, Jihyo will receive heparin therapy. You are the nurse caring for this patient.

Critical Thinking Questions

1. Jihyo asks, "How soon will the heparin dissolve my blood clot?" How would you respond to this question?
2. What patient education should you provide Jihyo about anticoagulation therapy?
3. What is an aPTT? How will this test be used to direct heparin therapy?
4. What factors predisposed this patient to DVT?
5. What should Jihyo be taught about taking aspirin for arthritis pain?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

You are attending your annual family reunion and begin talking to your favorite uncle, Lewis, about his recent hospitalization. Lewis Kinard, a 55-year-old man, was recently discharged from the hospital following an episode of atrial fibrillation. He returned home with instructions to take warfarin (Coumadin) 10 mg daily. He has many questions for you, his favorite relative.

1. Why would someone with atrial fibrillation be prescribed Coumadin?
2. What special precautions should Lewis take while on this drug?
3. Are there any foods that he should avoid or limit in his diet?
4. What laboratory testing will be done to determine this drug's effectiveness?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient with deep vein thrombosis is being treated with a heparin infusion. The nurse would monitor for therapeutic effectiveness by noting which of the following?
    1. Activated partial thromboplastin time (aPTT)
    2. Prothrombin time (PT)
    3. Platelet counts
    4. International normalized ratio (INR)

2. Which of the following should the nurse include in the teaching plan for a patient receiving subcutaneous heparin? (Select all that apply.)
    1. Inject medication in the deep fatty layer of the abdomen.
    2. When brushing your teeth, use a soft toothbrush.
    3. Hold direct pressure on any puncture sites for 15 minutes.
    4. Use dental floss daily after brushing.
    5. Take a daily aspirin tablet, 325 mg, to prevent inflammation at the injection site.

3. A patient who is taking warfarin (Coumadin) states, "I wake up every morning with arthritis pain and I always take aspirin or ibuprofen." The nurse's response would be based on which physiologic concepts?
    1. Aspirin and ibuprofen (Motrin) will counteract the therapeutic effects of many anticoagulants.
    2. Anticoagulants will reduce the half-life of drugs such as aspirin and ibuprofen.
    3. Many substances such as aspirin and ibuprofen will increase the risk of bleeding.
    4. The combination of aspirin products with anticoagulants will worsen arthritis pain.

4. What should the nurse teach the patient who is to receive alteplase (Activase) as part of the treatment for myocardial infarction?
    1. The drug will be given IV, and the patient should be able to go home later today.
    2. The patient should remain quiet and lying down during drug administration and for up to 8 hours after infusion.
    3. The risk of bleeding returns to normal within 24 hours after the drug has been infused.
    4. An increase in vitamin K–rich foods or a supplement will be needed for the week following the treatment.

5. A patient who is taking clopidogrel (Plavix) to prevent another stroke asks the nurse how the medication works. The nurse's response should be based on an understanding that Plavix:
    1. Inhibits platelet aggregation to prevent clot formation.
    2. Activates antithrombin III and subsequently inhibits thrombin.
    3. Inhibits enzymes involved in the formation of vitamin K.
    4. Converts plasminogen to plasmin to dissolve fibrin clots.

6. A patient will be receiving dabigatran (Pradaxa). Which of the following is true concerning this drug therapy? (Select all that apply.)
    1. Ginger, garlic, and green tea may increase the risk of bleeding.
    2. Vitamin B_{12} is used to augment this drug's response.
    3. Pradaxa is used for deep vein thrombosis.
    4. Activated partial thromboplastin time may be monitored to determine effectiveness.
    5. This drug is contraindicated for patients with gastritis.

Chapter 39
Pharmacotherapy of Hematopoietic Disorders

Chapter Outline

- Physiology of Hematopoiesis
- Hematopoietic Growth Factors

  Erythropoietin

  PROTOTYPE *Epoetin Alfa (Epogen, Procrit), p. 693*

  Colony-Stimulating Factors

  PROTOTYPE *Filgrastim (Granix, Neupogen, Zarxio), p. 697*

  Platelet Enhancers

  PROTOTYPE *Oprelvekin (Neumega), p. 700*
- Classification of Anemias
- Antianemic Drugs

  Iron Deficiency Anemia

  PROTOTYPE *Ferrous Sulfate (Feosol, Feostat, Others), p. 705*

  Pernicious Anemia

  PROTOTYPE *Cyanocobalamin (Nascobal), p. 708*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the physiology of hematopoiesis.
2. Describe how aspects of hematopoiesis can be modified by the administration of pharmacologic drugs.
3. Explain the functions of erythropoietin.
4. Explain the functions of colony-stimulating factors.
5. Classify types of anemia based on their causes.
6. Illustrate the metabolism, storage, and transfer of iron in the body.
7. Identify the role of intrinsic factor in the absorption of vitamin B_{12}.
8. Compare and contrast anemias caused by vitamin B_{12} and folate deficiency.
9. Describe the nurse's role in the pharmacologic management of hematopoietic disorders.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Apply the nursing process to care for patients receiving pharmacotherapy for hematopoietic disorders.

Key Terms

anemia, 702
colony-stimulating factors (CSFs), 695
ferritin, 703
folate, 708
folic acid, 708
hematopoiesis, 692
hemosiderin, 703
intrinsic factor, 707
pernicious anemia, 707
pluripotent stem cells (hemocytoblasts), 692
transferrin, 703

The blood serves all other cells in the body and is the only fluid tissue. Because of its diverse functions, diseases affecting blood constituents have widespread effects on the body. This chapter examines medications used to enhance the functions of erythrocytes, leukocytes, and platelets. Pharmacology of the hematopoietic system is a small, though emerging, branch of medicine.

Physiology of Hematopoiesis

39.1 Hematopoiesis is a dynamic process that is responsive to the changing demands of the body.

Blood is a highly dynamic tissue; over 200 billion new blood cells are formed every day. The process of blood cell formation is called **hematopoiesis**, or hemopoiesis. In adults, hematopoiesis occurs primarily in red bone marrow and requires B vitamins, vitamin C, copper, iron, and other nutrients. Before proceeding, the student should read the brief review of blood found in Chapter 28.

Hematopoiesis responds to internal and external challenges faced by the body. For example, the production of white blood cells (WBCs) can increase tenfold in response to infection. The number of red blood cells (RBCs) can increase as much as fivefold in response to anemia or hypoxia. Homeostatic control of hematopoiesis is influenced by a number of hormones and growth factors, which allow for points for pharmacologic intervention. The process of hematopoiesis is illustrated in Figure 39.1.

The process of hematopoiesis begins in bone marrow with **pluripotent stem cells (hemocytoblasts)**, which are capable of maturing (differentiating) into any blood cell type. What determines whether the stem cell produces RBCs, macrophages, lymphocytes, or perhaps platelets? The specific path taken by the pluripotent stem cell depends on the internal needs of the body. These needs are transmitted to pluripotent stem cells by regulatory substances that include various hormones and proteins. For example, high amounts of the hormone erythropoietin circulating through the blood signal the stem cells to differentiate into erythrocytes. Many types of cells secrete cytokines (interferons and interleukins) that signal the stem cells to increase or decrease the production of specific WBCs. Through recombinant deoxyribonucleic acid (DNA) technology some of these regulatory agents, shown in Figure 39.1, are now available in sufficient quantities to be used as medications.

PharmFACT

The recommended dietary allowance of iron for a woman is 10 to 15 mg. However, during pregnancy, a woman's body needs 1 g of iron daily: 300 mg for the fetus, 500 mg for expansion of the maternal RBCs, and 200 mg due to excretion (National Institutes of Health, 2016a).

The pharmacologic management of hematopoietic disorders often involves simply replacing a deficient substance that is essential to hematopoiesis. In some cases, the drug is identical, or very closely resembles, the deficient endogenous factor. For example, the drug epoetin alfa (Epogen, Procrit) is identical to the natural hormone erythropoietin and stimulates the production of RBCs in the same manner. Administration of antianemic medications such as ferrous sulfate or vitamin B_{12} supplies the patient with essential factors that may be deficient.

Some of the hematopoietic drugs have become important adjunct medications in the pharmacotherapy of malignancies. Antineoplastic drugs often are toxic to bone marrow and cause neutropenia, a reduced number of WBCs. Neutropenia is a primary cause of patient morbidity and mortality in the treatment of cancer. Hematopoietic drugs can be used to boost the WBC counts in these patients.

Natural hormones that regulate some aspect of blood formation are called hematopoietic growth factors. These drugs and their doses are listed in Table 39.1.

CONNECTION Checkpoint 39.1

From what you learned in Chapter 28, name the three formed elements of blood. What percentage of whole blood do the formed elements comprise? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hematopoietic Growth Factors

39.2 Erythropoietin stimulates production of red blood cells and is used to treat anemia.

The process of RBC formation, or erythropoiesis, is regulated by the hormone erythropoietin. In adults, 90% of

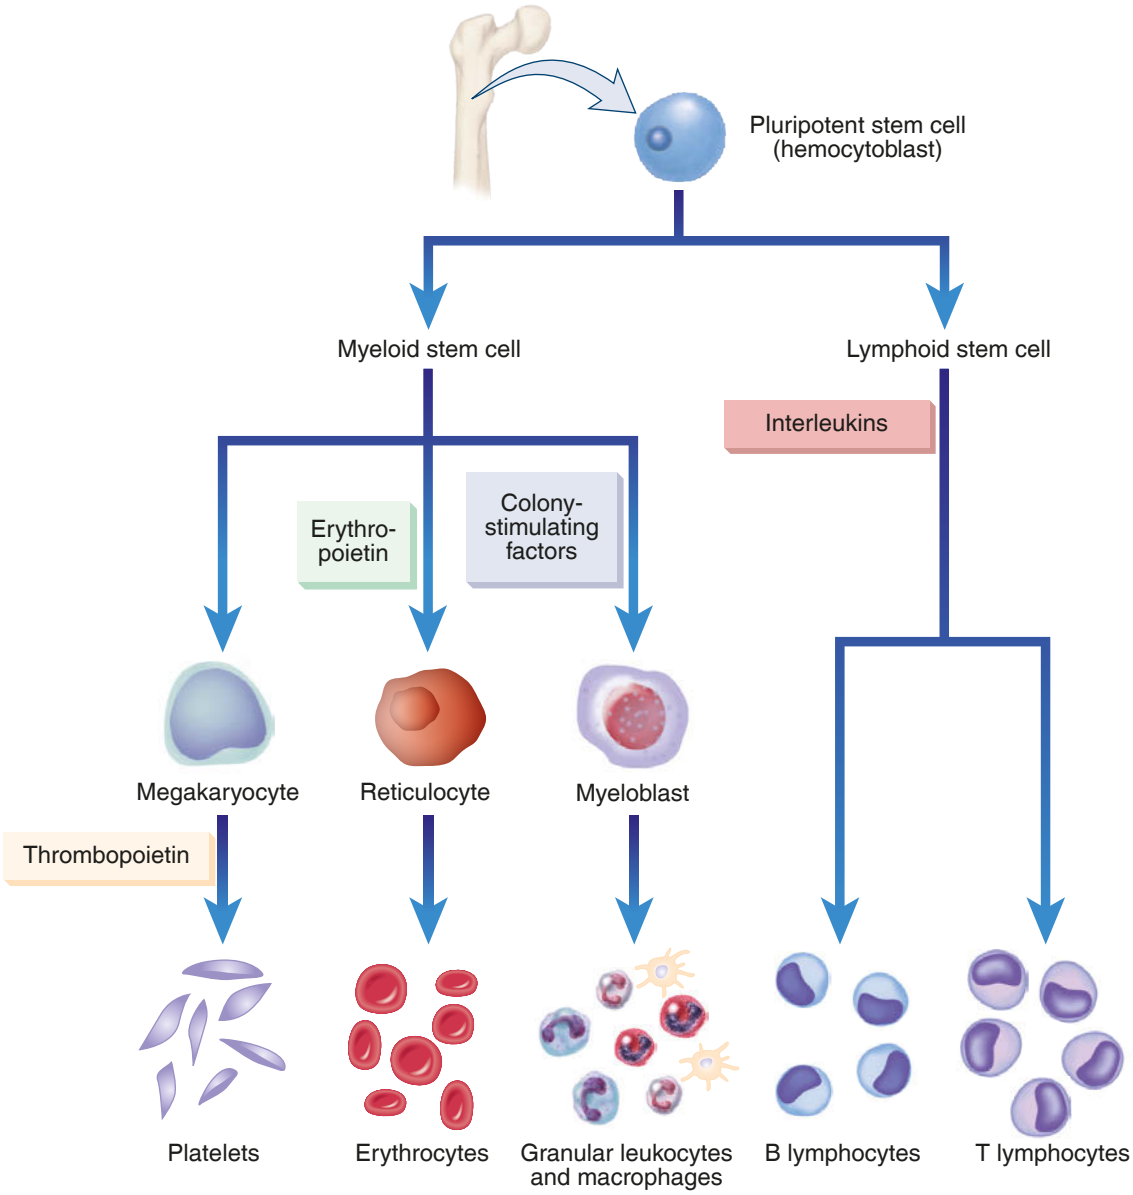

Figure 39.1 Hematopoiesis: Blood cells are formed from stem cells under the influence of hormones such as thrombopoietin, colony-stimulating factors, and erythropoietin.

erythropoietin is secreted by the kidneys and 10% is secreted by the liver.

The primary signal to increase the renal secretion of erythropoietin is hypoxia, a reduction in oxygen reaching the proximal tubule cells in the kidney. Once secreted, erythropoietin travels to the bone marrow where it interacts with receptors on stem cells and delivers the message to increase erythrocyte production. Just as important, erythropoietin also stimulates the production of hemoglobin (Hgb), which is required for a functional erythrocyte. Hemorrhage, chronic obstructive pulmonary disease, anemia, or high altitudes may increase serum levels of erythropoietin as much as 1000-fold in response to severe hypoxia. Erythropoietin is marketed as the drug epoetin alfa (Epogen, Procrit). Darbepoetin alfa (Aranesp) is closely related to epoetin alfa but has a duration of action that is 2 to 3 times longer. These drugs are sometimes called erythropoietic growth factors.

PROTOTYPE DRUG Epoetin Alfa (Epogen, Procrit)

Classification **Therapeutic:** Hematopoietic growth factor, drug for anemia
Pharmacologic: Erythropoietin

Therapeutic Effects and Uses: Approved in 1989 by the U. S. Food and Drug Administration, epoetin alfa is made through recombinant DNA technology and is functionally identical to human erythropoietin. Although the drug may be administered intravenously (IV), the

Table 39.1 Hematopoietic Growth Factors

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Erythropoietic Growth Factors		
darbepoetin alfa (Aranesp)	Subcutaneous/IV: 0.45 mcg/kg once per wk (max: 74 mg/kg)	*Headache, fever, nausea, vomiting, diarrhea, insomnia, cough, upper respiratory infection, edema, pyrexia, rash* HTN, seizures, HF, MI, stroke
epoetin alfa (Epogen, Procrit): erythropoietin	Subcutaneous/IV: Start with 50–100 units/kg/dose and adjust to target Hct range of 30–33% (max: 36%); Hct should not increase by more than 4 points in any 2-wk period	
Colony-Stimulating Factors		
filgrastim (Granix, Neupogen, Zarxio): granulocyte-CSF	IV: 5–10 mcg/kg by 30-min infusion or as a subcutaneous single bolus dose	*Flulike syndrome, fever, dyspnea, nausea, vomiting, weakness, alopecia, peripheral edema, arthralgia, bone pain* Thrombocytopenia, cutaneous vasculitis, pericardial effusion (sargramostim), tachycardia (sargramostim), acute respiratory distress syndrome
pegfilgrastim (Neulasta)	Subcutaneous: 6 mg once per chemotherapy cycle	
sargramostim (Leukine): GM-CSF	IV: 250 mcg/m^2/day infused over 2 h for 14 days, begin 2–4 h after bone marrow transfusion and not less than 24 h after last dose of chemotherapy or 12 h after last radiation therapy	
Platelet Enhancers		
eltrombopag (Promacta)	PO: 50 mg once daily (max: 75 mg/day)	*Arthralgia, myalgia, paresthesia, insomnia* Bone marrow fibrosis, thromboembolism, hematologic malignancy, hepatotoxicity
oprelvekin (Neumega)	Subcutaneous: 50 mcg/kg once daily starting 6–24 h after completing chemotherapy for 14–21 days or until platelet count is at least 50,000/mcL	*Edema, fever, headache, dizziness, dyspnea, fatigue, rash, nausea, vomiting* Tachycardia, febrile neutropenia, pleural effusion, anaphylaxis, dysrhythmias, candidiasis
romiplostim (Nplate)	Subcutaneous: 1 mcg/kg/wk initial dose; may increase by increments of 1 mg/kg weekly until platelet count is at least 50,000/mcL	*Arthralgia, dizziness, insomnia, myalgia, abdominal pain, dyspepsia, paresthesia* Thromboembolism, bone marrow fibrosis

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

subcutaneous route is generally preferred because lower doses are needed, absorption is slower, and a more sustained response can be achieved. Epoetin is not used for the emergency correction of severe anemia or as a substitute for transfusion because it has a gradual onset of action. The hematocrit (Hct) increases 2% per week during the initial weeks of epoetin therapy and some patients require 2 to 6 weeks for a change in Hct to occur. Most patients on epoetin therapy also receive iron supplements to meet the increased demands caused by the elevated erythrocyte production. Although epoetin alfa does not cure any primary disease, it reduces anemia symptoms and dramatically improves the patient's ability to perform activities of daily living (ADLs). A typical initial regimen for epoetin alfa requires 50 to 100 units/kg 3 times per week until a target Hgb level of 10 to 12 g/dL is achieved.

Epoetin is indicated for the treatment of anemia associated with chronic kidney disease (CKD). Patients with CKD often experience anemia because they are unable to secrete sufficient endogenous erythropoietin. The drug is occasionally prescribed to reduce the need for transfusions in patients with anemia prior to elective surgery, if a significant blood loss is expected. Patients with HIV infection who are receiving zidovudine may receive epoetin alfa to treat anemia caused by antiretroviral drugs.

Epoetin alfa is given to patients undergoing chemotherapy for nonmyeloid malignancies to counteract the anemia commonly caused by antineoplastic drugs. It should be carefully noted that the anemia must be secondary to the chemotherapy, not to the cancer itself. Research has shown that the administration of epoetin alfa does not benefit patients when the anemia is caused by the malignancy; in fact, mortality is increased in these patients by the administration of the drug. Care must be taken not to administer epoetin alfa to patients with myeloid malignancies such as myelogenous leukemia, because the drug may increase tumor growth.

Mechanism of Action: Epoetin alfa stimulates the division and differentiation of stem cells in the bone marrow to become erythrocytes. Erythropoietin also promotes the synthesis of Hgb and causes a shift of marrow reticulocytes into the circulation.

Pharmacokinetics:

Route(s)	IV, subcutaneous
Absorption	Readily absorbed (subcutaneous)
Distribution	Unknown if the drug crosses the placenta or is secreted in breast milk

Primary metabolism	Plasma
Primary excretion	Mostly feces; 10% renal
Onset of action	7–14 days
Duration of action	2 weeks; half-life: 4–13 h

Adverse Effects: The most serious adverse effect of epoetin alfa is hypertension (HTN), which occurs in 30% of patients receiving the drug. An antihypertensive drug may be indicated. Some patients with CKD develop neutralizing antibodies to subcutaneous epoetin alfa, which can lead to a rapidly developing severe anemia known as pure red cell aplasia. Seizures may occur during the first 90 days of therapy, especially if blood pressure and Hct rise rapidly. Common adverse effects include headache, fever, nausea, diarrhea, and edema. **Black Box Warning:** The risk of serious cardiovascular and thromboembolic events is increased with epoetin alfa therapy. Transient ischemic attacks (TIAs), myocardial infarctions (MIs), and strokes have occurred in patients with CKD who are on dialysis and being treated with epoetin alfa. Epoetin increased the rate of deep vein thrombosis (DVT) in patients not receiving concurrent anticoagulation. The lowest dose possible should be used in patients with cancer because the drug can promote tumor progression and shorten overall survival in some patients.

Contraindications/Precautions: The drug should not be given to patients with uncontrolled HTN because epoetin alfa may increase blood pressure. The risk of thromboembolic events, stroke, and MI greatly increases when Hgb level rises above 12 g/dL. Patients with known hypersensitivity to products derived from mammal cells, such as albumin, should not receive this drug.

Drug Interactions: Androgens can increase blood viscosity, resulting in an increased response from epoetin alfa. The effectiveness of epoetin alfa will be greatly reduced in patients with iron deficiency or other vitamin-depleted states. Whenever possible, such deficiencies should be corrected prior to initiating epoetin alfa therapy. Hemodialysis patients with preexisting heart disease who are taking epoetin may require increased doses of heparin. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose may lead to polycythemia (too many erythrocytes), which can be corrected by phlebotomy.

Nursing Responsibilities: Key nursing implications for patients receiving epoetin alfa are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Erythropoietin.

Drugs Similar to Epoetin Alfa (Epogen, Procrit)

The only other erythropoietic growth factor is darbepoetin alfa. A similar drug, peginesatide (Omontys), was approved in 2012 but recalled in 2013 due to serious safety concerns.

Darbepoetin alfa (Aranesp): Approved in 2001, darbepoetin alfa has a chemical structure that closely resembles that of epoetin alfa, differing only by two carbohydrate chains. It has the same mechanism of action, efficacy, and safety profile as epoetin alfa. It is administered by the subcutaneous or IV route and has an extended duration of action that allows it to be administered once weekly. Maximum response occurs in 2 to 4 weeks. Darbepoetin alfa is approved for the treatment of anemia associated with cancer chemotherapy or CKD. Like epoetin alfa, darbepoetin should be administered only to patients with anemia secondary to the chemotherapy and not caused by the malignancy itself. In addition, Hgb levels should be maintained below 12 g/dL to reduce the risks of serious cardiovascular adverse events. Darbepoetin has similar adverse effects and the same black box warning as epoetin alfa. This drug is pregnancy category C.

39.3 Colony-stimulating factors increase the production of leukocytes.

Regulation of WBC production, or leukopoiesis, is more complicated than erythropoiesis because the blood has different types of leukocytes. Adding to the complication is that a large number of substances modify the synthesis and activation of leukocytes and the processes of leukopoiesis regulation are incompletely understood. Pharmacologically, the most important substances are **colony-stimulating factors (CSFs)**. CSFs are hormones that stimulate the growth and differentiation of one or more types of leukocytes.

CSFs are produced by a diverse group of cells including endothelial cells, fibroblasts, macrophages, and T lymphocytes. Normally present at minute levels in the blood, the production of CSFs rapidly increases when the body receives a bacterial challenge. The leukopoietic growth factors are active at very low concentrations; each stem cell stimulated by these growth factors is capable of producing as many as 1000 mature leukocytes. The CSFs not only increase the production of new leukocytes, but they also activate existing WBCs. Examples of enhanced functions include increased migration of leukocytes to antigens, increased antibody toxicity, and increased phagocytosis.

CSFs are named according to the types of blood cells that they stimulate. For example, granulocyte colony-stimulating factor (G-CSF) increases the production of neutrophils, the most common type of granulocyte. Granulocyte-macrophage colony-stimulating factor (GM-CSF)

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Erythropoietin

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history: cardiovascular (including HTN, MI) and peripheral vascular disease, respiratory (including previous pulmonary embolism), neurologic (including stroke), hepatic disease, or CKD. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight and vital signs, especially blood pressure.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], activated partial thromboplastin time [aPTT], international normalized ratio [INR], transferrin and serum ferritin levels, renal and liver function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Continue assessment for therapeutic effects (e.g., Hct, RBC count significantly improved), patient's activity level and ability to carry out ADLs has improved.
- Continue frequent monitoring of appropriate laboratory values (e.g., CBC, aPTT, INR).
- Monitor vital signs frequently, especially blood pressure, during the first 2 wk of therapy.
- Assess for adverse effects: HTN, headache, neurologic changes in level of consciousness (LOC), or premonitory signs and symptoms of seizure activity (e.g., aura), angina, signs of thrombosis development in peripheral extremities (e.g., leg pain, pale extremity, diminished peripheral pulses).

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (RBC count increases rapidly in the first 2 wk of therapy. CBC and platelet count should show continued improvement. Blood pressure and pulse should remain within normal limits or within the parameters set by the healthcare provider.)	• Instruct the patient on the need to return frequently for follow-up laboratory work.
• Encourage adequate rest periods and fluid intake. (The patient may be significantly fatigued due to low Hgb and Hct levels. Adequate fluid intake helps maintain adequate fluid balance as Hct levels rise.)	• Encourage the patient to rest when fatigued, and to space activities throughout the day to allow for adequate rest periods. • Encourage intake of water and nonhyperosmolar beverages.
Minimizing adverse effects: • Continue to monitor for adverse effects, especially HTN, peripheral thrombosis, or seizure activity. (Because Hct rapidly increases during the first 2 wk of therapy, HTN or seizures may occur and should be reported immediately. Peripheral thrombosis, including coronary or cerebral, may also occur. **Lifespan:** Be especially cautious with the older adult who may be at greater risk for thromboembolic events due to age-related vascular changes.)	• Teach the patient, family, or caregiver how to monitor the pulse and blood pressure as appropriate. Ensure proper use and functioning of any home equipment obtained. • Instruct the patient, family, or caregiver to report headache (especially if sudden onset or severe), changes in LOC, weakness or numbness in extremities, or premonitory signs and symptoms of seizure activity (e.g., aura), angina, or symptoms of peripheral thrombosis (e.g., leg pain, pale extremity, diminished peripheral pulses).
• Assess transportation needs of the patient and refer to appropriate resources as needed. (Driving may be restricted up to 90 days after initiation of drug therapy.)	• Advise the patient, family, or caregiver to consult with the healthcare provider about driving or other hazardous activities during the first several months of drug therapy.
• Continue to monitor aPTT prior to dialysis in patients with CKD. (Heparin dose during dialysis may need to be increased as Hct increases.)	• Explain any changes in the medication routine to the patient and provide rationale.
• **Lifespan:** Assess for the possibility of pregnancy or breastfeeding before beginning the drug. (Epoetin is a pregnancy category C drug and the effects during breastfeeding are not fully known.)	• Instruct female patients who may be considering pregnancy, or are pregnant or breastfeeding, to notify their provider before starting the drug.
• **Lifespan:** When administering epoetin alpha to premature infants, use preservative-free formulations. (Epoetin alfa may contain preservatives such as benzyl alcohol. Benzyl alcohol may cause fetal gasping syndrome.)	• To allay anxiety, offer parents rationales for all treatments provided for the infant.
• Encourage adequate dietary intake of iron, folic acid, and vitamin B_{12}. Provide dietary consult as needed. Consider nutritional supplements of these nutrients if the diet is inadequate. (Response to epoetin alfa may be decreased if blood levels of iron, folic acid, and vitamin B_{12} are deficient.)	• Teach the patient to maintain a healthy diet with adequate amounts of iron, folic acid, and vitamin B_{12} (found in meats, dairy, eggs, fortified cereals and breads, leafy green vegetables, citrus fruits, beans and peas).
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, most commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.) Proper technique includes: • The vial should be gently rotated to mix the content, never shaken. Vials are kept under refrigeration and should be gently warmed in the hand. • All vials are for one-time use only and any remaining amount should be discarded. • If an indwelling subcutaneous soft catheter (e.g., Insuflon soft catheter) is left in place, the patient, family, or caregiver should be taught appropriate site care, insertion technique as appropriate, and the schedule for rotating sites.	• Teach the patient, family, or caregiver proper self-administration techniques. If an indwelling subcutaneous soft catheter (e.g., Insuflon soft catheter) is left in place for injections, teach the patient, family, or caregiver proper care of the site and catheter, and any schedule for rotating sites. • Have the patient, family, or caregiver return demonstrate until the proper technique is used and the individual is comfortable giving injections.

stimulates both neutrophil and macrophage production. The process of identifying the many endogenous CSFs, determining their normal functions, and discovering their potential value as therapeutic agents is an emerging area of pharmacology.

Through recombinant DNA technology, several CSFs are now available as medications (see Table 39.1). The goal of CSF therapy is to produce a rapid increase in the number of neutrophils in patients who have suppressed immune systems (neutropenia). CSF therapy shortens the length of time patients are neutropenic and susceptible to life-threatening bacterial and fungal infections. Neutropenia may also cause chemotherapy schedules to be delayed or abandoned. By raising neutrophil counts, CSFs can assist in keeping antineoplastic dosing regimens on schedule (and more effective). The degree of increase in circulating neutrophils is dose related. Indications for CSF therapy include the following:

- Patients with cancer whose bone marrow has been suppressed by antineoplastic drugs
- Patients with cancer who are receiving bone marrow transplants
- Patients with severe, chronic neutropenia (such as those with AIDS)
- Patients undergoing peripheral mobilization of hematopoietic progenitor cells for collection by leukapheresis (collection of WBCs from a blood sample).

It is often difficult to assess the adverse effects of CSF medications because the same types of patient symptoms may be caused by the condition or disease being treated. Nonspecific adverse effects include nausea, vomiting, fatigue, fever, and flushing. Therapy requires careful laboratory monitoring to avoid producing too many neutrophils. Several recent research studies have suggested that the risk of developing acute myeloid leukemia or myelodysplastic syndrome may be doubled when CSFs are administered to patients undergoing chemotherapy for breast cancer.

PROTOTYPE DRUG Filgrastim (Granix, Neupogen, Zarxio)

Classification **Therapeutic:** Drug for increasing neutrophil production
Pharmacologic: Colony-stimulating factor

Therapeutic Effects and Uses: Produced through recombinant DNA technology, filgrastim is nearly identical in structure to human G-CSF and has the same biologic activity. Approved in 1991, its primary actions are to increase neutrophil production in the bone marrow and to enhance the phagocytic and cytotoxic functions of existing neutrophils. The subcutaneous route is preferred, although filgrastim may also be administered by slow IV infusion. A typical regimen is 5 to 10 mcg/kg given once or twice daily. Continued therapy is based on absolute neutrophil counts (ANCs): Therapy is usually discontinued once laboratory results indicate 10,000 cells/mm^3 or greater.

TBO-filgrastim (Granix) was approved in 2012 as a self-administration kit so the drug may be injected at home. Although not chemically identical to Neupogen, it has identical actions and adverse effects. In 2015, filgrastim-sndz (Zarxio) was the first biosimilar product approved in the United States. It has the same indications, effectiveness, and adverse effects as Neupogen.

Mechanism of Action: Filgrastim acts by the same mechanism as endogenous G-CSF. The drug causes an increase in neutrophil production in the bone marrow, resulting in higher levels of circulating neutrophils.

Pharmacokinetics:

Route(s)	IV, subcutaneous
Absorption	Rapidly absorbed (subcutaneous)
Distribution	Unknown if it crosses the placenta or is secreted in breast milk

Primary metabolism	Unknown
Primary excretion	Renal
Onset of action	4 h
Duration of action	4 days

Adverse Effects: Although filgrastim is well tolerated, the drug is associated with potentially serious adverse effects and close monitoring is required. Nausea and vomiting occur in the majority of patients. Bone pain may occur in up to 33% of patients receiving filgrastim. The pain may be diffuse or localized to bones with the greatest amount of bone marrow: long bones, sternum, ribs, and pelvis. The degree of pain is dose dependent and can usually be managed with nonopioid analgesics. Frequent laboratory tests are conducted to ensure that excessive numbers of neutrophils (leukocytosis) do not occur. Leukocyte counts higher than 100,000 cells/mm^3 increase the risk of serious adverse effects such as respiratory failure, intracranial hemorrhage or infarction, retinal hemorrhage, and MI. Hyperuricemia and elevated lactate dehydrogenase and alkaline phosphatase levels occur in a significant number of patients. Splenomegaly may occur in 30% of patients receiving long-term therapy with filgrastim. Other common adverse effects include fatigue, rash, epistaxis, decreased platelet counts, neutropenic fever, alopecia, and diarrhea. Allergic reactions, including anaphylaxis, are rare.

Contraindications/Precautions: Patients with hypersensitivity to *Escherichia coli* (*E. coli*) proteins should not receive filgrastim because this microbe is used to produce the recombinant drug. Patients with sickle cell disease should be treated with caution because filgrastim may worsen this condition. Filgrastim should not be administered to patients with myeloid cancers.

Drug Interactions: Because antineoplastic drugs and CSFs produce opposite effects, filgrastim is not administered until at least 24 hours after a chemotherapy session. Lithium causes the release of neutrophils and may contribute to filgrastim-induced leukocytosis. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose can lead to leukocytosis and should be prevented by discontinuing the drug when ANC rises above 10,000 cells/mm^3. There is no specific therapy for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving filgrastim are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Colony-Stimulating Factors.

Drugs Similar to Filgrastim (Granix, Neupogen, Zarxio)

The two other CSFs are pegfilgrastim and sargramostim.

Pegfilgrastim (Neulasta): Approved in 2002, pegfilgrastim is a form of filgrastim bonded to a molecule of polyethylene glycol (PEG). This delays the renal excretion of the molecule, allowing the drug to remain in the body with a sustained duration of action. Its only approved indication is prophylaxis of chemotherapy-induced neutropenia. The drug is given by the subcutaneous route, once per chemotherapy cycle. It should not be administered 14 days before or 24 hours after the administration of cytotoxic chemotherapy. Adverse effects, interactions, and contraindications are the same as those of filgrastim. This drug is pregnancy category C.

Sargramostim (Leukine): Sargramostim is structurally very similar to natural GM-CSF and has the same biologic activity. It may be administered IV, but subcutaneous is the preferred route. The drug has multiple effects that include increasing the number of circulating neutrophils, eosinophils, and monocytes; activating macrophages; increasing the cytotoxic activity of monocytes; and enhancing the bactericidal activity of other cells of the immune system. Indications include decreasing the period of neutropenia in patients treated for acute lymphocytic leukemia or Hodgkin's disease and those having autologous bone marrow transplantation. Typically, therapy with sargramostim is initiated when ANC is less than 500 cells/mm^3 and continues until an ANC of 1500 cells/mm^3 for 3 consecutive days is achieved. To prevent leukocytosis, sargramostim should be discontinued if the ANC rises above 10,000 cells/mm^3.

Like filgrastim, bone pain is a common adverse effect. A serious adverse effect of sargramostim is respiratory distress that occurs during the IV infusion the first time the drug is administered, which appears to be related to the trapping of granulocytes in the pulmonary circulation. The patient develops difficulty breathing, tachycardia, low blood pressure, and lightheadedness. These symptoms usually call for discontinuing sargramostim therapy. This drug is pregnancy category C.

CONNECTION Checkpoint 39.2

Zarxio is a biosimilar drug to filgrastim (Neupogen). From Chapter 1, define the term *biosimilar* and describe how a biosimilar drug compares to its reference product. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

39.4 Platelet enhancers may be used to treat thrombocytopenia.

The production of platelets, or thrombocytopoiesis, begins when megakaryocytes in the bone marrow start shedding membrane-bound packets. These packets enter the bloodstream and become platelets. A single megakaryocyte can produce thousands of platelets.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Colony-Stimulating Factors

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including recent or current infections; recent surgeries, injuries, or wounds; yeast infections (e.g., thrush); vaccination history; cardiac conditions (e.g., dysrhythmias, heart failure [HF]); respiratory, renal, and hepatic conditions. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight and vital signs. Assess level of fatigue.
- Evaluate appropriate laboratory findings (e.g., CBC, WBC, or ANC, renal and liver function studies, uric acid levels, and electrocardiogram [ECG]). ANC = total WBC count multiplied by the total percentage of neutrophils (segmented plus bands); e.g., WBC 5,000 × (0.45 segs + 0.05 banded neutrophils) = 5000 × 0.5 = ANC of 2500.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Continue assessment for therapeutic effects (e.g., CBC, WBC, or ANC has increased, no signs or symptoms of infection).
- Continue frequent monitoring of appropriate laboratory values (e.g., CBC, WBC, or ANC, Hct, platelet count, renal and hepatic laboratory results, uric acid levels).
- Monitor vital signs and level of fatigue.
- Assess for adverse effects: bone pain (especially lower back, posterior iliac crests, and sternum), fever, nausea, anorexia, hyperuricemia, anemia, ST-segment depression on ECG, angina, respiratory distress, and allergic reaction. Continue to assess for infection and fatigue related to the drug treatment (e.g., chemotherapy).

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Rise in WBC or ANC counts will depend on the condition treated, e.g., depth and length of nadir from cytotoxic chemotherapy. Counts are usually monitored twice per week or as ordered by the healthcare provider.)	• Instruct the patient on the need to return frequently for follow-up laboratory work.
• Encourage adequate rest periods and adequate fluid intake. (The patient may be significantly fatigued due to the drug therapy. Adequate fluid intake helps maintain adequate urinary output and prevent urinary tract infections.)	• Encourage the patient to rest when fatigued and to space activities throughout the day to allow for adequate rest periods. • Encourage intake of water and nonhyperosmolar beverages, and drinking whenever thirsty.
Minimizing adverse effects: • Continue to monitor for adverse effects: bone pain (especially lower back, posterior iliac crests, and sternum), fever, nausea, anorexia, hyperuricemia, anemia, ST-segment depression on ECG, angina, respiratory distress, and allergic reaction. Continue to assess for infection and fatigue related to drug treatment, e.g., chemotherapy. (Bone pain tends to occur 2–3 days prior to rise in circulating WBCs due to the production of WBCs in bone marrow. ST-segment depression on ECG may occur with potential for serious dysrhythmias. Respiratory distress may develop after administration of sargramostim and should be reported immediately. Hyperuricemia may cause gout-like conditions.)	• Instruct the patient to report any severe bone pain not relieved by nonnarcotic analgesics. • Teach the patient to report any palpitations, dizziness, angina, or dyspnea immediately. • Gout-prone patients should report signs and symptoms of gout and increase fluid intake to enhance renal elimination of uric acid.
• Maintain meticulous infection control measures. Immediately report any signs and symptoms of fever or infections, especially viral or fungal. (The patient will continue to be at risk for infections until WBC or ANC levels rise. Opportunistic infections, such as yeast, and viruses, such as herpes simplex, may occur. Parameters will be set by the healthcare provider for reporting fever, e.g., any temperature over 38°C [100.5°F], dependent on the underlying disease condition and drug therapy.)	Instruct the patient in hygiene and infection control measures such as: • Wash hands frequently. • Avoid crowded indoor places. • Avoid people with known infections or young children, because they have a higher risk of having an infection. • Cook food thoroughly and do not consume raw fruits or vegetables. Allow the family or caregiver to prepare raw meats or fish and to clean up. • Instruct the patient to report any fever per the parameters set by the healthcare provider, and symptoms of infection such as wounds with redness or drainage, increasing cough, increasing fatigue, white patches on oral mucous membranes, white and itchy vaginal discharge, or itchy blister-like vesicles on the skin.
• Monitor ECG periodically for ST-segment depression or dysrhythmias, and report immediately. (Sargramostim may cause significant ST-segment depression with potential for serious dysrhythmias, especially in patients with previous cardiac conditions.)	• Instruct the patient to report any palpitations, dizziness, or angina immediately.
• Monitor for signs of dyspnea or respiratory distress, especially when accompanied by tachycardia and hypotension, and report immediately. (Sargramostim may cause respiratory distress as granulocyte counts rise, especially in patients with preexisting respiratory disorders.)	• Instruct the patient to immediately report any dyspnea, respiratory distress, palpitations, or dizziness.
• Monitor for signs and symptoms of allergic-type reactions. (The patient may be hypersensitive to proteins used in the drug development process.)	• Instruct the patient to immediately report symptoms of allergic reaction such as rash, urticaria, wheezing, and dyspnea.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor hepatic status during drug administration period. (Filgrastim may cause an elevation in liver enzymes.)	• Instruct the patient to report any significant itching, yellowing of the sclera or skin, darkened urine, or light or clay-colored stools.
• Stop administration when WBC counts reach a level determined by the healthcare provider. (Filgrastim may be stopped when neutrophil counts reach 10,000/mm^3, sargramostim when neutrophil counts reach 20,000/mm^3, or as ordered by the provider.)	• Instruct the patient on the importance of returning regularly for laboratory work.
• Assess for spleen enlargement periodically and report. (Filgrastim has been associated with rare but potentially fatal cases of splenomegaly and rupture.)	• Instruct the patient, family, or caregiver to report any symptoms of left upper abdominal pain or left shoulder pain, which may indicate spleen enlargement or rupture.
• **Lifespan:** Monitor laboratory results for pediatric patients with forms of congenital neutropenia (e.g., congenital agranulocytosis) more frequently. (Patients with these disorders are at greater risk for developing acute myelogenous leukemia [AML] and myelodysplastic neutropenia [MDS] related to drug therapy.)	• Teach the patient, family, or caregiver that frequent laboratory studies may be needed.
• **Lifespan:** Assess for the possibility of pregnancy or breastfeeding before beginning the drug. (Colony-stimulating factors are pregnancy category C drugs and the effects during breastfeeding are not fully known.)	• Instruct women who may be considering pregnancy, or are pregnant or breastfeeding, to notify their provider before starting the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.) Proper technique includes: • The vial should be gently rotated to mix the contents, never shaken. Vials are kept under refrigeration and should be gently warmed in the hand. • All vials are for one-time use only and any remaining amount should be discarded. • If an indwelling subcutaneous soft catheter (e.g., Insuflon soft catheter) is left in place, the patient, family, or caregiver should be taught appropriate site care, insertion technique as appropriate, and schedule for rotating sites.	• Teach the patient, family, or caregiver in proper self-administration techniques. If indwelling subcutaneous soft catheter (e.g., Insuflon soft catheter) is left in place for injections, teach the patient, family, or caregiver proper care of the site, catheter, and any schedule for rotating sites. • Have the patient, family, or caregiver return demonstrate until the proper technique is used and the individual is comfortable giving the injection.

Megakaryocyte activity is controlled by the hormone thrombopoietin, which is produced by the liver and bone marrow. Thrombopoietin is not available as a medication, although it has undergone clinical trials. Oprelvekin (Neumega) is a hematopoietic growth factor available to enhance platelet production. This drug is functionally equivalent to endogenous interleukin-11 (IL-11). Interleukins are cytokines secreted by monocytes, lymphocytes, and other cell types that signal cells in the immune system to respond to an infection. Over 30 interleukins have been identified but only a few have been isolated and approved as drugs.

Romiplostim (Nplate) and eltrombopag (Promacta) are classified as thrombopoietin receptor agonists. These drugs activate the natural thrombopoietin receptor, thus inducing megakaryocyte division and differentiation. Both drugs take 10 to 15 days to produce their effects. They are approved to improve platelet function in patients with chronic immune (idiopathic) thrombocytopenia purpura (ITP). Chronic ITP is a disorder characterized by inadequate platelet production or increased platelet destruction. Patients with ITP experience a high risk for bruising and bleeding, which may occur anywhere in the body.

PROTOTYPE DRUG Oprelvekin (Neumega)

Classification **Therapeutic:** Platelet enhancer
Pharmacologic: Interleukin

Therapeutic Effects and Uses: Produced through recombinant DNA technology, oprelvekin is used to stimulate the production of platelets in patients who are at risk for severe thrombocytopenia caused by the chemotherapy of nonmyeloid cancers. Approved in 2002, the drug shortens the time that the patient is thrombocytopenic and most

susceptible to adverse bleeding events. Dosing is initiated 6 to 24 hours after chemotherapy and continues daily until the platelet count is greater than 50,000/mm^3. Dosing beyond 21 days is not recommended. Platelet counts will remain elevated for about 7 days after the last dose. Therapy with oprelvekin decreases the need for platelet infusion. Oprelvekin is only given by the subcutaneous route.

Mechanism of Action: Oprelvekin is equivalent to endogenous IL-11 and directly stimulates the synthesis and maturation of megakaryocytes into platelets.

Pharmacokinetics:

Route(s)	Subcutaneous
Absorption	80% absorbed
Distribution	Well distributed to highly perfused organs; unknown if it crosses the placenta or is secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	5–9 days
Duration of action	7 days; half-life: 6.9 h

Adverse Effects: Oprelvekin causes many adverse effects, although most are reversible upon discontinuation of therapy. The most common adverse effects include nausea, vomiting, edema, neutropenic fever, dyspnea, mucositis, and diarrhea. Fluid retention is a serious adverse effect that occurs in about 60% of patients and can be a concern for patients with preexisting cardiovascular disease or CKD. Adverse effects related to fluid retention may be severe and include pulmonary edema, pericardial effusion, and ascites. Cardiovascular adverse effects include transient atrial dysrhythmias, sinus tachycardia, vasodilation, and peripheral edema. Papilledema (swelling of the optic nerve) can occur during therapy and result in blurred vision, loss of visual acuity, and blindness, in rare cases. **Black Box Warning:** Although not common, allergic reactions, including anaphylaxis, have been reported with oprelvekin. The drug should be permanently discontinued if a patient experiences a hypersensitivity reaction.

Contraindications/Precautions: Oprelvekin is contraindicated in patients who have shown hypersensitivity to the drug on a previous exposure. It should be used with caution in patients with cardiac disease, especially HF, dysrhythmias, and left ventricular dysfunction, since fluid retention is a common adverse effect that can worsen these conditions. Oprelvekin should not be used following myeloablative therapy because the drug exhibits increased toxicity. The drug should be used with caution in patients with preexisting visual impairment; papilledema is a dose-limiting adverse effect in children receiving this drug.

Drug Interactions: Oprelvekin should not be administered within 24 hours of chemotherapy because the cytotoxic effects of the antineoplastic drugs decrease the effectiveness of the drug. Concurrent use with thiazide or loop diuretics may cause serious hypokalemia. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose may result in serious adverse effects, and close monitoring of cardiovascular and renal function is necessary. No specific therapy is available.

Nursing Responsibilities:

- Notify the prescriber prior to administration if the patient has a history of leukemia, multiple myeloma, or other myeloid malignancies.
- Monitor for and immediately report signs and symptoms of fluid overload, hypokalemia, and cardiac dysrhythmias.
- Monitor patients with preexisting fluid retention conditions carefully, such as HF, pleural effusion, or ascites, for worsening of symptoms.
- This drug has a black box warning for possible anaphylaxis. Promptly report any signs and symptoms of allergic reaction to the provider and discontinue the drug.

Lifespan and Diversity Considerations:

- Tachycardia, cardiomegaly, papilledema, conjunctival redness, and bone changes may occur more frequently in children taking oprelvekin than in adults. Carefully monitor heart rate and heart sounds, changes in visual acuity or eye pain, and for complaints of bone pain or changes in gait. Further cardiac testing (e.g., echocardiography) and frequent eye exams may be warranted.

Patient and Family Education:

- Do not take any other prescription or nonprescription drugs, dietary supplements, or herbal products without the approval of the healthcare provider.
- Immediately report shortness of breath, swelling of feet or ankles, rapid weight gain, chest pain, unusual fatigue or weakness, irregular heartbeat, fever of 38°C (100.5°F) or higher, unusual bruising or bleeding, or blurred vision.
- For self-administration, follow the procedure demonstrated to prevent contamination of the vial, syringe, or medicine. Never touch the rubber stopper of the vial or the needle of the syringe with your fingers. Dispose of needles and syringes as directed by a healthcare provider.
- Do not drive or perform other hazardous activities until the effects of the drug are known because this drug may cause drowsiness or dizziness.

- Notify the healthcare provider of any difficulty walking or bone pain, changes in visual acuity or eye pain, or rapid heart rate.
- Immediately notify the healthcare provider of any known or suspected pregnancy.
- Do not breastfeed while using this drug without approval of the healthcare provider.

Drugs Similar to Oprelvekin (Neumega)

The two other platelet enhancers are eltrombopag and romiplostim.

Eltrombopag (Promacta): Approved in 2008, eltrombopag is an oral medication that increases the number of platelets in the blood by activating thrombopoietin receptors. Its only indication is for the treatment of thrombocytopenia in patients with chronic ITP who have not responded to corticosteroids, immunoglobulins, or splenectomy. The drug carries a black box warning that it may cause hepatotoxicity. Liver laboratory values (alanine aminotransferase [ALT], aspartate aminotransferase [AST], and bilirubin) must be closely monitored and the drug discontinued if abnormal values persist. The most common adverse effects include nausea, diarrhea, upper respiratory tract infection, vomiting, increased ALT, myalgia, urinary tract infection, oropharyngeal pain, increased AST, pharyngitis, back pain, influenza, paresthesia, and rash. Because of the potential for serious adverse effects, the drug is available through a restricted distribution program. This drug is pregnancy category C.

Romiplostim (Nplate): Like eltrombopag, romiplostim was approved in 2008 and increases platelet count by activating the thrombopoietin receptor. Also like eltrombopag, the only indication is for the treatment of thrombocytopenia in patients with chronic ITP who have not responded to corticosteroids, immunoglobulins, or splenectomy. Romiplostim, however, does not exhibit hepatotoxicity. The most common adverse effects are arthralgia, dizziness, insomnia, myalgia, pain in extremity, abdominal pain, shoulder pain, dyspepsia, and paresthesia. It is only administered by subcutaneous injection and the drug has a restricted distribution program. This drug is pregnancy category C.

CONNECTION Checkpoint 39.3

Abciximab, eptifibatide, and tirofiban are drugs that can cause severe ITP. From what you learned in Chapter 38, to what class do these drugs belong and what is the primary indication for their use? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Classification of Anemias

39.5 Anemias may be caused by hemorrhage or a change in red blood cell production or destruction.

Anemia is a condition in which RBCs have a reduced capacity to deliver oxygen to tissues. Anemia is a serious health problem that can have a major impact on the quality of life. It is estimated that over 3.4 million Americans have the disorder. Although there are dozens of possible causes of anemia, most fall into one of the following categories:

- Blood loss due to hemorrhage
- Increased erythrocyte destruction
- Decreased erythrocyte production.

Anemia is considered a sign of an underlying disorder, rather than a distinct disease. For example, anemia is commonly associated with peptic ulcer, various malignancies, and CKD. For therapy to be successful, the underlying pathology must be identified and treated. Despite the fact it is often considered secondary to other diseases, proper treatment of anemia is necessary to improve the patient's ability to adequately perform ADLs.

Classification of anemia is generally based on a description of the erythrocyte's size and color. Sizes are described as normal (normocytic), small (microcytic), or large (macrocytic). Color is based on the amount of Hgb present and is described as normal red (normochromic) or light red (hypochromic). This classification is shown in Table 39.2. It is not unusual for patients to have more than one type of anemia concurrently.

Depending on the type of anemia, several vitamins and minerals may be given to enhance the oxygen-carrying capacity of blood. The most common antianemic drugs are iron salts, cyanocobalamin (Nascobal), and folic acid. Doses of these drugs are listed in Table 39.3.

Table 39.2 Classification of Anemia

Morphology	Description	Examples
Macrocytic-normochromic	Large, abnormally shaped erythrocytes with normal Hgb concentration	Pernicious anemia, folate deficiency anemia
Microcytic-hypochromic	Small, abnormally shaped erythrocytes with decreased Hgb concentration	Iron deficiency anemia, thalassemia
Normocytic-normochromic	Destruction or depletion of normal erythroblasts or mature erythrocytes	Aplastic anemia, hemorrhagic anemia, sickle cell disease, hemolytic anemia

Table 39.3 Antianemic Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
cyanocobalamin (Nascobal)	IM/deep subcutaneous: 30 mcg/day for 5–10 days, then 100–200 mcg/month Intranasal: 1 spray (500 mcg) in one nostril once weekly	*Diarrhea, hypokalemia, rash* Anaphylaxis
folic acid	PO/IM/subcutaneous/IV: less than 1 mg/day	*Flushing, rash* Hypersensitivity
Iron Salts		
ferrous fumarate (Feostat, others)	PO: 200 mg tid or qid	*Nausea, heartburn, constipation, dark stools* Cardiovascular collapse, aggravation of peptic ulcers or ulcerative colitis, hepatic necrosis, hypotension (ferumoxytol), anaphylaxis (iron dextran), respiratory arrest (iron dextran), seizures (iron dextran)
ferrous gluconate (Fergon, Ferralet)	PO: 325–600 mg qid; may be gradually increased to 650 mg qid as needed	
ferrous sulfate (Feosol, Feostat, others)	PO: 100–200 mg elemental iron q12h	
ferumoxytol (Feraheme)	IV: Single dose of 510 mg followed by a second 510-mg dose 3–8 days later	
iron dextran (Dexferrum)	IM/IV: Dose is individualized and determined from a table supplied by the drug manufacturer that correlates body weight to Hgb values (max: 100 mg within 24 h)	
iron sucrose (Venofer)	IV: 100–200 mg by slow IV injection or infusion	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CONNECTIONS: Community-Oriented Practice

Epoetin Alfa for Blood Doping

Blood doping, withdrawing blood from an athlete and then re-transfusing it before a competitive sporting event, has been used by some athletes in an attempt to gain a competitive edge. With increased RBCs and higher Hgb levels, oxygen-carrying capacity is thought to increase, boosting endurance. With the advent of epoetin alfa, blood doping took on new meaning. Some athletes found that the use of epoetin well before an athletic meet achieved the same effects without the ability to detect the drug through testing. Charges of blood doping with epoetin were initially difficult to prove, but as more sophisticated tests became available, detection of the presence of the drug was possible, and athletes were ejected from events or had their winnings disqualified. Newer drugs, without new tests to detect them initially, are on the horizon, and the race against cheating in sports continues.

Blood doping is not without a price, however. Increased blood volume and viscosity have led to hypertension, thrombosis, and death. Undeterred, some athletes, desperate for a competitive edge, continue to use it. Adolescents involved in competitive sports activities may have heard about epoetin and may question its advantages. The nurse plays a key role in providing accurate information about epoetin and related drugs and counseling athletes about the risks and adverse effects of performance-enhancing drugs.

Antianemic Drugs

39.6 Administration of iron salts can rapidly reverse symptoms of iron deficiency anemia.

Iron is a mineral essential to the function of several mitochondrial enzymes involved in metabolism and energy production in cells. It is also a component of certain antioxidant enzymes that assist in clearing the body of free radicals. Most iron in the body, 60% to 80%, is associated with Hgb inside erythrocytes. Knowledge of iron balance and homeostasis is necessary to understand the pharmacotherapy of iron deficiency anemia. Factors affecting iron balance are illustrated in Figure 39.2.

The two basic forms of iron in biological systems are ferrous (Fe^{2+}) and ferric (Fe^{3+}). Most food contains iron in the ferric state, which is not absorbed in the gastrointestinal (GI) tract. In the presence of stomach acid, however, the ferric form is converted to the ferrous form, which is readily absorbed in the duodenum. Iron absorption is dynamic; if the body senses a shortage of iron in the blood, GI absorption increases. When iron stores are plentiful, less iron is absorbed from food. Since adults only need about 8 mg of iron per day, a normal diet supplies sufficient amounts of the mineral for most people.

Other factors affect the absorption of iron. Iron in heme, which is found in meat, fish, and poultry, is 3 times more absorbable than the nonheme iron found in vegetables and grains. Thus meats are considered the best natural source of absorbable iron. Calcium inhibits the absorption of iron; thus, those who drink milk with meals are at greater risk for iron deficiency. Vitamin C increases iron absorption about 30%, while black tea diminishes absorption.

Because free iron is toxic, the body binds the mineral to the protein complexes **ferritin**, **hemosiderin**, and **transferrin**. Ferritin and hemosiderin maintain iron stores inside cells, whereas transferrin transports iron to sites throughout the body where it is needed, such as to the bone marrow for incorporation into Hgb. Serum ferritin levels are a reliable indicator of how much iron is being stored by the body. Low serum ferritin levels (less than 12 ng/mL) are characteristic of iron deficiency anemia. In addition to Hgb,

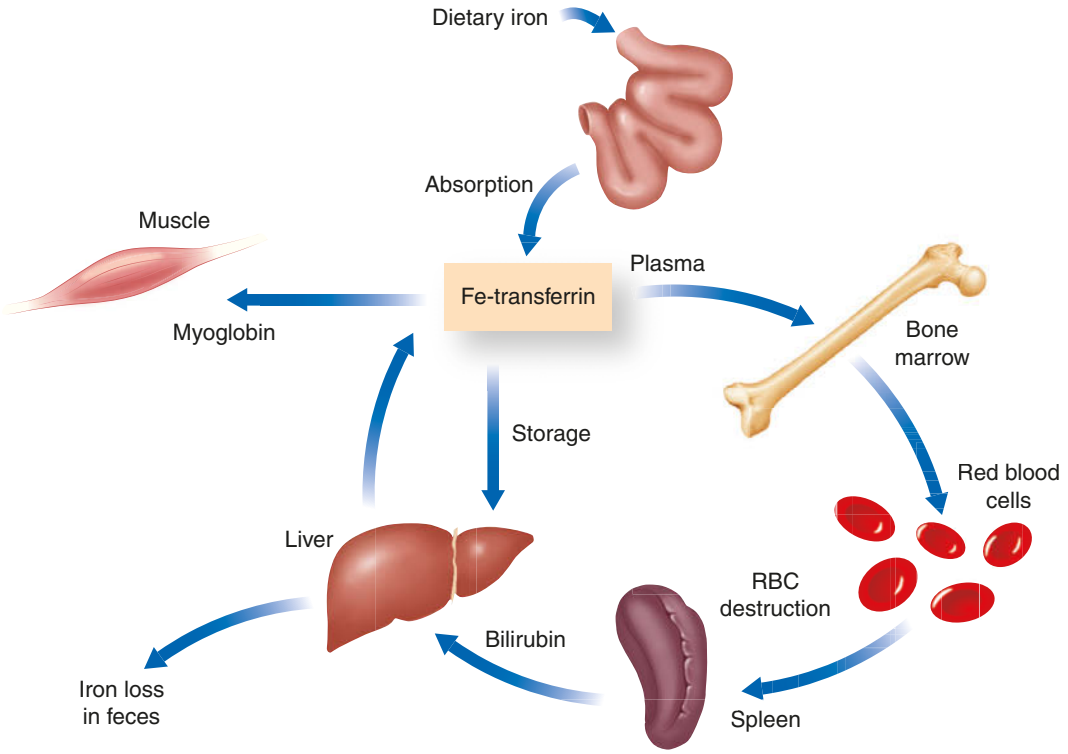

Figure 39.2 Iron metabolism.

major storage depots for iron are the liver and myoglobin in skeletal muscle.

After erythrocytes die, nearly all of the iron in their Hgb is incorporated into transferrin and recycled for later use. Because of this efficient recycling, only about 1 mg of iron is excreted from the body per day, making daily dietary iron requirements in most individuals quite small. Vegetarians are at higher risk of iron deficiency anemia because of a lack of heme intake from meat and must take care to select foods rich in iron. Iron requirements may double during growth, pregnancy, and menses; thus, intake of iron must be increased to maintain proper iron balance.

Iron deficiency is the most common cause of anemia worldwide. More than 50% of patients diagnosed with iron deficiency anemia have GI bleeding, such as may occur from GI malignancies or chronic peptic ulcer disease (PUD). In the United States and Canada, iron deficiency most commonly occurs in women of childbearing age due to pregnancy and as a result of blood losses during menses. Low-dose iron supplements are recommended during pregnancy to prevent this condition. Certain individuals have an increased demand for iron, including those who are on meat-free diets or undergoing intensive athletic training. These conditions may require more than the recommended dietary allowance (RDA) of iron (see Chapter 61). In undeveloped countries, the primary cause of iron deficiency anemia is the lack of meat or fresh fruits and vegetables in the diet. The most significant effect of iron deficiency is a reduction in erythropoiesis, resulting in symptoms of anemia.

Iron therapy is initiated to alleviate symptoms of anemia caused by blood loss or dietary deficiency. Once diagnosed, a primary goal is to identify the etiology of the disorder and treat the underlying pathology. Choice of therapy depends on the etiology and severity of the deficiency:

- Mild anemia may be prevented or corrected in most patients by increasing the intake of iron-rich foods, such as fish, red meat, fortified cereal, and whole-grain breads.
- Moderate anemia is corrected by oral iron supplementation.
- Severe anemia, and that caused by iron malabsorption disorders, is corrected by parenteral iron therapy.

CONNECTIONS: Patient Safety

Iron Poisoning in Children

While talking with a group of young mothers, the nurse becomes concerned about the remarks made by one of the members. The mother states, "I insist that my children take iron-fortified vitamins every day. My children really enjoy taking the cute little cartoon vitamins. They call the vitamins their 'morning candy.'" How should the nurse respond? Is this statement made by the mother concerning to the nurse?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

PROTOTYPE DRUG **Ferrous Sulfate (Feosol, Feostat, Others)**

Classification **Therapeutic:** Drug for anemia
Pharmacologic: Iron supplement

Therapeutic Effects and Uses: Ferrous sulfate is an iron supplement containing about 20% elemental iron. Desiccated (dried) ferrous sulfate contains 30% elemental iron. It is inexpensive and available in a wide variety of dosage forms to prevent or rapidly reverse symptoms of iron deficiency anemia. Enteric-coated and extended release forms are available. If tolerated, the drug should be taken on an empty stomach, at least 1 hour before or 2 hours after a meal.

In general, patients with iron deficiency respond rapidly to the administration of ferrous sulfate. Although a positive therapeutic response may be achieved in 48 hours, therapy may continue for several months to replenish the storage depots for iron. As the deficiency is corrected, the body will absorb a smaller percentage of elemental iron in each dose until iron intake balances iron loss. This is assuming, of course, that the source of the iron imbalance, such as bleeding or dietary insufficiency, has been corrected. Laboratory evaluation of Hgb, transferrin, and Hct levels is conducted regularly to assess the progress of pharmacotherapy. Dosage is decreased as therapy progresses and the deficiency is corrected.

If rapid, symptomatic improvement is not experienced, the reasons for the treatment failure must be carefully explored. The patient may be experiencing continued bleeding or may have a malabsorption disorder that prevents the iron from being absorbed. A common reason for treatment failure is lack of adherence to pharmacotherapy. Patients may stop taking the drug due to severe nausea and vomiting, or they may take the drug with food or other drugs that inhibit iron absorption. Excellent assessment and teaching skills on the part of the nurse are key to achieving successful pharmacotherapeutic outcomes in these patients.

Mechanism of Action: After absorption, most iron is used by the body to make Hgb. Laboratory values of Hgb should increase 2 to 4 g/dL every 3 weeks until normal values are achieved. In addition, therapy is continued until serum ferritin levels return to normal, indicating that the iron storage depots are filled.

Pharmacokinetics:

Route(s)	PO
Absorption	5–30% absorbed
Distribution	Well distributed; crosses the placenta
Primary metabolism	Undergoes extensive enterohepatic recirculation
Primary excretion	Feces, urine, and skin
Onset of action	3 days to 4 weeks
Duration of action	Unknown

Adverse Effects: The most common adverse effects of ferrous sulfate are nausea and vomiting, which will occur to some degree in most patients. Taking the drug with food will diminish GI upset but can decrease the absorption of iron by 50% to 70%. The degree of nausea and vomiting is dose related and serious symptoms may require a dosage adjustment. Contact of liquid iron with teeth should be avoided because the drug can cause brown stains. Iron preparations will darken stools but this is a harmless adverse effect. Because constipation is common, especially in older adults, an increase in dietary fiber intake is indicated. **Black Box Warning:** Unintentional overdoses of iron-containing products are a leading cause of fatal poisoning of children.

Contraindications/Precautions: Iron salts should not be administered for anemia other than that caused by iron deficiency, because iron will not correct these conditions and may build to toxic levels. The drug should not be administered to patients with hemochromatosis, a disease in which the patient has excess iron stores. Ferrous sulfate may irritate the stomach mucosa and increase bleeding in patients with PUD. The drug may cause diarrhea if administered to patients with regional enteritis or ulcerative colitis.

Drug Interactions: Absorption is reduced when oral iron salts are given concurrently with antacids, proton pump inhibitors, or calcium supplements. Iron decreases the absorption of tetracyclines, fluoroquinolones, levodopa, and etidronate. To prevent possible interactions, it is advisable to take iron supplements 1 to 2 hours before or after other medications. **Herbal/Food:** Food (especially dairy products), coffee, and tea will inhibit iron absorption. Vitamin C will increase absorption.

Pregnancy: Category A.

Treatment of Overdose: Iron is very toxic and most overdoses are unintentional, occurring in children under the age of 6 years. The antidote for acute iron intoxication is the parenteral drug deferoxamine (Desferal). This chelating drug binds iron, which is removed by the kidneys, turning the urine a reddish-brown color.

Nursing Responsibilities:

- Give on an empty stomach if possible because oral iron preparations are best absorbed between meals. If GI adverse effects are prominent, give with or immediately after meals with adequate liquid.
- If the patient experiences difficulty swallowing tablets or capsules, recommend a liquid formulation or a less corrosive form, such as ferrous gluconate.

- Dilute liquid preparations well and give them through a straw or place them on the back of the tongue with a dropper to prevent staining of teeth and to mask the unpleasant taste.
- Mix Feosol elixir with water because it is not compatible with milk or fruit juice. Fer-In-Sol (drops) may be given in water or in fruit or vegetable juice, according to the manufacturer.
- Iron therapy may be continued for 2 to 3 months after the Hgb level has returned to normal (roughly twice the period required to normalize Hgb concentration).
- Monitor bowel movements because constipation is a common adverse effect. Increase the amount of fluids and soluble fiber in the diet.

Lifespan and Diversity Considerations:

- Due to age-related changes in peristalsis and bowel function, monitor the older adult for constipation. Increase the amount of fluids and soluble fiber in the diet. A stool softener or laxative may be needed.
- Keep iron preparations in a secured location if there are young children in the household to prevent unintentional poisoning.

Patient and Family Education:

- Do not take tablets or capsules within 1 hour of bedtime.
- Do not crush tablets or empty the contents of capsules because this may cause GI distress.
- Take ferrous sulfate with a full glass of water. Rinse mouth with clear water immediately after ingestion.
- Consume citrus fruit or tomato juice with iron preparations (except the elixir form) because ascorbic acid (vitamin C) increases iron absorption.
- Avoid taking iron salts with milk, eggs, antacids, or caffeine beverages, because these inhibit drug absorption.
- Iron preparations cause dark green or black stools. This is a harmless side effect.
- Report constipation or diarrhea to the healthcare provider. Symptoms may be relieved by adjustments in dosage or diet, or by changing to another iron preparation.

Drugs Similar to Ferrous Sulfate (Feosol, Feostat, Others)

At least eight iron salts are available for administration to patients with iron deficiency anemia. Iron salts are often classified by their route of administration, either oral (PO) or parenteral.

Oral iron salts: Oral iron salts include ferrous fumarate, ferrous gluconate, polysaccharide-iron complex, and carbonyl iron. The choice of specific drug and dose are based on iron content and degree of GI tolerability. Table 39.4 lists the amount of elemental iron in these drugs.

Table 39.4 Iron Content of Oral Iron Formulations

Preparation	Elemental Iron	Dose Needed to Provide 200 mg of Elemental Iron per Day
carbonyl iron	100%	200 mg
ferrous fumarate	33%	600 mg
ferrous gluconate	12%	720 mg
ferrous sulfate: desiccated	30%	660 mg
ferrous sulfate: regular	20%	1000 mg
polysaccharide-iron complex	100%	200 mg

A large number of brand-name iron products and formulations are available, including tablets, drops, elixirs, and suspensions. Nausea, vomiting, constipation, and diarrhea are common adverse effects with all oral iron preparations. Slow-release products, called carbonyl iron (Feosol-caps, Ferronyl), are more expensive but are less dangerous in children following unintentional ingestion because there is a longer period for intervention before toxic effects materialize. Some products have an enteric coating so that the capsule or tablet dissolves in the intestine, thus causing less gastric irritation. Recall, however, that stomach acid is necessary to convert iron to its more absorbable form. In addition, enteric coatings are less reliable because they may dissolve after the drug has passed the duodenum, which is the primary site for iron absorption. Vitamin C is added to many oral iron supplements because it enhances iron absorption. Some products are formulated as multivitamins. For example, Niferex PN Forte, which is formulated specifically for pregnant or lactating women, contains a polysaccharide-iron complex and vitamins A, D, C, folic acid, B complex, calcium, iodine, magnesium, copper, and zinc. Adding extra enhancers such as additional vitamins, extended release properties, or an enteric coating increases the cost of the drug but not necessarily its effectiveness. The amount of elemental iron in the product and adverse effects should be the primary factors guiding therapy.

Parenteral iron salts: Ferumoxytol (Feraheme), iron dextran (Dexferrum), iron sucrose (Venofer), and ferric gluconate (Ferrlecit) are parenteral preparations reserved for patients who cannot tolerate oral iron preparations or who have a malabsorption disorder preventing iron absorption from the GI tract. Giving parenteral iron does not lead to a faster recovery for patients with iron deficiency anemia because the body is limited as to how quickly it can make Hgb and new RBCs. These drugs are clearly more toxic than the oral iron products and require careful monitoring during pharmacotherapy.

Ferumoxytol (Feraheme) is a newer iron salt approved to treat iron deficiency associated with chronic kidney disease (with or without dialysis). The drug consists of iron oxide protected by a carbohydrate shell. The shell remains intact until the drug enters macrophages, whereby the iron is released to its storage depots. The advantage of ferumoxytol over other iron salts is that it can be administered safely by the IV route and can raise iron levels more rapidly.

All parenteral drugs are equally effective at raising iron levels. All are given IV. Iron dextran is also available by the IM route although this is rarely used due to pain at the injection site and unreliable absorption from the muscle. Iron sucrose and iron gluconate have more limited application. They are approved only for patients with iron deficiency anemia undergoing chronic hemodialysis who are also receiving erythropoietin.

Anaphylaxis has been reported with all parenteral iron salts, and several contain a black box warning to this effect. Patients should be observed for at least 30 minutes following the completion of the infusion to assess for possible allergic reactions, which may cause respiratory arrest and circulatory collapse. Some healthcare providers order test doses prior to every administration of IV iron salts, because anaphylaxis may occur on second and subsequent doses. Ferric gluconate produces a lower incidence of anaphylactic shock.

Common adverse reactions of iron dextran are hypotension, headache, muscle pain, and joint pain; these are more severe when given IV. Iron dextran appears to increase bone density in the joints, which is the probable cause of the muscle and joint pain. Frequent adverse effects with ferric gluconate include cramping, nausea, vomiting, hypotension, and rash. Iron sucrose is well tolerated, with some patients experiencing leg cramps and hypotension.

CONNECTION Checkpoint 39.4

From what you learned in Chapter 8, explain why a patient who is pregnant has a substantially higher iron requirement compared to a nonpregnant woman. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

39.7 Pernicious anemia may be successfully treated with the administration of vitamin B_{12}.

Vitamin B_{12} and folic acid are dietary nutrients essential for rapidly dividing cells. The continuous, high rate of erythropoiesis occurring throughout the lifespan demands a continuous supply of these vitamins. Without them, the normal production of RBCs is interrupted and large, immature erythrocytes that are unable to carry the same amount of oxygen as normal RBCs are released into the blood, and anemia results.

Vitamin B_{12} is an essential component of two coenzymes required for normal cell growth and DNA replication. Neither plants nor animals synthesize vitamin B_{12}; only bacteria can make this vitamin. Because the body requires only miniscule amounts of vitamin B_{12} (3 mcg/day), deficiency of this vitamin is usually not due to insufficient dietary intake. Instead, the most common cause of vitamin B_{12} deficiency is absence of **intrinsic factor**, a protein secreted by stomach cells. Intrinsic factor forms a complex with vitamin B_{12}, which is then absorbed into the circulation. Without the formation of this complex, vitamin B_{12} is not absorbed from the intestine. Figure 39.3 illustrates the metabolism of vitamin B_{12}.

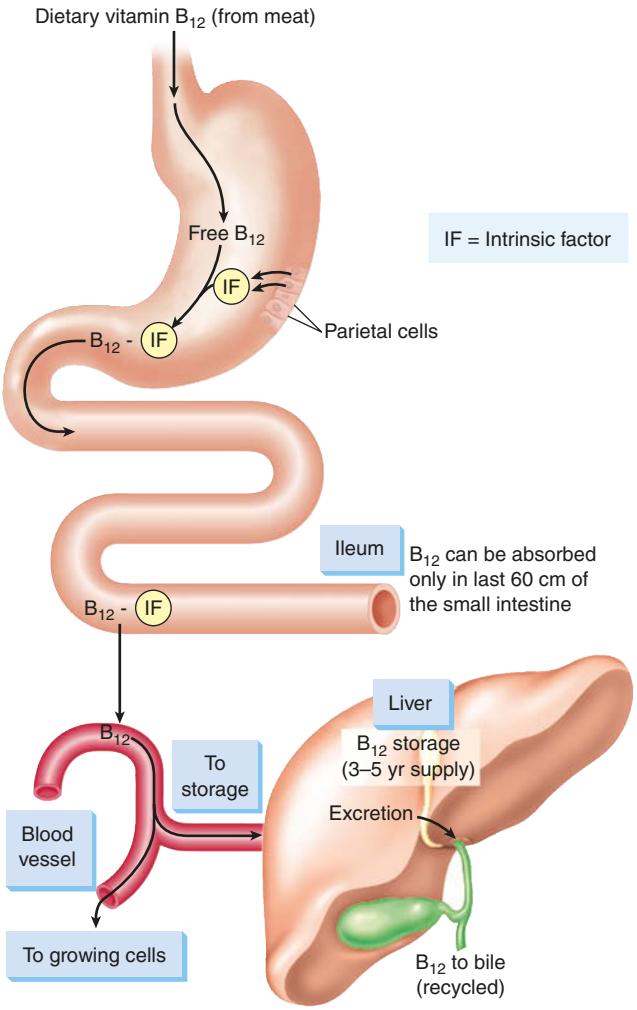

Figure 39.3 Metabolism of vitamin B_{12}.

Deficiency of intrinsic factor is caused by inflammatory diseases of the stomach or by gastric resection. Inflammatory diseases of the small intestine that affect food and nutrient absorption may also cause vitamin B_{12} deficiency. Because vitamin B_{12} is found primarily in foods of animal origin, strict vegetarians may require a vitamin supplement to avoid deficiency. The center portion of the vitamin B_{12} molecule contains the metal ion cobalt, which is a micromineral essential to human nutrition.

The most profound consequence of vitamin B_{12} deficiency is a megaloblastic anemia called **pernicious anemia**, which affects both the hematologic and nervous systems.

In pernicious anemia, the hematopoietic stem cells produce abnormally large erythrocytes that do not fully mature. Although RBCs are most affected, lack of maturation of all blood cell types may occur in severe disease. Symptoms of pernicious anemia are often nonspecific and develop slowly, sometimes over several years. Profound nervous system symptoms distinguish this disease from most other anemias and include memory loss, confusion, unsteadiness, tingling or numbness in the limbs, delusions, mood disturbances, and even hallucinations in severe deficiencies. Permanent nervous system impairment may result if the disease remains untreated for 6 to 12 months. Pharmacotherapy includes the administration of cyanocobalamin, a form of vitamin B_{12}. Prior to administration of vitamin B_{12}, the nurse should assess for other causes of anemia including GI bleeding, GI surgery, tapeworm infestation, and gluten enteropathy.

Folic acid, or **folate**, is a B-complex vitamin that is essential for normal DNA and ribonucleic acid (RNA) synthesis. Like B_{12} deficiency, insufficient folic acid levels can manifest as anemia. In fact, the metabolisms of vitamin B_{12} and folic acid are intricately linked; a B_{12} deficiency will create a lack of activated folic acid. Folate deficiency is one of the most common types of anemias in the United States.

Folic acid does not require intrinsic factor for intestinal absorption, and the most common cause of deficiency is insufficient dietary intake. This is often observed in patients with chronic alcoholism because their diets are often deficient in this nutrient, and ethanol interferes with folate metabolism in the liver. Fad diets and absorption diseases of the small intestine can also lead to folate-deficiency anemia. Hematopoietic symptoms of folate deficiency are the same as those for B_{12} deficiency; however, no neurologic signs are present. Folate deficiency during pregnancy has been linked to neural birth defects such as spina bifida. Mild deficiency or prophylaxis of folate deficiency is accomplished by increasing the dietary intake of folic acid through fresh green vegetables, beans, and wheat products. In cases when adequate dietary intake cannot be achieved, therapy with folic acid is warranted. Folic acid is presented as a drug prototype for water-soluble vitamins in Chapter 61.

PharmFACT

A deficiency of vitamin B_{12}, folate, or vitamin B_6 may increase the blood level of homocysteine, an amino acid normally found in the blood. An elevated blood level of homocysteine is a risk factor for heart disease and stroke (National Institutes of Health, 2016b).

PROTOTYPE DRUG Cyanocobalamin (Nascobal)

Classification **Therapeutic:** Agent for anemia
Pharmacologic: Vitamin supplement

Therapeutic Effects and Uses: Cyanocobalamin is a purified form of vitamin B_{12} that is indicated for patients with vitamin B_{12} deficiency anemia. Treatment of vitamin B_{12} deficiency is most often by weekly, biweekly, or monthly intramuscular (IM) or subcutaneous injections. A typical regimen for pernicious anemia would be 100 mcg IM or subcutaneous once daily for 1 week, followed by 100 mcg on alternate days for 7 doses. Dose reduction continues, with administration every 3 to 4 days for another 2 to 3 weeks, then 100 mcg IM monthly for life. Oral vitamin B_{12} formulations are available primarily as vitamin supplementation, although they are only effective in patients who have sufficient amounts of intrinsic factor and normal absorption in the small intestine.

An intranasal spray formulation (Nascobal) is available that provides for once-weekly dosage. Nascobal is generally used for maintenance therapy after normal vitamin B_{12} levels have been restored by parenteral preparations. The intranasal form is also indicated to prevent vitamin B_{12} deficiency in people who are strict vegetarians.

Parenteral administration of cyanocobalamin rapidly reverses most signs and symptoms of B_{12} deficiency, usually within a few days or weeks. If the disease has been prolonged, symptoms may take longer to resolve, and some neurologic damage may be permanent. In most cases, treatment must often be maintained for the remainder of the patient's life. Periodic laboratory blood testing and Hgb values are used to gauge the success of pharmacotherapy.

Mechanism of Action: Administration of cyanocobalamin reverses vitamin B_{12} deficiency and results in rapid improvement of anemia symptoms. Normal RBC production resumes, with laboratory evaluation of blood and bone marrow showing continuous improvement over about 7 days. Therapy may extend to several months to restore hepatic stores of the vitamin.

Pharmacokinetics:

Route(s)	PO, IM, deep subcutaneous, intranasal
Absorption	Well absorbed; PO absorption requires intrinsic factor
Distribution	Widely distributed; crosses the placenta; secreted in breast milk
Primary metabolism	Primarily converted in tissues to coenzyme B_{12} and stored in liver; extensive enterohepatic recirculation
Primary excretion	Renal
Onset of action	Peak serum level: 8–12 h (PO), 1–2 h (intranasal), and 1 h (IM/subcutaneous)
Duration of action	Half-life: 6 days

Adverse Effects: Adverse effects from cyanocobalamin are uncommon. Because hypokalemia may occur, serum potassium levels are monitored periodically. A small percentage of patients receiving B_{12} exhibit rashes, itching, or other signs of allergy. Anaphylaxis is possible, though rare, with parenteral administration. Sodium retention occurs in some patients, with possible worsening of HF.

Contraindications/Precautions: Patients with suspected sensitivity to cobalt should receive an intradermal test dose because they may experience allergic reactions or anaphylaxis to the drug. Monotherapy with folic acid will not improve symptoms of vitamin B_{12} deficiency anemia. Cyanocobalamin is contraindicated in patients with severe pulmonary disease and should be used cautiously in patients with heart disease because of the potential for sodium retention caused by the drug.

Drug Interactions: Drug interactions with cyanocobalamin are minor and are normally not clinically significant. **Herbal/Food:** Unknown.

Pregnancy: Category A (C when used parenterally). Maternal requirements for vitamin B_{12} increase during pregnancy and lactation, although the drug should not be taken in higher than recommended amounts.

Treatment of Overdose: Overdosage has not been reported with this drug.

Nursing Responsibilities:

- Monitor serum potassium levels during the first 48 hours. Conversion to normal erythropoiesis increases the erythrocyte potassium requirement and can result in severe hypokalemia and sudden death.
- Monitor vital signs in patients with cardiac disease and in those receiving parenteral cyanocobalamin. Be alert to symptoms of pulmonary edema, which may occur early in therapy.
- Obtain a complete diet and drug history and inquire into alcohol drinking patterns for all patients receiving cyanocobalamin to identify and correct poor dietary habits.

Lifespan and Diversity Considerations:

- Evaluate the older adult's nutritional status and weight during each monthly visit for their injection and laboratory work.
- Due to undetected heart disease, monitor the older adult for edema or signs and symptoms of HF.

Patient and Family Education:

- Do not discontinue taking this drug without approval of the healthcare provider. The drug will be required lifelong.
- If using the spray form, prime the pump before the first use by pumping the spray a few times until a fine mist appears. If it has been longer than 5 days between uses, prime the pump again. Sniff gently while spraying.
- Eat foods that are rich sources of B_{12} (nonpernicious anemia) such as nutrient-fortified breakfast cereals, vitamin B_{12}-fortified soy milk, organ meats, clams, oysters, egg yolk, crab, salmon, sardines, muscle meat, milk, and dairy products.

Drugs Similar to Cyanocobalamin (Nascobal)

There are no drugs similar to cyanocobalamin.

Understanding Chapter 39

Key Concepts Summary

39.1 Hematopoiesis is a dynamic process that is responsive to the changing demands of the body.

39.2 Erythropoietin stimulates production of red blood cells and is used to treat anemia.

39.3 Colony-stimulating factors increase the production of leukocytes.

39.4 Platelet enhancers may be used to treat thrombocytopenia.

39.5 Anemias may be caused by hemorrhage or a change in red blood cell production or destruction.

39.6 Administration of iron salts can rapidly reverse symptoms of iron deficiency anemia.

39.7 Pernicious anemia may be successfully treated with the administration of vitamin B_{12}.

CASE STUDY: Making the Patient Connection

Remember the patient "Carl Guenther" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

"A real people-person who never met a stranger." That is how family and friends have always described Carl Guenther. His positive and outgoing personality is well known in the community. When Carl was informed about his prostate cancer, he handled the diagnosis well and with his usual optimism. He was confident that the chemotherapy would be successful. His mantra for years had been to "Live every day as if it were your last." However, the treatment for the cancer had adverse effects that he did not expect and his enthusiasm diminished.

Carl is a 72-year-old retired sales representative for a chain of department stores. His entire career was centered on interacting with all kinds of people. When he retired, his outgoing nature was an asset for the many community agencies at which he volunteered. He was active in the local Lions Club, his church's outreach ministry, and at the children's hospital. He had even considered working as a greeter at his neighborhood department store.

As he went through chemotherapy, the associated nausea and vomiting were well managed with antiemetic drugs. His physical appearance did not change much because Carl had minimal hair loss due to the chemotherapy. Now he faces an exceedingly low WBC count and has been advised to avoid potential sources of infection, including people. By far this is the worst adverse effect of the chemotherapy for Carl. He feels socially isolated and depressed. *Is this the end?*, he wonders. *Am I to die lonely?*

Critical Thinking Questions

1. The healthcare provider orders filgrastim (Neupogen) 10 mcg/kg daily for 4 days. Carl asks you, his nurse, "How does this drug work?" What is your response?
2. List interventions that should be followed during this period of chemotherapy-induced neutropenia to protect Carl from infection.
3. What adverse effects would you monitor in patients receiving Neupogen?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

When the blood test returned from Betty Arnold's preemployment physical, the results indicated anemia. "No wonder I feel so exhausted all the time," she said. "I thought my fatigue was from taking care of my five children, my home, and my aging parents." When she saw her primary healthcare provider, she was diagnosed with iron deficiency anemia and prescribed ferrous sulfate (Feosol) 160-mg sustained release tablets daily.

1. As the nurse, you will provide teaching for this patient about dietary sources of iron. Create a list of foods high in iron.
2. What adverse effects should Betty watch for while taking Feosol?
3. Is there a best time of the day to take this medication? Why?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Which statement would the nurse include in the care plan for a patient receiving epoetin alfa?
   1. Avoid fresh fruit and vegetables and partially cooked meats.
   2. Encourage frequent rest periods to minimize fatigue.
   3. Limit exposure to direct sunlight and use sunscreen when outdoors.
   4. Protect tissues and mucous membranes from traumatic injury.
2. Darbepoetin (Aranesp) is prescribed for each of the following patients. A nurse should question the order for which condition?
   1. A patient with HIV who is receiving zidovudine
   2. A patient with uncontrolled hypertension
   3. A patient with chronic kidney disease
   4. A patient with chemotherapy-induced anemia

3. The patient is being treated with filgrastim (Neupogen). Which of the following would the nurse monitor to determine the effectiveness of this drug?
   1. Red blood cell counts
   2. Platelet counts
   3. White blood cell counts
   4. Reticulocyte count and mean cell volume (MCV)

4. The nurse is teaching the patient about oprelvekin (Neumega). Which statement, if made by the patient, indicates that additional health teaching is needed?
   1. "This drug stimulates the production of platelets."
   2. "I should weigh myself and watch for fluid retention."
   3. "I will report vision changes to my healthcare provider."
   4. "I will add more iron-rich foods to my diet."

5. A patient who regularly consumes significant amounts of alcohol is prescribed cyanocobalamin (Nascobal) and states, "I don't understand why my healthcare provider has prescribed B_{12} injections." The nurse's response would be based on which physiologic concept?
   1. Patients who regularly consume large amounts of alcohol are often deficient in this nutrient.
   2. Alcohol facilitates folate metabolism in the liver, which destroys vitamin B_{12}.
   3. Patients who regularly consume large amounts of alcohol are at high risk for neutropenia, a condition that develops from vitamin B_{12} loss.
   4. Liver cirrhosis caused by large amounts of alcohol ingestion diminishes natural physiologic deposits of B_{12}.

6. The nurse is teaching a patient about ferrous sulfate (Feosol). What instructions should be included in the teaching plan for this patient? (Select all that apply.)
   1. This drug should be taken on an empty stomach at least 1 hour before or 2 hours after a meal.
   2. Getting liquid iron on teeth should be avoided because the drug can cause brown stains.
   3. Iron preparation may darken stools and cause constipation.
   4. Vitamin E is added to many oral iron supplements because it enhances iron absorption.
   5. This drug can be taken with caffeinated beverages.

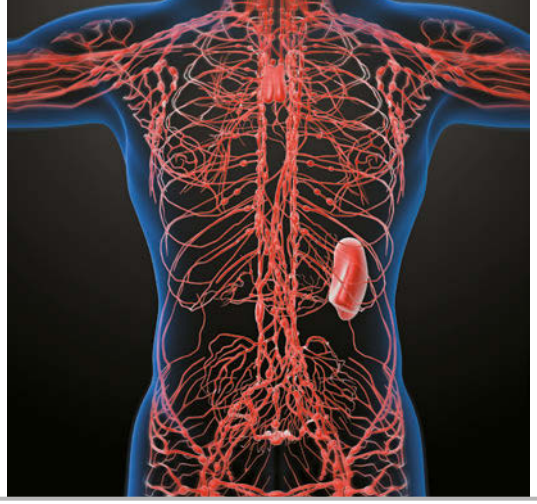
Pharmacology of Body Defenses



CHAPTER 40 Review of Body Defenses and the Immune System / 714

CHAPTER 41 Pharmacotherapy of Inflammation and Fever / 723

CHAPTER 42 Immunostimulants and Immunosuppressants / 741

CHAPTER 43 Immunizing Agents / 762

Chapter 40
Review of Body Defenses and the Immune System

Chapter Outline

- Organization of the Lymphatic System
- Innate (Nonspecific) Body Defenses
  - Inflammation
- Specific (Adaptive) Body Defenses
  - Humoral Immune Response
  - Cell-Mediated Immune Response

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the major components of the lymphatic system.
2. Describe the components of the nonspecific body defense system and their functions.
3. Compare and contrast specific and nonspecific body defenses.
4. Identify the signs and symptoms of inflammation.
5. Outline the basic steps in the acute inflammatory response.
6. Explain the role of histamine and other chemical mediators in the inflammatory response.
7. Compare and contrast the humoral and cell-mediated immune responses.

Key Terms

adaptive defenses, 719
antibodies, 720
antigens, 719
B cell, 720
complement system, 717
cytokines, 720
histamine, 718
immunity, 715
inflammation, 718
innate body defenses, 715
interferons (IFNs), 718
lymph nodes, 715
lymphatic system, 715
phagocytes, 717
plasma cells, 720
T cells, 720

The human body is under continuous attack from a host of foreign invaders, including viruses, bacteria, fungi, and even single-celled animals. Some of these pathogens intentionally seek out humans because it is an essential part of their life-cycle, whereas others happen to be "at the right place and time" when a cut or scrape allows entrance into the body. Fortunately, the body's extensive defenses are capable of mounting a rapid and effective response against most of these pathogens. Drugs used to modify body defenses, which include anti-inflammatory drugs, immunostimulants, immunosuppressants, and vaccines, are presented in Chapters 41 through 43. The purpose of this chapter is to review the fundamental concepts of body defenses that apply to the pharmacotherapy of the immune system and infectious disease. For a more thorough review of this topic, the student should consult an anatomy and physiology textbook.

Organization of the Lymphatic System

40.1 The lymphatic system is the primary organ system that protects the body from invasion by foreign agents.

The components of the lymphatic system provide the body with **immunity**, which is the ability to resist injury and infections. The **lymphatic system** comprises a network of cells, vessels, and tissues that provide immune surveillance. This monitoring function begins when fluid leaves the capillaries due to the osmotic forces and high pressure in the capillaries. This fluid, known as lymph, enters blind-ended lymphatic vessels and slowly travels on its journey through the lymphatic system. As much as 3 L of fluid per day travel through the highly branched lymphatic vessel network to eventually return to the cardiovascular circulation.

Lymphatic vessels carry more than escaped fluid. Viruses, bacteria, cellular debris, and even cancer cells can enter these vessels. Should these pathogens or cancer cells be permitted to return to the bloodstream, an infection (or cancer) could quickly spread throughout the body with potentially disastrous consequences. Fortunately, before these pathogens can return to the general circulation, they must pass through dozens of **lymph nodes**, which are the principal lymphoid organs in the body. Lymph nodes are solid, spherical bodies that are packed with macrophages and lymphocytes, which are cells specialized to recognize anything that is "non-self" or foreign to the body. Recognition of these foreign agents activates the immune response, which neutralizes or removes the pathogens before they can reach the general circulation. Each lymph node serves as a minifilter, removing up to 99% of the foreign agents entering the node. Should a pathogen be clever enough to escape surveillance in a particular lymph node, it is then faced with passing through dozens, and sometimes hundreds, more lymph nodes in the lymphatic system.

In addition to lymph vessels and nodes, lymphoid tissues line connective tissue at every potential portal of entrance into the body, including the gastrointestinal (GI) tract, respiratory tract, and genitourinary tract. Lymphoid tissue contains lymphocytes, which "patrol" the region for potential injury or exposure to microbes. Other large collections of lymphoid tissue include the tonsils, spleen, and thymus. These are considered organs of the lymphatic system.

Although the lymphatic system can be divided into individual structures and components for ease of study, it is best to think of it as an integrated whole. The various components of this system are in continuous communication and work together as a single unit to accomplish effective immune surveillance. A malfunction in a single component may affect the effectiveness of the entire lymphatic system. An overview of the primary divisions of immunity is shown in Figure 40.1.

PharmFACT

Tumors are able to create new lymphatic vessels, a process called lymphangiogenesis. The new lymphatic vessels induced by the cancer closely correlate to metastasis and clinical outcome (Dieterich & Detmar, 2016).

Innate (Nonspecific) Body Defenses

40.2 Innate body defenses are the body's first line of defense against pathogens.

Innate body defenses are those that are present even before an infection has occurred and that provide the

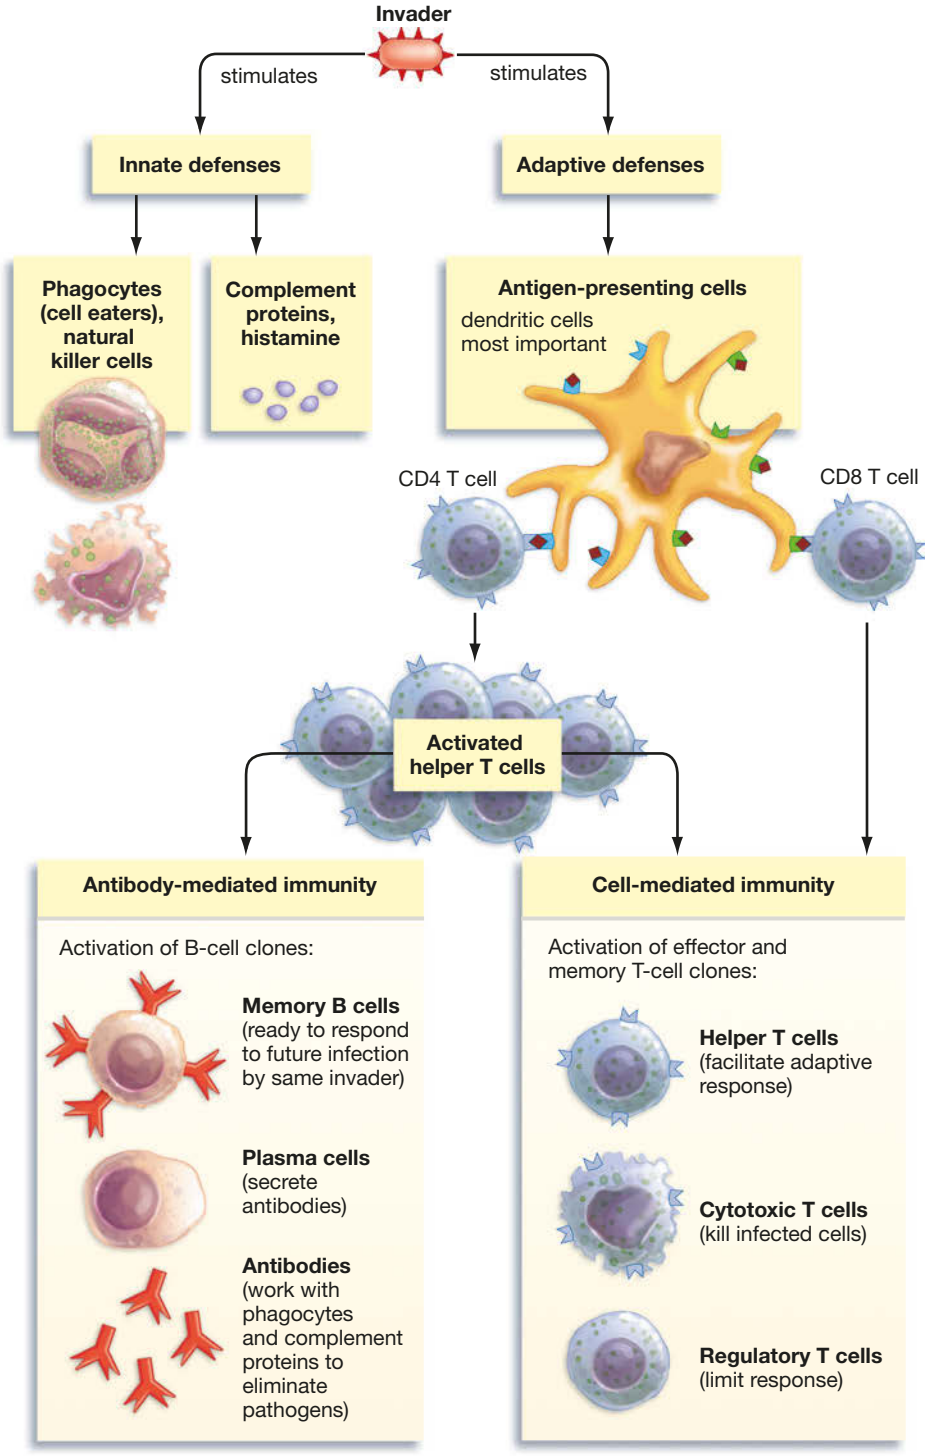


Figure 40.1 Overview of body defenses.
From *Biology: A Guide to the Natural World, Technology Update* (5th ed., p. 563), by D. Krogh, 2014. San Francisco, CA: Benjamin Cummings.

first line of protection from pathogens. These are sometimes referred to as *nonspecific defenses* because they are unable to distinguish one type of threat from another; the body's response is the same regardless of the particular pathogen. A summary of nonspecific body defenses is given in Table 40.1. A useful way of categorizing the innate defenses is to consider them as types of barriers:

- Physical barriers: skin and mucous membranes
- Cellular barriers: phagocytes and natural killer cells
- Process barriers and antimicrobial proteins: complement, fever, inflammation, and interferons.

Table 40.1 Summary of Nonspecific Body Defenses

Component	Functions
Physical Barriers	
Skin	Forms a mechanical barrier to prevent pathogens and other harmful substances from entering the body. Surface contains keratin, which is resistant to water and acid.
Mucous membranes	Line the portals of entry to inhibit the entry of pathogens. Mucus inhibits microbial growth. Cilia in the respiratory tract and saliva in the mouth discourage pathogen entry.
Cellular Barriers	
Phagocytes	Ingest antigens. Specific types include neutrophils, eosinophils, and monocytes, which differentiate into macrophages. Also include dendritic cells that reside deep in the skin, in lymph nodes, and in the inner lining of the respiratory and digestive tracts.
Natural killer (NK) cells	Directly attack virus-infected and cancer cells by releasing substances that are toxic to the antigen.
Process Barriers and Antimicrobial Proteins	
Complement	Promotes inflammation and phagocytosis; lyses microbes.
Fever	Systemic response that increases body temperature to activate body defenses; inhibits the growth of some microbes.
Inflammation	Limits the spread of infection and releases substances that attract phagocytes; initiates repair of the injured area.
Interferons	Proteins secreted by cells infected by viruses. They protect uninfected cells and also stimulate the activity of phagocytes and NK cells; used as medications to treat certain types of cancer.

Physical barriers: The skin and mucous membranes are considered the first line of defense against pathogen invasion. The intact skin is a formidable physical barrier to pathogens. The cells of the epidermis are packed tightly together, which discourages penetration by microbes. The outer layer of skin cells is continually shed, along with any microbes that may be clinging to them. The accessory structures of the skin secrete sebum (oil), sweat, and antimicrobial peptides that discourage microbial growth on the surface. The skin is also colonized with a variety of bacteria and fungi that are normally harmless to the host. This microbiota (flora) competes with pathogens for space and nutrients, thus creating an unfavorable growth environment for harmful organisms. However, should the skin become broken or compromised by needlesticks or catheters, some species of normal flora may become pathogenic.

The body cavities that open to the outside environment are lined with a mucosal epithelium that not only provides a physical barrier, but also contains proteins, lysozymes, and other substances that discourage pathogen growth. The respiratory tract secretes a sticky mucus that traps microbes. The stomach and genitourinary tracts provide an acidic environment that kills many microbes. Like the skin, the mucosa of the mouth, colon, and vagina have a normal population of flora, which discourages pathogen growth by competing for space and nutrients.

Cellular barriers: Once physical barriers are breached, **phagocytes** are the primary cells of innate immunity. The primary job of phagocytes is to engulf pathogens and other foreign substances that enter the body. Once engulfed, the phagocytes destroy the microbe in vesicles called lysosomes, which contain powerful destructive enzymes. As expected, phagocytes are found in large numbers in the blood, in lymphatic tissues, and in locations where pathogens have the highest likelihood of entering. For example, the deeper layers of the epidermis contain specialized phagocytes called dendritic cells, which are able to remove pathogens that penetrate the superficial layers. Phagocytes have the ability to migrate to distant sites when an infection is detected, a process called *chemotaxis*.

Phagocytes have proteins on their surface that allow them to recognize cells and cellular components that are "non-self." When recognized as "non-self," the pathogen is internalized and destroyed within the phagocyte. Pieces of the microbe are sometimes displayed on the plasma membrane of the phagocyte, which serves to activate other components of the immune response. Not all pathogens can be engulfed by phagocytosis. Some, such as *Mycobacterium tuberculosis*, are not only resistant to phagocytosis, but they can also multiply while residing inside macrophages.

Cancer cells or virus-infected cells attract a different type of innate cellular response: natural killer (NK) cells. Found in most lymphoid organs, NK cells are not phagocytic, but they do release toxins that kill cancer cells or virus-infected cells. NK cells also secrete chemicals that enhance inflammation and modulate the adaptive immune response.

Process barriers and antimicrobial proteins: Processes and proteins associated with innate defenses are complement activation, fever, inflammation, and interferons. The **complement system** is a cluster of 20 plasma proteins that combine in a specific sequence and order when an infection occurs. Activation of complement attracts phagocytes to the infection site, attacks and breaks down the cell walls of pathogens, and stimulates the inflammatory process.

Fever and inflammation are also key processes of the nonspecific defense system. Fever accelerates body defenses

Table 40.2 Selected Chemical Mediators of Inflammation

Mediator	Description
Bradykinin	Protein present in an inactive form in plasma and mast cells; increases vascular permeability and causes pain; effects are similar to those of histamine; broken down by angiotensin-converting enzyme (ACE).
Complement	Series of at least 20 proteins that combine in a cascade fashion to neutralize or destroy an antigen; stimulates histamine release by mast cells; causes cell lysis.
C-reactive protein	Occurs as an early response to acute inflammation; activates complement; used as a biomarker to gauge the extent of inflammation.
Cytokines	Proteins produced by macrophages, leukocytes, and dendritic cells that mediate and regulate immune and inflammatory reactions; examples include interleukins and tumor necrosis factor (TNF)
Histamine	Stored and released by mast cells; causes vasodilation, smooth muscle constriction, tissue swelling, and itching.
Leukotrienes	Lipids stored and released by mast cells; effects are similar to those of histamine; synthesized from arachidonic acid; responsible for some symptoms of asthma and allergies.
Prostaglandins	Lipid present in most tissues and stored and released by mast cells; increase capillary permeability, attract white blood cells to the site of inflammation, cause pain, and induce fever; aspirin inhibits their synthesis; some are available as medications.

and associated repair processes by raising the temperature of the body. When excessive, however, fever can harm the body and must be treated with drugs known as antipyretics (see Chapter 41). From a pharmacologic perspective, one of the most important nonspecific defenses is inflammation. Because of its significance, inflammation is presented separately in Sections 40.3 and 40.4.

Interferons (IFNs) are antimicrobial proteins that are crucial components of the innate body defense system. Released by infected macrophages and lymphocytes, IFNs protect uninfected cells from pathogens. IFNs have been isolated and are now available as medications for the treatment of immune disorders (see Chapter 42), viral infections (see Chapter 54), and cancer (see Chapter 57).

Inflammation

40.3 Inflammation is a nonspecific defense mechanism that neutralizes or destroys foreign substances and microbes.

Inflammation occurs in response to many different stimuli, including physical injury, exposure to toxic chemicals, extreme heat, invading microorganisms, or death of cells. Inflammation is considered a nonspecific defense mechanism because it proceeds in the same manner regardless of the cause.

The central purposes of inflammation are to contain the injury, destroy the pathogen, and initiate repair of the area. The repair of the injured area can proceed at a faster pace by neutralizing the foreign agent and removing cellular debris and dead cells. Signs of inflammation include swelling, pain, warmth, and redness of the affected area.

Inflammation may be classified as acute or chronic. During acute inflammation, such as that caused by minor physical injury, 8 to 10 days are normally needed for the symptoms to resolve and for repair to begin. If the body cannot neutralize the damaging agent, inflammation may continue for long periods and become chronic. In chronic autoimmune disorders such as lupus and rheumatoid arthritis (RA), inflammation may persist for years, with symptoms becoming progressively worse over time. Other disorders such as seasonal allergy arise at predictable times during each year, and inflammation may produce only minor, annoying symptoms.

40.4 Inflammation proceeds with the release of chemical mediators.

During inflammation, pathogens, chemicals, or physical trauma cause the damaged tissue to release chemical mediators that act as alarms to notify the surrounding area of the injury. Chemical mediators of inflammation include histamine, leukotrienes, bradykinin, complement, and prostaglandins. These inflammatory mediators, some of which are listed in Table 40.2, are called proinflammatory substances. Several inflammatory mediators are important targets for anti-inflammatory drugs. For example, aspirin and ibuprofen are prostaglandin inhibitors that are effective at treating fever, pain, and inflammation.

The rapid release of the chemical mediators of inflammation on a large scale throughout the body is responsible for anaphylaxis, a life-threatening allergic response that may result in shock and death. A number of chemicals, insect stings, foods, and some therapeutic drugs can cause this widespread release of histamine from mast cells if the individual has an allergy to these substances.

Histamine is a key chemical mediator of inflammation. It is stored primarily within mast cells located in tissue spaces under epithelial membranes such as the skin, bronchial tree, and digestive tract and along blood vessels. Mast cells detect foreign agents or injury and respond by releasing histamine, which initiates the inflammatory response within seconds. In addition to its role in inflammation, histamine also directly stimulates pain receptors and is a primary agent responsible for the symptoms of seasonal allergies.

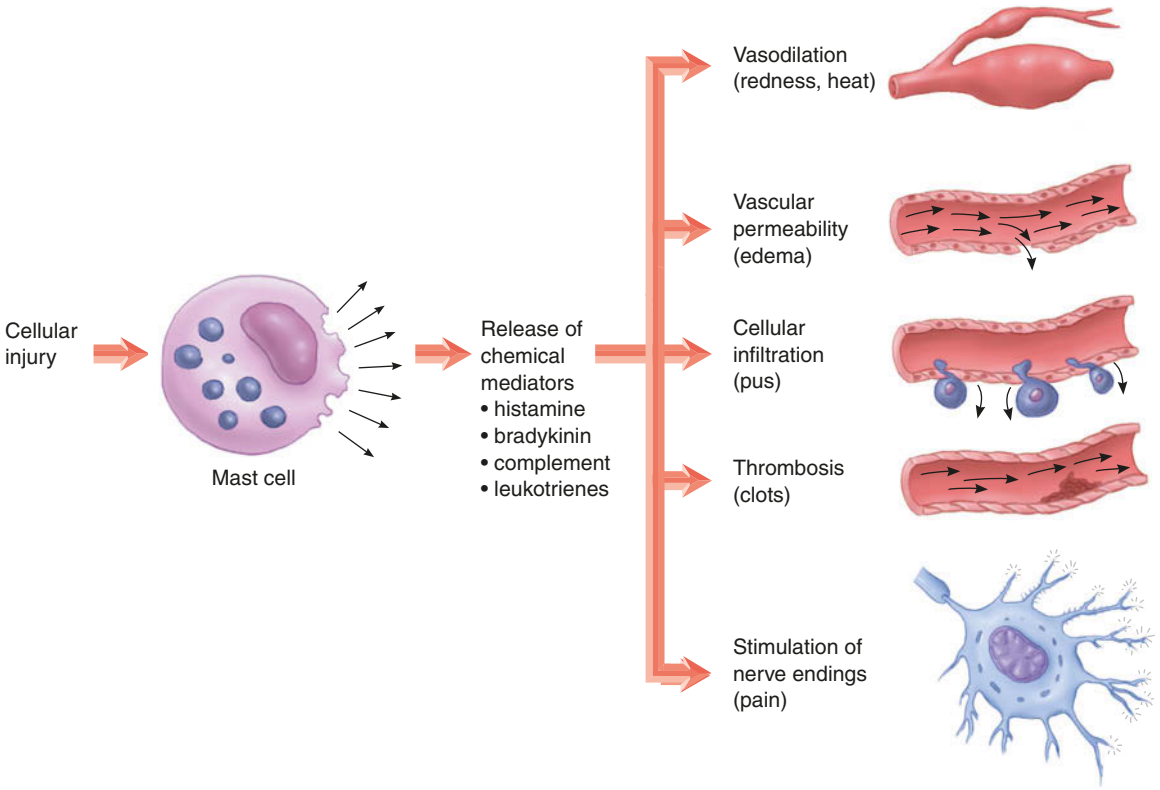

Figure 40.2 Steps in acute inflammation.

When released at an injury site, histamine dilates nearby blood vessels, causing the capillaries to become more permeable. Plasma, complement proteins, and phagocytes can then enter the area to neutralize microbes or their toxins. The affected area may become congested with blood, which can lead to significant swelling and pain. Figure 40.2 illustrates the fundamental steps in acute inflammation.

Histamine interacts with two different receptors to elicit an inflammatory response. H_1 receptors are present in the smooth muscle of the vascular system, the respiratory passages, and the digestive tract. Stimulation of these receptors results in itching, pain, edema, vasodilation, bronchoconstriction, and the characteristic symptoms of inflammation and allergy. In contrast, H_2 receptors are present primarily in the stomach, and their stimulation results in the secretion of large amounts of hydrochloric acid.

Drugs that act as specific antagonists for H_1 and H_2 receptors are in widespread therapeutic use. H_1-receptor antagonists, which are used to treat allergies and inflammation, are discussed in Chapter 45. H_2-receptor antagonists are used to treat peptic ulcers and are discussed in Chapter 59.

CONNECTION Checkpoint 40.1

In addition to being a mediator of inflammation, bradykinin is responsible for one of the most common adverse effects of ACE inhibitors. From what you learned in Chapter 31, describe this adverse effect. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Specific (Adaptive) Body Defenses

40.5 The specific body defenses include the humoral and cell-mediated immune systems.

The body also has the ability to mount a third line of defense that is specific to certain threats. For example, a specific defense may act against only a single species of bacteria and be ineffective against all others. These are known as **adaptive defenses** or, more commonly, the immune response. The primary cell of the immune response is the lymphocyte.

Microbes and foreign substances that elicit an immune response are called **antigens**. Foreign proteins, such as those present on the surfaces of pollen grains, bacteria, nonhuman cells, and viruses, are the strongest antigens. Typically, only a small fragment or piece of a foreign protein is required to activate the immune system. It is estimated that the immune system is able to recognize and react to over a billion different antigens.

The immune response is extremely complex. Several important aspects of the immune response are discussed next.

Specificity: Each aspect of the immune response recognizes only particular pathogens and not others. Recognition of the antigen is dependent on the immune cells interacting with specific foreign proteins. Once an immune response is mounted, it generally only affects the one specific antigen that was recognized.

Systemic: Despite being specific to a particular antigen, the immune response is systemic. Thus antigens that exist in remote regions beyond the initial site of infection will be neutralized.

Memory: After an antigen interaction occurs, cells of the adaptive immune system remember the immune response. This is different from the components of nonspecific defenses, which have no memory. Upon subsequent exposures to the *same* antigen, the body is able to mount a stronger and more rapid response.

The basic steps of the immune response involve recognition of the antigen, communication and coordination with other defense cells, and destruction or suppression of the antigen. A large number of chemical messengers and complex interactions are involved in the immune response, many of which have yet to be discovered. The two primary divisions of the immune response are antibody-mediated (humoral) immunity and cell-mediated immunity.

Humoral Immune Response

40.6 The humoral immune response is mediated by B lymphocytes and includes the secretion of antibodies.

The humoral immune response is triggered when an antigen encounters a B lymphocyte, more simply known as a **B cell**. The activated B cell divides to form millions of identical copies of itself in a process known as clonal division. Most cells in this clone are called **plasma cells**, and their primary function is to secrete antibodies specific to the antigen that initiated the challenge. Each plasma cell is capable of manufacturing antibodies at an astounding rate, as many as 2000 each second.

Circulating through body fluids are **antibodies**, also known as immunoglobulins (Ig), which physically interact with antigens to neutralize or mark them for destruction by other cells of the immune response. The activation of complement, with subsequent inflammation and enhanced phagocytosis, is a major defense mechanism resulting from the formation of antigen–antibody complexes. Peak production of antibodies occurs about 10 days after an initial antigen challenge. The important functions of antibodies are illustrated in Figure 40.3.

After the antigen challenge, memory B cells are formed that will remember the specific antigen–antibody interaction. Should the body be exposed to the same antigen in the future, the humoral immune system will manufacture even higher levels of antibodies in a shorter period, approximately 2 to 3 days. For some antigens, such as those for measles, mumps, or chickenpox, memory can be retained for an entire lifetime. Vaccines are sometimes administered to produce these memory cells in advance of exposure to the antigen, so that when the body is exposed to the actual organism it can mount a fast, effective response (see Chapter 43).

It is important to remember that the body contains millions of different B cells, each programmed to react to a specific antigen. These B cells, in turn, are able to construct millions of different types of antibodies, each specific to a particular antigen. The body is preprogrammed with the genetic information to defend against millions of different antigens. Although it is unlikely that an individual will ever be infected during a lifetime with all the different antigens, the body is waiting for the challenge.

PharmFACT

Once generated, a single plasma cell is capable of manufacturing antibodies at an astounding rate, as many as 2000 antibodies each second. The cell dies after about 4 to 5 days (Marieb & Hoehn, 2016).

Cell-Mediated Immune Response

40.7 The cell-mediated immune response is mediated by T lymphocytes and includes the secretion of cytokines.

A second branch of the immune response involves T lymphocytes, or **T cells**. Two major types of T cells are called helper T cells and cytotoxic T cells. These cells are named after a protein receptor on their plasma membrane. The helper T cells have a CD4 receptor, and the cytotoxic T cells have a CD8 receptor. The helper (CD4) T cells are particularly important because they are responsible for activating most other immune cells, including B cells and other types of T cells. Cytotoxic (CD8) T cells travel throughout the body, directly killing certain bacteria, parasites, virus-infected cells, and cancer cells.

PharmFACT

T cells move quickly throughout the body. In a typical day, a T cell may spend 30 minutes in the blood, 5 to 6 hours in the spleen, and 15 to 20 hours in a lymph node (Martini, Nath, & Bartholomew, 2015).

T cells rapidly form clones after they are activated or sensitized following an encounter with their specific antigen. Unlike B cells, however, T cells do not produce antibodies. Instead, activated T cells produce huge amounts of **cytokines**, which are hormone-like proteins that regulate the intensity and duration of the immune response and mediate cell-to-cell communication. Some cytokines kill foreign organisms directly, whereas others induce inflammation or enhance the killing power of macrophages. Specific cytokines released by activated T cells include interleukins, gamma interferon, tumor necrosis factor (TNF), and perforin. Some cytokines are used therapeutically to stimulate the immune system (see Chapter 42). Small amounts of

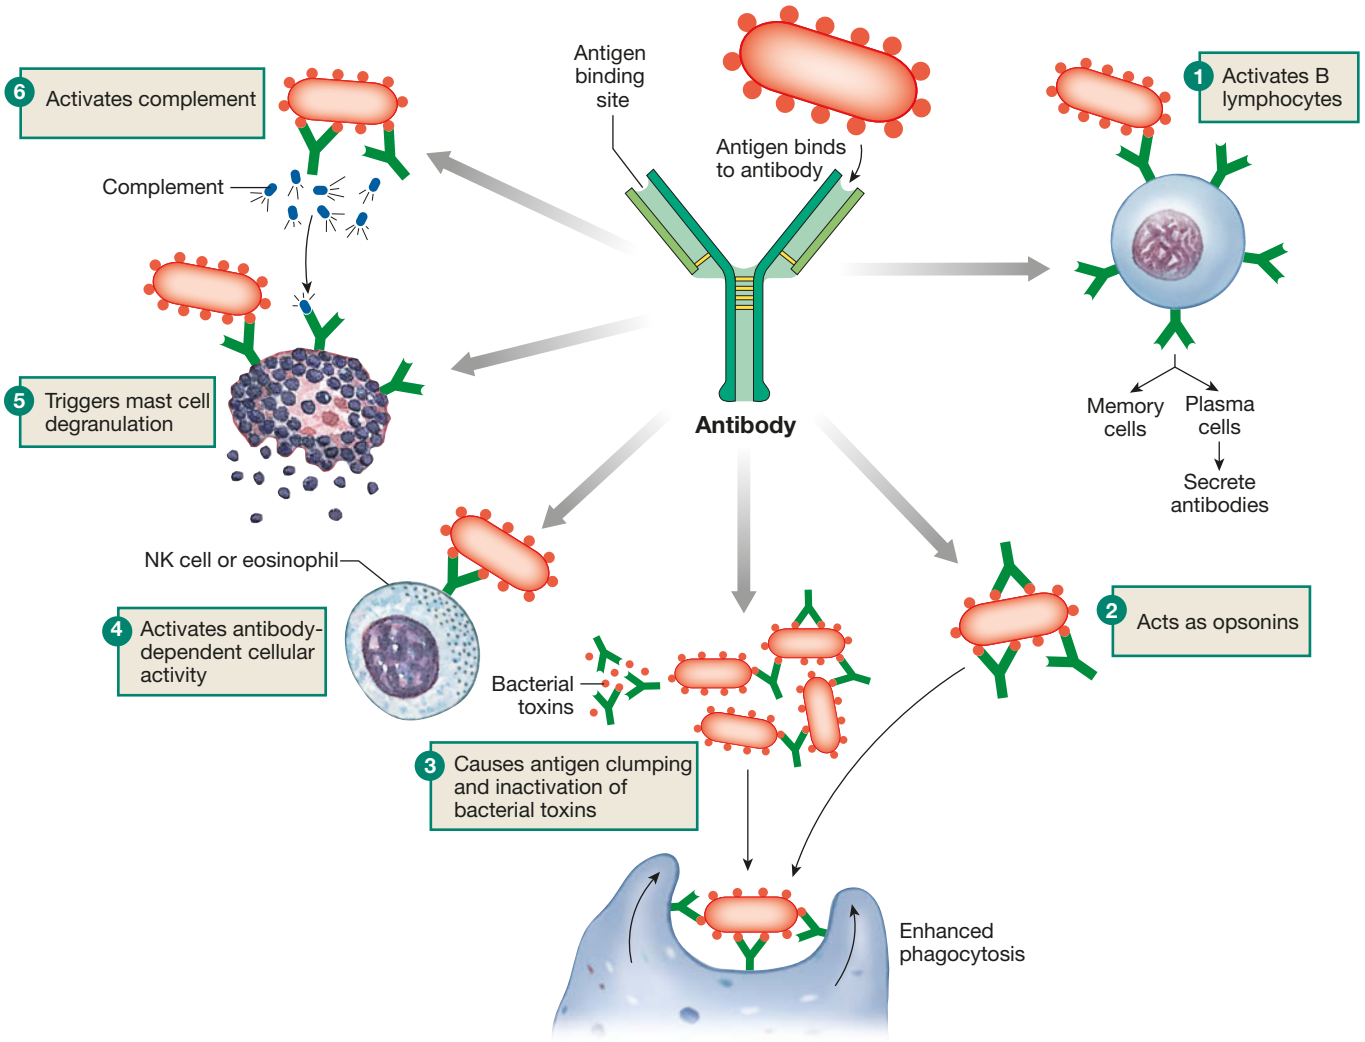

Figure 40.3 Functions of antibodies.

From *Human Physiology: An Integrated Approach* (5th ed.), by D. U. Silverthorn, 2010. Printed and electronically reproduced by permission. Upper Saddle River, NJ: Pearson Education, Inc.

cytokines are also secreted by certain macrophages, B lymphocytes, mast cells, endothelial cells, and the stromal cells of the spleen, thymus, and bone marrow.

Like B cells, some sensitized T cells become memory cells. If the patient encounters the same antigen in the future, the memory T cells assist in mounting a more rapid immune response.

CONNECTION Checkpoint 40.2

Proinflammatory cytokines such as interleukin-1 and TNF have been associated with a higher risk of Alzheimer's disease and progression of this disorder. From what you learned in Chapter 21, describe the primary drug classes for treating Alzheimer's disease. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Understanding Chapter 40

Key Concepts Summary

40.1 The lymphatic system is the primary organ system that protects the body from invasion by foreign agents.

40.2 Innate body defenses are the body's first line of defense against pathogens.

40.3 Inflammation is a nonspecific defense mechanism that neutralizes or destroys foreign substances and microbes.

40.4 Inflammation proceeds with the release of chemical mediators.

40.5 The specific body defenses include the humoral and cell-mediated immune systems.

40.6 The humoral immune response is mediated by B lymphocytes and includes the secretion of antibodies.

40.7 The cell-mediated immune response is mediated by T lymphocytes and includes the secretion of cytokines.

Chapter 41
Pharmacotherapy of Inflammation and Fever

Chapter Outline

- Pathophysiology of Inflammation and Fever
- Pharmacotherapy of Inflammation
- Nonsteroidal Anti-Inflammatory Drugs

  Salicylates

  PROTOTYPE *Aspirin (Acetylsalicylic Acid), p. 728*

  Ibuprofen-Like Drugs

  PROTOTYPE *Ibuprofen (Advil, Motrin, Others), p. 731*

  Cyclooxygenase-2 Inhibitors

  PROTOTYPE *Celecoxib (Celebrex), p. 734*
- Antipyretic and Analgesic Drugs

  PROTOTYPE *Acetaminophen (Tylenol), p. 735*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the pathophysiology of inflammation and fever.
2. Identify drug classes used to treat inflammation and fever.
3. Explain how aspirin damages the gastrointestinal mucosa.
4. Describe the symptoms and treatment of salicylism.
5. Compare the actions and adverse effects of aspirin to ibuprofen and ibuprofen-like drugs.
6. Compare the actions and adverse effects of the cyclooxygenase-2 inhibitors to other nonsteroidal anti-inflammatory drugs.
7. Describe the nurse's role in the pharmacologic management of inflammation and fever.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients receiving pharmacotherapy for fever or inflammation.

Key Terms

anaphylaxis, 724
antipyretics, 725
cyclooxygenase (COX), 726
prostaglandins, 725
salicylates, 725
salicylism, 729

Inflammation is a response to injury that destroys agents that could damage human tissue. A large number of conditions can trigger inflammation, including physical trauma, burns, chemical injury, infections, hypersensitivity reactions, or tissue necrosis (death). Although it is a natural defense mechanism, excessive inflammation causes symptoms that range from minor discomfort to severe, disabling pain, fever, and limitation of mobility. This chapter examines drugs used to diminish the inflammatory response and reduce fever.

Pathophysiology of Inflammation and Fever

41.1 Inflammation is a nonspecific body response to antigens and tissue injury.

The basic process of inflammation and the proinflammatory chemical mediators involved are described in Chapter 40. The student should review that chapter before proceeding.

Acute inflammation: Acute inflammation has an immediate onset and lasts 1 to 2 weeks. The inflammatory process is initiated when the body is exposed to a foreign substance, or antigen. The antigen may be anything from ragweed pollen to a microorganism; it may even be a normal cell that has been damaged or changed. Once the inflammation process is initiated, nearby blood vessels become permeable, allowing phagocytic cells to reach and neutralize the antigen. The increased permeability causes edema of the surrounding tissue, which often leads to acute pain and, possibly, joint immobility. The greater the tissue damage from the antigen or the inflammation, the greater the edema and the greater the immobility at the site.

Occasionally, acute inflammation is initiated by a rapid, massive release of inflammatory chemical mediators throughout the entire body. This condition, known as **anaphylaxis**, is a life-threatening allergic response that may cause cardiovascular shock and death. A number of chemicals, insect stings, foods, and some therapeutic drugs can cause this widespread release of histamine from mast cells if an individual has hypersensitivity to these substances.

The resolution of acute inflammation occurs when damaged tissue begins the process of regeneration and may conclude within a matter of weeks or continue throughout the individual's life with the regeneration of new tissue. Regeneration processes may replace normal cells with scar tissue, especially in nerve, cardiac, and muscle tissues. Replacement with fibrotic tissue can impair the function of the inflamed tissue.

Chronic inflammation: Chronic inflammation has a slow onset and may lack the distinct stages characteristic of acute inflammation. Whereas acute inflammation is the result of an influx of neutrophils, chronic inflammation is caused primarily by lymphocytes and macrophages. The chronic invasion of an area by macrophages and the resultant chemical reaction at the tissue site activates fibroblasts and generates scar tissue, which may limit mobility or narrow vessel lumens. Lymphocytes sometimes surround macrophages, resulting in granulomas. For example, chronic inflammation from *Mycobacterium tuberculosis* in the lung may occur over many years and yield the development of granulomas. The granulomas serve as a means of protection, walling off the agent from the rest of the body. In the event that the host's immune response diminishes, the host is susceptible to the reemergence of inflammation and the possible onset of active infection.

When acute or chronic inflammation is caused by an infection, the patient is at risk for the development of a febrile episode, which is characterized by an increase in body temperature due to cytokine-induced changes in the hypothalamus. The systemic manifestations of inflammation associated with an infection are elevated temperature above 39°C (102°F), pulse rate greater than 90 beats/min, respirations greater than 20 breaths/min, and a white blood cell count greater than 12,000/mm^3.

Pharmacotherapy of Inflammation

41.2 Treatment of inflammation includes nonpharmacologic therapies and the administration of anti-inflammatory drugs.

Because inflammation is a nonspecific process and may be caused by a variety of physical and infectious etiologies, it may occur in virtually any tissue or organ system. When treating the patient with inflammation, the following general principles apply:

- Inflammation is not a disease but a symptom of an underlying disorder. Whenever possible, the cause of the inflammation is identified and treated.

- Inflammation is a natural process for ridding the body of antigens, and it is usually self-limiting. Nonpharmacologic treatments such as ice packs and rest should be used for mild symptoms whenever applicable.
- Topical drugs should be used when applicable because they cause few adverse effects. Inflammation of the skin and mucous membranes of the mouth, nose, rectum, and vagina are best treated with topical drugs. These include creams, ointments, patches, suppositories, and intranasal sprays. Inhalation drugs may be used for pulmonary inflammation.

The goal of pharmacotherapy with anti-inflammatory drugs is to prevent or decrease the intensity of the inflammatory response and reduce fever, if present. Most anti-inflammatory drugs are nonspecific; that is, whether the inflammation is caused by an injury, autoimmune disease, or allergy, the drug will exhibit the same inhibitory actions. Common diseases that benefit from anti-inflammatory medications include allergic rhinitis, anaphylaxis, ankylosing spondylitis, contact dermatitis, Crohn's disease, glomerulonephritis, Hashimoto's thyroiditis, peptic ulcer disease (PUD), rheumatoid arthritis (RA), systemic lupus erythematosus, and ulcerative colitis.

If fever is associated with the inflammation, medications used to reduce body temperature, or **antipyretics**, may be administered. The goal of antipyretic therapy is to lower body temperature while treating the underlying cause of the fever, which is usually an infection. Many of the drugs used for inflammation also reduce fever and relieve mild to moderate pain.

Two major drug classes are used for nonspecific inflammation: nonsteroidal anti-inflammatory drugs (NSAIDs) and the corticosteroids. For mild to moderate pain, inflammation, and fever, NSAIDs are the preferred class of drugs. Should inflammation become severe or disabling, corticosteroid therapy is begun. Due to the potential for serious long-term adverse effects, oral or parenteral corticosteroids are usually used for only 1 to 3 weeks to bring inflammation under control. The patient is then switched to NSAIDs. Corticosteroids are used for a large number of conditions, and their pharmacotherapy is presented in Chapter 68.

A few anti-inflammatory drug classes are specific to certain disorders. For example, the 5-aminosalicylic acid drugs such as sulfasalazine (Azulfidine) are specific to treating inflammatory bowel disease (see Chapter 60). Colchicine and allopurinol (Zyloprim) are used for the inflammation specifically caused by gouty arthritis (see Chapter 72). These specific anti-inflammatory drugs are less widely prescribed because they are more toxic than the NSAIDs.

PharmFACT

In the United States, approximately 70 million NSAID prescriptions are written each year. If over-the-counter (OTC) use is included, more than 30 billion NSAID doses are consumed each year (Wiegand, 2016).

Nonsteroidal Anti-Inflammatory Drugs

The NSAIDs consist of three major classes: salicylates, ibuprofen (including ibuprofen-like drugs), and cyclooxygenase-2 (COX-2) inhibitors. These drug classes are sometimes grouped as first-generation NSAIDs (salicylates and ibuprofen-like drugs) and second-generation NSAIDs (COX-2 inhibitors). This is not a particularly useful means of grouping the drugs because there are over 20 first-generation NSAIDs and only one second-generation NSAID. The ibuprofen-like NSAIDs are described in Section 41.4 and the COX-2 inhibitors are presented in Section 41.5.

Salicylates

41.3 Aspirin is an inexpensive, effective, first-generation nonsteroidal anti-inflammatory drug commonly used by adults.

The first NSAID to be discovered was originally extracted from the bark of the common willow tree. The medical uses of willow bark, especially for pain relief and fever reduction, had been known for centuries but it was not until 1828 that the active ingredient, called salicin, was identified and converted to salicylic acid. Quite toxic in concentrated amounts, salicylic acid was converted into its most useful form, known as aspirin or acetylsalicylic acid, by a scientist at the Bayer Pharmaceutical Company in 1897. The chemical family to which aspirin belongs is known as the **salicylates**. Since its discovery, aspirin has become one of the most highly used therapeutic drugs in the world. Aspirin has the following indications for use:

- **Analgesic.** The ability to relieve mild to moderate pain
- **Anti-inflammatory.** The ability to decrease mild to moderate inflammation
- **Antipyretic.** The ability to lower body temperature
- **Suppression of platelet aggregation.** The ability to prevent or treat cardiovascular conditions such as acute myocardial infarction (MI) and stroke.

Understanding the mechanism of action of aspirin is important because it explains both the therapeutic actions of the drug as well as its adverse effects. All NSAIDs act by inhibiting the synthesis of prostaglandins. **Prostaglandins** are local hormones found in virtually every tissue that have many diverse functions depending on their location.

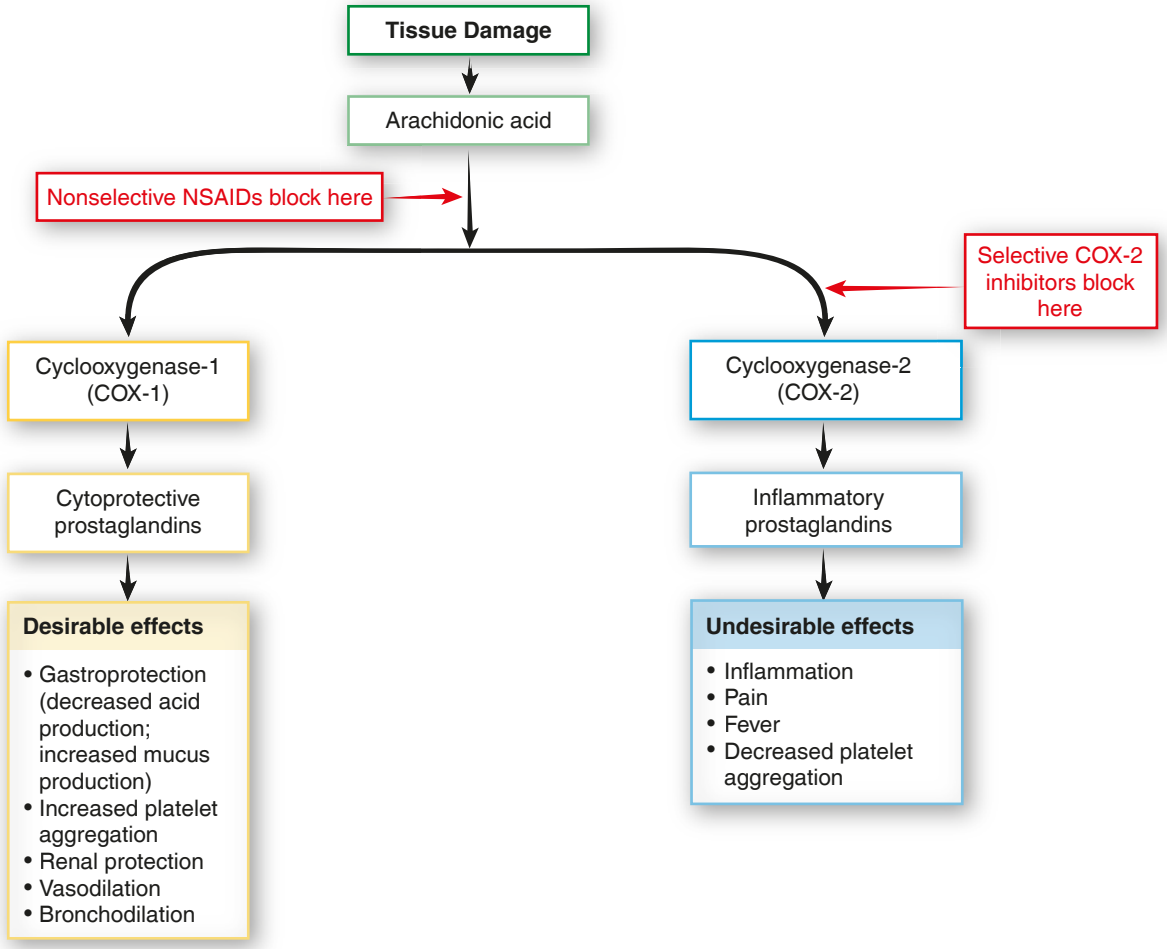

Figure 41.1 Inhibition of cyclooxygenase-1 and -2. Nonselective NSAIDs block the cytoprotective effects as well as inflammation. Selective COX-2 inhibitors block only the inflammation effects.

Several prostaglandins are available as drugs, including carboprost (Hemabate, prostaglandin F_2 alpha), dinoprostone (Cervidil, prostaglandin E_2), and misoprostol (Cytotec, prostaglandin E_1). The physiologic properties of prostaglandins include the following:

- **Mediation of inflammation.** Cause vasodilation and pain, and increase capillary permeability
- **GI protection.** Increase bicarbonate and mucus production to protect the stomach mucosa from acid
- **Renal protection.** Help maintain blood flow through the kidneys
- **Smooth muscle.** Help regulate smooth muscle tone in blood vessels; increase smooth muscle tone in the uterus; may cause bronchodilation or bronchoconstriction
- **Blood clotting.** Increase platelet aggregation to promote clot formation.

Aspirin blocks the synthesis of prostaglandins by inhibiting the enzyme **cyclooxygenase (COX)**. Aspirin and the ibuprofen-like NSAIDs block both forms of the enzyme, known as COX-1 and COX-2, by changing their structures and preventing the formation of prostaglandins. This inhibition of COX is responsible for the therapeutic and adverse effects of these drugs, depending on the location and function of the prostaglandin that is being blocked. For example, the inhibition of COX in peripheral tissues will reduce the pain and inflammation caused by prostaglandins. The inhibition of COX in the stomach, however, will remove the protective effect of prostaglandins and result in damage to the gastrointestinal (GI) mucosa. The mechanism by which aspirin produces its effects is illustrated in Figure 41.1.

Aspirin is a potent inhibitor of thromboxane, a substance secreted by platelets. The inhibition of thromboxane in platelets is especially prolonged and may last for the entire 8- to 11-day lifespan of the platelet. This antithrombotic action inhibits platelet aggregation and reduces the risk of adverse cardiovascular events, including MI and stroke. The antipyretic effect of aspirin results from a suppression of prostaglandin synthesis in the hypothalamus of the brain. It lowers temperature by indirectly causing centrally mediated peripheral vasodilation and sweating. The principal analgesic effect of aspirin occurs in the peripheral areas of the body and in the central nervous system (CNS).

Table 41.1 Salicylates

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aspirin (acetylsalicylic acid, ASA)	Mild to moderate pain or fever: PO: 350–650 mg, q4h (max: 4 g/day) Arthritic conditions: PO: 3.6–5.4 g/day in 4–6 divided doses TIA prophylaxis: PO: 5–325 mg/day MI or thromboembolic disorder prophylaxis: PO: 80–325 mg/day	*Tinnitus, deafness, urticaria, nausea, vomiting, confusion, drowsiness, prolonged bleeding time, dyspepsia, stomach pain* Bronchospasm, anaphylactic shock, laryngeal edema, hemolytic anemia, salicylism, angioedema, Reye's syndrome, metabolic acidosis, severe GI bleeding, hepatotoxicity
choline magnesium trisalicylate (Trilisate)	PO: 1.0–2.5 g/day in 1–3 divided doses (max: 4.5 g/day)	
magnesium salicylate (Doan's Pills)	Analgesic/antipyretic: PO: 650 mg tid or qid Arthritic conditions: PO: 9.6 g/day in divided doses (max: 4.8 g/day)	
salsalate (Mono-Gesic, Salsitab)	PO: 325–3000 mg/day in divided doses (max: 4 g/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Doses for aspirin and the other salicylates are listed in Table 41.1.

Aspirin is sometimes combined with prescription and OTC medications, and its presence is not always obvious unless the label is carefully inspected. This is especially important for patients with aspirin allergy, which is present in about 1% of the population. Patients with asthma or food allergies are most likely to be allergic to aspirin. Aspirin allergy symptoms include rash, urticaria, dyspnea, wheezing, rhinorrhea, and cough. To prevent aspirin allergy, the patient should be instructed to read labels carefully and avoid products containing salicylates. This is not always possible because salicylates are naturally found in certain foods and are used as preservatives in others. Patients with aspirin allergies should consult with a dietitian regarding which food sources to avoid. Allergists may be able to desensitize a patient if exposure to the drug is unavoidable or if the patient's allergy is severe. Patients who are hypersensitive to aspirin will likely be sensitive to other NSAIDs. For pain or fever relief, acetaminophen may be an option for these adult patients.

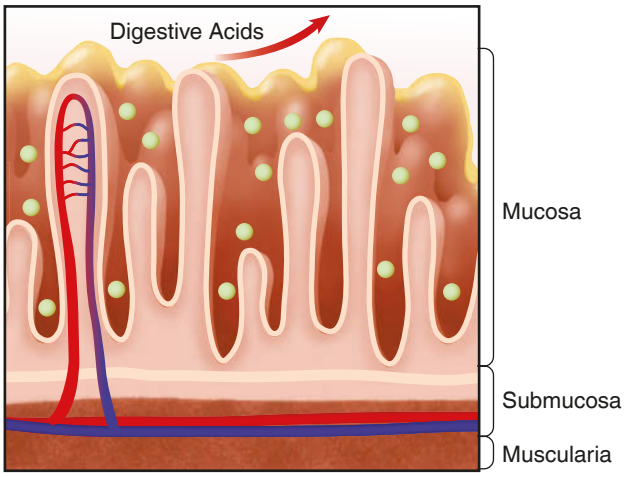
The most significant adverse effect of aspirin and other NSAIDs is GI bleeding, which is shown in Pharmacotherapy Illustrated 41.1. Although the risk is dose related, even low doses of aspirin (75–325 mg/day) may double the risk of GI bleeding. Risk factors for aspirin-induced GI bleeding include history of peptic ulcers, age greater than 60, use of anticoagulants or corticosteroids, *Helicobacter pylori* infection, smoking, and use of alcohol. Aspirin has the following adverse effects on the GI mucosa:

- As aspirin is absorbed across the stomach mucosa, it causes direct cellular injury. This topical damage to the stomach may be lessened by the use of enteric-coated formulations.
- After aspirin is absorbed systemically, it inhibits COX-1 and depletes the GI mucosa of prostaglandins. Prostaglandins normally provide a protective function in the GI mucosa by directing the secretion of mucus and bicarbonate and promoting cellular repair of mucosal damage.
- If GI damage or active ulcers are already present, the antiplatelet effects of aspirin will prolong bleeding.

In addition to GI bleeding, aspirin can cause dyspepsia, nausea, and ulcer perforation. For patients who must take high doses of aspirin, proton pump inhibitors (PPIs), such as omeprazole, may provide some degree of protection against GI damage by reducing acid secretion in the stomach. PPIs are effective and relatively safe drugs (see Chapter 59). An alternative therapy for GI protection is oral misoprostol (Cytotec), which is a prostaglandin. Misoprostol is a pregnancy category X drug, which limits its use in women with childbearing potential.

The antiplatelet effects of aspirin can promote bleeding at sites other than the GI tract. Because it irreversibly inhibits COX-1 in platelets, the antiplatelet action of aspirin can be prolonged. It may take longer for minor cuts and injuries to stop bleeding. Patients undergoing surgical or dental procedures should discontinue aspirin use a week prior to the procedure. Patients with known bleeding disorders should not take aspirin at all.

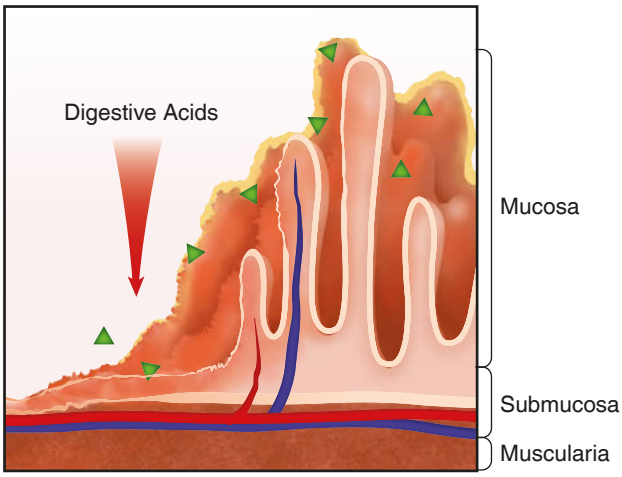
Children under age 19 should never be administered products that contain aspirin when they have flu symptoms, fever, or chickenpox due to the risk of Reye's syndrome, a potentially fatal disease. It is unclear how aspirin contributes to Reye's syndrome, because the condition can appear without aspirin use. The incidence of Reye's syndrome is now very rare due to public awareness of the risk associated with aspirin use.



Pharmacotherapy Illustrated 41.1

NSAID-induced Ulcer Formation

(a)



COX converts arachidonic acid to prostaglandins ( ).
- Less acid
- More mucus protection

(b)

NSAIDs ( ) inhibit COX and prevent prostaglandin formation.
- More acid/less mucus
- Direct irritation of mucosa

PharmFACT

More than 24,000 salicylate poisonings occur each year, of which about 5000 are intentional overdoses. Approximately 15 deaths from acute salicylate overdose occur each year (Waseem, 2016).

PROTOTYPE DRUG **Aspirin (Acetylsalicylic Acid)**

Classification **Therapeutic:** Nonnarcotic analgesic, antipyretic, antiplatelet
Pharmacologic: Salicylate, NSAID

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1939, aspirin is one of the best known medications. The ability of aspirin to reduce pain, inflammation, and fever makes it an extremely versatile and widely used drug. It is used to reduce pain and inflammation that is mild to moderate in intensity. The doses of aspirin needed to control severe pain or inflammation often result in a high incidence of adverse effects.

Aspirin is approved by the FDA for the prevention of thromboembolic events. Aspirin is a first-line treatment for stroke prophylaxis in patients with a history of transient ischemic attacks (TIAs) or who have persistent or paroxysmal atrial fibrillation. It is approved for MI prophylaxis in patients who are at risk for a cardiac event and who are not already taking warfarin or an antiplatelet drug, including those with coronary artery disease who have already experienced an MI. To lower the risk of thromboembolic events, emergency medical services professionals administer aspirin to patients with a suspected coronary thrombosis prior to hospital arrival. Patients

with a high risk for arterial thromboembolism may receive low-dose aspirin therapy.

An off-label use of aspirin is to prevent colorectal cancer. Regular, long-term aspirin use has been determined to reduce the risk of colorectal cancer in certain populations (Dehmer, Maciosek, Flottemesch, LaFrance, & Whitlock, 2016). Researchers are still unclear whether the reduction in the incidence of colorectal cancer from the drug is worth the increased risk of GI bleeding. The effectiveness of aspirin in preventing cancer is an area of active research.

Mechanism of Action: The anti-inflammatory action of aspirin is caused by the inhibition of COX-1 and COX-2 that leads to reduced prostaglandin synthesis. The analgesic action of aspirin occurs peripherally with limited action in the CNS on the hypothalamus. The suppression of prostaglandin synthesis in or near the hypothalamus results in the lowering of body temperature. Aspirin acts indirectly, causing centrally mediated peripheral vasodilation and sweating.

Pharmacokinetics:

Route(s)	Oral (PO), rectal
Absorption	80–100% absorbed
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 80–90% bound to plasma protein
Primary metabolism	Hepatic; metabolized to salicylic acid, an active metabolite, in the GI mucosa, plasma, and erythrocytes
Primary excretion	Renal
Onset of action	PO: 5–30 min; rectal: 1–2 h
Duration of action	PO: 1–4 h; rectal: 7 h

Adverse Effects: A major adverse effect of aspirin is the risk of a serious hypersensitivity reaction, which is noted with symptoms such as bronchospasm, laryngeal edema, and anaphylaxis. It also causes significant stomach irritation, heartburn, nausea, vomiting, diarrhea, and stomach pain in 10% to 30% of patients. The risk of GI bleeding increases with dose. The hematologic adverse effects of aspirin administration include thrombocytopenia, hemolytic anemia, and occult bleeding. Long-term administration of aspirin may produce nephrotoxic effects and hepatotoxicity. Tinnitus and hearing loss are common adverse effects with high doses.

Contraindications/Precautions: Patients who have a hypersensitivity to any salicylate (including that found in foods) should not be administered aspirin or other NSAIDs. Patients who have the "aspirin triad," which includes aspirin allergy, nasal polyps, and asthma, should not be administered aspirin. Aspirin is also contraindicated in chronic rhinitis, acute bronchospasm, agranulocytosis, head trauma, increased intracranial pressure, history of GI bleeding, hypoprothrombinemia, vitamin K deficiency, heart failure (HF), pregnancy, and lactation. Children and teenagers should not be administered aspirin or products containing aspirin if they have a fever or a flulike illness. Patients over age 60 are especially prone to GI ulceration and bleeding due to aspirin. It should be used cautiously in patients with hypothyroidism, immunosuppression, asthma, and gout. It should also be used cautiously in patients with chronic kidney disease (CKD), hepatic impairment, G6PD deficiency, anemia, preoperatively, and in the presence of Hodgkin's disease. Aspirin should not be taken during pregnancy, especially in the third trimester; it may prolong bleeding and inhibit natural contractions caused by prostaglandins in the uterus.

Drug Interactions: Concurrent administration of aspirin with other salicylates such as 5-aminosalicylic acid increases the risk of salicylate toxicity. The combined use of aspirin with acetaminophen may cause additive nephrotoxicity. Ammonium chloride and other acidifying agents decrease the renal elimination of aspirin, resulting in salicylate toxicity. The administration of aspirin with anticoagulants, thrombolytics, or antiplatelet drugs increases the patient's risk for bleeding. When oral antidiabetic drugs are administered concurrently with high doses of aspirin, hypoglycemic activity increases. Patients who consume three or more alcoholic drinks per day may experience additive GI ulceration. Corticosteroids increase the risk of gastric irritation and result in ulcerogenic effects when administered with aspirin. Methotrexate administered with aspirin results in methotrexate toxicity. Low doses of salicylates may antagonize the uricosuric effects of probenecid and sulfinpyrazone. The antihypertensive effects of beta blockers may decrease if administered concurrently with aspirin. **Herbal/Food:** The administration of feverfew, garlic, ginger, horse chestnut, and red clover will increase the patient's risk for bleeding. Taking aspirin with caffeine will increase the rate of aspirin absorption. St. John's wort may increase sedation.

Pregnancy: Categories C (first and second trimester) and D (third trimester).

Treatment of Overdose: Acute or chronic overdose of aspirin is known as **salicylism**, which is defined as a serum salicylate level above 200 mcg/mL. The symptoms depend on the dose but include tinnitus, metabolic acidosis, hyperventilation, respiratory alkalosis (secondary to stimulation of the respiratory center), dehydration, agitation, CNS depression, nausea, and vomiting. Emesis, gastric lavage, and alkalinization of urine are indicated. Hemodialysis is of benefit in severe salicylate poisonings.

Nursing Responsibilities: Key nursing implications for patients receiving aspirin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Inflammation and Fever.

Drugs Similar to Aspirin (Acetylsalicylic Acid)

Drugs that produce similar actions to aspirin include choline magnesium trisalicylate, magnesium salicylate, and salsalate.

Choline magnesium trisalicylate (Trilisate): Approved in 1938, this drug combines choline salicylate and magnesium salicylate. It is an oral drug approved for fever and mild to moderate pain and inflammation associated with osteoarthritis, RA, bursitis, and other muscle or joint conditions. This drug causes less GI irritation than aspirin, and it exhibits less antiplatelet activity. Choline magnesium trisalicylate should not be administered to patients with known hypersensitivity to other salicylates. Other contraindications and adverse effects are similar to those of aspirin. This drug is pregnancy category C; category D if used for prolonged periods or near term.

Magnesium salicylate (Doan's Pills): Approved in 1938, magnesium salicylate is an oral drug approved for fever and mild to moderate pain and inflammation associated with osteoarthritis, RA, bursitis, and other muscle or joint conditions. It inhibits prostaglandin synthesis in the same manner as aspirin, but it is less potent, causes less GI irritation, and has less effect on platelet aggregation than aspirin. Magnesium salicylate should not be administered to patients with known hypersensitivity to other salicylates. Other contraindications and adverse effects are similar to those of aspirin. This drug is pregnancy category C for the first and second trimesters and D for the third trimester.

Salsalate (Mono-Gesic, Salsitab): Approved in 1977, salsalate has analgesic properties similar to those of aspirin but it causes less gastric irritation. It is an oral drug approved to treat mild and moderate pain due to osteoarthritis and RA. Like other salicylates, salsalate produces its effects by inhibiting prostaglandin synthesis. It has little antipyretic activity and has less effect on platelet aggregation than aspirin. Salsalate should not be administered to patients with known hypersensitivity to other salicylates. Other contraindications and adverse effects are similar to those of aspirin. This drug is pregnancy category C.

CONNECTION Checkpoint 41.1

Aspirin is classified as an antiplatelet drug in Chapter 38. Name the other two classes of drugs that are antiplatelets and state the prototype drug for each class. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Ibuprofen-Like Drugs

41.4 Ibuprofen and similar nonsteroidal anti-inflammatory drugs are the most common medications for treating mild to moderate pain and inflammation.

In the 1950s researchers began searching for safer alternatives to aspirin or corticosteroids for treating the severe inflammation of RA. An exhaustive search of over 600 potential compounds over a 15-year period resulted in the discovery of ibuprofen, one of the safest and most widely prescribed NSAIDs in the world. The drug was introduced in the United States in 1974, and it became one of the first prescription-only drugs to be changed to OTC status in 1984.

Since the discovery of ibuprofen, over 20 other nonaspirin NSAIDs have been approved by the FDA. Although their chemical structures vary, they are grouped as "ibuprofen-like" because they share very similar actions and adverse effects with the original drug. Doses for the NSAIDs are listed in Table 41.2. When used at recommended doses, NSAIDs have the following similarities:

- All have the same mechanism of action: They inhibit both COX-1 and COX-2.
- All have analgesic properties: They are widely prescribed to treat patients with mild to moderate pain.
- All have anti-inflammatory properties: Most are specifically approved for osteoarthritis and RA.
- All have antipyretic properties, although not all of them are approved for this indication.
- Most are weak acids that are readily absorbed in the GI tract.
- Most are strongly bound to albumin in the blood.
- Most are metabolized in the liver to inactive metabolites, which are excreted by the kidneys.
- All have the ability to damage the GI mucosa, including bleeding and ulcer formation.
- Many pose an increased risk of cardiac events, such as heart failure and MI.
- Many are nephrotoxic at high doses.

From the preceding list, it should be obvious that the available nonaspirin NSAIDs share many properties. There are, however, some differences in pharmacokinetic profiles. For example, some have longer half-lives or are available in sustained release formulations that permit once-daily dosing. Some are available by the parenteral route, and a few are formulated for children. Some are enteric coated, which may reduce stomach pain but does not appear to be protective against the formation of ulcers. Another consideration that is important to many consumers is cost. A month's supply of generic ibuprofen 200 mg or naproxen 220 mg costs less than $25 and is available OTC. At the opposite extreme are prescription-only celecoxib (Celebrex) 200 mg

Table 41.2 Nonaspirin NSAIDs and Acetaminophen

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
acetaminophen (Tylenol)	PO: 325–650 mg q4–6h (max: 4 g/day for all products containing this drug) Rectal: 650 mg q4–6h	*Epigastric pain, abdominal pain* Hepatotoxicity, acute renal failure
celecoxib (Celebrex)	PO: 100–400 mg bid (max: 800 mg/day)	*Back pain, peripheral edema, abdominal pain, dyspepsia, flatulence, dizziness, headache, insomnia, hypertension,* Increased risk of cardiovascular events, acute renal failure
diclofenac (Cataflam, Voltaren, others)	PO: 25–100 mg/day in one or more doses	*Dyspepsia, dizziness, headache, drowsiness, tinnitus, rash, pruritus, increased liver enzymes, prolonged bleeding time, edema, nausea, vomiting, occult blood loss* Peptic ulcer, GI bleeding, anaphylactic reactions with bronchospasm, blood dyscrasias, CKD, MI, HF, hepatotoxicity
diflunisal	PO: 250–500 mg bid (max: 1500 mg/day)	
etodolac	PO: 200–1200 mg/day in 2–4 divided doses (max: 1200 mg)	
fenoprofen (Nalfon)	PO: 200–600 mg tid or qid (max: 3200 mg/day)	
flurbiprofen	PO: 200–300 mg in 2–4 divided doses (max: 300 mg/day and 100 mg/dose)	
ibuprofen (Advil, Motrin, others)	PO: 400–800 mg tid to qid (max: 3200 mg/day)	
indomethacin (Indocin, Tivorbex)	PO (immediate release): 25–50 mg bid or tid PO (extended release): 75–100 once daily or bid	
ketoprofen	PO (immediate release): 25–75 mg tid or qid (max: 300 mg/day) PO (extended release): 200 mg once daily	
ketorolac (Sprix, Toradol)	IM/IV: 30–60 mg qid (max: 120 mg/day) PO: 10–20 mg qid (max: 40 mg/day) Intranasal: 1 spray (15.75 mg) in each nostril q4–6h	
meclofenamate	PO: 200–400 mg/day in 3–4 divided doses (max: 400 mg/day)	
mefenamic acid (Ponstel)	PO: 500-mg loading dose followed by 250-mg maintenance dose qid (max: 1250 mg/day for no longer than 7 days)	
meloxicam (Mobic)	PO: 7.5–15 mg once daily (max: 15 mg/day)	
nabumetone (Relafen)	PO: 1000 mg/day as a single dose (max: 2000 mg/day)	
naproxen (Naprosyn) and naproxen sodium (Aleve, Anaprox, others)	PO: 250–500 mg bid (naproxen/naproxen controlled release max: 1500 mg/day; naproxen sodium max: 1650/day; nonprescription max: 660 mg/day)	
oxaprozin (Daypro)	PO: 600–1200 mg daily (max: 1800 mg/day)	
piroxicam (Feldene)	PO: 10–20 mg once daily (max: 20 mg/day)	
sulindac (Clinoril)	PO: 150–200 mg bid (max: 400 mg/day)	
tolmetin (Tolectin)	PO: 400 mg tid (max: 1800 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

and flurbiprofen 100 mg, which cost $150 to $240 for a monthly supply. Indications for each of the NSAIDs are listed in Table 41.3.

There are important differences between aspirin and the ibuprofen-like drugs in their effects on the blood and heart. Although ibuprofen-like drugs affect blood coagulation, their inhibitory effects on platelets are reversible and short lived. Because they have less antiplatelet effect than aspirin, the ibuprofen-like drugs are not used for the prophylaxis of adverse cardiovascular events. In fact, some of the nonaspirin NSAIDs such as indomethacin and sulindac significantly increase the risk of cardiovascular events. Caution should be used with all the nonaspirin NSAIDs when they are given for prolonged periods to patients with a history of cardiac disease.

NSAIDs are considered equivalent to aspirin in their effectiveness for treating pain, inflammation, and fever. For the occasional user who takes the medications at recommended doses and who has no risk factors, the drugs are very safe and rarely produce any significant adverse effects. For patients who must take high doses for a chronic illness, ibuprofen appears to cause less GI bleeding than aspirin, although both drugs place patients at high risk for GI adverse effects.

PROTOTYPE DRUG Ibuprofen (Advil, Motrin, Others)

Classification **Therapeutic:** Analgesic, anti-inflammatory drug, antipyretic
Pharmacologic: NSAID

Table 41.3 Indications for Selected Nonsteroidal Anti-Inflammatory Drugs

NSAID	Arthritis	Mild to Moderate Pain	Fever	Dysmenorrhea	Other Approved Indications
celecoxib (Celebrex)	A	A		A	Ankylosing spondylitis; familial adenomatous polyposis
diclofenac (Cataflam, Voltaren, others)	A	A		A	Ankylosing spondylitis; actinic keratosis (topical); ocular pain and inflammation (ophthalmic)
diflunisal	A	A			
etodolac	A	A			
fenoprofen (Nalfon)	A	A			
flurbiprofen	A				Miosis inhibition (ophthalmic)
ibuprofen (Advil, Motrin, others)	A	A	A	A	Acute migraine
indomethacin (Indocin, Tivorbex)	A	A			Ankylosing spondylitis; close patent ductus arteriosus (IV)
ketoprofen	A	A	A	A	
ketorolac (Sprix, Toradol)		A			Allergic conjunctivitis; reduce ocular pain and inflammation (ophthalmic)
meclofenamate	A	A		A	
mefenamic acid (Ponstel)		A		A	
meloxicam (Mobic)	A				
nabumetone (Relafen)	A				
naproxen (Naprosyn) and naproxen sodium (Aleve, Anaprox, others)	A	A	A	A	Ankylosing spondylitis
oxaprozin (Daypro)	A				
piroxicam (Feldene)	A				
sulindac (Clinoril)	A				Ankylosing spondylitis; acute painful shoulder
tolmetin (Tolectin)	A				

A = FDA approved.

Therapeutic Effects and Uses: Approved in 1974, ibuprofen was the first nonaspirin NSAID marketed in the United States. Like aspirin, it possesses analgesic, anti-inflammatory, and antipyretic properties. It is indicated for the relief of fever and mild to moderate pain associated with chronic symptomatic RA and osteoarthritis, myalgia, headache, dental pain, and dysmenorrhea. Chewable tablets, drops, and solutions are available in low doses for administration to children.

Unlike aspirin, ibuprofen is not indicated to treat or prevent any cardiovascular conditions. Ibuprofen inhibits platelet aggregation and prolongs the bleeding time without affecting the prothrombin time (PT) or whole-blood clotting times. Its effects on platelets are reversible within 24 hours after discontinuation of the drug.

Ibuprofen lysine (NeoProfen) is an intravenous (IV) form of the drug that was approved in 2006 to close patent ductus arteriosus in premature infants. The drug has a 75% success rate in infants who are no more than 32 weeks gestational age. Although the mechanism of action is not known, it is believed that prostaglandins delay closing of the ductus. By blocking prostaglandin synthesis with ibuprofen, the ductus closes.

Mechanism of Action: Ibuprofen inhibits COX-1 and COX-2, which block prostaglandin synthesis and modulate T-cell function. Ibuprofen inhibits inflammatory cell chemotaxis, decreases the release of superoxide radicals, and increases the scavenging of these products at the inflammatory sites.

Pharmacokinetics:

Route(s)	PO
Absorption	80% absorbed
Distribution	Crosses the placenta; unknown if secreted in breast milk; highly protein bound
Primary metabolism	Hepatic
Primary excretion	Renal; small amount biliary
Onset of action	1 h
Duration of action	6–8 h

Adverse Effects: In low to moderate doses, ibuprofen is well tolerated and serious adverse effects are uncommon. The most frequent adverse events are GI related and include bleeding, anorexia, heartburn, nausea, vomiting, and constipation or diarrhea. Adverse CNS effects include dizziness, headache, drowsiness, and tinnitus. Rare, though serious, adverse effects include peripheral edema, aplastic anemia, leukopenia, and anaphylaxis. Chronic use of ibuprofen may lead to polyuria, azotemia, hematuria, and increased creatinine and blood urea nitrogen (BUN) levels. **Black Box Warnings:** Ibuprofen may increase the risk of serious and potentially fatal cardiovascular thrombotic events, MI, and stroke. This risk may increase with duration of use and in patients with cardiovascular risk factors. Ibuprofen also increases the risk of serious GI adverse effects including bleeding, ulcer, and stomach or intestine perforation. These GI events may occur at any time during use and without prior warning. Older adults are at greater risk for serious GI events.

Contraindications/Precautions: Patients who have a known allergy to aspirin or other NSAIDs should not be administered ibuprofen. In addition, patients who have been diagnosed with PUD, bleeding abnormalities, and perioperative pain related to coronary artery bypass graft (CABG) should not receive ibuprofen. The drug should be used cautiously in patients with hypertension (HTN), history of GI bleeding, diabetes mellitus, and impaired renal or hepatic function. It should also be used cautiously in patients who have HF or a history of stroke or MI. Children with asthma may experience diminished respiratory function when administered ibuprofen. Patients with severe hepatic impairment should not receive ibuprofen because the drug can accumulate to toxic levels.

Drug Interactions: Oral anticoagulants and antiplatelet drugs taken with ibuprofen increase the risk of bleeding. Ibuprofen may increase the toxicity of digoxin, lithium, or methotrexate if taken concurrently. Use with other NSAIDs, alcohol, or corticosteroids may cause serious adverse GI events. The antihypertensive action of diuretics, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors may be reduced if taken with ibuprofen. **Herbal/Food:** Ibuprofen combined with feverfew, garlic, ginger, and ginkgo may result in an increased risk of bleeding.

Pregnancy: Categories B (first and second trimesters) and D (third trimester).

Treatment of Overdose: Overdose may lead to acute renal failure, apnea, cyanosis, drowsiness, GI bleeding, nausea, vomiting, and sweating. Treatment is supportive and includes the administration of activated charcoal and nasogastric suction.

Nursing Responsibilities: Key nursing implications for patients receiving ibuprofen are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Inflammation and Fever.

Drugs Similar to Ibuprofen (Advil, Motrin, Others)

There are a number of subclasses of NSAIDs that are based on the chemical structures of the molecules. These subclasses include the propionic acids (e.g., ibuprofen), phenylacetic acids (e.g., diclofenac), indole acetic acids (e.g., indomethacin), fenamates (e.g., mefenamic acid), ketones (e.g., nabumetone), and oxicams (e.g., piroxicam). From a clinical perspective, the nonaspirin NSAIDs are remarkably similar to ibuprofen. Doses and indications for these drugs differ, as listed in Tables 41.2 and 41.3.

PharmFACT

It is estimated that NSAID use is associated with about 100,000 hospitalizations and 16,000 deaths annually in the United States, largely as a result of GI complications (Wiegand, 2016).

Cyclooxygenase-2 Inhibitors

41.5 Celecoxib is an effective second-generation nonsteroidal anti-inflammatory drug, but its use is limited due to an increased risk of myocardial infarction and stroke.

Celecoxib (Celebrex) is a second-generation NSAID that blocks COX-2 without inhibiting COX-1. The selective inhibition of COX-2 produces the analgesic, anti-inflammatory, and antipyretic effects typical of other NSAIDs, but without causing platelet aggregation or GI irritation. The primary advantage of celecoxib is that it causes less GI bleeding and ulcer formation than aspirin or ibuprofen. This medication is the newest and most controversial of the NSAIDs.

The ability to treat arthritis without adverse effects caused excitement throughout the medical field in the 1990s, and the three drugs originally in this class were widely prescribed. This elation quickly ended when postmarketing data revealed that rofecoxib (Vioxx) doubled the risk of MI and strokes in patients taking the drug for extended periods. At that time, more than 84 million people had used rofecoxib since its approval. Based on the research data, the drug manufacturer voluntarily removed rofecoxib from the market. Shortly afterward a second COX-2 inhibitor, valdecoxib (Bextra),

was also voluntarily withdrawn, leaving celecoxib (Celebrex) the sole drug in this class. A large number of lawsuits were subsequently filed, and the development of new COX-2 inhibitors has stopped in the United States. Other COX-2 inhibitors are still available outside the United States.

PROTOTYPE DRUG Celecoxib (Celebrex)

Classification **Therapeutic:** Anti-inflammatory
Pharmacologic: COX-2 inhibitor, NSAID

Therapeutic Effects and Uses: Initially approved in 1998, celecoxib is used to treat mild to moderate pain and inflammation associated with RA, osteoarthritis, dysmenorrhea, dental procedures, headache, and ankylosing spondylitis. It is also an effective antipyretic drug. The effectiveness of celecoxib at reducing pain and inflammation is equivalent to that of other NSAIDs.

In addition to its anti-inflammatory indications, celecoxib also is used for the prophylaxis of adenomas or colorectal polyps in adults with familial adenomatous polyposis (FAP). Patients with this condition have an inherited mutation in a gene that results in hundreds of polyps and an almost 100% risk of colon cancer. Although celecoxib reduces the number of polyps in these patients, it has not been proven to reduce the risk of malignancies.

Mechanism of Action: Celecoxib selectively inhibits the enzyme COX-2. It inhibits prostaglandin synthesis to reduce inflammation. This action relieves pain and inflammation in the joints and smooth muscle tissue.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Widely distributed; is likely secreted in breast milk; 97% protein bound
Primary metabolism	Hepatic by CYP2C9
Primary excretion	Primarily feces (57%), with some in urine (27%)
Onset of action	Peak: 3 h
Duration of action	Half-life: 11.2 h

Adverse Effects: Common adverse effects include headache, HTN, fever, dyspepsia, upper respiratory tract infection, arthralgia, cough, vomiting, and diarrhea. CNS adverse effects include headache, dizziness, and insomnia. Adverse effects of the integumentary system are generally rare and include erythema multiforme, exfoliative dermatitis, rash, Stevens–Johnson syndrome, and toxic epidermal necrolysis. The long-term use of celecoxib may cause CKD and hepatic impairment. **Black Box Warnings:** Celecoxib carries the same warnings as the ibuprofen-like drugs. It may increase the risk of serious and potentially fatal cardiovascular thrombotic events, MI, and stroke. This risk may increase with duration of use and in patients with cardiovascular risk factors. Celecoxib also increases the risk of serious GI adverse effects including bleeding, ulcer, and stomach or intestine perforation. These GI events may occur at any time during use and without prior warning. Older adults are at greater risk for serious GI events.

Contraindications/Precautions: Celecoxib should not be administered to patients with hepatic insufficiency because the primary site of drug metabolism is the liver. It is also contraindicated in patients with chronic kidney disease (CKD). Celecoxib is contraindicated in patients with anemia or in the postoperative phase of a CABG. Celecoxib is administered cautiously in patients who are poor CYP2C9 metabolizers. This drug is contraindicated in patients with a history of GI bleeding or PUD, and it should be administered with caution to patients receiving anticoagulants. Patients with a history of asthma, bone marrow suppression, stroke, peripheral vascular disease, elevated liver function tests, heart failure, kidney disease, and fluid retention should be administered celecoxib cautiously.

Drug Interactions: If taken with celecoxib, oral coagulation modifiers such as clopidogrel or warfarin may cause an increased risk of bleeding. Celecoxib may increase the toxicity of lithium if taken concurrently. Use with alcohol, corticosteroids, aspirin, or other NSAIDs may cause serious adverse GI events. The antihypertensive action of diuretics or ACE inhibitors may be reduced if taken with celecoxib. Concurrent use with fluconazole may increase serum celecoxib levels. **Herbal/Food:** Feverfew, garlic, ginger, ginkgo, horse chestnut, and red clover may increase the risk of bleeding if used during celecoxib therapy.

Pregnancy: Category C; category D in the third trimester.

Treatment of Overdose: Overdose may cause acute renal failure, apnea, cyanosis, drowsiness, GI bleeding, nausea, vomiting, and sweating. Treatment is supportive and includes the administration of activated charcoal and nasogastric suction.

Nursing Responsibilities: Key nursing implications for patients receiving celecoxib are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Inflammation and Fever.

Drugs Similar to Celecoxib (Celebrex)

Celecoxib (Celebrex) is the sole medication in this class.

CONNECTIONS: Preparing for Advanced Practice

Intravenous Acetaminophen—Is it Worth the Cost?

Case

Sarah is a 27-month-old who had a surgical reduction of intussusception (telescoping of the intestines). The surgery was uncomplicated and the patient has been brought into the pediatric postoperative area on IV morphine prn. Her parents are with her and she has already received 2 doses of IV morphine but continues to cry out in pain. Her parents are distraught, and they ask you, the pediatric nurse practitioner (NP) hospitalist, to evaluate Sarah for pain management. IV acetaminophen has recently become available at your institution, and you wonder if it could be added to her pain plan. Would this help minimize the potential for adverse opioid effects for this patient?

Discussion

IV acetaminophen (Ofirmev) was approved by the FDA in November 2010 for the management of mild to moderate pain, the management of moderate to severe pain (along with opioid analgesics), and the reduction of fever in patients ages 2 years and older. Ofirmev has been advertised as an opioid-sparing analgesic with a potential for reducing opioid-related side effects. Recent studies have shown several benefits in using IV acetaminophen such as a reduction in opioid administration by up to 20%, a decreased length of hospital stay, and a reduction in opioid-related complication rates (Jibril, Sharaby, Mohamed, & Wilby, 2015; Shaffer et al., 2017).

The cost of IV acetaminophen is significantly higher than that of oral or rectal acetaminophen. On average, IV acetaminophen costs more than $10 per dose compared to less than $1 for the oral and rectal routes. The clinician must weigh its benefits against the risk of increased overall healthcare costs due to adverse events related to increased opioid consumption by patients. The IV route should primarily be used for patients who cannot tolerate oral and rectal acetaminophen, such as those who are NPO (nothing by mouth) or who cannot receive NSAIDs due to risk of bleeding or opioid complications.

IV acetaminophen is administered over 15 minutes and may be given as a single or repeated dose. The maximum daily dose of acetaminophen is based on all routes of administration (IV, oral, and rectal) and all products (prescription and nonprescription) containing acetaminophen.

The recommended dosage of Ofirmev is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours, with a maximum single dose of 15 mg/kg, a minimum dosing interval of 4 hours, and a maximum daily dose for all routes of acetaminophen of 75 mg/kg per day.

CONNECTION Checkpoint 41.2

Several NSAIDs are approved to treat mild migraines. From what you learned in Chapter 25, what non-NSAID drug classes are used to terminate severe migraine episodes? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Antipyretic and Analgesic Drugs

41.6 Acetaminophen is administered for pain relief and to reduce fever, but it has no anti-inflammatory properties.

Acetaminophen (Tylenol) is administered for pain relief and to reduce fever. Unlike aspirin, ibuprofen, and celecoxib, acetaminophen has no anti-inflammatory properties, and therefore is not classified as an NSAID. Acetaminophen has equal effectiveness to the NSAIDs in reducing pain and fever, and it is often a preferred drug for treating noninflammatory pain. It is the primary alternative to NSAIDs when patients have a contraindication to taking aspirin or ibuprofen. Acetaminophen is frequently combined with other OTC drugs in treating severe flu symptoms. It is often combined with opioid analgesics; adding acetaminophen provides additive pain relief and allows for lower doses of the narcotic (see Chapter 25). Due to a safety recommendation from the FDA, drug manufacturers now limit the strength of acetaminophen in prescription combination products to 325 mg per tablet, capsule, or dosing unit to lower the potential for acetaminophen-induced hepatotoxicity.

Acetaminophen has no effect on platelet aggregation and does not exhibit cardiotoxicity. Most importantly, it does not cause GI bleeding or ulcers, as do the NSAIDs.

PROTOTYPE DRUG **Acetaminophen (Tylenol)**

Classification **Therapeutic:** Nonopioid analgesic, antipyretic
Pharmacologic: Para-aminophenol derivative

Therapeutic Effects and Uses: Approved in 1950, acetaminophen relieves mild to moderate pain but has no effect on inflammation. Acetaminophen is approved to treat pain associated with osteoarthritis of the hip or knee, dysmenorrhea, dental procedures, headache, and myalgia. It is a preferred drug for reducing fever. Acetaminophen is administered as a substitute for aspirin when NSAIDs are contraindicated due to age, allergy, or gastric irritation. It is not linked with Reye's syndrome, as is aspirin; thus it is safe to administer to infants, children, and adolescents who have flulike symptoms or chickenpox.

Acetaminophen is available for the oral (suspension, tablets, chewable tablets, extended release tablets, and oral granules) or rectal route. Childhood and infant preparations are available. Ofirmev is an IV formulation of acetaminophen.

Mechanism of Action: Acetaminophen acts centrally in the CNS by inhibiting COX. It has no effect on COX in peripheral tissues. It also may inhibit the chemical mediators of pain, but its mechanism is unclear. The reduction of fever occurs by its direct action on the heat-regulating center of the hypothalamus to produce peripheral vasodilation, sweating, and dissipation of heat.

Pharmacokinetics:

Route(s)	PO, rectal, IV
Absorption	Rapid and complete absorption
Distribution	Distributed to all body fluids; crosses the placenta; secreted in breast milk; 25% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	PO: 30–60 min; IV: 15 min
Duration of action	3–8 h

Adverse Effects: At recommended doses, acetaminophen is well tolerated and serious adverse effects are rare. The risk for adverse effects is dose related and increases with long-term use. Acute acetaminophen poisoning is very serious, and symptoms include anorexia, nausea, vomiting, dizziness, lethargy, diaphoresis, chills, epigastric or abdominal pain, and diarrhea. Excessive acetaminophen use is the number one cause of acute hepatic failure in the United States. The onset of hepatotoxicity is noted with elevated transaminases (alanine aminotransferase [ALT], aspartate aminotransferase [AST]) and bilirubin. The patient may also experience hypoglycemia, hepatic coma, and acute renal failure. Chronic ingestion of acetaminophen results in neutropenia, pancytopenia, leukopenia, thrombocytopenic purpura, hepatotoxicity in alcohol-dependent patients, and CKD. In 2013, the FDA issued a safety alert that recommended the drug be immediately discontinued if skin reactions or blisters develop. These skin lesions may indicate the development of rare, though serious, disorders such as Stevens–Johnson syndrome. **Black Box Warning:** Acetaminophen has the potential to cause severe liver injury and may cause serious allergic reactions with symptoms of angioedema, difficulty breathing, itching, or rash.

Contraindications/Precautions: Patients who are allergic to acetaminophen should not be administered this medication. It should be used cautiously in patients with anemia, G6PD deficiency, or hepatic disease. Acetaminophen should be administered cautiously to patients with rheumatoid or osteoarthritis, malnutrition, bone marrow depression, and immunosuppression. Chronic administration of acetaminophen should be avoided in patients with CKD because this drug can worsen kidney function.

Drug Interactions: Acetaminophen should not be administered with alcohol or to patients who consume alcohol with regularity because this greatly increases the risk of hepatotoxicity. Alcohol-induced hepatotoxicity can occur at therapeutic doses of acetaminophen. Due to additive hepatotoxic effects, acetaminophen should not be administered with barbiturates, carbamazepine, diphenylhydantoin, isoniazid, rifampin, and sulfinpyrazone. Long-term use of acetaminophen will increase the anticoagulant actions of warfarin. Zidovudine administered with acetaminophen may increase the risk of bone marrow suppression. **Herbal/Food:** Caffeine will enhance the analgesic effects of acetaminophen. Hepatotoxicity has been reported with concurrent echinacea use.

Pregnancy: Category B.

Treatment of Overdose: Acetaminophen overdose is treated with oral or IV acetylcysteine (Acetadote). For maximum effectiveness, the antidote should be administered within 8 hours of acetaminophen ingestion. The IV form (Acetadote) is administered by the "three-bag method":

- **Loading dose.** Dilute 150 mg/kg in 200 mL of 5% dextrose and administer over 60 minutes.
- **Second dose.** Dilute 50 mg/kg in 500 mL of 5% dextrose and administer over 4 hours.
- **Third dose.** Dilute 100 mg/kg in 1,000 mL of 5% dextrose and administer over 16 hours.

Nursing Responsibilities: Key nursing implications for patients receiving acetaminophen are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Inflammation and Fever.

Drugs Similar to Acetaminophen (Tylenol)

Acetaminophen is the only medication in this class.

CONNECTIONS: Treating the Diverse Patient

Ethnic Differences in Acetaminophen Metabolism

Certain ethnic populations, including patients of Asian, African American, or Middle Eastern descent, may have higher rates of an enzyme deficiency that affects how they metabolize certain drugs. More than 200 million people worldwide are believed to have a hereditary deficiency of the enzyme glucose-6-phosphate dehydrogenase (G6PD). Patients with G6PD deficiency are at risk for developing hemolysis after ingesting certain drugs, including acetaminophen. In patients with the deficiency, therapeutic dosages of acetaminophen may cause hemolysis. Because acetaminophen is one of the most common drugs used for fever, pain control, and in many OTC cough and cold medicines, and because patients may not know that they have the deficiency, healthcare providers should recommend that ethnically diverse patients exercise caution when using acetaminophen and report any signs or symptoms associated with anemia. Patients with known G6PD deficiency should avoid this drug. Patients receiving IV forms of acetaminophen should have frequent CBC laboratory monitoring.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Inflammation and Fever

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, respiratory, cardiovascular or neurologic disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], coagulation panels, bleeding time, electrolytes, glucose, lipid profile, and hepatic or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., temperature returns to within normal range, pain is decreased or absent, signs and symptoms of inflammation such as redness or swelling are decreased).
- Continue periodic monitoring of CBC, coagulation studies, bleeding time, electrolytes, glucose, lipids, hepatic, and renal function studies.
- Assess vital signs and weight periodically or if symptoms warrant. Report any weight gain over 1 kg (2 lb) in a 24-h period or more than 2 kg (5 lb) in 1 wk.
- Assess for and promptly report adverse effects: symptoms of GI bleeding (dark or tarry stools, hematemesis, coffee-ground emesis, or blood in the stool), abdominal pain, severe tinnitus, dizziness, drowsiness, lightheadedness, palpitations, tachycardia, HTN, increased respiratory rate and depth, pulmonary congestion, or edema.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished fever, pain, or signs and symptoms of infection should begin after taking the first dose and continue to improve. The provider should be notified if fever remains present after 3 days or if increasing signs of infection are present.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures (e.g., RICE: rest, ice or cool compresses, compression bandage [e.g., ACE wrap], elevation of the inflamed joint or limb); increased fluid intake for fever; positioning for comfort; diversionary distractions (e.g., television or music).
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present, and blood pressure and pulse for patients on ibuprofen and similar drugs. Immediately report undiminished fever, changes in level of consciousness (LOC), febrile seizures, tachycardia, blood pressure over 140/90 mmHg, or per parameters as ordered by the healthcare provider. (Fever should begin to diminish within 1–3 h after taking the drug. Ibuprofen and similar drugs may increase the risk for cardiovascular thrombotic events such as MI and stroke.)	• Teach the patient to immediately report a fever that does not diminish below 37.8°C (100°F) or per established parameters, febrile seizures, changes in behavior or LOC, tachycardia, palpitations, or increased blood pressure to the healthcare provider. • Teach the patient on ibuprofen or similar drugs how to monitor the pulse and blood pressure. Ensure proper use and functioning of any home equipment obtained.
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBC, electrolytes, glucose, lipid levels, coagulation studies, or bleeding time. **Lifespan:** Monitor the older adult frequently because age-related physiologic changes increase the risk of adverse renal and hepatic effects. (Aspirin and salicylates affect platelet aggregation and should be monitored if used long term or if excessive bleeding or bruising is noted. Acetaminophen can be hepatotoxic in large doses or if taken when hepatic dysfunction is present.)	• Instruct the patient on the need to return periodically for laboratory work. • Teach the patient to abstain from alcohol while taking acetaminophen. Men who consume more than two alcoholic beverages per day or women who consume more than one alcoholic beverage per day should consult their healthcare provider before taking acetaminophen.
• Monitor for abdominal pain, black or tarry stools, blood in the stool, hematemesis, coffee-ground emesis, dizziness, lightheadedness, and hypotension, especially if associated with tachycardia. **Lifespan:** Monitor the older adult frequently for GI irritation or bleeding because age-related physiologic changes increase the risk of adverse effects. (NSAIDs may cause GI irritation and bleeding.)	• Instruct the patient to immediately report any signs or symptoms of GI bleeding. • Teach the patient to take the drug with food or milk to decrease GI irritation. Enteric-coated tablets should be swallowed whole without chewing, crushing, or breaking. Alcohol use should be avoided or eliminated.
• Monitor for tinnitus, difficulty hearing, lightheadedness, or difficulty with balance, and report promptly. (NSAIDs and salicylates may be ototoxic and cause hearing loss.)	• Instruct the patient to immediately report any signs or symptoms of ringing, humming, buzzing in ears, difficulty with balance, dizziness or vertigo, or nausea.
• Monitor urine output and renal function studies periodically. Weigh patient on corticosteroids daily, and report weight gain of 1 kg (2 lb) or more in a 24-h period or more than 2 kg (5 lb) per week, or increasing peripheral edema. (NSAIDs and salicylates may be nephrotoxic and patients on long-term or high-dose therapy should monitor urine output and have periodic renal function studies. Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses.)	• Instruct the patient on NSAIDs and salicylates to report promptly any changes in the quantity of urine output, darkening of urine, or edema. • Teach the patient on NSAIDs and salicylates to increase fluid intake, especially if fever is present. • Instruct the patient to weigh self daily, ideally at the same time of day. The patient should report a weight gain of more than 1 kg (2 lb) in a 24-h period or more than 2 kg (5 lb) per week, or increasing peripheral edema.
• Periodically monitor vision in patients on NSAIDs. Immediately report unusual changes in visual acuity, blurred or diminished vision, reports of spots in vision, or changes in color sense to the provider. (NSAIDs may cause blurred or diminished vision, decreased color sense, diplopia, or scotomas.)	• Teach the patient on NSAIDs to obtain eye exams twice yearly or more frequently as instructed by the provider. Immediately report any eye pain, diminished or blurred vision, or changes in color sense.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• **Lifespan:** Avoid the use of aspirin or salicylates in children under age 19 unless explicitly ordered by the healthcare provider. (Aspirin has been associated with an increased risk of Reye's syndrome in children under age 19, particularly associated with the flu virus and varicella infections.)	• Instruct parents to use NSAIDs or acetaminophen in children under age 19 for fever or pain control, unless otherwise ordered by the provider. Do not use aspirin or salicylates in children under age 19 unless ordered by the provider or within 2–3 wk after the varicella vaccination has been administered to these children. • Teach parents to read labels on all OTC medications and to avoid formulations with aspirin or salicylate on the label.
• **Lifespan:** Assess for the possibility of pregnancy before beginning the drug. (Many NSAIDs are pregnancy category C or D.)	• Instruct women who may be considering pregnancy, or are pregnant, to notify their provider before starting the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, most commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration, e.g., with food or milk. (Utilizing time during nurse administration of these drugs helps to reinforce teaching. Household measuring devices such as teaspoons differ significantly in size and amount and should not be used for pediatric or liquid doses.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs, including:
	  • NSAIDs should be taken with food or milk to decrease GI upset.
	  • Liquid doses of acetaminophen or NSAIDs should be measured with the dosage cup, dropper, or spoon enclosed with the prescription. If that measuring device is no longer available, do *not* use a household spoon. Obtain another calibrated measuring cup or dropper.

Understanding Chapter 41

Key Concepts Summary

41.1 Inflammation is a nonspecific body response to antigens and tissue injury.

41.2 Treatment of inflammation includes nonpharmacologic therapies and the administration of anti-inflammatory drugs.

41.3 Aspirin is an inexpensive, effective, first-generation nonsteroidal anti-inflammatory drug commonly used by adults.

41.4 Ibuprofen and similar nonsteroidal anti-inflammatory drugs are the most common medications for treating mild to moderate pain and inflammation.

41.5 Celecoxib is an effective second-generation nonsteroidal anti-inflammatory drug, but its use is limited due to an increased risk of myocardial infarction and stroke.

41.6 Acetaminophen is administered for pain relief and to reduce fever, but it has no anti-inflammatory properties.

CASE STUDY: Making the Patient Connection

Remember the patient "Joycee Layne" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Joycee Layne is a 17-year-old high school student in her senior year. She is an honors student, works hard to get good grades, and hates to miss school. For the past 3 days, she has not been feeling well. This morning her temperature is 39°C (102.2°F), and she has chills and a headache. Several of her friends at school have the flu. She has taken ibuprofen for fevers and menstrual cramps in the past, but Joycee cannot find any in the house as she prepares to leave for

school. Her parents have already left for work, and they trust her to check with you, the nurse who lives next door, before taking any medication. Joycee calls you to ask "Is it okay to take the aspirin that my mom uses for her arthritis so I can go to school?" As the nurse, this presents an opportunity for you to teach Joycee about aspirin and her fever.

Critical Thinking Questions

1. Describe the pathophysiology of fever and inflammation.
2. Why is aspirin administered for fever?
3. Should Joycee take the aspirin? Why or why not?
4. What will you teach Joycee about aspirin and the flulike symptoms she is having? What additional patient teaching will she need?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Tameeka Jones has a postoperative infection following a vaginal hysterectomy. The infection is noted at the site of the laparoscopic incision of the lower abdomen. She has developed a fever of 38.8°C (102°F). The healthcare provider has ordered acetaminophen (Tylenol) 650 mg PO every 4 to 6 h as needed for the fever.

1. What is the action of acetaminophen (Tylenol)?
2. What pain medications should be avoided while the patient is receiving acetaminophen (Tylenol) for fever reduction?
3. What patient teaching is important for the patient who has a fever related to infection?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A 30-year-old patient with depression has attempted suicide by overdosing on acetaminophen (Tylenol). The nurse in the emergency department will anticipate that the patient's treatment will consist of:
    1. An intravenous infusion with normal saline to infuse at 1000 mL per hour.
    2. The administration of acetylcysteine (Acetadote) by intravenous infusion.
    3. Preparation for cardioversion due to the impending arrhythmia.
    4. The assessment of liver hepatic enzymes to determine hepatotoxicity.

2. A patient has a fever and is allergic to aspirin. Which medication will the nurse anticipate administering to reduce the patient's fever?
    1. Ibuprofen (Motrin, Advil)
    2. Ketorolac (Toradol)
    3. Acetaminophen (Tylenol)
    4. Celecoxib (Celebrex)

3. An anti-inflammatory drug is ordered to be given intravenously to the patient for pain. Which anti-inflammatory drug is administered parenterally?
    1. Ketorolac (Toradol)
    2. Ketoprofen
    3. Ibuprofen (Motrin, Advil)
    4. Celecoxib (Celebrex)

4. An 80-year-old woman, who is scheduled for a total knee replacement next month, currently takes ibuprofen (Motrin, Advil) 600 mg 3 times per day. Which patient teaching intervention is most important?
    1. Continue ibuprofen (Motrin, Advil) until surgery.
    2. Stop ibuprofen (Motrin, Advil) today.
    3. Decrease ibuprofen (Motrin, Advil) to 2 times per day.
    4. Stop ibuprofen (Motrin, Advil) 7 to 14 days before surgery.

5. The nurse should question the order of acetaminophen (Tylenol) for which patient?
    1. A patient with cirrhosis of the liver
    2. A patient with chronic obstructive pulmonary disease
    3. A patient with breast cancer
    4. A patient who is taking warfarin (Coumadin)

6. A patient takes aspirin (acetylsalicylic acid) daily for pain in the right knee. Which toxic effects may be present with aspirin overdosage? (Select all that apply.)
    1. Tinnitus
    2. Hyperventilation
    3. Gastrointestinal bleeding
    4. Decreased urinary output
    5. Peripheral neuropathy

See Answers to Chapter Review in Appendix A.

Chapter 42
Immunostimulants and Immunosuppressants

Chapter Outline

- Immunostimulants
  - Interferons
    - **PROTOTYPE** *Interferon Alfa-2b (Intron A), p. 743*
  - Interleukins
    - **PROTOTYPE** *Aldesleukin (Proleukin), p. 746*
- Immunosuppressants
  - Calcineurin Inhibitors
    - **PROTOTYPE** *Cyclosporine (Gengraf, Neoral, Sandimmune), p. 751*
  - Cytotoxic Drugs and Antimetabolites
    - **PROTOTYPE** *Azathioprine (Azasan, Imuran), p. 753*
  - Antibodies
    - **PROTOTYPE** *Basiliximab (Simulect), p. 755*
  - Corticosteroids

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the therapeutic applications of the immunostimulants and immunosuppressants.
2. Describe the roles of interferons, interleukins, and other cytokines in modulating the immune response.
3. Explain how pegylation of the interferon molecule allows for less frequent dosing.
4. Explain why therapy with immunosuppressant medications is necessary following organ transplants.
5. Identify the classes of drugs used as immunosuppressants.
6. Compare and contrast polyclonal and monoclonal antibodies.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy with immunostimulants and immunosuppressants.

Key Terms

biologic response modifiers, 743
calcineurin, 750
capillary leak syndrome, 746
cytokine release syndrome, 756
immunostimulants, 742
immunosuppressants, 743
interleukins (ILs), 746
monoclonal antibody (MAB), 755
pegylation, 743
polyclonal antibodies, 755
transplant rejection, 749

The immune system and other body defenses are truly formidable deterrents to invading microorganisms. A healthy defense system can protect the body from life-threatening infections caused by thousands of different species of organisms often over an entire lifetime. In addition, body defenses can protect against internal invaders such as cancer cells. In certain circumstances, however, drugs may be necessary to modulate the body's defenses. This chapter examines pharmacotherapy with drugs that either stimulate or suppress immune function.

42.1 Immunomodulators are substances that either enhance or suppress the ability of the body to fight infection and disease.

Body defenses are composed of a complex system of cells, tissues, and processes designed with a single goal: to protect the body from invasion by foreign substances, or antigens, that may cause harm. Some of these defenses are specific to a single species of microbe, whereas others are nonspecific and provide the same response or protection regardless of the invading pathogen. The student should review the components of body defenses in Chapter 43 before proceeding.

Immunomodulator is a general term referring to any drug or therapy that affects body defenses. An overview of the immunomodulators is given in Figure 42.1. Two basic types of immunomodulators are used for pharmacotherapy:

- **Immunostimulants** are drugs that increase the ability of the immune system to fight infection and disease. In most cases, these drugs are used to treat patients with cancer. The use of immunostimulants to treat cancer is called *immunotherapy*. Some immunostimulants are also used to treat hepatitis. The use of colony-stimulating factors to treat neutropenia was presented in Chapter 39 and the application of vaccines to boost the immune response is presented in Chapter 43.

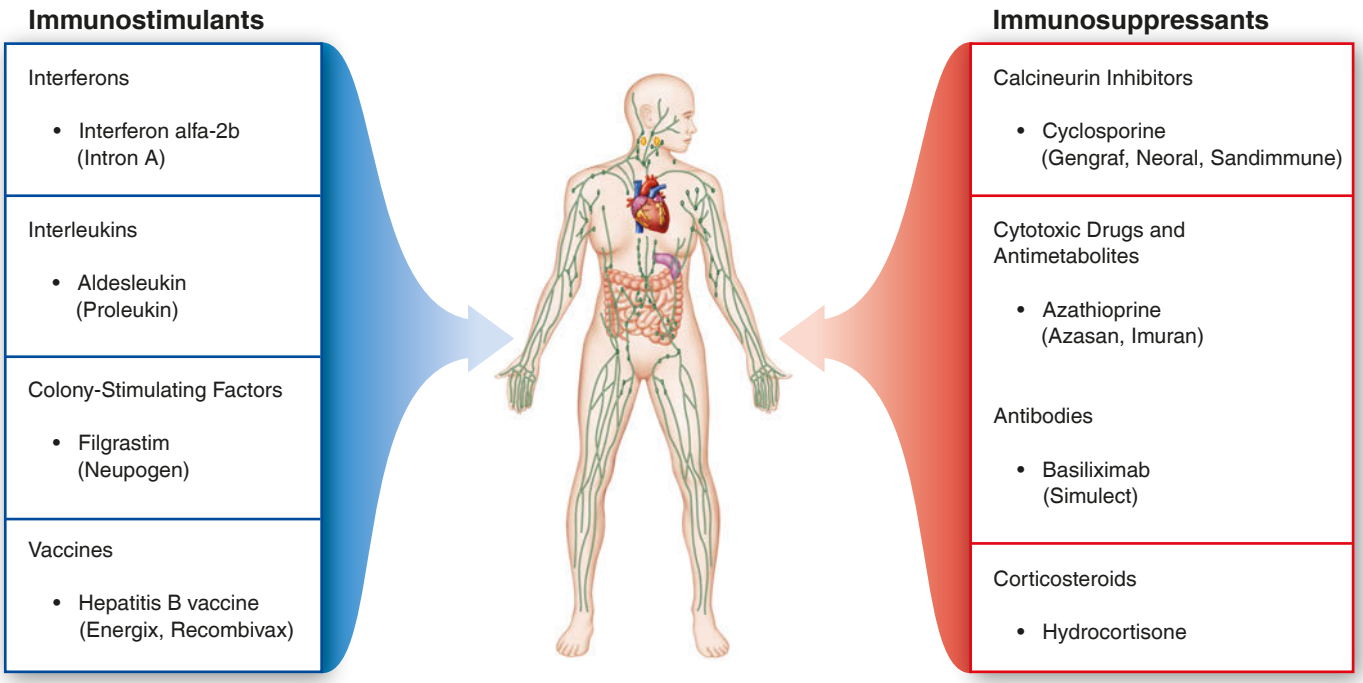

Figure 42.1 Overview of immunomodulators.

- **Immunosuppressants** are drugs that diminish the ability of the immune system to fight infection and disease. Immunosuppressants are used to prevent transplant rejection and to dampen hyperactive immune responses, such as those that may occur during exacerbations of systemic lupus erythematosus (SLE) or rheumatoid arthritis (RA).

Immunostimulants

42.2 Interferons are biologic response modifiers that have antiviral and antineoplastic activity.

When challenged by antigens, certain cells of the immune system secrete cytokines, which are substances that help the body mediate and intensify the immune response. Because cytokines have powerful actions on the immune system, the body generally only produces them when challenged by an antigen; their production is rapid though transient. Although cytokines are essential components of body defenses, a chronic high level of cytokines can greatly worsen symptoms of disorders such as psoriasis, Crohn's disease, or RA.

Cytokines exhibit multiple complex actions. A single cytokine can affect multiple target cells, each resulting in a different action. There is also considerable overlap or redundancy among the cytokines in that different cytokines can produce the same biologic actions. In addition to affecting their target cells, cytokines interact with each other by turning the synthesis of other cytokines on or off. The physiology of cytokines is complex and is an active research field.

Natural cytokines have been identified and, through recombinant deoxyribonucleic acid (DNA) technology, enough quantity has been made available to treat certain disorders. Also called **biologic response modifiers**, some of these drugs have been approved to boost specific functions of the immune system.

Interferons (IFNs) are cytokines secreted by lymphocytes and activated macrophages that have been infected with a virus. IFNs are unable to protect the infected cell, but they warn surrounding cells that a viral infection has occurred. IFNs attach to nearby uninfected cells, inducing the production of protective antiviral proteins. When the virus attempts to attack the protected cell, the pathogen is inactivated.

IFNs are part of the body's nonspecific defense system. Their actions slow the spread of viral infections, stimulate the activity of existing leukocytes, increase phagocytosis, and enhance the cytotoxic ability of T cells. Interestingly, IFNs promote apoptosis in infected cells, which is a form of programmed cell death in which the infected cell kills itself to limit the replication and spread of the virus. In addition to their antiviral actions, IFNs have antineoplastic and anti-inflammatory properties.

Many different cell types produce IFNs. Although their functions are nearly identical, each IFN has a slightly different structure, and some have different receptors. To distinguish among the different IFNs, each type is assigned numbers and a Greek letter. The most common types are IFN alfa-2b, IFN beta-1a, IFN beta-1b, and IFN gamma-1a. When the drug consists of a mixture of IFNs, the letter "n" is assigned. For example, IFN alfa-n3 is a mixture of IFN alfa subtypes. The alfa IFNs have the greatest clinical utility. The formulations available are shown in Table 42.1.

The two "peg" formulations have the molecule polyethylene glycol (PEG) bonded to the IFN. PEG is a polymer with low toxicity that can be found in skin creams, laxatives, lubricants, toothpastes, and many other products. The addition of PEG to another molecule, known as **pegylation**, increases the molecule's solubility and extends its stability. The addition of PEG to an IFN extends the half-life of the drug to allow for once-weekly dosing. Indications for IFN alfa therapy include hairy cell leukemia, non-Hodgkin's lymphoma, acquired immunodeficiency syndrome (AIDS)–related Kaposi's sarcoma, and chronic hepatitis B or C. The use of IFN alfa in the pharmacotherapy of hepatitis is presented in Chapter 54. Doses of the IFNs are listed in Table 42.1.

IFN beta consists of two different formulations, beta-1a and beta-1b, which are primarily reserved for the treatment of severe multiple sclerosis (MS) (see Chapter 21). A third drug in this class, called IFN gamma-1b, has limited clinical application in the treatment of chronic granulomatous disease and severe osteoporosis.

PROTOTYPE DRUG **Interferon Alfa-2b (Intron A)**

Classification **Therapeutic:** Immunostimulant
Pharmacologic: Interferon, biologic response modifier

Therapeutic Effects and Uses: Approved in 1986, IFN alfa-2b is a biologic response modifier prepared by recombinant DNA technology. Indications include neoplastic conditions such as hairy cell leukemia, malignant melanoma, non-Hodgkin's lymphoma, and AIDS-related Kaposi's sarcoma as well as viral infections (chronic hepatitis virus B and C). IFN alfa-2b is also indicated for the intralesional treatment of condylomata acuminata, which are genital warts caused by the human papillomavirus. Off-label indications include chronic myelogenous leukemia, bladder cancer, herpes simplex virus, multiple myeloma, renal cell carcinoma, human immunodeficiency virus (HIV), varicella-zoster virus (VZV), and West Nile virus. It is available for intravenous (IV), intramuscular (IM), and subcutaneous administration.

Mechanism of Action: IFN alfa-2b has both antiviral and antineoplastic activities. It is a nonspecific inhibitor of

Table 42.1 Immunostimulants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aldesleukin (Proleukin)	IV: 600,000 units/kg (0.037 mg/kg) q8h by a 15-min IV infusion for a total of 14 doses	*Flulike symptoms, rash, anemia, nausea, vomiting, diarrhea, confusion, dyspnea* Cardiac arrest, hypotension, tachycardia, thrombocytopenia, oliguria, anuria, pulmonary edema, capillary leak syndrome
bacillus Calmette-Guérin (BCG) vaccine (TheraCys, Tice)	Interdermal (Tice): 0.1 mL as vaccine Intravesical (TheraCys): Bladder instillation for bladder carcinoma	*Flulike symptoms, dysuria, hematuria, anemia, lymphadenopathy* Thrombocytopenia, cystitis, urinary tract infection (UTI), disseminated mycobacteria
Interferons		
IFN alfa-2b (Intron A)	IM/Subcutaneous: Hairy cell leukemia: 2 million units/m^2 3 times/wk for up to 6 months Kaposi's sarcoma: 30 million units/m^2 3 times/wk for 16 wk Chronic hepatitis B: 30–35 million units/wk for 16 wk	*Flulike symptoms, myalgia, fatigue, headache, anorexia, diarrhea, nausea* Myelosuppression, thrombocytopenia, neutropenia, suicide ideation, severe depression, seizures (IFN beta), myocardial infarction (MI) (IFN gamma), anaphylaxis, hepatotoxicity
IFN alfa-n3 (Alferon N)	Intralesion: 0.05 mL (250,000 international units) per wart twice/wk for up to 8 wk	
IFN beta-1a (Avonex, Rebif)	IM (Avonex): 30 mcg/wk Subcutaneous (Rebif): 44 mcg 3 times/wk	
IFN beta-1b (Betaseron, Extavia)	Subcutaneous: 0.25 mg (8 million units) every other day	
IFN gamma-1b (Actimmune)	Subcutaneous: 50 mcg/m^2 3 times/wk	
pegIFN alfa-2a (Pegasys)	Subcutaneous: 180 mcg once weekly for 48 wk	
pegIFN alfa-2b (Pegintron, Sylatron)	Subcutaneous (Pegintron): 1.5 mcg/kg once weekly for 48 wk Subcutaneous (Sylatron): 6 mg/kg/wk for 8 doses followed by 3 mg/kg/wk for up to 5 years	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

viral replication. It affects cancer cells by two mechanisms. First, it enhances the general functions of the immune system: IFNs increase the phagocytic activity of macrophages and monocytes, resulting in enhanced cytotoxicity against tumor cells. Second, this drug suppresses the growth of cancer cells.

Pharmacokinetics:

Route(s)	IV, IM, subcutaneous
Absorption	80% absorbed
Distribution	Unknown if secreted in breast milk
Primary metabolism	Minimal hepatic metabolism
Primary excretion	Renal
Onset of action	Peak: 3–12 h
Duration of action	Half-life: 2–3 h

Adverse Effects: The most common adverse effect of IFN therapy is a flulike syndrome of fever, chills, dizziness, weight loss, and fatigue that occurs in about 50% of patients and that usually diminishes as therapy progresses. Fatigue may be severe at higher doses. Neutropenia occurs in most patients and headache, nausea, vomiting, diarrhea, and anorexia are common. Hair loss may occur with prolonged therapy. Depression and suicidal ideation have been reported and may be severe enough to require discontinuation of the drug. The depression may persist after the drug is discontinued. With prolonged therapy, serious adverse effects such as immunosuppression, hepatotoxicity, and neurotoxicity may be observed. **Black Box Warning:** IFNs may cause or aggravate fatal or life-threatening neuropsychiatric, autoimmune, ischemic, or infectious disorders. The drug should be discontinued if these symptoms are persistent or severe.

Contraindications/Precautions: Contraindications include hypersensitivity to IFNs, autoimmune hepatitis, or hepatic decompensation. Neonates and infants should not receive this drug because it contains benzyl alcohol, which is associated with an increased incidence of neurologic and other serious complications in this age group. If infection occurs during therapy, anti-infectives should be started immediately. Hepatic enzymes may become elevated during IFN therapy and may require discontinuation of the drug. This effect is worse in patients with preexisting hepatic impairment. IFN alfa-2b should be used with caution in patients with cardiac disease, herpes zoster, and recent exposure to chickenpox. Triglycerides should be monitored during therapy because elevated levels have resulted in symptoms of pancreatitis in some patients.

Drug Interactions: IFN alfa-2b may increase theophylline levels. Zidovudine may increase hematologic toxicity and cause immunosuppression. **Herbal/Food:** Unknown.

Pregnancy: Category C. If used with ribavirin, the combination is category X.

Treatment of Overdose: Overdose with IFN may cause lethargy and coma. Treatment is by general supportive measures.

Nursing Responsibilities: Key nursing implications for patients receiving IFN alfa-2b are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Immunomodulators.

Drugs Similar to Interferon alfa-2b (Intron A)

Other available IFNs include IFN alfa-n3, IFN beta-1a, IFN beta-1b, IFN gamma-1b, pegIFN alfa-2a, and pegIFN alfa-2b. IFN alfa-n1 (Wellferon) and IFN alfa-2a are no longer available in the United States. IFN alfacon-1 was discontinued in 2013.

IFN alfa-n3 (Alferon N): Approved in 1989, IFN alfa-n3 is a mixture of IFN alfa subtypes purified from human leukocytes. Indications include genital warts caused by human papillomavirus. Two injections per week for 8 weeks are usually sufficient to cause warts to disappear. Unlike the other IFNs, this drug is injected directly into lesions (intralesionally). Its off-label indications include treatment of hepatitis C, herpes simplex, and other viral infections by the subcutaneous route. This product may contain egg protein and is contraindicated in patients with egg sensitivity. IFN alfa-n3 exhibits few adverse effects when administered intralesionally. This drug is pregnancy category C.

IFN beta-1a (Avonex, Rebif) and IFN beta-1b (Betaseron, Extavia): The beta interferons are first-line drugs for the pharmacotherapy of MS. These medications decrease the frequency of clinical exacerbations and slow the progression to physical disability, which is characteristic of MS. Both beta interferons are available by the subcutaneous route; beta-1b can also be administered. Adverse effects are similar to those of other IFNs, with flulike symptoms being observed in the majority of patients. Patients should be monitored for depression and suicidal ideation. Additional details on the pharmacotherapy of MS and a drug prototype feature for IFN beta-1b are presented in Chapter 21. The beta interferons are pregnancy category C.

IFN gamma-1b (Actimmune): Approved in 1999, IFN gamma-1b is produced by recombinant DNA technology and is very similar to natural IFN gamma. IFN gamma-1b has both direct and indirect antiviral activity. This drug activates macrophages to increase the production of interleukin-12 and tumor necrosis factor (TNF), which increases the killing ability of these cells. IFN gamma-1b also promotes the recruitment of leukocytes to the sites of infection or inflammation. IFN gamma-1b is the only IFN indicated for the treatment of chronic granulomatous disease (CGD). CGD is an inherited disorder of phagocytic cells that leads to recurrent life-threatening bacterial and fungal infections. A second characteristic of CGD is the development of nodular granulomas in the skin, gastrointestinal (GI) tract, and genitourinary (GU) tract due to chronic infections at these sites. IFN gamma-1b reduces the frequency and severity of infections in patients with CGD. Off-label indications include infections by *Mycobacterium avium* complex (MAC), pulmonary fibrosis, and ovarian cancer. The most common adverse effects include flulike symptoms, nausea, vomiting, diarrhea, rash, and elevated hepatic enzymes. Because of the potential for neutropenia and thrombocytopenia, periodic CBCs are required. This drug is pregnancy category C.

PegIFN alfa-2a (Pegasys): PegIFN alfa-2a is a biologic response modifier that has a molecule of PEG attached to IFN alfa-2a, which is identical to the natural IFN produced by human lymphocytes and macrophages. Approved in 2002, it is prepared through recombinant DNA technology and is available as single-use prefilled syringes and administered by the subcutaneous route. Approved indications for pegIFN alfa-2a include chronic hepatitis B and hepatitis C virus infections that show evidence that the virus is replicating. Off-label uses include renal cell carcinoma and chronic myelogenous leukemia. Patients should be monitored for serious depression and suicidal ideation. Neutropenia and thrombocytopenia are uncommon but may be severe. Other potential adverse effects include colitis, pancreatitis, hyper- or hypothyroidism, hypertension (HTN), and dysrhythmias. A black box warning for IFNs states that these drugs may cause or aggravate fatal or life-threatening neuropsychiatric, autoimmune, ischemic, or infectious disorders. This drug is pregnancy category C.

PegIFN alfa-2b (Pegintron, Sylatron): Approved in 2001, pegIFN alfa-2b (Pegintron) is indicated for the treatment of chronic hepatitis C in patients ages 3 years and older with compensated liver disease. It may be used off-label to treat chronic hepatitis B infections and neoplastic disease. Pegintron is usually given in combination with the antiviral ribavirin over a period of 24 to 48 weeks. It is important to note that ribavirin can cause fetal injury and death and is a possible carcinogen. Sylatron was approved in 2011 for the adjunctive treatment of melanoma that has lymph node involvement.

PegIFN alfa-2b has a molecule of PEG attached to the IFN molecule, which gives the drug an extended half-life. Peak concentrations can be sustained for 48 to 72 hours, which results in greater antiviral activity. The most frequently reported adverse effects with pegIFN alfa-2b are injection-site reactions, fatigue, headache, rigors, fever, nausea, myalgia, and emotional lability. A black box warning for IFNs states that these drugs may cause or aggravate fatal or life-threatening neuropsychiatric, autoimmune,

ischemic, or infectious disorders. This drug is pregnancy category C (category X if used with ribavirin).

42.3 Interleukins, vaccines, and colony-stimulating factors are used to boost the immune system.

Interleukins (ILs) are a class of cytokines synthesized by lymphocytes, monocytes, macrophages, and certain other cells in response to antigen exposure. Like IFNs, ILs are signaling molecules that enable cells of the immune system to communicate with each other. The ILs, however, work by different mechanisms than the IFNs. The ILs have widespread effects on immune function that include the following:

- Stimulation of cytotoxic T-cell activity against tumor cells
- Activation and increased production of natural killer (NK) cells
- Increased B-cell and plasma cell production
- Increased neutrophil chemotaxis
- Promotion of inflammation.

More than 30 different ILs have been identified, though only a few are available as medications. IL-2, which is derived from helper T cells, promotes the proliferation of both T cells and activated B cells. It is available as aldesleukin (Proleukin), which is indicated for the treatment of metastatic renal cell carcinoma and metastatic melanoma. IL-11, which is derived from bone marrow cells, is a growth factor with multiple hematopoietic effects. It is marketed as oprelvekin (Neumega) for its ability to stimulate platelet production in patients with immunosuppression. Oprelvekin is featured as a prototype drug in Chapter 39. Some interleukins are used in the pharmacotherapy of RA.

Bacillus Calmette-Guérin (BCG) vaccine (TheraCys, Tice) is a biologic response modifier that is available to enhance the immune system. BCG is an attenuated strain of *Mycobacterium bovis* used for the pharmacotherapy of certain types of bladder cancer.

Vaccines are types of immunostimulants that have the ability to mobilize the body against specific antigens. A small amount of an inactivated antigen is administered and the patient develops a subclinical immune reaction. If reexposed to the antigen in future years, memory B or T cells will develop a rapid response, eliminating the antigen before it causes disease. Vaccines are presented in Chapter 43.

The final type of immunostimulant includes the colony-stimulating factors, which are drugs that promote the production of white blood cells (WBCs). For example, filgrastim (Neupogen) stimulates the production of granulocytes, and sargramostim (Leukine) activates multiple types of leukocytes. These drugs are used to shorten the length of neutropenia in patients with cancer and in those who have had a bone marrow transplant and whose bone marrow has been suppressed by drugs. Filgrastim, the prototype, and other colony-stimulating factors are presented in Chapter 39.

CONNECTION Checkpoint 42.1

From what you learned in Chapter 39, what is the primary indication of oprelvekin (Neumega) therapy, and what is its most important adverse effect? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Aldesleukin (Proleukin)**

Classification **Therapeutic:** Immunostimulant
Pharmacologic: Interleukin, biologic response modifier

Therapeutic Effects and Uses: Approved in 1992, aldesleukin has a structure very similar to natural IL-2, and it has identical actions in the body. It is approved by the U.S. Food and Drug Administration (FDA) for the pharmacotherapy of metastatic renal cell carcinoma and metastatic malignant melanoma. It has been designated by the FDA as an orphan drug for the chemotherapy of non-Hodgkin's lymphoma and acute myelogenous leukemia. It is used off-label to treat leprosy.

Aldesleukin is a very toxic drug that should be administered only by personnel familiar with its use. It must be administered in multiple, brief IV infusions because of its short half-life.

Mechanism of Action: The mechanism of action of aldesleukin is identical to that of endogenous IL-2. It initiates a series of actions that activate IFNs, TNF, and other ILs. The drug promotes proliferation of both B cells and T cells, macrophages, and NK cells, which in turn increase the body's ability to fight cancer cells.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Widely distributed; unknown if secreted in breast milk
Primary metabolism	Renal
Primary excretion	Renal
Onset of action	Unknown
Duration of action	Half-life: 85 min

Adverse Effects: Aldesleukin is a toxic drug that has the potential to cause serious adverse effects in virtually any organ system. Many of the adverse effects are caused by **capillary leak syndrome**, a serious condition in which plasma proteins and other substances leave the

blood and enter the interstitial spaces because of porous capillaries. If not monitored carefully, capillary leak syndrome can result in death. Over 70% of patients taking aldesleukin will experience hypotension, which can sometimes be severe enough to cause tissues and organs to receive an insufficient blood supply to function properly. Tachycardia and other dysrhythmias occur in a significant number of patients. Diarrhea, nausea, or vomiting may occur in as many as half the patients taking the drug. Other common adverse effects include confusion, drowsiness, oliguria, stomatitis, anorexia, hyperbilirubinemia, hypothyroidism, elevated hepatic enzymes, weight gain, dyspnea, and pulmonary congestion. Common changes in blood values include thrombocytopenia, anemia, and leukopenia. Flulike symptoms such as fever and malaise occur frequently. **Black Box Warnings:** Aldesleukin can cause severe capillary leak syndrome. Death may result from infection that can spread throughout the body because of impaired neutrophil function. If moderate to severe fatigue develops, the drug should be withheld. The drug should be used with extreme caution in patients with a history of cardiac or pulmonary disease.

Contraindications/Precautions: There are many contraindications to using aldesleukin, and a thorough baseline assessment of health status is required. If the assessment indicates a preexisting bacterial infection, this should be treated prior to initiating therapy with aldesleukin. Aldesleukin should not be administered to patients with developing moderate to severe lethargy because the drug may induce coma. Patients with significant cardiac, central nervous system (CNS), pulmonary, renal, or hepatic impairment should not receive this drug. Aldesleukin may cause seizures and should be used with caution in patients with epilepsy. This drug may worsen the condition of patients with autoimmune disease, including those with scleroderma, RA, diabetes mellitus, and thyroiditis.

Drug Interactions: Aldesleukin has the potential to interact with nearly any other drug. Given concurrently with aldesleukin, drugs that affect mental status such as many antianxiety drugs, opioids, sedatives, or antipsychotic medications may cause mood disturbances and drowsiness. Concurrent administration with drugs that are hepatotoxic or nephrotoxic may cause additive organ damage. Caution should be practiced when using drugs that modify coagulation such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or platelet inhibitors due to an increased risk of bleeding. Antihypertensive drugs may cause additive hypotension when used with aldesleukin. **Herbal/Food:** None known.

Pregnancy: Category C.

Treatment of Overdose: Dexamethasone may be used to reverse some of the toxicities observed from an overdose of aldesleukin.

Nursing Responsibilities: Key nursing implications for patients receiving aldesleukin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Immunomodulators.

Drugs Similar to Aldesleukin (Proleukin)

The only other IL approved by the FDA is IL-11, a platelet enhancer marketed as oprelvekin (Neumega), which is featured as a prototype in Chapter 39. BCG vaccine is a miscellaneous biologic response modifier.

Bacillus Calmette-Guérin vaccine (TheraCys, Tice): BCG vaccine is a live, attenuated vaccine that is available in two distinct strains with different indications. Both forms are pregnancy category C.

TheraCys: TheraCys is approved for the prophylaxis and treatment of patients with superficial bladder cancer. This drug is instilled into the urinary bladder for 2 hours, after which the patient voids the medication. The treatment may be repeated at 3-month intervals. TheraCys produces a nonspecific immune reaction in the bladder that attracts lymphocytes, macrophages, and NK cells to the site of the cancer. Adverse effects include local reactions such as bladder irritability, hematuria, dysuria, cystitis, incontinence, and nocturia. A flulike syndrome may occur. This drug contains a black box warning that intravesical instillation may cause disseminated infections because the drug contains live attenuated mycobacteria.

Tice: Tice is used to stimulate immunity against *Mycobacterium tuberculosis*. Vaccination with BCG simulates exposure to tuberculosis and induces an immune response against the organism. This drug is used to prevent tuberculosis and is not given to treat active infections. It is the only FDA-approved treatment for tuberculosis prophylaxis. The drug is not 100% effective and its length of protection is variable. Flulike symptoms often develop 1 to 2 days after administration. Minor skin papules appear at the site of percutaneous puncture.

Immunosuppressants

42.4 Immunosuppressants are used to prevent transplant rejection and for the treatment of autoimmune disorders.

Used to inhibit the immune response, immunosuppressants are prescribed for patients who are receiving transplanted tissues or organs and to treat autoimmune disorders. Doses for these medications are listed in Table 42.2.

Table 42.2 Immunosuppressants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Antibodies		
antithymocyte globulin (Atgam, Thymoglobulin)	IV (Atgam): 10–30 mg/kg daily IV (Thymoglobulin): 1.5 mg/kg daily infused over 4–6 h for 7–14 days	*Local reactions at the injection site (pain, erythema, myalgia), flulike symptoms (malaise, fever, chills), headache, dizziness* Anaphylaxis, HTN, serious infections, thrombocytopenia, leukopenia, kidney impairment (basiliximab), antithymocyte globulin, post-transplant lymphoproliferative disorder (PTLD) (belatacept)
basiliximab (Simulect)	IV: 20 mg times 2 doses (first dose 2 h before surgery; second dose 4 days after transplant)	
belatacept (Nulojix)	IV: 5–10 mg/kg using enclosed silicone-free disposable syringe	
Calcineurin Inhibitors		
cyclosporine (Gengraf, Neoral, Sandimmune)	Transplants: PO: 5–15 mg/kg/day Autoimmune disorders: PO: 1.25–2.5 mg/kg/day (max: 4 mg/day)	*Hirsutism, tremor, nausea, vomiting* HTN, MI, nephrotoxicity, hyperkalemia, seizures, paresthesia, hepatotoxicity
tacrolimus (Astagraf XL, Prograf, others)	PO (immediate release): 0.1–0.15 mg/kg/day in 2 divided doses q12h; give first PO dose 8–12 h after discontinuing IV therapy IV: 0.03–0.05 mg/kg/day as continuous infusion	*Oliguria, nausea, constipation, diarrhea, headache, abdominal pain, insomnia, peripheral edema, fever* Infections, HTN, nephrotoxicity, neurotoxicity (tremors, paresthesia, psychosis), hyperkalemia, anemia, hyperglycemia, malignancy, thrombocytopenia, seizures
Cytotoxic Drugs and Antimetabolites		
anakinra (Kineret)	Subcutaneous: 100 mg (0.67 mL) once daily	*Injection-site reactions, UTI, headache, nausea, diarrhea, sinusitis, arthralgia, flulike symptoms* Leukopenia, infections, malignancy, anaphylaxis
azathioprine (Azasan, Imuran)	PO/IV: 3–5 mg/kg/day initially; may be able to reduce to 1–3 mg/kg/day	*Nausea, vomiting, anorexia* Severe nausea and vomiting, bone marrow suppression, thrombocytopenia, serious infections, malignancy, hepatotoxicity
cyclophosphamide (Cytoxan)	PO: 2.5–3 mg/kg daily for a period of 60–90 days (higher doses are used for malignant disease)	*Nausea, vomiting, anorexia, neutropenia, alopecia* Anaphylaxis, leukopenia, pulmonary emboli, interstitial pulmonary fibrosis, toxic epidermal necrolysis, Stevens–Johnson syndrome, hemorrhagic cystitis, oligospermia
etanercept (Enbrel)	Subcutaneous: 50 mg once/wk	*Injection-site reactions (pain, erythema, myalgia), abdominal pain, vomiting, headache* Infections, pancytopenia, leukopenia, anemia, MI, heart failure, malignancy
ibrutinib (Imbruvica)	PO: 420 mg once daily	*Fatigue, bruising, diarrhea, muscle spasms* Hemorrhage, fetal toxicity, thrombocytopenia, anemia, infections
methotrexate (Rheumatrex, Trexall)	PO/IM/IV: 15–30 mg/day for 5 days; repeat every 12 wk for three courses	*Headache, glossitis, gingivitis, mild leukopenia, nausea, alopecia* Ulcerative stomatitis, myelosuppression, aplastic anemia, hepatic cirrhosis, nephrotoxicity, sudden death, pulmonary fibrosis, or pneumonia
mycophenolate (CellCept, Myfortic)	PO/IV: 720 mg bid in combination with corticosteroids and cyclosporine; start within 24 h of transplant	*Peripheral edema, diarrhea, headache, tremor, dyspepsia, abdominal pain* UTI, leukopenia, anemia, thrombocytopenia, sepsis, HTN
Kinase Inhibitors (Rapamycins)		
everolimus (Afinitor, Zortress)	PO (Afinitor): 10 mg once daily PO (Zortress): Begin with 0.75 mg bid and adjust to achieve a trough concentration of 3–8 ng/mL	*Peripheral edema, hyperlipidemia, nausea, HTN, UTI, asthenia, weight changes (loss or gain), elevated serum creatinine, hyperglycemia and fever* Leukopenia, anemia, thrombocytopenia, sepsis, secondary infections, malignancy, anaphylaxis, interstitial lung disease or pneumonia, birth defects
sirolimus (Rapamune)	PO: 6–15 mg loading dose immediately after the transplant, then 2–5 mg/day maintenance dose	
temsirolimus (Torisel)	IV: 25 mg once weekly infused over 30–60 min	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Transplantation: Transplants may include specific cells, parts of tissues, or complete organs. They may originate from the patient's own body (autografts), genetically identical donors (isografts), or genetically dissimilar donors (allografts). Most transplantation procedures use allografts.

Typing for transplanted tissues attempts to match, as closely as possible, donor and recipient human leukocyte

CONNECTIONS: Community-Oriented Practice

Fever in the Patient on Immunosuppressant Drugs

Immunosuppressant drugs are now given to treat a variety of conditions, and more uses are being discovered. Patients taking immunosuppressants are at greater risk for infection but may not always exhibit symptoms to the same degree that patients with competent immune systems do. The patient must be assessed for subtle signs of infection including low-grade fevers (less than 37.8°C [100°F]), unusual skin lesions with or without drainage, excessive fatigue, malaise, arthralgias, cough, headache, diarrhea, or nausea. Any of these symptoms should be immediately reported to the healthcare provider so that appropriate follow-up examination can be conducted.

Before going home with an immunosuppressant drug, the patient should receive explicit instructions on when to call the provider for a fever and how often the temperature should be taken when fever is present or symptoms such as those listed above are present. Self-administration of antipyretics such as acetaminophen and ibuprofen is usually not appropriate because they can mask the symptoms of a significant infection. Fevers that fall outside of the parameters set by the healthcare provider need to be evaluated.

Many patients on immunosuppressant drugs are able to live active, normal lives. However, they should be taught measures to reduce their exposure to infections, and should always receive appropriate instruction for fever management before they begin to take the medication.

antigen (HLA) and ABO blood-type antigens. Despite accurate tissue matching, allografts always contain certain antigens that have the potential to trigger the patient's immune defenses. This response, called **transplant rejection**, is often acute; antibodies sometimes destroy the transplanted tissue within 48 hours after a transplant. The cell-mediated branch of the immune system responds more slowly to the transplant, attacking it about 2 weeks following surgery. Chronic rejection of the transplant may occur months or even years after surgery.

Successful transplantation requires the use of immunosuppressant drugs. One or more immunosuppressants are administered at the time of transplantation and are continued for several months following surgery. In some cases, they are continued indefinitely at low doses. Transplantation would be impossible without the use of effective immunosuppressant drugs. Although immunosuppressant therapies have proven very successful at preventing acute transplant rejection, they have been less successful at preventing chronic rejection.

Prior to the initiation of immunosuppressant therapy, it is critical that the patient be carefully assessed to rule out active infections. This includes screening for viruses such as cytomegalovirus (CMV), hepatitis B and C viruses, Epstein-Barr virus (EBV), VZV, HIV, and herpes simplex virus (HSV). If an active infection is discovered, it should be treated prior to transplantation. In addition, patients should be screened for the presence of cancer prior to surgery because immunosuppression will allow preexisting cancers to grow rapidly.

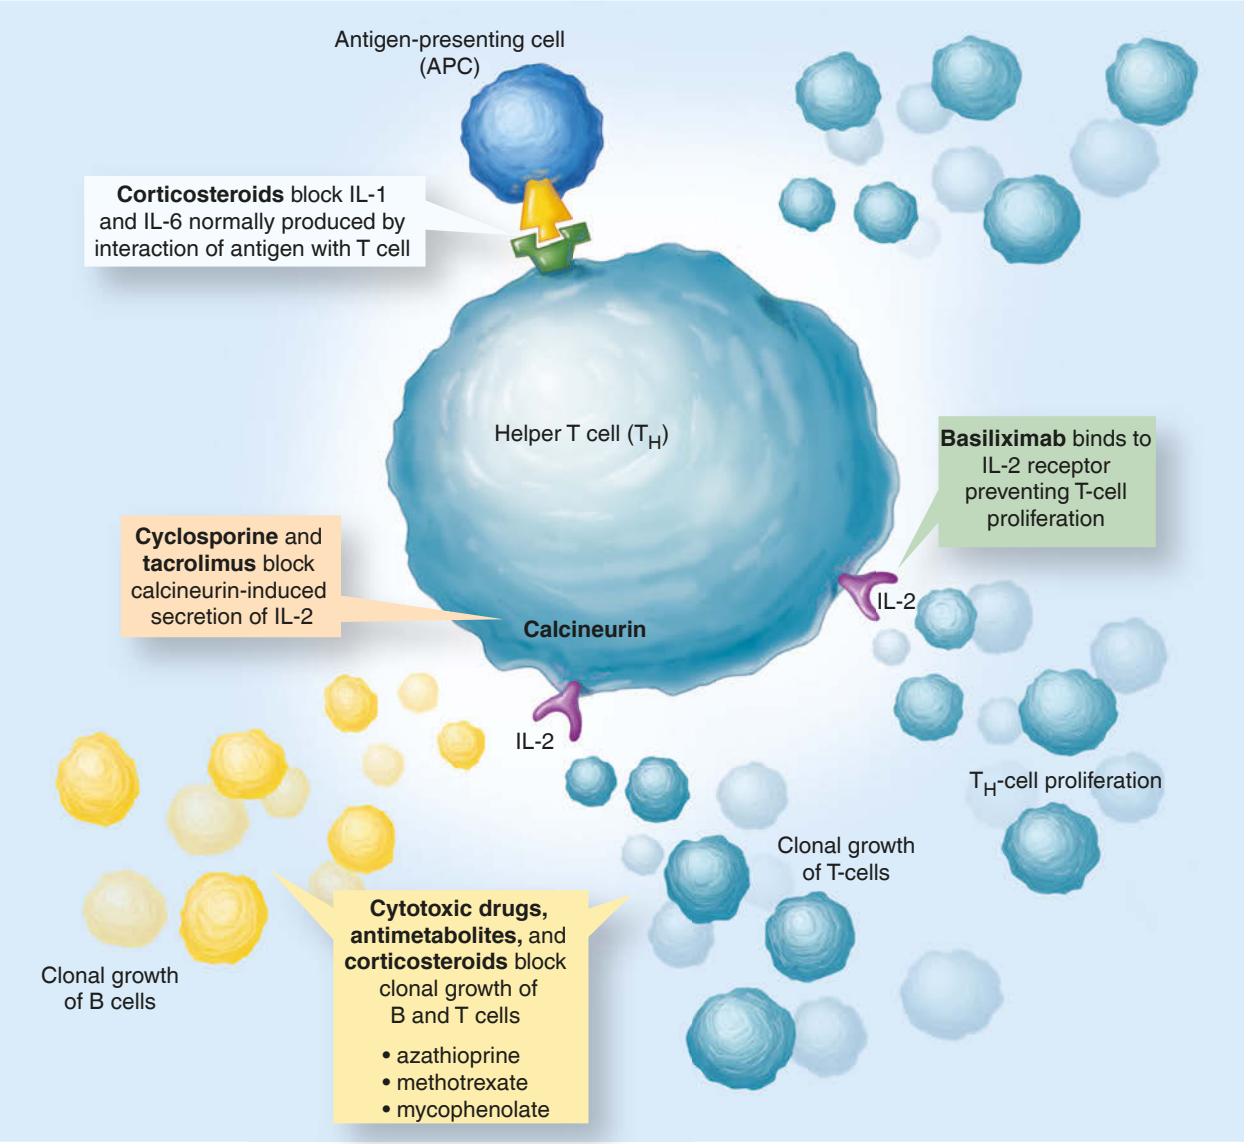
During immunosuppressant therapy the patient is susceptible to infection from all types of pathogens: viral, bacterial, fungal, or protozoan. Infections in immunosuppressed patients are called opportunistic infections. Opportunistic pulmonary infections are the leading cause of morbidity and mortality in patients receiving a transplant. Many patients receive antibiotics for the prophylaxis of opportunistic infections for 4 to 12 months following surgery. Six months following the transplant, 80% of patients will return to their baseline risk of infection, but the remainder will remain at high risk indefinitely.

Long-term survivors of transplants are also at high risk of developing cancers. These include non-Hodgkin's lymphoma, squamous and basal cell skin cancer, cervical cancer, and Kaposi's sarcoma. Regular follow-up monitoring for cancer is required in these patients.

PharmFACT

More than 119,000 patients are waiting for organ transplants. About 83% of these are waiting for a kidney, 12% for a liver, and 3.5% for a heart (Organ Procurement and Transplantation Network, 2017).

Autoimmune disorders: Autoimmune disorders are those in which the body creates antibodies against normal tissues. The body attacks its own cells as if they were foreign, resulting in tissue injury. Examples of autoimmune disorders include RA, SLE, myasthenia gravis, and Hashimoto's thyroiditis.



Autoimmune diseases are characterized by symptomatic periods alternating with remissions. Although the remissions may last many months or even years, relapses are often progressive, with symptoms worsening as the disease progresses. During acute relapses, fever and signs of widespread inflammation may be present. Virtually any tissue or organ may be affected, depending on the specific autoimmune disease.

Unlike transplant recipients who may receive immunosuppressants indefinitely, patients with autoimmune disease are usually given these drugs for brief periods in high doses to control relapses. In some cases, however, these patients may receive low doses for longer periods for prophylaxis.

The immunosuppressant class includes drugs that block the immune response by several different mechanisms, as shown in Pharmacotherapy Illustrated 42.1. These include blocking the receptors and production of IL-2,

Pharmacotherapy Illustrated 42.1

Mechanism of Action of Immunosuppressants

inhibiting the proliferation of T cells, and using antibodies specific to certain receptors or cells of the immune response. The drugs may be classified into the following categories:

- Calcineurin inhibitors and similar drugs
- Cytotoxic drugs and antimetabolites
- Antibodies
- Corticosteroids (glucocorticoids).

42.5 Calcineurin inhibitors are preferred drugs for the prophylaxis of transplant rejection.

When a T cell encounters an antigen, calcineurin is activated. **Calcineurin** is an enzyme that acts as an intracellular messenger, telling the T cell to begin synthesizing IL-2. As described in Section 42.3, IL-2 is an important chemical mediator in promoting the proliferation of B cells, T cells, macrophages, and NK cells. Blocking IL-2 suppresses the immune response.

Two of the most important drugs in transplant medicine, cyclosporine (Gengraf, Neoral, Sandimmune) and tacrolimus (Astagraf XL, Prograf), are calcineurin inhibitors. These drugs revolutionized the pharmacotherapy of transplant rejection and have been the mainstay of transplant therapy since the 1980s. Although newer medications have been developed, the calcineurin inhibitors remain critical drugs for transplant recipients. They allow the doses of corticosteroids to be lowered, thereby reducing the incidence of opportunistic infections following transplants.

Approved in 1983, cyclosporine was the first calcineurin inhibitor and remains the prototype for this class. Some data suggest that tacrolimus may be more effective in preventing transplant rejection and reducing the mortality associated with transplants. It is the most common immunosuppressant used in certain types of transplants. In addition to their use in preventing transplant rejection, the calcineurin inhibitors are also of value in treating the acute inflammation associated with RA and psoriasis, an inflammatory disorder of the skin.

Everolimus (Afinitor, Zortress), sirolimus (Rapamune), and temsirolimus (Torisel) produce immunosuppressant effects similar to the calcineurin inhibitors. They prevent the activation of T cells by inhibiting a key regulatory protein kinase called mTOR. Thus, these drugs are sometimes called mTOR inhibitors or kinase inhibitors. The kinase inhibitors used to treat cancer (see Chapter 57) inhibit a different cellular kinase than the mTOR inhibitors.

PROTOTYPE DRUG **Cyclosporine (Gengraf, Neoral, Sandimmune)**

Classification **Therapeutic:** Immunosuppressant
Pharmacologic: Calcineurin inhibitor

Therapeutic Effects and Uses: Cyclosporine is a complex chemical obtained from a soil fungus. It is FDA approved for the prophylaxis of kidney, heart, and liver transplant rejection; psoriasis; severe RA; and xerophthalmia, an eye condition of diminished tear production caused by ocular inflammation. Off-label indications include a number of autoimmune and inflammatory conditions such as ulcerative colitis, SLE, myasthenia gravis, aplastic anemia, Crohn's disease, psoriatic arthritis, and graft-versus-host disease (GVHD).

Cyclosporine may be administered as capsules, oral solution, or IV or as an ophthalmic solution (Restasis) for xerophthalmia. Due to the risk of anaphylaxis, the IV route is used only when patients are unable to take oral (PO) medications. Cyclosporine (modified) refers to the capsule, microemulsion dosage formulation of cyclosporine (Gengraf, Neoral). Cyclosporine (modified) has increased bioavailability compared to that of cyclosporine (nonmodified) and cannot be used interchangeably without close monitoring.

Unlike some of the more cytotoxic immunosuppressants, cyclosporine is less harmful to bone marrow cells. When prescribed for transplant recipients, it is often used in combination with a corticosteroid such as prednisone.

Mechanism of Action: Cyclosporine inhibits the function of calcineurin. This diminishes the activity of T cells and B cells and suppresses the immune response.

Pharmacokinetics:

Route(s)	PO, IV, ophthalmic
Absorption	Oral absorption is highly variable
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 90% bound to lipoproteins
Primary metabolism	Hepatic (CYP3A), extensive first-pass metabolism
Primary excretion	Bile and feces
Onset of action	Peak: 3–4 h
Duration of action	Half-life: 16–27 h

Adverse Effects: The primary adverse effect of cyclosporine is nephrotoxicity, with up to 75% of patients experiencing a reduction in urine flow. Over half the patients taking the drug will experience HTN and tremor. Hirsutism occurs in many patients. Other common adverse effects are elevated hepatic enzymes, mild to moderate HTN, headache, and gingival hyperplasia. Infections are common during cyclosporine therapy, including reactivation of latent herpes or varicella infections. Periodic blood counts are necessary to ensure that leukocytes do not fall below 4000, or platelets below 75,000. Anaphylaxis has been reported with IV administration. Long-term therapy increases the risk of malignancy, especially lymphomas and skin cancers. **Black Box Warning:** This drug should only be administered by healthcare providers experienced in immunosuppressive therapy. Use may result in serious infections and possible malignancies. Kidney damage may occur, thus renal function should be monitored during therapy. Patients with psoriasis who are taking cyclosporine with other psoriasis medications are at an increased risk of developing skin malignancies.

Contraindications/Precautions: Patients who are taking cyclosporine should avoid direct exposure to the sun due to an increased risk of skin cancer. Because cyclosporine is nephrotoxic, the drug is either contraindicated or should be used with extreme caution in patients with chronic kidney disease: Renal laboratory function should be regularly evaluated. The drug should not be used during pregnancy or lactation. Because cyclosporine is primarily eliminated via the bile, its dose should be reduced in patients with hepatic or biliary impairment. Patients with active infections should be treated with anti-infectives prior to cyclosporine therapy. Caution should be used in patients with preexisting HTN because the drug may worsen this condition.

Drug Interactions: Cyclosporine is a major substrate of CYP3A4 and may interact with drugs that inhibit or induce this enzyme. Drugs that may decrease cyclosporine levels include phenytoin, phenobarbital, carbamazepine,

and rifampin. Azole antifungal drugs, oral hypoglycemics, and macrolide antibiotics may increase cyclosporine levels. Because cyclosporine increases blood pressure, the doses of antihypertensives will require adjustment. Potassium-sparing diuretics should be avoided because their concurrent use with cyclosporine causes hyperkalemia. Cyclosporine should be given with caution with other nephrotoxic drugs due to the potential for additive kidney damage. Statins should not be used concurrently with cyclosporine due to the potential for myopathy or rhabdomyolysis. **Herbal/Food:** Food decreases the absorption of the drug. Grapefruit juice can raise cyclosporine levels by 50% to 200%. The immune-enhancing effects of astragalus and echinacea may interfere with the action of immunosuppressants.

Pregnancy: Category C.

Treatment of Overdose: An overdose of cyclosporine can result in significant nephrotoxicity and hepatotoxicity. General supportive measures are indicated.

Nursing Responsibilities: Key nursing implications for patients receiving cyclosporine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Immunomodulators.

Drugs Similar to Cyclosporine (Gengraf, Neoral, Sandimmune)

The only other calcineurin inhibitor is tacrolimus. Although not calcineurin inhibitors, everolimus, sirolimus, and temsirolimus are immunosuppressants similar to tacrolimus.

Everolimus (Afinitor, Zortress): Everolimus was initially approved in 2009 (Afinitor) to treat advanced renal cell carcinoma, astrocytoma, and other forms of cancer. Subsequently, Zortress was approved for the prophylaxis of organ rejection in patients receiving a kidney or liver transplant. When used as an antineoplastic, the dose is much higher than that when used in transplant patients (see Table 42.2). In transplant medicine, the drug is given in combination with basiliximab and concurrently with reduced doses of cyclosporine and corticosteroids. To prevent potential toxicity, therapeutic drug monitoring is recommended.

Everolimus is functionally similar to sirolimus and temsirolimus and blocks a key kinase enzyme that activates B and T cells. Like most immunosuppressants, the drug carries a black box warning regarding its potent immunosuppressive actions and the possible development of serious infections and malignancies. In addition the black box warning includes an increased risk of kidney damage, including renal arterial and venous thrombosis. The drug is pregnancy category C.

Sirolimus (Rapamune): Approved in 1999, sirolimus is a PO drug isolated from a soil bacterium that shares a similar structure and potent immunosuppressant properties with tacrolimus. Sirolimus, however, acts by a unique mechanism; that is, it binds to a protein known as FKBP that prevents T-cell activation and proliferation and the production of antibodies by B cells. Sirolimus does not exhibit the serious organ toxicity characteristic of tacrolimus. This drug appears to be less effective than the calcineurin inhibitors, but it does exert synergistic immunosuppression when used with other immunosuppressive drugs. Sirolimus is only approved for use in the prophylaxis of kidney transplant rejection in combination with cyclosporine and corticosteroids for the first year after transplantation. At 2 to 4 months post-transplantation, the cyclosporine may be gradually withdrawn over a 4- to 8-week period. The serum levels of sirolimus must be adjusted upward when cyclosporine is withdrawn. Adverse effects include hyperlipidemia, hypercholesterolemia, peripheral edema, tremor, azotemia, elevated serum creatinine, HTN, diarrhea, and anemia. Like most immunosuppressants, the drug carries a black box warning regarding its potent immunosuppressive actions and the possible development of serious infections and malignancies. In addition, the black box warning states that the use of this drug is not recommended in patients with liver transplants (excess mortality and graft loss) or lung transplants (bronchial rupture). This drug is pregnancy category C.

Tacrolimus (Astagraf XL, Prograf, others): Approved by the FDA in 1994, tacrolimus is available in PO capsule or IV forms for the prophylaxis of heart and liver transplant rejection. Envarsus XR and Astagraf XL are extended release forms approved as once-daily oral drugs to prevent rejection of kidney transplants. A topical form of tacrolimus (Protopic) is approved for the short-term treatment of eczema and atopic dermatitis. The topical form contains a black box warning of possible lymphoma and skin cancer. Tacrolimus is also used off-label for other transplants as well as for GVHD, nephritic syndrome, psoriasis, and uveitis. Tacrolimus is 100 times more potent than cyclosporine and appears to be more effective in some patients at preventing transplant rejection. Nephrotoxicity may occur in half the patients taking this drug. Neurotoxicity symptoms are common and include headache, tremor, paresthesias, insomnia, and dizziness. Hypertension, anemia, hyperglycemia, and GI complaints occur in a significant number of patients who are taking tacrolimus. Like cyclosporine, an increased incidence of infections and malignancies may occur with tacrolimus use. This drug is pregnancy category C.

Temsirolimus (Torisel): Approved in 2007, temsirolimus is metabolized in the liver to sirolimus. It is approved to treat patients with advanced renal cell carcinoma that has not

responded to other therapies. This drug is administered only by the IV route. Temsirolimus is toxic to the hematologic system; 94% of patients will experience anemia, 53% will experience lymphopenia, and 32% will experience leukopenia. Hyperglycemia occurs in most patients; thus patients with diabetes require close monitoring. Most patients who are taking the drug will also experience hyperlipidemia that may be serious enough to require pharmacotherapy. Interstitial lung disease is a rare though potentially fatal adverse effect. This drug is pregnancy category D.

PharmFACT

Each day in the United States about 22 people die waiting for transplants. One organ donor can save up to eight lives (organdonor.gov, 2015).

42.6 Cytotoxic drugs and antimetabolites are used to suppress proliferating B cells and T cells.

Cytotoxic drugs are immunosuppressive medications used to kill B cells and T cells. Antimetabolites do not kill directly, but instead severely restrict the replication of B cells and T cells. Each of these medications acts by a different mechanism. Some of the drugs resemble essential chemical building blocks needed for the biosynthesis of DNA and block replication. Others inhibit protein synthesis. Most of the cytotoxic and antimetabolite immunosuppressants are nonspecific, affecting many different cells of the immune response. They have similar indications and adverse effects as the calcineurin inhibitors.

PROTOTYPE DRUG **Azathioprine (Azasan, Imuran)**

Classification **Therapeutic:** Immunosuppressant
Pharmacologic: Cytotoxic drug

Therapeutic Effects and Uses: An older immunosuppressant approved in 1968, azathioprine is indicated for the prophylaxis of kidney transplant rejection and for the treatment of severe RA. Off-label indications include other inflammatory disorders such as Crohn's disease, autoimmune hepatitis, myasthenia gravis, SLE, and ulcerative colitis. When treating nontransplant conditions, it is generally prescribed only when standard treatments fail.

Azathioprine is usually given PO, but it may be given by the IV route to patients who are unable to take the drug by mouth. When used to prevent transplant rejection, it is usually administered in combination with other immunosuppressants.

Mechanism of Action: Azathioprine inhibits DNA synthesis, resulting in DNA damage and chromosome breakage. The drug is metabolized to mercaptopurine in the liver, an active substance marketed as an antineoplastic drug for leukemia.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Well absorbed
Distribution	Crosses the placenta; secreted in breast milk; 30% bound to plasma proteins
Primary metabolism	Hepatic; metabolized to mercaptopurine, an active metabolite
Primary excretion	Renal
Onset of action	7–14 days
Duration of action	Half-life: 3 h

Adverse Effects: Azathioprine causes bone marrow suppression that can result in pancytopenia, agranulocytosis, leukopenia, and thrombocytopenia. Serious infections may occur secondary to immunosuppression, and latent herpes or varicella infections may become reactivated during azathioprine therapy. Hepatotoxicity has been reported with this drug. Nausea and vomiting are common, especially during the first few weeks of therapy. Patients who have received a kidney transplant and who are being treated with azathioprine have an increased risk of developing skin and lymphoid malignancies. The toxicities of azathioprine are dose related and occur more frequently in patients who have received a kidney transplant compared with those who are treated for RA. **Black Box Warning:** Use may result in serious or fatal infections and possible malignancies. Complete blood counts (CBCs) should be monitored during therapy.

Contraindications/Precautions: Azathioprine should be used with extreme caution in patients with preexisting hematologic disease or hepatic impairment. Blood counts and hepatic enzymes must be regularly monitored. Azathioprine is contraindicated during pregnancy and lactation.

Drug Interactions: Additive bone marrow suppression is expected if azathioprine is given concurrently with other immunosuppressants. Concurrent use of allopurinol with azathioprine can result in a large increase in azathioprine activity and hematologic toxicity. The use of angiotensin-converting enzyme (ACE) inhibitors with azathioprine may induce anemia and severe leukopenia. **Herbal/Food:** None known.

Pregnancy: Category D.

Treatment of Overdose: Hemodialysis may be of value in removing some azathioprine from the blood following an overdose. Other treatment measures are supportive.

Nursing Responsibilities: Key nursing implications for patients receiving azathioprine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Immunomodulators.

Drugs Similar to Azathioprine (Azasan, Imuran)

Other cytotoxic and antimetabolite drugs indicated for immunosuppression include anakinra, cyclophosphamide, etanercept, methotrexate, and mycophenolate.

Anakinra (Kineret): Approved in 2001, anakinra is an IL-1 receptor antagonist that prevents the formation of certain inflammatory cytokines. The only indication for anakinra is for the treatment of moderate to severe RA that has not responded to first-line drugs. It is administered only by the subcutaneous route, and injection-site reaction is the most frequent adverse effect. Because the drug lowers WBC counts, secondary infections occur in almost 40% of patients taking anakinra. This drug is pregnancy category B.

Cyclophosphamide (Cytoxan): Cyclophosphamide is one of the most commonly prescribed antineoplastic medications for patients with malignancies. It acts by forming cross-links in DNA, which prevents cancer cell replication. It is a powerful immunosuppressant, affecting both B cells and T cells. It is used off-label for SLE, GVHD, and RA, and for the transplant prophylaxis of solid organs. Hematologic toxicity (pancytopenia, leukopenia, anemia, and thrombocytopenia) is a major dose-limiting adverse effect. Cyclophosphamide is a prototype antineoplastic drug discussed in Chapter 57. This drug is pregnancy category D.

Etanercept (Enbrel): Approved in 1998, etanercept is a protein that mimics the natural receptor for TNF. Rather than binding to its receptors on T cells, TNF binds with the etanercept. This inhibition of TNF activity reduces the levels of damaging cytokines responsible for causing inflammation and joint destruction in patients with RA. The drug is FDA approved to treat RA, psoriatic arthritis, plaque psoriasis, and ankylosing spondylitis. It is used off-label to prevent transplant rejection. It is administered only by the subcutaneous route. The most common adverse effects are injection-site reactions and infections. Etanercept has a black box warning regarding the possibility of malignancy and serious infections during therapy, including tuberculosis and bacterial sepsis. This drug is pregnancy category B.

Methotrexate (Rheumatrex, Trexall): Methotrexate is an older antimetabolite approved in 1953 that acts by inhibiting the enzyme responsible for folic acid metabolism. Like cyclophosphamide, it is indicated for various cancers as well as serious inflammatory disorders such as RA, psoriasis, SLE, and ulcerative colitis. Methotrexate is used off-label to prevent transplant rejection. The most frequently reported adverse reactions include nausea, vomiting, stomatitis, esophagitis, oral ulceration, and abdominal distress. Hematologic adverse reactions are common. The drug carries a black box warning regarding the possibility of malignancy and serious hematologic, GI, hepatic, pulmonary, and dermatologic toxicity. Methotrexate is a prototype antineoplastic drug discussed in Chapter 57. This drug is pregnancy category X.

CONNECTIONS: Complementary and Alternative Therapies

Echinacea

Description

Nine species of echinacea have been identified, and all are native to the midwestern United States and central Canada. *Echinacea purpurea* (purple coneflower) and *Echinacea angustifolia* (narrow-leaf coneflower) are the two most commonly studied species. All portions of the plant contain chemicals that have potential pharmacologic activity.

History and Claims

Echinacea was used by Native Americans to treat various wounds and injuries. Until the widespread manufacture of antibiotics in the late 1940s, echinacea was commonly used as an anti-infective.

Standardization

The flowers, leaves, and stems of this plant are harvested and dried. Preparations include dried powder, tincture, fluid extracts, and teas. No single ingredient seems to be responsible for the herb's activity. A large number of potentially active chemicals have been identified from the extracts. Recommended doses include 300 mg dry powdered extract (standardized to 3.5% echinacoside) or 0.5 to 1 g dried root or tea.

Evidence

The quality and doses of echinacea used in research studies have varied widely, which makes comparisons and conclusions extremely difficult. Echinacea is claimed to boost the immune system by increasing IFN levels, increasing phagocytosis, and inhibiting the bacterial enzyme hyaluronidase. Some substances in echinacea appear to have antiviral activity; thus the herb is sometimes taken to treat the common cold and influenza—indications for which it has received official approval in Germany. No large-scale studies have demonstrated significant differences between research participants taking echinacea and those taking a placebo (National Center for Complementary and Integrative Health, 2016), although some evidence demonstrates that echinacea may reduce the odds of getting a cold (University of Maryland Medical Center, 2016). Adverse effects are rare, although it may cause allergic reactions in patients who are allergic to plants in the daisy family such as ragweed, marigolds, daisies, and chrysanthemums. It may also interfere with drugs that have immunosuppressant effects.

Mycophenolate (CellCept, Myfortic): Approved in 1995, mycophenolate is a potent immunosuppressant that acts by inhibiting the DNA synthesis of B cells and T cells. There are two forms of mycophenolate. Mycophenolate mofetil (CellCept) is a prodrug that is converted in the body to its active form, mycophenolic acid. It is given IV or PO, usually in combination with other immunosuppressants such as cyclosporine and corticosteroids. Mycophenolate sodium (Myfortic) is a delayed release tablet.

Indications for mycophenolate include the prophylaxis of heart, kidney, or liver transplant rejection. Mycophenolate also was given orphan drug status for the treatment of patients with myasthenia gravis and pemphigus vulgaris. Off-label indications include SLE, GVHD, and atopic dermatitis. GI adverse effects such as nausea, vomiting, constipation, diarrhea, dyspepsia, and abdominal pain are common. Other relatively frequent adverse effects include tachycardia, tremor, back pain, sinusitis, increased urinary frequency, and blood dyscrasias. Weekly CBCs should be obtained and the drug withheld if the absolute neutrophil count (ANC) falls below $1.3 \times (10)^3$ cells/mcL. Mycophenolate carries a black box warning regarding the possibility of malignancy, serious infections, and embryofetal toxicity. This is a pregnancy category D drug.

42.7 Antibodies are used to prevent acute transplant rejection, autoimmune disorders, and malignancies.

Recall from Chapter 40 that antibodies are proteins that are produced following an antigen challenge. B cells become plasma cells, which subsequently produce massive amounts of antibodies that help rid the body of the antigen through multiple mechanisms. Antibodies that are produced by a plasma cell are very specific to the antigen. For example, exposure to *Streptococcus* would result in different antibodies than would *Escherichia coli*. In this example, antibodies *boost* the immune system. It may seem puzzling then to learn that certain antibodies may be administered to patients to *suppress* the immune response. How is this possible?

The answer is to create antibodies against human immune cells. A simple method is to inject animals (usually horses, rabbits, or mice) with human T cells, B cells, or thymocytes. The animal forms antibodies against the human immune cells, which can be collected and purified. When injected in humans, the animal's antibodies will attack the T cells (or T-cell receptors). These are called **polyclonal antibodies** because they contain a wide mixture of different antibodies. This polyclonal drug product, called antithymocyte globulin (Atgam, Thymoglobulin), is a potent immunosuppressant and is available for the prophylaxis of kidney transplant rejection and aplastic anemia.

In the 1980s a technique was developed to harvest antibodies produced by a single B cell. Because a single B cell produces a single antibody, it is called a **monoclonal antibody (MAB)**. A MAB is very specific, targeting a single type of target cell or receptor. This allows greater effects on the target cell or receptor at lower doses and with fewer adverse effects than using polyclonal antibodies.

The first MABs were derived from mouse cells and had short half-lives. The human immune system quickly recognized them as foreign when they were injected in patients. Through genetic engineering, scientists have been able to replace the mouse portions of the antibody with human sequences, thus allowing it to escape detection by the immune system for longer periods and extending its half-life.

Scientists have created approximately 30 different MABs to attack a diverse number of targets. The majority of the MABs are designed to attack specific types of cancer cells. Others are used to treat autoimmune or inflammatory disorders such as RA or psoriasis by attacking specific cells of the immune system that secrete proinflammatory mediators. The FDA-approved MABs are listed in Table 42.3. Those used exclusively for cancer are found in Chapter 57.

The MABs are challenging to learn because many have similar names that end in *-mab* (for monoclonal antibody). There is, however, some consistency to the names—they reflect the origin of the antibody:

- MABs that have 75% human sequences are called chimeric and have *-xi* in the name (e.g., basiliximab).
- MABs that have 90% human sequences are called humanized and have *-zu* in their name (e.g., trastuzumab).
- MABs that are 100% human have *-mumab* in their name (e.g., golimumab).

PROTOTYPE DRUG **Basiliximab (Simulect)**

Classification **Therapeutic:** Immunosuppressant
Pharmacologic: Monoclonal antibody

Therapeutic Effects and Uses: Basiliximab is a monoclonal antibody approved in 1998 for the prophylaxis of acute kidney transplant rejection. The drug dampens the immune response by inhibiting CD25, a receptor on the surface of activated T cells. By binding to CD25, basiliximab stops IL-2 from activating the T cell, and the immune response is prevented. This drug does not lower the total number of circulating T cells; it does, however, lower their ability to respond to an antigen challenge.

Administered by IV infusion, the standard regimen is two doses; one is given 2 hours prior to transplantation and the other is given 4 days later. Following the two infusions, the actions of basiliximab may last for 4 to 6 weeks. It is administered in combination with other immunosuppressants, usually cyclosporine and corticosteroids.

Table 42.3 Selected Monoclonal Antibodies for Immunosuppression

Drug/Antibody	Approval Date	Target	Approved Indication(s)
adalimumab (Humira)	2002	Inhibition of TNF-α signaling	Inflammatory diseases (mostly autoimmune disorders)
basiliximab (Simulect)	1998	IL-2 receptor blocker	Transplant rejection
belatacept (Nulojix)	2011	Inhibition of T-cell CD28 activation	Kidney transplant rejection
belimumab (Benlysta)	2011	B lymphocytes	Systemic lupus erythematosus
certolizumab pegol (Cimzia)	2008	TNF blocker	Crohn's disease, ankylosing spondylitis, and RA
eculizumab (Soliris)	2007	Blocks complement protein C5	Atypical hemolytic uremic syndrome and paroxysmal nocturnal hemoglobinuria
golimumab (Simponi)	2009	TNF blocker	Psoriatic arthritis, ankylosing spondylitis, and RA
infliximab (Remicade)	1998	Inhibition of TNF-α signaling	Inflammatory diseases (mostly autoimmune disorders)
natalizumab (Tysabri)	2006	T-cell VLA4 receptor	Inflammatory diseases (mainly autoimmune-related MS therapy)
siltuximab (Sylvant)	2014	IL-6 receptor blocker	Castleman disease (rare blood disorder)
tocilizumab (Actemra)	2010	IL-2 receptor blocker	RA and cytokine release syndrome
tofacitinib (Xeljanz)	2012	JAK enzyme inhibitor	RA

Mechanism of Action: Basiliximab inhibits the binding of IL-2 to CD25 on the surface of activated T cells. This prevents the rapid proliferation of T cells that would normally release cytokines to attack transplanted tissue.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Unknown
Primary metabolism	Unknown
Primary excretion	Unknown
Onset of action	30 min
Duration of action	7.2-day half-life

Adverse Effects: Basiliximab causes few adverse effects compared to the calcineurin inhibitors or the cytotoxic immunosuppressants. The most common adverse effects are GI related such as nausea, vomiting, abdominal pain, and diarrhea. Anaphylaxis has been reported. **Black Box Warning:** Basiliximab should be administered only by healthcare providers experienced in immunosuppressive therapy.

Contraindications/Precautions: The only contraindication to the use of basiliximab is hypersensitivity to the drug. Because patients receiving this drug have suppressed immune systems, vaccinations are normally postponed until immune function returns.

Drug Interactions: Basiliximab does not interact significantly with the major drugs used in transplant medicine. However, caution must always be used when administering multiple drugs that suppress immune function. **Herbal/Food:** None known.

Pregnancy: Category B.

Treatment of Overdose: Overdose with this drug is very rare, since only 2 doses are administered.

Nursing Responsibilities: Key nursing implications for patients receiving basiliximab are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Immunomodulators.

Drugs Similar to Basiliximab (Simulect)

The other antibody drugs used in transplant medicine are antithymocyte globulin and belatacept. The MABs used for RA such as adalimumab (Humira) and infliximab (Remicade) are discussed in Chapter 72.

Antithymocyte globulin (Atgam, Thymoglobulin): Approved in 1981, antithymocyte globulin consists of polyclonal antibodies obtained from the serum of horses (Atgam) or rabbits (Thymoglobulin) exposed to human T cells. Doses of the two are not interchangeable. The drug is a potent immunosuppressant used for the prophylaxis and management of transplant rejection and for the treatment of moderate to severe aplastic anemia in patients who are unable to have bone marrow transplantation. It is used off-label to treat GVHD and myelodysplastic syndrome. Given by the IV route, a single infusion may lower the lymphocyte count by 85% to 90%. After discontinuation of therapy, T-cell counts take several months to return to baseline levels. The most common adverse effects are fever, chills, malaise, headache, diarrhea, itching, and other flulike symptoms. Corticosteroids, antihistamines, and acetaminophen may be administered 1 hour prior to antithymocyte globulin therapy to prevent **cytokine release syndrome**. Anaphylaxis has been reported. Like other immunosuppressants, an increased incidence of infections and malignancies is expected. A black box warning states that antithymocyte globulin should be administered only by healthcare providers experienced in immunosuppressive therapy. This drug is pregnancy category C.

Belatacept (Nulojix): Belatacept is a MAB approved in 2011 for the prophylaxis of organ rejection in patients receiving kidney transplants. The drug blocks specific receptors on T lymphocytes, inhibiting their proliferation and stopping the production of cytokines that could damage a newly transplanted organ. The drug acts by the same mechanism as abatacept (Orencia), which is approved to treat RA. Belatacept is always used in combination with basiliximab, mycophenolate mofetil, and corticosteroids. The drug carries a black box warning that it may increase the risk for developing post-transplant lymphoproliferative disorder (PTLD). PTLD is a serious condition in which B cells proliferate unchecked and may cause B-cell tumors. Recipients who have never been exposed to the Epstein-Barr virus are especially susceptible to PTLD. The warning also states that the drug may increase the risk for malignancies and that it should not be used for liver transplants due to possible graft rejection. Belatacept is pregnancy category C.

CONNECTION Checkpoint 42.2

Basiliximab (Simulect) binds to CD25 and an immune response is prevented. From what you learned in Chapter 40, which type of immunity—humoral or cell mediated—does this drug affect? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

42.8 Corticosteroids are widely used as immunosuppressants but have significant long-term adverse effects.

The corticosteroids, or glucocorticoids, are potent inhibitors of inflammation and are discussed in detail in Chapters 41 and 68. They are often the preferred drugs for the short-term therapy of severe inflammation.

In addition to their anti-inflammatory effects, corticosteroids affect nearly every aspect of the immune response. They intervene at multiple steps in the immune response, including antigen presentation, production of cytokines, and the proliferation of lymphocytes.

- **Lymphocyte effect.** A single dose of corticosteroid reduces circulating lymphocyte counts within a few hours. This inhibits the ability of the body to react to an antigen challenge.
- **Monocyte effect.** Corticosteroids quickly deplete the body of monocytes and macrophages. Macrophages are responsible for presenting antigens to lymphocytes.
- **Neutrophil effect.** Corticosteroids cause neutrophils to move from the bone marrow into the general circulation, resulting in increased numbers of circulating neutrophils. The drug then prevents the neutrophils from migrating out of the circulation to sites of inflammation.
- **Other effects.** Corticosteroids block the production of prostaglandins and ILs. This results in T cells being unable to react to antigens and proliferate.

Two common drugs in this class, prednisone and methylprednisolone, have been widely used to prevent transplant rejection since the 1960s. When used for a few weeks, the corticosteroids are safe and effective immunosuppressants. The long-term adverse effects of corticosteroids, however, are serious and include osteoporosis, cataract formation, mental status changes, fluid and salt retention, HTN, hyperglycemia, obesity, and adrenal atrophy. Because of their long-term effects, healthcare providers have begun to look at the possibility of eliminating corticosteroids from the transplant regimen. Some regimens call for the initial use of corticosteroids, with their gradual withdrawal at some point, usually within 3 to 6 months following the transplant. The issue remains unresolved and an active area of research.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Immunomodulators

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including previous history or current case of cancer; fever; active infections (especially herpes, varicella, and CMV); hepatic, renal, cardiovascular, neurologic, or autoimmune disease; dermatologic conditions; HIV infection; pregnancy or breastfeeding. Obtain a drug history, especially the use of corticosteroids.
- Obtain a dietary history, especially the intake of grapefruit or grapefruit juice.
- Obtain baseline vital signs, especially blood pressure and temperature, height, and weight.
- Assess oral and dental health.
- Evaluate appropriate laboratory findings (e.g., CBC, platelets, electrolytes, glucose, hepatic and renal laboratory values, and lipid levels).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., no signs or symptoms of transplant rejection, no severe inflammatory response; suppression of autoimmune responses).
- Continue monitoring CBC, platelets, electrolytes, glucose, liver and renal function studies, and lipid levels.
- Assess vital signs, especially blood pressure and temperature.
- Assess for and immediately report adverse effects: fever, chills, visible signs of infection, nausea, vomiting, dizziness, confusion, muscle weakness, tremors, tachycardia, HTN, angina, syncope, dyspnea, pulmonary congestion, skin rashes, bruising or bleeding, decreased urine output.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Monitoring will be specific to the transplant, e.g., maintenance of urine output, or specific patient condition. Severe inflammatory conditions and autoimmune disorders should show gradually lessening inflammation and pain.)	• Advise the patient on the treatment and condition-specific monitoring requirements (e.g., urine output, improvement of movement in joints with lessened swelling).
Minimizing adverse effects: • Continue to monitor vital signs, especially blood pressure and temperature. (Immunosuppressant drugs may cause HTN and increase the risk of infections. Immunostimulants may cause hypotension. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension and at greater risk for falls.)	• Teach the patient how to monitor blood pressure. Ensure proper use and functioning of any home equipment obtained. The patient should report blood pressure over 140/90 mmHg or parameters set by the healthcare provider. Chest pain or pressure should be reported immediately. • Teach the patient to report any fever over 38.3°C (101°F) or as instructed by the healthcare provider. • Instruct the patient taking immunostimulants to rise from lying to sitting or standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.

• Observe for signs and symptoms of infection: fever over 38.3°C (101°F) or parameters set by the healthcare provider, sore throat, diarrhea, malaise, white patches in the oral cavity, painful or vesicular rashes, reddened or warm areas at the site of injury, or lethargy. (Immunosuppressants increase the risk of infections, especially with opportunistic infections such as herpes, varicella, CMV, and fungal infections. **Diverse Patients:** Because some drugs such as cyclosporine [Gengraf, Neoral, Sandimmune] metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Teach the patient to immediately report signs and symptoms of infection such as wounds with redness or drainage, increasing cough, increasing fatigue, white patches on oral mucous membranes, white and itchy vaginal discharge, or itchy blister-like vesicles on the skin.
	• Instruct the patient, family, and caregivers on infection control measures, including:
	  • Washing hands frequently. Use lotion afterward to prevent excessive drying and cracking of the skin.
	  • Avoiding large crowds, especially indoors.
	  • Avoiding people with known infection or young children because they have a higher risk of having an infection.
	  • Cooking food thoroughly, allowing the family or caregiver to prepare raw meat or fish and clean up, and not consuming raw fruits or vegetables.

• Assess for changes in level of consciousness, disorientation, confusion, or tremors. (Neurologic changes may indicate adverse drug effects.)	• Instruct the patient, family, or caregiver to immediately report increasing lethargy, disorientation, confusion, changes in behavior or mood, slurred speech, tremors, or ataxia.
• Continue to monitor CBC, platelets, electrolytes, glucose, liver and renal function studies, and lipid levels. (Immunosuppressants may cause leukopenia, anemia, thrombocytopenia, hyperglycemia, and hyperkalemia. **Lifespan:** Monitor the older adult frequently because age-related physiologic changes increase the risk of adverse renal and hepatic effects.)	• Instruct the patient on the need to return frequently for follow-up laboratory work. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating immunosuppressant therapy.
• Inspect oral mucous membranes, and schedule dental appointments prior to starting drug therapy and frequently thereafter. (Immunosuppression increases the risk of oral candidiasis and gingivitis. Oral antifungal rinses may be required.)	• Teach the patient to maintain excellent oral hygiene, inspecting the oral cavity daily. Keep regular dental visits, and consult the dentist about the required frequency.
• Assess diet and consumption of grapefruit or grapefruit juice. (Grapefruit juice significantly increases cyclosporine levels and should be avoided or eliminated while on immunosuppressant therapy.)	• Teach the patient to avoid grapefruit and grapefruit juice while on cyclosporine. Flavored beverages without juice are permissible.
• **Lifespan:** Assess for pregnancy. (Pregnancy should be avoided during and for up to 4 months after discontinuing immunosuppressive therapy. Women who become pregnant while on the drug should consult with their healthcare provider.)	• Discuss pregnancy and family planning with women of childbearing age. Explain the effect of medications on pregnancy and breastfeeding and the need to discuss any pregnancy plans with the healthcare provider. Discuss the need for additional forms of contraception, including barrier methods, with patients taking immunosuppressants.
• Assess for development of hirsutism or alopecia. (Hirsutism is reversible when the drug is discontinued. Alopecia may indicate significant immunosuppression.)	• Advise the patient to notify the provider of changes to hair growth or texture.
• Continue to monitor neurologic and mental status in patients receiving IFN therapy. (Psychosis, depression, and suicidal ideations are potential adverse effects of IFN use.)	• Instruct the patient, family, or caregiver to immediately report increasing lethargy, disorientation, confusion, changes in behavior or mood, agitation or aggression, slurred speech, or ataxia.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by return demonstration. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication by:
	  • Using the enclosed equipment to measure or mix the drug.
	  • Using a glass, and not paper or plastic cups, unless the package directions indicate they are to be used.
	  • Mixing the drug with milk, chocolate milk, or orange juice, and stirring well. After taking the drug, rinse the cup with additional liquid and drink it to ensure the entire dose is taken.
	  • Taking the medication at the same time each day.

Understanding Chapter 42

Key Concepts Summary

42.1 Immunomodulators are substances that either enhance or suppress the ability of the body to fight infection and disease.

42.2 Interferons are biologic response modifiers that have antiviral and antineoplastic activity.

42.3 Interleukins, vaccines, and colony-stimulating factors are used to boost the immune system.

42.4 Immunosuppressants are used to prevent transplant rejection and for the treatment of autoimmune disorders.

42.5 Calcineurin inhibitors are preferred drugs for the prophylaxis of transplant rejection.

42.6 Cytotoxic drugs and antimetabolites are used to suppress proliferating B cells and T cells.

42.7 Antibodies are used to prevent acute transplant rejection, autoimmune disorders, and malignancies.

42.8 Corticosteroids are widely used as immunosuppressants but have significant long-term adverse effects.

CASE STUDY: Making the Patient Connection

Remember the patient "Carole Banks" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Carole Banks is a 42-year-old woman diagnosed with hepatitis C who was recently seen by her healthcare provider at an office visit. She reported having right upper quadrant pain, fatigue, anorexia, nausea, and vomiting. She has been feeling progressively worse for the past year but did not seek medical care for her problem. She has lost 5.4 kg (12 lb) over the past 6 months.

Carole was initially hospitalized to receive IV fluids for dehydration and to be further evaluated. Once in the hospital, a full hepatitis panel found that she was positive for hepatitis C virus (HCV).

During the initial interview with Carole, she discloses that she was addicted to illegal IV drugs for 15 years and was an alcohol abuser for 20 years. However, Carole claims that she has abstained from substance abuse for the past 5 years. She resides with her husband and three children and is employed as a clerk in a local retail convenience store.

As part of the treatment for Carole's hepatitis she is prescribed IFN alfa-2b (Intron A). She is taught to self-administer (subcutaneously) the standard dose of IFN, 3 million units, 3 times weekly.

Critical Thinking Questions

1. Discuss the rationale for the use of IFN alfa-2b (Intron A) in the treatment of hepatitis C.

2. What adverse effects might Carole experience with this drug therapy? How can the nurse assist Carole to cope with the related adverse effects?
3. Identify the patient education that Carole will need concerning her drug therapy.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Gordon Sharp had been on kidney dialysis since his car crash 2 years ago. He sustained severe traumatic injuries and subsequently developed renal failure. Gordon has recently received a kidney transplant and is currently on cyclosporine (Sandimmune).

1. How does cyclosporine work and why is Gordon receiving the drug?
2. Describe the patient teaching that the nurse should give to Gordon concerning this drug therapy.
3. What dietary precautions would be indicated for this patient?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is monitoring the laboratory findings of a patient who is taking interferon alfa-2b (Intron A). Which findings would indicate that the patient is experiencing common adverse effects?
    1. Flulike symptoms of fever, chills, fatigue, and weight loss
    2. Depression with thoughts of suicide
    3. Edema, hypotension, and tachycardia
    4. Fluid volume overload, hypertension, renal insufficiency
2. The patient is receiving basiliximab (Simulect) and cyclosporine (Sandimmune) after a kidney transplant to prevent organ rejection. The patient develops a high fever and chills, with a temperature of 39.4°C (103°F). The nurse interprets that the patient is most likely experiencing:
    1. Capillary leak syndrome.
    2. A significant infection related to immunosuppression.
    3. Graft-versus-host rejection.
    4. Androgen-insensitivity syndrome.
3. The nurse who is caring for a patient receiving cyclosporine (Sandimmune) will discontinue the medication immediately and call the provider if which of the following occurs?
    1. Red blood cell count above 8.5 million/mm^3
    2. White blood cell count below 4000/mm^3
    3. Platelet count above 100,000/mm^3
    4. Serum creatinine level less than 1.0 mg/100 mL
4. Azathioprine (Imuran) is prescribed to a patient who had a kidney transplant. A nurse reviews the patient's medical record and would question the medication order for the patient with a history of:
    1. Benign prostatic hyperplasia.
    2. Cataracts.
    3. Varicella zoster.
    4. Rheumatoid arthritis.
5. A nurse is instructing a patient who is receiving tacrolimus (Prograf) following a liver transplant. Which point should be included in the teaching plan?
    1. Take a "baby" strength aspirin every day.
    2. Increase physical activity to avoid weight gain.
    3. Record radial pulse rate every morning in a journal.
    4. Avoid raw fruits and vegetables and eat only fully cooked meats.
6. A nurse is particularly cautious in monitoring the patient who is prescribed aldesleukin (Proleukin). To monitor for the development of capillary leak syndrome, the nurse would frequently assess:
    1. Skin condition and rashes.
    2. Laboratory values for increasing amylase and lipase.
    3. Blood pressure and urine output.
    4. Vision and hearing.

Chapter 43
Immunizing Agents

Chapter Outline

- Discovery of Vaccines
- Vaccines and the Immune System
- Types of Vaccines
- General Principles of Vaccine Administration
- Active Immunity: Bacterial Immunizations
- Active Immunity: Viral Immunizations

  PROTOTYPE *Hepatitis B Vaccine (Engerix-B, Recombivax HB), p. 770*
- Passive Immunity

  PROTOTYPE *Rho(D) Immune Globulin (RhoGAM), p. 776*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain why the development of vaccines was one of the most significant discoveries of modern medicine.
2. Compare and contrast active and passive immunity.
3. Explain the immune response that leads to the development of active immunity.
4. Prepare a table listing the types of vaccines, their indications, and potential adverse effects.
5. Explain why it is important to administer childhood vaccines at specific ages.
6. Identify contraindications for vaccine administration.
7. Describe the pathogenesis and immunization of bacterial infections, including diphtheria, pertussis, tetanus, pneumococcus, and meningococcus.
8. Describe the pathogenesis and immunization of viral infections, including hepatitis A and B, influenza, rabies, measles, mumps, rubella, polio, varicella zoster, human papillomavirus, and rotavirus.
9. Explain the rationale for administering antibodies to establish passive immunity.
10. For each of the major vaccines and patient age groups, identify the schedule for the recommended dosage sequence established by the Centers for Disease Control and Prevention.
11. Apply the nursing process to care for patients receiving immunizing agents.

Key Terms

active immunity, 763
attenuated, 764
boosters, 763
immunization, 763
incubation period, 763
inoculation, 763
passive immunity, 764
postherpetic neuralgia, 774
shingles, 774
toxoids, 765
vaccination, 763

The earliest attempts at treatments to prevent infection were reported in ancient Indian and Chinese literature when dried, powdered scabs from infected individuals were administered to healthy people. Vaccinations have since become one of the most important medical interventions for the prevention of serious infectious disease. Routine vaccinations for polio, pertussis, diphtheria, tetanus, and measles are estimated to prevent 3 million deaths annually. This chapter examines the role of vaccines in promoting the health of both children and adults and the potential adverse effects of these drugs.

Discovery of Vaccines

43.1 The eradication of smallpox was a great triumph in modern medicine.

In the 1790s, Dr. Edward Jenner was experimenting with the use of **inoculation**, the placement of a foreign substance on or in an individual for the purpose of disease prevention. Inoculation uses live virus particles obtained from an infected patient. Jenner used the cowpox virus, a benign pathogen in humans, because he predicted that exposure to that virus would provide immunity to smallpox, which was one of the most dreaded human diseases of that era. Case fatality rates of 30% or more were reported with smallpox infections. In the 18th century, the disease was a frequent cause of blindness and death for 400,000 people worldwide annually.

Jenner's inoculation of a single 8-year-old boy ultimately led to one of the greatest triumphs in disease prevention. On May 8, 1980, the World Health Assembly certified that global medical interventions had actually eradicated smallpox infections from the planet. Although this announcement was heralded by the scientific community as proof of the success of routine immunization, it also has presented new challenges. With the last known case of the disease, the need for smallpox immunization ceased, resulting in a growing, nonimmune population. The widespread reappearance of the pathogen in an unvaccinated population could have disastrous consequences.

Vaccines and the Immune System

43.2 Vaccines are used to activate the immune system for the purpose of disease prevention.

An immune response occurs when an antigen is recognized by the B or T lymphocytes. Antigens are microbes and foreign substances that elicit an immune response. Most microbes, nonhuman proteins, bacterial or plant toxins, and normal cells that become damaged or cancerous are considered antigens. Following the first exposure to an antigen, sufficient time is needed for the body to process the antigen and mount an effective response. It is during this time, known as the **incubation period**, that the symptoms of infection and tissue injury develop. During this first antigen exposure, memory B cells or T cells are formed. Should a second or subsequent exposure to the same antigen occur, the memory cells react quickly to produce a more rapid immune response with fewer (or no) symptoms of infection. The student should review Chapter 40 for a summary of the humoral and cell-mediated immune responses before proceeding.

Edward Jenner was the first to use the term *vaccination*. **Vaccination** is the process of introducing foreign proteins or inactive cells (vaccines) into the body to trigger immune activation *before* the patient is exposed to the real pathogen. As a result of the vaccination, memory B cells or T cells are formed. When later exposed to the real infectious organism, these cells will react quickly by producing large quantities of antibodies and cytokines that help to neutralize or destroy the antigen. Whereas some vaccinations are needed only once, most require follow-up doses, known as **boosters**, to provide prolonged protection. The type of response induced by the real pathogen, or its vaccine, is called **active immunity**. During this response the body produces its own antibodies in response to exposure. The active immunity induced by vaccines closely resembles that caused by natural exposure to the antigen, including the generation of memory cells. The term **immunization** is considered equivalent to the term *vaccination*, and either one may be used to describe this process of disease prevention.

The effectiveness of most vaccines can be assessed by measuring the amount of antibodies produced after the vaccine has been administered, a quantity called *titer*. If the

Table 43.1 Vaccine Types

Type of Vaccine	Immune System Response	Vaccine Examples	Remarks
Attenuated (live) virus	B-cell response; T-cell response	Polio (oral), measles, mumps, rubella, varicella	Risk for disease in individuals with reduced immune function
Inactivated (killed) virus	B-cell response	Salk polio (injectable), influenza, rabies, hepatitis A	Does not confer lifelong immunity
Toxoid	B-cell response	Tetanus toxoid, diphtheria toxoid	Large quantities of antigen needed
Recombinant technology vaccine	B-cell response	Hepatitis B, human papillomavirus	Contains no viral genetic material

titer falls below a specified, protective level over time, a booster dose is indicated. Antibodies are a product of the humoral immune system. The cell-mediated immune system is also important in producing immunity, but its cellular responses are less readily measured.

Passive immunity occurs when preformed antibodies are transferred or "donated" from one person to another. For example, maternal antibodies cross the placenta and provide protection for the fetus and newborn. Other examples of passive immunity include the administration of immune globulin following exposure to hepatitis, antivenins for snakebites, and sera to treat botulism, tetanus, and rabies. The drugs for passive immunity are administered when the patient has already been exposed to a virulent pathogen, or when the patient is at very high risk for exposure and there is not sufficient time to develop active immunity. Patients who are immunosuppressed may receive these drugs to prevent infections. Because these medications do not stimulate the patient's immune system, no memory cells are produced and protective effects last only 2 to 3 weeks. Passive immunity is presented in Section 43.7.

Most vaccines are administered with the goal of *preventing* illness. Common vaccines include those used to prevent patients from acquiring measles, influenza, diphtheria, polio, pertussis (whooping cough), tetanus, and hepatitis B. Anthrax vaccine has been used to immunize people who are at high risk for exposure to anthrax from a potential bioterrorism incident (see Chapter 75). In the case of infection by the human immunodeficiency virus (HIV), experimental HIV vaccines are given after infection has occurred for the purpose of enhancing the immune response, rather than preventing the disease. Unlike other vaccines, experimental vaccines for HIV have thus far been unable to prevent acquired immunodeficiency syndrome (AIDS).

CONNECTION Checkpoint 43.1

The humoral and cell-mediated immune responses are components of the specific (adaptive) body defenses. From what you learned in Chapter 40, compare and contrast the humoral and cell-mediated responses to an antigen. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Types of Vaccines

43.3 Four traditional methods are used to produce vaccines.

The goal of vaccine administration is to induce long-lasting immunity to a pathogen without producing an illness in an otherwise healthy individual. Therefore, the microorganisms and other substances used as vaccines must be able to strongly activate the immune system but be modified to pose no significant risk of disease development. The vaccine must be economical to develop and be stable for storage and administration. For long-standing disease protection, the vaccine must be able to stimulate the production of memory B cells and T cells. Four traditional methods are used to produce safe and effective vaccines, as listed in Table 43.1. All four methods are capable of inducing active immunity.

Attenuated (live) vaccines: Live vaccine products contain microorganisms that are capable of replicating and causing disease. Live vaccines are very effective at inducing immunity but are not used for vaccination because of their risk. However, effective vaccines can be developed from organisms that are **attenuated** or rendered less able to cause disease through the application of heat or chemicals. Attenuated (live) vaccines cause the development of a mild or subclinical case of the disease while still inducing lasting immunity. The type of immune response obtained from the administration of a live or attenuated organism is the same as if the patient had been exposed to the natural, nonattenuated organism. There must, however, be adequate immune functioning for the vaccine to work. The use of attenuated (live) vaccines is dangerous for individuals who are immunosuppressed because the organism may retain some residual ability to replicate and cause disease. In very rare cases, the attenuated virus may mutate to an infectious form in patients who received the vaccine. An example of a live or attenuated vaccine is the measles, mumps, and rubella (MMR) vaccine.

Inactivated (killed) vaccines: Inactivated or killed vaccines are of two types: whole agent and subunit. Whole-agent vaccines consist of microbes killed by heat or chemicals. Subunit vaccines consist of specific segments of

a cell membrane, foreign proteins, or sequences of a chromosome rather than the whole microbe.

Inactivated or killed vaccines are safer than live vaccines because the organism is unable to replicate, mutate, or cause disease. Subsequent booster doses are required to maintain immunity if inactivated or killed vaccines are used. Examples of inactivated or killed vaccines include the influenza and hepatitis A vaccines. Examples of subunit vaccines are the human papillomavirus (HPV) vaccine and the acellular pertussis vaccine.

Toxoid vaccines: Some pathogens secrete toxins, which are responsible for the symptoms of the infection. **Toxoids** are bacterial toxins that have been chemically modified to be incapable of causing disease. When injected as a type of immunization, toxoids induce the formation of antibodies that are capable of neutralizing the real toxins. Toxoids attack the bacterial toxin, not the invading pathogen itself. Examples include the diphtheria and tetanus toxoids.

Recombinant technology vaccines: Modern biologic techniques have allowed the development of vaccines that contain viral subunits or proteins that are generated in the laboratory. Two examples of the use of this form of biotechnology are immunizations for the hepatitis B virus (HBV) and HPV. These vaccines do not contain viral genetic material; therefore, the viruses cannot multiply or become infectious.

General Principles of Vaccine Administration

43.4 Vaccines should be administered by an established schedule with precautions taken for patients who are immunosuppressed or pregnant.

The effective use of vaccines requires that they be delivered according to a specified schedule at the proper dose. Childhood vaccines have a specific age range at which they should be administered. Should a child miss the recommended vaccination date, "catch-up" doses can sometimes be administered to provide adequate protection. In addition, comorbid health conditions sometimes cause the delay of vaccinations in certain patients. Although each vaccine has different indications, certain general principles apply to the administration of most immunizations.

In the United States, the Centers for Disease Control and Prevention (CDC) is the government agency that establishes immunization schedules. Immunization protocols are reviewed on a regular basis by the CDC's Advisory Committee on Immunization Practices, and revisions are frequently made based on current research. The practicing nurse should refer often to the CDC website for updates.

Many of the vaccine-preventable diseases are rare in the United States, but endemic to specific regions of the world. The nurse should advise patients traveling to these regions to check that their vaccinations are current. The CDC provides updated country-specific health information for those traveling abroad.

Dose and timing: The total dose of a vaccine is important for the development of immunity. For some vaccinations, multiple doses are required to achieve immunity. Omitting subsequent doses could result in less-than-full disease protection.

To prevent childhood diseases, certain vaccinations should begin at birth and proceed with booster doses at specific ages according to the schedule recommended by the CDC. The timing established by the CDC allows the vaccine to be given prior to the expected exposure to the pathogen. For example, the pertussis vaccine is begun in the first few months of life because infection by *Bordetella pertussis* often occurs by age 1 or 2 years. On the other hand, vaccination for HPV is recommended at 11 to 12 years of age because this virus is spread by sexual contact, which often occurs during the teen years. Vaccination outside the guidelines of the vaccination schedule is permitted, but its effectiveness may be reduced.

Route of administration: Vaccines must be administered by the specific route indicated for each product. Failure to follow administration protocol may result in an insufficient immune response. For example, hepatitis B vaccine elicits a satisfactory response when administered into the deltoid muscle but not the gluteus muscle. Injection into the gluteus muscle also risks injury to the sciatic nerve. Varicella vaccine is given subcutaneously.

Precautions and contraindications: There are few absolute contraindications for the use of vaccines. However, caution must be used in immunocompromised patients, such as those with cancer, recent tissue transplant recipients, or those infected with HIV. Patients receiving high-dose, systemic corticosteroid therapy may also have suppressed immune systems. Vaccinations in an immunocompromised patient should be avoided if the patient is having an exacerbation of his or her disorder. In some cases, only inactivated (killed) vaccines are indicated for these patients. Because it is suppressed, the patient's immune system may not be able to develop effective immunity in response to the vaccine, and subsequent laboratory results should be assessed to confirm that immunity has actually occurred.

The CDC provides guidelines for receiving vaccines during pregnancy (CDC, 2016b). Inactivated (killed) vaccines may be administered to pregnant patients if the benefits of disease prevention outweigh the possible risk to the mother and fetus. For example, the CDC recommends

vaccination for influenza (inactivated) and Tdap (tetanus, diphtheria, and pertussis booster vaccine). A woman should be vaccinated for HBV if she is at risk for HBV infection during pregnancy. Some vaccines, including those for HPV, varicella, and MMR, should not be administered to pregnant women due to the potential risk to the fetus. For other vaccines, the pregnant patient should consult with her healthcare provider.

Anaphylaxis and allergy: The most common adverse effects of vaccination are pain, swelling, and redness at the injection sites. Allergy or anaphylaxis following vaccination is extremely rare. Some preparations may contain preservatives such as gelatin or the mercury compound thimerosal, which could trigger an allergic response. Patients with confirmed vaccine anaphylaxis should not receive subsequent doses of that vaccine.

Adverse event reporting: Healthcare providers are required to report all vaccine-related adverse events requiring medical attention to the Vaccine Adverse Event Reporting System (VAERS). The VAERS is a postmarketing surveillance program conducted by the CDC and the U.S. Food and Drug Administration (FDA). Voluntary reports may be submitted to the VAERS by patients and parents as well as healthcare providers. Vaccine manufacturers are required to report any adverse effects of which they are aware.

VAERS has a number of limitations. VAERS merely collects data and reports incidences of adverse events; it does not attempt to confirm that the reported event was actually caused by the vaccine. Reports are not checked by the FDA or CDC for accuracy or completeness. Despite its limitations, VAERS serves as an important, central repository of information for identifying potential adverse effects of vaccines.

CONNECTION Checkpoint 43.2

Vaccines are sometimes contraindicated in patients who are receiving immunosuppressant drugs. From what you learned in Chapter 42, identify the following drugs as being either an immunosuppressant or an immunostimulant: aldesleukin (Proleukin), cyclosporine (Gengraf, Neoral, Sandimmune), basiliximab (Simulect), and hydrocortisone. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Active Immunity: Bacterial Immunizations

43.5 Active immunity can be induced to prevent bacterial infections.

Vaccinations are performed to provide protection against both viral and bacterial pathogens. However, the role of vaccines is very different for each type of infectious agent. Table 43.2 summarizes the epidemiology and immunizations associated with these pathogens. Immunizations against viruses are presented in Section 43.6.

Many bacterial infections cause host cellular injury by releasing toxic substances. Vaccination for bacterial infections, therefore, may be achieved by exposing the immune system to inactive bacterial toxins. When later faced with the actual bacterial infection, the immune system will remember the protein-based toxin and respond rapidly by producing antibodies to neutralize it.

It is common practice to combine several childhood vaccines for a single administration. For example, DTaP combines diphtheria, tetanus, and pertussis into a single injection. Combining vaccines is less traumatic for the child and is more convenient and efficient for the caregiver and the healthcare provider.

Diphtheria

Pathophysiology: Diphtheria is an infection of the upper respiratory tract caused by the gram-positive bacterium *Corynebacterium diphtheriae*. The bacterium releases a potent toxin that causes a low-grade fever, malaise, and a painful oropharynx. The organism causes the formation of a thick, gray coating across the membranes of the soft palate, tonsillar areas, and uvula. The thickened membranes can partially occlude the airway and cause difficulty swallowing or a feeling of choking. Attempts to remove the membrane result in pain and bleeding. If untreated, the membrane softens and gradually disappears approximately 1 week following its appearance. A majority of deaths associated with diphtheria are related to toxin escape, leading to acute systemic toxicity or myocarditis. Because of effective immunization programs, the disease has almost been entirely eradicated from the United States.

Diphtheria toxoid: Diphtheria toxin is produced by organisms in culture that are rendered inactive by the addition of formalin. The diphtheria toxoid triggers immune memory without producing disease in the upper airways. Currently diphtheria toxin is available as a combination immunization with tetanus toxoid and acellular pertussis (DTaP) as well as in combination with other compatible immunizations. DTaP is part of the recommended routine immunization schedule for infants older than 6 months.

Pertussis (Whooping Cough)

Pathophysiology: Pertussis is a highly contagious infection by the gram-negative bacterium *Bordetella pertussis* that is transmitted via aerosolized droplets from an infected individual. Once inhaled, the bacteria attach to the ciliated respiratory epithelial cells and release a toxin.

Table 43.2 Disease Epidemiology and Immunizations

Disease	Worldwide Incidence (Annually)	U.S. Incidence (Annually)	Immunization (Age)	Remarks
Diphtheria	About 7000 cases, usually in developing countries	Under 10 reported cases	2, 4, 6, and 15–18 months; 4–6 years	Mucous membrane bacterial toxin infection
Hepatitis A	Estimated 1.4 million cases, usually in developing countries	About 2500 new cases; has declined by 90% since 1995	Two-dose series: 12 months and 6–12 months later Adults at risk for infection	Route: oral–fecal from carriers; immune globulin available
Hepatitis B	About 240 million chronic carriers worldwide	Fewer than 19,000 new cases; has declined by over 80% since 1988	Three-dose series: 0, 1, and 6–18 months	Vaccine recommended for all healthcare providers; immune globulin available
Human papilloma virus (HPV)	Associated with about 70% of all cases of cervical and oropharyngeal cancers	About 42% of population ages 18–59 (genital HPV) and 7% (oral HPV) are infected	First dose at ages 11–12; second 6–12 months after the first	4 years after vaccine approval, the incidence of HPV among females ages 14–19 dropped over 60%
Influenza (*Haemophilus influenzae* type b [Hib])	Estimated 250,000–500,000 deaths; endemic during winter months	About 36,000 deaths (high risk to those over 65 years of age and in general ill health)	Annual vaccine based on estimated exposure	Vaccine recommended for children, immunocompromised patients, older adults, and healthcare workers
Measles (rubeola)	About 134,000 deaths, usually in developing countries (mostly children)	Fewer than 100 cases	MMR: 12–15 months; booster: 4–6 years	Highly contagious; airborne and droplet exposure
Meningococcus	About 12,000 cases, with about half in central Africa	About 1000 cases; rates are highest for children under age 1	11–12 years; booster: age 16	Airborne droplet exposure; antibiotics if known exposure
Mumps	Endemic in many countries; rarely fatal	About 2300 cases, mostly due to outbreaks in unvaccinated college students	MMR: 12–15 months; booster: 4–6 years	Viral parotitis; respiratory droplet infection
Pertussis	Endemic worldwide; 16 million cases with about 200,000 deaths	About 32,000 cases	2, 4, 6, and 15–18 months; 4–6 years	Gram-negative bacterial infection, cough; increased incidence in adolescent age group
Pneumococcal disease	Over 14 million cases with over 820,000 deaths	About 1 million cases with about 5000 deaths	All children younger than 2 years (PCV13) and all people over age 65 (PPSV23)	Most deaths occur in individuals ages 65 and older
Poliomyelitis	About 74 cases: almost eradicated	Very rare	Inactivated virus: 2, 4, and 12 months; booster: 4–6 years	20% of children in Nigeria younger than 5 years are not vaccinated because of fear of AIDS and female infertility
Rabies	Canine rabies epidemic in Africa, Asia, and Central America; fewer than 200 deaths	Found in all continents	Preexposure vaccine for veterinarians; postexposure immune globulin	Viral infection; transmitted via contaminated saliva; from peripheral nervous system to central nervous system
Rubella	About 100,000 cases acquired congenitally	Very rare	MMR: 12–15 months; booster: 4–6 years	Mild disease but fetal cataracts, deafness, and cardiac malformations
Tetanus	About 59,000 deaths	Very rare; about 30 cases	2, 4, 6, and 15–18 months; 4–6 years	Spores in soil; illness follows inadequate or missed immunizations
Varicella (chickenpox)	Endemic worldwide; rarely fatal	About 3.5 million cases and 100 deaths	Two-dose series: 12–15 months and 4–6 years	Highly contagious; airborne spread; latent in nerve ganglia; reoccurs as herpes zoster (shingles)

Pertussis begins with a low-grade fever and irritated cough and progresses to spasmodic coughing episodes characterized by an inspiratory "whoop," leading to the common name "whooping cough." The coughing episodes are productive and may be induced by laughing, talking, or activity in children, and lead to gagging or vomiting. The cough will usually resolve at the termination of the infection in approximately 2 to 6 weeks. Exhaustion is common in patients experiencing pertussis, as are secondary respiratory infections. Active pertussis infection is treated with the antibiotic erythromycin, with the best results seen when treatment is early and aggressive.

Immunization: Originally the pertussis vaccine was made from inactivated or killed whole cells and was highly effective in providing immunity. The whole-cell vaccines, however, were associated with adverse effects that prompted the development of an acellular form (aP). The aP vaccine remains highly effective in producing immunity but has a lower rate of adverse effects than the whole-cell vaccine. The acellular form of pertussis vaccine became available in 1996 and has replaced the original form.

Local injection-site reactions, drowsiness, persistent crying, and fever occur in 3% to 5% of patients receiving the vaccine. The vaccine is always administered concurrently with the diphtheria and tetanus toxoids. The childhood vaccine is called DTaP. Children receive five intramuscular (IM) doses of DTaP, one dose at each of the following ages: 2 months, 4 months, 6 months, 15 to 18 months, and 4 to 6 years. Because the severity of pertussis declines with age, vaccination for pertussis is not recommended for children after age 7 or for adults. Adults, however, may receive a booster vaccine (Tdap) if they are anticipating contact with patients with pertussis.

Tetanus

Pathophysiology: *Clostridium tetani* normally lives in soil as a spore but can infect humans when the gram-positive anaerobe enters an open wound. Symptoms of infection may present over a wide range of time, averaging from 3 days to 3 weeks after exposure. *C. tetani* produces a toxin that is one of the most toxic substances known; receiving 2.5 mg (one billionth of a gram) per kilogram of body weight can be lethal. The toxin enters the peripheral nervous system (PNS) and migrates to the central nervous system (CNS). The toxin causes continuous, painful muscular contractions. Symptoms range from local muscle spasm, including the muscles of the jaw (lockjaw), to neck stiffness and seizures that are sometimes unresponsive to drug therapy. Treatment includes the administration of antibiotics but is primarily supportive in advanced cases.

Immunization: Tetanus toxoid (TT) is available alone, combined with diphtheria (DT), or combined with both diphtheria and pertussis (DTaP). The initial series of recommended immunizations uses the DTaP and is given in five doses during the first 6 years of the child's life. A contaminated wound in an adult with an appropriate immunization history requires only the booster administration of TT. To retain immunity, the booster for tetanus prevention should be given to adults every 10 years. TT can be injected IM, subcutaneously, or via jet injector. In patients with symptomatic tetanus infection, the TT injection may be coupled with passive immunization of antibodies against the toxin. The vaccine is nearly 100% effective at preventing tetanus and its widespread use has nearly eradicated this disease in the United States.

Pneumococcus

Pathophysiology: Infection by *Streptococcus pneumoniae* is the most common cause of bacterial otitis media, meningitis, and pneumonia. Pneumococcal infection begins in the nasopharynx and may spread to the middle ear, sinuses, and lower respiratory tract. It occurs with a higher incidence in the winter months, when air pollution increases, or as a secondary infection following viral disease. The immune health of the patient greatly impacts the progress of *S. pneumoniae* infection and those with decreased immune function are at greater risk for the development of serious infections. Also at risk are patients with diminished cough and gag reflexes who have difficulty clearing secretions from the upper airways, such as in cases of neuromuscular diseases, or postanesthetic exposure. Smoking is a contributing factor in approximately half of the *S. pneumoniae* infections in nonelderly populations, probably due to the change in upper airway clearance of secretions in these patients. All strains of *S. pneumoniae* have a common polysaccharide in their cell wall that is used for vaccine development.

Immunization: The immunization for pneumococcal infection has changed over time and currently has two different formulations. The first to be approved by the FDA, called pneumococcal polysaccharide vaccine (PPSV23), is derived from the cell walls of 23 strains of *S. pneumoniae*. PPSV23 is recommended for those who are age 65 or older and for patients from ages 2 to 64 who have a chronic illness, smoke cigarettes, have asthma, or live in environments where exposure risk is increased. The vaccine is also recommended in immunocompromised patients (ages 2–64) who have HIV infection, leukemia, lymphoma, Hodgkin's disease, or multiple myeloma; patients who receive dialysis; patients who are receiving high-dose corticosteroid therapy; and transplant recipients. A booster 5 or more years following the first vaccination is recommended.

A second vaccine, called pneumococcal conjugate vaccine (PCV13), has been specially developed for routine immunization in children under the age of 5. This immunization differs from PPSV23 in that the *S. pneumoniae* polysaccharides are coupled with a protein that leads to improved immune activation in infants with immature immune function. PCV13 protects against 13 types of pneumococcal bacteria. PCV13 is used in a series of four IM injections at 2 months, 4 months, 6 months, and 12 to 15 months. PCV13 is also approved for adults 65 years or older who have had no previous pneumococcal vaccinations.

Both PPSV23 and PCV vaccines are well tolerated and contraindicated only in individuals with prior severe reactions to immunizations. The most common symptoms following the administration of either PPSV23 or PCV13 are

mild fever, local redness, swelling, and pain at the injection site, which lasts from 1 to 3 days.

Meningococcus

Pathophysiology: Meningococcal infection (meningitis) is caused by *Neisseria meningitidis*, a highly virulent gram-negative, toxin-secreting organism. Although meningitis usually occurs sporadically in the United States, it sometimes causes epidemics in other nations. Early meningococcal infection is very difficult to discriminate from other viral or bacterial infections, because it initially presents with nonspecific fever and rash; frequently symptoms appear less than 24 hours before individuals are hospitalized. Neurologic symptoms rapidly develop, including nuchal rigidity, headache, photophobia, and seizures. Infants present with reduced feeding, irritability or lethargy, and bulging fontanels. A rash is seen in most cases, which appears as petechiae or larger purpuric eruptions on the arms, chest, or axilla. Early hospitalization and aggressive treatment with intravenous (IV) penicillin-based antibiotics have reduced the mortality and morbidity of meningococcal infection. About 10% of patients die from the infection and up to 20% experience some degree of permanent neurologic disability.

Immunization: There are at least 12 types (serogroups) of *N. meningitidis*. Groups A, B, C, W, and Y cause most of the infections in the United States. The various types of meningococcal vaccine are indicated for different age groups.

For children, meningococcal conjugate vaccine (MenACWY or Hib-MenCY-TT) is recommended for children 2 months through 10 years of age who are at high risk for meningococcal infection. This includes children with certain medical conditions, those traveling to countries with high rates of meningococcal disease, or because of a community outbreak. Hib-MenCY-TT (MenHibrix) combines the three vaccines: meningococcus, tetanus toxoid, and *Haemophilus influenza* type b. Neither vaccine protects against meningococcus serogroup B, which is responsible for about two thirds of all cases of meningitis in children 0 to 59 months of age.

For preteens and teens, MenACWY (Menactra, Menveo) is a two-dose regimen at ages 11 to 12 years with a booster at age 16. This vaccine protects against serogroups ACWY, but not B. Populations that should receive MenACWY include individuals traveling to regions where meningococcal infection is endemic or those living in crowded conditions, such as college residence halls. Because college freshmen living in dormitories are at increased risk for infection, some colleges now require meningococcal vaccination for these students. Serogroup B meningococcal vaccine (Bexsero, Trumenba) is available for community outbreaks of this strain.

Adults may receive MenACWY or meningococcal polysaccharide vaccine (MPSV-4) (Menomune). Adults who have already received their first MenACWY dose, should receive MenACWY as their second dose. MPSV-4 is generally recommended for adults over age 55 who anticipate requiring only a single dose, such as travelers or during a community outbreak.

Active Immunity: Viral Immunizations

43.6 Effective vaccines that prevent viral infections have been developed.

Vaccinations for viral infections have a different form and function than those for bacterial infections. Viruses are nonliving and contain only a few strands of nucleic acid (deoxyribonucleic acid [DNA] or ribonucleic acid [RNA]), an outer protein coat, and a few viral enzymes. Viruses require a host cell for replication and transmission. The signs and symptoms that follow viral invasion may be caused by either the effects of the viral infection itself or by the host's immune response.

Viral proteins are readily recognized as foreign by the immune system and will normally trigger an immune response. In some cases, immune cells are able to recognize that a virus has entered one of its own cells and has become infected. Recognition of infected cells takes place through the host secretion of special communication proteins called interferons (IFNs), which signal the surrounding noninfected cells of the approaching virus. The infected cells are programmed to undergo cell death, or apoptosis, when they are invaded, thus decreasing the viral spread to adjacent cells. Because viruses undergo rapid mutations that allow them to constantly change structure and evade the host's defense mechanisms, they present enormous challenges for effective vaccine development.

The term *live viral vaccine* is commonly used in clinical practice. The student should understand, however, that viruses are nonliving particles. In vaccine terminology, the term *live* refers to a virus's ability to infect the host and does not indicate that the virus is actually alive.

CONNECTION Checkpoint 43.3

From what you learned in Chapter 42, what are the indications for pharmacotherapy with interferons? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Hepatitis B

Pathophysiology: Infection with HBV leads to symptoms that range from a self-limiting acute illness to life-threatening liver failure. Patients with HBV infection are at risk for developing a chronic carrier state, which is associated with

the development of cirrhosis and hepatic cancer. Of the five viral infections known to cause hepatitis, HBV has the highest incidence worldwide.

Hepatitis B cannot be discriminated from the other forms of viral hepatitis by symptoms alone; serologic testing is required for diagnosis. The onset of symptoms ranges between 6 weeks and 6 months postexposure and includes low-grade fever, nausea, vomiting, malaise, fatigue, and anorexia. The patient may present with signs of hepatitis, including jaundice, dark urine, and clay-colored stools that appear 1 to 2 weeks following the onset of symptoms. Approximately 30% of patients are hospitalized during the acute phase of hepatitis infection. End-stage hepatitis includes encephalopathy, confusion and disorientation, and coma, and carries a mortality rate of 60% to 70% without transplantation. Details on the pathophysiology and pharmacotherapy of HBV infections are presented in Chapter 54.

Immunization: The first HBV vaccine became available in 1982 and was derived from the blood of chronic carriers of the disease. Concerns regarding the possibility of transmitting HIV infection with the vaccine resulted in the development of a recombinant form of the vaccine in 1986. Current HBV vaccines contain highly antigenic proteins from the viral coat, which is known as hepatitis B surface antigen (HBsAg). Recombinant hepatitis vaccines contain no blood products and therefore do not represent a risk for HIV infection.

Because of the potential for occupational exposure, healthcare providers have a 10-fold increased risk of acquiring HBV. Dried HBV can remain infectious on an environmental surface for up to 1 week, and although needlestick injuries have the highest risk of infection (37–62%), the virus can gain entry via scratches, rashes, burns, or other disruptions of the mucosal surface. The CDC now recommends preexposure immunization against HBV infection for healthcare providers.

PROTOTYPE DRUG Hepatitis B Vaccine (Engerix-B, Recombivax HB)

Classification **Therapeutic:** Vaccine
Pharmacologic: Vaccine

Therapeutic Effects and Uses: The HBV vaccine is a noninfectious, highly immunogenic vaccine that provides immunity to HBV in 99% to 100% of patients when given in the recommended three-dose regimen. The effectiveness of the vaccine in producing immunity in adults declines with age. The vaccine is 98% effective in patients ages 20 to 29, 94% in patients ages 30 to 39, and 89% in those age 40 or older. The HBV vaccine may be administered in combination with hepatitis B immunoglobulin for postexposure prophylaxis or to prevent the perinatal transmission of the virus from mother to infant. The vaccine is indicated for immunity against all known subtypes of HBV. Indications for the HBV vaccine include the following (CDC, 2016a):

- All infants at birth
- All children younger than age 19 who have not been vaccinated
- Healthcare and public safety workers who are at risk for exposure to blood on the job and residents and staff of facilities for people with developmental disabilities
- People engaging in high-risk sexual practices: multiple sex partners, men who have sex with men, sex partners of infected individuals
- Those who inject drugs
- Patients with end-stage renal disease
- Travelers to regions with intermediate or high rates of HBV infection
- People with chronic liver disease (including those infected with the hepatitis C virus [HCV]), HIV, or diabetes.

Mechanism of Action: The HBV vaccine consists of HBsAg produced through recombinant DNA technology using yeast cells. Antibodies induced by the HBV vaccine decline over time and may require a booster dose for continued immunization.

Pharmacokinetics:

Route(s)	IM injection in the deltoid or anterolateral thigh in infants and small children
Absorption	Rapid, following IM injection
Distribution	Unknown
Primary metabolism	Unknown
Primary excretion	Unknown
Onset of action	Antibodies to HBV appear within 2 weeks
Duration of action	Immunity lasts 5–7 years

Adverse Effects: The most common adverse effects from HBV vaccination are pain at the injection site and mild to moderate fever. Approximately 15% of patients will experience systemic effects, usually fatigue, dizziness, fever, and headache. Children may experience irritability, fever, diarrhea, fatigue, weakness, diminished appetite, and rhinitis. Anaphylaxis is rare and is usually reported within a few hours after the vaccination. Guillain-Barré syndrome is a very rare adverse effect of the HBV vaccine.

Contraindications/Precautions: Known hypersensitivity to yeast or any component of the vaccine is an absolute contraindication. Patients who demonstrated severe hypersensitivity to the first dose should not receive subsequent doses. Although anaphylaxis is rare, proper

emergency equipment or facilities should be available. Patients with active infections or unexplained fever should delay use of the vaccine unless the health of the patient is endangered by withholding the vaccine. Caution should be exercised when administering the vaccine to patients with severe cardiopulmonary impairment. The vaccine should be given to pregnant or lactating women only if clearly needed to protect the health of the mother or child.

Drug Interactions: Hepatitis B immunoglobulin should not be administered in the same syringe or at the same site as the vaccine because it can impair the development of immunity from the vaccine. Patients receiving immunosuppressant drugs may require a higher dose of vaccine. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with this drug has not been reported.

Nursing Responsibilities: Key nursing implications for patients receiving hepatitis B vaccination are included in the Nursing Practice Application for Patients Receiving Immunizations.

Drugs Similar to Hepatitis B Vaccine (Engerix-B, Recombivax HB)

There are no other vaccines similar to the HBV vaccine.

Hepatitis A

Pathophysiology: Unlike HBV, which is mostly bloodborne, hepatitis A virus (HAV) is acquired by coming in contact with the stools of an infected individual. At highest risk for HAV infection are household contacts or sexual partners of infected individuals and travelers to regions of the world where HAV is endemic (Africa, South America, and most of Asia). Good personal hygiene and proper sanitation can prevent HAV infection. Children are at risk due to generally poor hygiene habits.

Approximately one third of the U.S. population has lifelong immunity to HAV based on a past infection. Symptoms associated with HAV infection are age dependent. In children less than 5 years old, 50% to 90% of infections are asymptomatic, whereas 70% to 95% of adults will exhibit symptoms. Signs and symptoms include elevation in the liver enzyme levels, jaundice, fatigue, anorexia, fever, dull abdominal pain, nausea, and vomiting. Symptoms are often mild, and most patients report the resolution of symptoms in several weeks. The disease is rarely fatal and normally produces no permanent hepatic impairment.

Immunization: Following the introduction of the HAV vaccine in 1995, the number of cases of HAV infection in the United States dropped dramatically. Current recommendations for hepatitis A vaccinations include all children at age 1 year, travelers to regions where HAV is endemic, illicit drug users, individuals with clotting factor disorders, people with chronic liver disease (including those with HBV and HCV infections), family and caregivers of recent adoptees from countries where HAV is common, and men who have sex with men (CDC, 2016c). Twinrix is a vaccine that protects against both HAV and HBV and is administered in three doses.

Given by the IM route, children should receive two doses: an initial vaccination at 12 months of age and a follow-up dose 6 to 12 months later. For individuals traveling to endemic regions, three doses may be given with 4 weeks between the three injections. This vaccine is highly immunogenic, with 95% to 100% of vaccinated individuals developing protective antibodies. Antibody coverage may last as long as 20 years following vaccination. Adverse effects of the HAV vaccine are mild and include soreness at the injection site, headache, anorexia, and fatigue.

Influenza

Pathophysiology: Influenza, or flu, is a respiratory disease spread by the three forms of the influenza virus: types A, B, and C. Influenza type A is the most dangerous and the primary focus for the annual development of a vaccine for the prevention of epidemic outbreaks. Influenza type A causes seasonal outbreaks during the winter months that are usually self-limiting but may lead to serious health consequences in patients who are debilitated, immunosuppressed, or who have chronic medical conditions. Influenza type A is also harbored in wild aquatic birds and is responsible for outbreaks of bird flu. Influenza types B and C are less common and generally do not cause epidemics or result in serious symptoms. The influenza viruses mutate at a rapid rate and change their antigenic appearance; almost every time the viral RNA replicates, a new mutant is created. Once an outbreak of influenza occurs, immunization is no longer effective and pharmacotherapy of the active infection may be initiated. Because treatment of influenza infection is minimally effective, the best approach for dealing with this infection is through prevention. The pharmacotherapy of influenza infection is presented in Chapter 54.

Immunization: The first influenza immunization took place in 1945 following a worldwide outbreak during World War II. Throughout the history of influenza immunization, the viral particles used for the inoculation have been incubated in chicken eggs, leading to an increased risk of anaphylaxis in patients with egg allergies. With the development of recombinant human DNA preparations, the risk of allergy has decreased.

The development of the annual influenza vaccine begins with a prediction on the part of scientists as to what

strains of the virus are most likely to appear that year. Each year one influenza vaccine is prepared that contains portions of the most likely strains of type A and type B. If their prediction is accurate, the vaccine will prevent 70% to 90% of flu cases; however, the effectiveness of the vaccine is significantly lower in some years.

Two types of influenza vaccines are available: trivalent and quadrivalent. The trivalent inactivated influenza vaccine (TiIV) is a subcutaneous formulation that contains protection against two viruses (H1N1 and H3N2). The trivalent vaccine is approved for patients older than 6 months, including healthy people, women who anticipate being pregnant during the flu season, and those with chronic medical conditions. In 2016, a higher dose formulation became available that helps create a stronger immune system in those 65 years of age and older.

The quadrivalent vaccine protects against two influenza type A viruses as well as two type B viruses. It comes in two forms: an intradermal form that is injected under the skin for individuals ages 18 to 64, and a form containing the virus grown in culture for those ages 4 and older.

Annual influenza vaccination is recommended for the following groups:

- All children ages 6 through 59 months
- All individuals ages 50 and older
- Residents of nursing homes or long-term care facilities
- People who have extreme obesity (BMI greater than 40)
- Adults and children who have chronic conditions such as asthma, diabetes, or heart disease
- Anyone whose immune system is compromised due to HIV or AIDS, high-dose corticosteroid therapy, or cancer chemotherapy
- Women who are or will be pregnant during the influenza season
- Healthcare providers
- Household contacts (including children) and caregivers of individuals at high risk of acquiring influenza.

The most common adverse effects of the subcutaneous vaccine are soreness and redness at the injection site. Nasal congestion, headache, and sore throat are common adverse effects of the nasal spray vaccine. About 1% of patients may experience fever, chills, muscle aches, and other symptoms of influenza that last 1 to 2 days. Serious adverse effects are rare. Caution should be used in patients who are allergic to eggs or mercury, both of which are sometimes used as preservatives.

Rabies

Pathophysiology: Rabies is caused by a virus that can invade the nervous system of most mammals. The rabies virus is carried in saliva and is passed to humans through animal bites from infected dogs, coyotes, wolves, foxes, raccoons, skunks, and bats. In unvaccinated individuals, the mortality rate is nearly 100%.

Following the bite of an infected animal, the incubation period for rabies infection is long, from 20 to 60 days. When possible, the biting animal is confined and examined for rabies infection. Because the infection is always fatal if untreated, therapy is immediately implemented while waiting for the results of animal testing.

Pain or paresthesia surrounding the bite is reported by most patients with rabies. Other symptoms include fever, headache, malaise, irritability, anxiety, and insomnia. Short periods of agitation, aggressiveness, hyperactivity, and disorientation are followed by normal behavior. Nuchal rigidity, seizures, bizarre behavior, and hydrophobia indicate a progression of the disease; if untreated, rabies will progress to cardiac or respiratory arrest or paralysis, requiring mechanical ventilation. Death usually occurs within 10 days of the onset of symptoms.

Immunization: preexposure and postexposure: Prevention of rabies may be accomplished through vaccination. Although the vaccine is effective, few people are administered preexposure immunization because of the very small risk of coming into contact with a rabid animal during their lifetime. However, this immunization is offered to individuals with potential exposure to rabid animals, such as animal handlers or veterinarians, and to travelers to countries where rabies is prevalent. Cave explorers often receive prophylactic treatment because of their potential exposure to rabid bats. Preexposure immunization includes three inoculations.

Once a potential exposure to rabies is reported, the patient should immediately receive postexposure vaccination. The immune response to dead or attenuated organisms in a rabies vaccine takes approximately 2 weeks to develop, which is well within the incubation period of rabies. Patients receive one dose of rabies immunoglobulin, which offers immediate protection. Five doses of rabies vaccine are then administered over a 28-day period. If instituted promptly, postexposure vaccination is very successful. If the biting animal is shown not to have rabies, the sequence of vaccinations may be discontinued.

The most common adverse effects of the rabies vaccine are pain and redness at the injection site. Mild, transient flulike symptoms may occur. Pregnant women may receive the vaccine if exposure to the rabies virus is suspected.

Measles, Mumps, and Rubella

Measles (rubeola) pathophysiology: The measles virus, *Morbillivirus*, is one of the most contagious viral pathogens, being readily transmitted by airborne particles and respiratory secretions. Because humans are the only known reservoir for the virus, routine immunization has

eliminated measles as a common childhood disease in the United States. Measles is still widespread in other countries and occasional outbreaks across the United States emphasize the importance of continued MMR immunizations.

Symptoms of measles infection appear 10 to 12 days following airborne exposure and begin with nonspecific cough, malaise, and low-grade fever. The fever can subsequently spike to as high as 40.6°C (105°F). A rash appears first on the oral mucosa but then develops into a reddened, raised rash on the face, hairline, ears, and neck, spreading to the trunk and extremities. The rash lasts approximately 1 week and then fades and disappears. Individuals are considered to be infectious 4 days prior to and after rash appearance. In developing countries, measles infection carries a mortality rate as high as 2% to 15%.

Mumps pathophysiology: Mumps is a viral infection in the parotid salivary glands that is transmitted by exposure to contaminated saliva. Symptoms develop 16 to 18 days after exposure, resulting in mild fever, headache, anorexia, and malaise. The fever usually lasts 1 to 6 days but the swelling in the parotid glands may continue for 10 days or more. The infection is usually self-limiting and mortality is rare. Complications of mumps include orchitis (swelling of the testes) in approximately 37% of infected, postpubescent boys and deafness in children.

Rubella (German measles) pathophysiology: Rubella, also called German measles, is a viral infection that produces mild symptoms in most people. The rubella virus is transmitted by infected aerosol droplets. Symptoms include enlarged cervical lymph nodes, mild fever, and malaise, followed by a raised rash 14 to 17 days later.

The major concerns with rubella are the consequences of maternal infection during pregnancy. Infection occurring during the first 12 weeks of pregnancy carries the greatest risk of fetal defects. Rubella infection rapidly spreads to all fetal organ systems and may cause a wide variety of consequences. The most frequently described are congenital cataracts and blindness from retinal destruction, heart disease, and deafness in infants. Since the initiation of routine rubella immunization and maternal antibody screening, the incidence of rubella infection of the fetus or newborn has declined to 0.01 per 10,000 pregnancies in the United States. A single, subcutaneous rubella vaccine made from attenuated (live) virus grown in human tissue cultures is available and usually very well tolerated.

Immunization: The MMR vaccine has incorporated live or attenuated viruses since its development in the 1960s, and widespread immunization has led to a 98% decrease in the incidences of these viral infections. Current recommendations include a two-dose subcutaneous immunization, with the first given at 12 to 15 months of age and the second at 4 to 6 years of age. The overall immunity rate for MMR vaccination is 92% to 95%. In 2005, the FDA approved the addition of varicella vaccine to the combination, which is known as MMRV (ProQuad).

A single dose of MMR vaccine is recommended for those individuals born after 1957 without contraindication or past history of measles infection or positive immunity. A second dose of MMR is recommended in the following situations: epidemic outbreak or exposure to measles infection, vaccination with an unknown vaccine between 1963 and 1967 or vaccination with killed organism, healthcare workers or those traveling internationally, or nonimmune students in postsecondary educational settings.

Although generally well tolerated, several groups are usually excluded from vaccination:

- Pregnant patients or women planning conception within 3 months of vaccination because the live or attenuated rubella virus poses a hypothetical risk of infection with subsequent congenital malformations.
- Patients who are immunosuppressed; however, MMR can be given to individuals living in the same setting with asymptomatic HIV disease and individuals with mild immunosuppression.
- People reporting an allergy to neomycin or gelatin because the vaccine contains these substances. Those reporting egg allergy have a very low risk of allergic reaction but it is recommended that these patients be observed for 90 minutes following immunization.

Adverse reactions to MMR vaccination are minimal and include fever and lymphadenopathy, rare encephalitis (1 occurrence per 1 million vaccinations), and arthralgia in adults. MMR is now available in an aerosolized formulation that has fewer associated adverse effects and an improved immunogenicity as compared to the injected forms.

Polio

Pathophysiology: Poliomyelitis was the leading cause of permanent disability in the era just prior to vaccines. Highly contagious polio epidemics in the 1800s and early

CONNECTIONS: Patient Safety

Adequate Patient History to Avoid Adverse Effects

A nurse new to working in the outpatient clinic is preparing an MMR injection for a patient who has just moved to the United States and was not vaccinated previously. The nurse-mentor assigned to the new nurse asks if the patient's history was taken and the nurse replies, "Yes, and there is no history of vaccination." What else should be assessed in the history before administering the MMR injection?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

1900s prompted the search for, and eventual discovery of, vaccines. The virus replicates in the gastrointestinal (GI) tract and is spread by the oral–fecal route via contaminated food and water.

Over 90% of those exposed to the poliovirus are asymptomatic. Rarely (less than 1%), the virus reaches the motor tracts of the spinal cord, where it leads to the development of flaccid muscle paralysis of the infected motor cells. On rare occasions the respiratory muscles are involved, leading to the need for artificial ventilation. Global immunization has made the disease extremely rare and global eradication is possible.

Immunization: Two forms of vaccination are currently used for the prevention of poliovirus infection. Developed by Dr. Jonas Salk, the inactivated polio vaccine (IPV) was first marketed in 1955. In 1978 it was reformulated to be more potent. The oral polio vaccine (OPV) was developed in the early 1960s and was used extensively until vaccine-associated paralytic polio (VAPP) was found to be a rare, though devastating, adverse effect. The OPV is still widely used in regions of the world where polio is endemic due to its ease of administration. The OPV also prevents the intestinal spread of the virus, which is of critical importance in areas of the world that have poor sanitation.

Since 2000, the IPV has been exclusively used in the United States for the immunization of infants. Children get four doses of IPV, at 2 months, 4 months, 12 months, and a booster dose at 4 to 6 years. IPV is available as a single suspension or in combination with DTaP, hepatitis B, or influenza vaccines. Routine IM administration of IPV results in redness, swelling, and tenderness at the administration site. Children receiving the complete IPV regimen are provided 99% to 100% lifelong immunity.

Varicella Zoster

Pathophysiology: Infection by the varicella zoster virus (VZV) leads to the development of two very different diseases. The initial outbreak of VZV, known as chickenpox (varicella), generally occurs during childhood. Following the initial infection, the virus becomes dormant for 30 to 40 years in nerve roots until it reactivates to cause herpes zoster (HZ), or shingles.

The initial VZV infection is transmitted through inhaled droplets or by direct contact with infectious skin lesions. The virus replicates in the local lymph nodes for several days and then becomes bloodborne. By day 10 to 14, a blistered rash appears, with new lesions opening, draining, and crusting within 24 hours. Intense itching may lead to secondary bacterial infections and permanent scarring. General illness is common in individuals for 5 to 7 days with fever, malaise, and anorexia. Adults with chickenpox have more intense symptoms than children and have a 7 times greater risk of encephalitis. Furthermore, women who acquire VZV during pregnancy have a small risk of passing the infection to the fetus, resulting in birth defects.

Following the initial infection, the virus migrates to the spinal nerves, where it may remain dormant for the life of the individual. In about 20% of patients, however, the virus becomes reactivated and causes an HZ infection, or **shingles**, usually after age 50; this increases to approximately 50% for individuals over the age of 85. Shingles often begins with a burning or tingling pain, numbness, or itch in one particular location on the surface of the body. After several days or a week, fluid-filled blisters, similar to chickenpox, appear in one area of the body. Shingles lesions can be very painful and may require up to a month for resolution. In immunocompromised individuals the infection may be prolonged, taking 3 to 4 weeks for lesion scabbing and several months for complete resolution. Up to 30% of patients with shingles experience a serious form of the disease called **postherpetic neuralgia** in which the pain lasts for years. In about 15% of patients with shingles, the virus infects the eye and can cause blindness.

Antiviral drugs such as acyclovir (Zovirax) are sometimes administered to reduce the severity and duration of a shingles attack and postherpetic neuralgia. Other treatments for postherpetic neuralgia include corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs).

Immunization: An attenuated or live VZV vaccine (Varivax) has been used in the United States since 1995, and it is estimated that widespread vaccination has reduced the incidence of varicella infection by more than 70%. In 2006, new standards were adopted with the following recommendations:

- Implementation of a routine two-dose varicella vaccination schedule for children. The first dose is administered at ages 12 to 15 months and the second dose at age 4 to 6 years.
- Routine vaccination of all healthy individuals over age 13, without evidence of immunity.
- Prenatal assessment and postpartum vaccination.
- Expanding the use of the varicella vaccine for children infected with HIV.
- Establishing middle school, high school, and college entry vaccination requirements.

The effectiveness of the vaccine varies widely, and 10% to 15% of immunized individuals will still acquire the infection, which is a condition known as breakthrough varicella. Breakthrough varicella infection produces milder symptoms compared to those in nonimmunized patients.

The CDC recommends that all people receive the shingles vaccine (Zostavax) at age 60. The shingles vaccine contains a live or attenuated form of the virus and is 60%

effective at preventing the reactivation of VZV. The shingles vaccine is essentially a booster of the VZV vaccine administered to prevent chickenpox. It is not effective at treating symptoms of shingles or postherpetic neuralgia once they develop.

Adverse effects associated with VZV vaccine include low-grade fever, tenderness at the injection site, and rash localized to the injection site. The vaccine should be used with caution in individuals with a history of allergy to eggs or gelatin. Caution should be exercised with the use of this immunization in pregnant or breastfeeding women. Although there have been no documented problems with receiving the immunization while pregnant, VZV has been linked to the development of birth defects. Finally the administration of this vaccine in immunosuppressed patients may increase the incidence of adverse effects or cause a decrease in the developed immunity.

PharmFACT

Approximately 95% of adults in the United States have antibodies to the varicella zoster virus, indicating prior exposure to and reactivation of this pathogen. Incidence of reactivation increases with advancing age due to declining immunity (Janniger, 2016).

Human Papillomavirus

Pathogenesis: Genital HPV, the most common sexually transmitted infection (STI) in the United States, is associated with a higher risk of cervical cancer, which is a significant cause of cancer deaths in women. Although there are over 100 different forms of HPV, only 7 are associated with cervical cancer. HPV is also associated with a higher risk of other types of cancer, including vaginal, vulvar, and anal. Some types of HPV are responsible for causing genital warts. The virus may infect both males and females, and it may be transmitted from mother to child during vaginal delivery.

Spread through sexual contact, HPV infection may be asymptomatic or lead to the development of a low-grade infection that resolves spontaneously in individuals with a healthy immune system. A high-grade HPV infection may lead to the development of dysplasia, a precancerous change in the cervical cells that is directly related to the viral infection.

Immunization: The HPV vaccine has been created with virus-like particles using recombinant DNA technology. Great caution was necessary in the development of this vaccine because the HPV contains oncogenes, which are modified forms of a gene that are believed to lead to a cancerous transformation. Because of the potential cancer risk, the HPV vaccine is a noninfectious, virus-like particle (VLP) containing only proteins from the coat of the virus, rather than a complete attenuated virus. The HPV vaccine is intended to prevent cervical, vulvar, and vaginal cancer and certain precancerous lesions in women. In men and women, the HPV vaccine is indicated to prevent genital warts caused by HPV. It is not effective against existing cancers or genital diseases not caused by HPV.

CONNECTIONS: Preparing for Advanced Practice

The Need for the HPV Vaccination

Case

James and Janice are 15-year-old twins who are freshman in high school and live with their parents. They present to the community clinic for a sports physical. They both are excited to try out for their school basketball team.

While taking their health history separately, you determine that neither twin has much knowledge about STIs. They understand that engaging in sex can result in pregnancy, but do not know much more about STIs. They show very little understanding of how STIs are contracted and how they can be avoided. When asked about what they learned in high school health class or at home about HPV, both said they had never heard of it or that it could cause cancer. You individually educated the twins about HPV and the risks and the benefits of the HPV vaccine. Should both Janice and James be encouraged to get the HPV vaccine?

Discussion

The CDC recommends HPV vaccination for boys and girls at age 11 or 12. HPV is the most common STI in the United States and, according to the CDC, 50% of all sexually active men and women will get it at some point in their lives. Most HPV infections do not cause any symptoms but some may result in cervical cancer, the second-leading cause of cancer deaths among women worldwide. Men and women can contract and transmit HPV to sexual partners.

Common cancers caused by HPV infections include cancers of the anus and rectum, mouth or throat (oropharynx), and penis (Osazuwa-Peters, 2013). The oropharynx is uniquely susceptible to HPV. By the year 2020, the annual number of cases of HPV-associated oropharyngeal cancer is projected to outnumber the cases of HPV-associated cervical cancer in the United States and has been deemed an epidemic of our time (Lloyd, 2015).

Nurses and nurse practitioners have been identified by many young adults as approachable and informative resources regarding HPV vaccination and STIs in general (Bellia-Weiss, Parsons, Sebach, & Rockelli, 2013). More information about teen vaccines can be found at the CDC website.

The CDC recommends the routine vaccination of boys and girls at 11 to 12 years of age. The HPV vaccine is administered as a two-dose series of IM injections with the second dose given 6 to 12 months after the first. The vaccine has close to 100% effectiveness in preventing HPV infection and appears to offer long-lasting protection. For those receiving their first vaccination at age 15 years or older, a three-dose series is recommended. Mild adverse effects include pain, swelling, and redness at the injection site.

PharmFACT

About 79 million Americans are infected with HPV and 14 million new infections occur every year (CDC, 2017).

Rotavirus

Pathophysiology: Approximately 680,000 children die worldwide each year from rotavirus infection, mostly in developing countries. Although the virus rarely causes death in the United States, it is estimated that nearly every child is infected by age 5 and that most will experience gastroenteritis, resulting in severe diarrhea and dehydration. Viral replication of the rotavirus occurs only in mature red blood cells found in the tips of the intestinal villi, leading to a strictly oral–fecal means of viral transmission.

Immunization: Rotavirus vaccines received approval in 2006 (RotaTeq) and 2008 (Rotarix) for routine immunization in infants. The CDC recommends rotavirus vaccine be administered before 15 weeks of age for the prevention of gastroenteritis. The vaccine has been shown to reduce the overall incidence of gastroenteritis by 74% and of hospitalization due to the virus by 96%. No serious adverse effects are associated with immunization with RotaTeq, but mild cases of diarrhea and vomiting occur in small numbers of patients receiving the drug.

Passive Immunity

43.7 Antibodies are administered to provide passive immunity.

Passive immunization is very different from active immunization. Whereas active immunity requires mobilization of the patient's immune response, which leads to the development of memory cells, passive immunity is the administration of preformed antibodies (immunoglobulins). During passive immunity the immune system is not activated and memory cells are not produced.

Passive immunization is typically used to provide immediate protection against a recent infection, a potential infection, or a disease in progress. Several examples serve to illustrate the benefits of passive immunization:

- Someone has just been bitten by a potentially rabid dog. It will take several days to determine if the dog is infected with rabies.
- An individual has been in a motorcycle crash and sustained serious trauma. He has never had a tetanus vaccination.
- A student nurse has learned that she has been exposed to blood from a patient with confirmed HBV. She has not been vaccinated for HBV.

What do these three scenarios have in common? First, immediate treatment is indicated because the consequences of infection can be serious or fatal. The disease would have the opportunity to create serious illness before a vaccine activates an immune response. In these cases, antibodies against the infection can be administered to provide immediate prevention against rabies, tetanus, or HBV infection. Antibodies are sometimes given concurrently with the vaccine series to provide complete immunity against the disease. For example, following an exposure to rabies the patient is given rabies immunoglobulin (RI) as well as the rabies vaccine.

The preceding scenarios illustrate a second message of importance to the nurse. If the patients had kept their tetanus and HBV vaccinations up to date, they would have developed active immunity to these pathogens and there would be no need to provide passive immunity.

A second indication for the use of passive immunity is for situations where the activation of the immune system and the development of memory are not desirable. In this case, the individual is given the antibodies against the foreign agent and the immune system does not mount a response. The administration of RhoGAM is an example of this type of indication.

Table 43.3 lists selected immunoglobulin preparations. Pharmacotherapy Illustrated 43.1 shows the development of immunity through vaccines or the administration of antibodies.

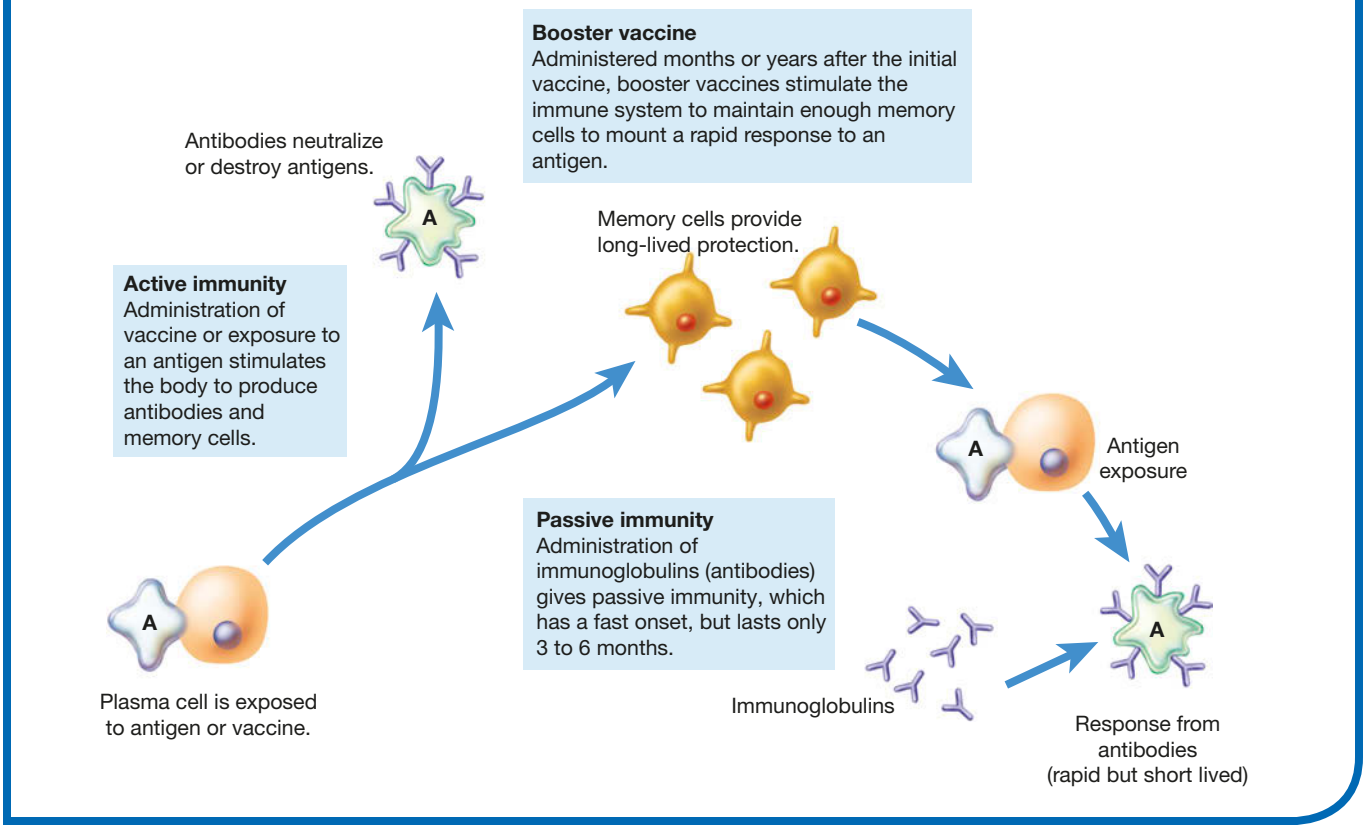
PROTOTYPE DRUG **Rho(D) Immune Globulin (RhoGAM)**

Classification **Therapeutic:** Immunizing agent (passive)
Pharmacologic: Antibody, immunoglobulin

Therapeutic Effects and Uses: Erythrocytes contain two types of surface antigens that are used to designate the blood type. The first identifier is ABO; the presence or absence of antigen A and antigen B will determine the blood type as A, B, AB, or O. A second identifier on the cell membrane of the red blood cell (RBC) is the Rhesus factor, or Rh antigen. If the antigen is present, the individual is said to be Rh positive (Rh^+) and if it is missing, Rh negative (Rh^-); 85% of individuals living in North America are Rh positive.

Table 43.3 Immunoglobulin Preparations

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
cytomegalovirus immune globulin (CytoGam)	IV: 150 mg/kg within 72 h of transplantation; then 100 mg/kg for 2, 4, 6, and 8 wk post-transplant; then 50 mg/kg for 12 and 16 wk post-transplant	*Local reactions at the injection site (pain, erythema, myalgia), flulike symptoms (malaise, fever, chills), headache, joint stiffness* Anaphylaxis, nephrotoxicity, thrombosis
hepatitis B immune globulin (HBIG)	IM: 0.06 mL/kg as soon as possible after exposure, preferably within 24 h, but no later than 7 days; repeat 28–30 days after exposure	
immune globulin infusion and hyaluronidase (HyQvia)	Subcutaneous: Start with 7.5 g and increase over 7 wk to 30 g, then 300–600 mg/kg at 3- to 4-wk intervals	
immune globulin intravenous (Carimune, Gammagard, IGIV, Octagam)	IV: 100–400 mg/kg per month IM: 1.2 mL/kg followed by 0.6 mL/kg q2–4wk	
rabies immune globulin (BayRab, HyperRAB, Imogam Rabies-HT, Kedrab)	IM: 20 units/kg as a single dose with rabies vaccine	
Rho(D) immune globulin (RhoGAM)	IM/IV: 1 vial or 300 mcg at 28 wk; followed by 1 vial of minidose or 120 mcg within 72 h of delivery if infant is Rh^+	
tetanus immune globulin (BayTet, HyperTET, HyperTET S/D)	IM: 250 units for prophylaxis	
varicella zoster immune globulin (Varizig)	IM: 62.5–625 international units	



Note: Italics indicate common adverse effects. Underline indicates serious adverse effects.

Erythroblastosis fetalis (EF), or hemolytic disease of the newborn, is a disorder that was first described in 1940 and is caused by an Rh incompatibility between the mother and her fetus. This condition can occur only if the mother is Rh negative.

EF does not occur with the first pregnancy because the two types of RBC (Rh^- mother and Rh^+ child) are separated by the placenta and the blood is not physically exchanged. At birth, however, their blood mixes and the mother's immune system reacts by producing antibodies

Pharmacotherapy Illustrated 43.1

Mechanisms of Active and Passive Immunity

against the foreign Rh^+ antigen. The presence of circulating antibodies against the Rh antigen creates a potential risk for an Rh incompatibility in future pregnancies. If in a subsequent pregnancy the fetus is Rh^+, the mother's antibodies against the Rh^+ antigen will cross the placenta and destroy erythrocytes in the fetus. This may lead to a severe anemia or brain damage in the developing fetus and even fetal death.

Rho immunoglobulins are obtained from filtered human serum for the prevention of Rh incompatibility in Rh^- women. This drug has been used to provide passive immunity since 1968 and has significantly reduced the incidence of EF. Administration of Rho immunoglobulins will prevent the mother from forming Rh antibodies, so that there will be no risk of incompatibility in subsequent pregnancies. Rho(D) immune globulin prophylaxis is not indicated if either the father or the fetus is Rho(D) negative.

The administration of RhoGAM is recommended:

- At 28 weeks gestation
- Within 72 hours postpartum
- Within 3 hours of spontaneous or induced pregnancy termination
- Following any event that could lead to transplacental hemorrhage (such as amniocentesis, chorionic villi sampling, or abdominal trauma).

Mechanism of Action: Rho(D) antibodies act by suppressing the immune response of Rh^- mothers to Rh^+ fetuses or newborns. Sensitization to Rho(D)-positive blood in future pregnancies is therefore less likely to occur.

Pharmacokinetics:

Route(s)	IM, IV
Absorption	Unknown
Distribution	Unknown
Primary metabolism	Unknown
Primary excretion	Unknown
Onset of action	Peak antibody levels: 2 h (IV) or 5–10 days (IM)
Duration of action	Half-life: 24–30 days

Adverse Effects: The most commonly reported adverse reactions include local swelling, redness, and mild pain at the injection site. A small number of patients experience low-grade fever. Hypersensitivity reactions are rare and may include hives, generalized urticaria, tightness of the chest, wheezing, hypotension, and anaphylaxis. Also rarely reported are anemia, anorexia, bruising, disseminated intravascular coagulation (DIC), dyspnea, dysuria, edema, hematuria, hemolysis, hypertension, increased risk of bleeding, lower back pain, malaise, nausea, polydipsia, vomiting, and weight gain.

Contraindications/Precautions: This drug is contraindicated in individuals with a history of hypersensitivity reaction to human immunoglobulin injection. Rho(D) antibodies are also contraindicated in patients having immunoglobulin A (IgA) deficiencies or in patients with severe anemia and should be used with caution in patients who have DIC, hemolysis, renal disease, and splenectomy.

Drug Interactions: No drug interactions have been reported. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with this drug has not been reported.

Nursing Responsibilities: Key nursing implications for patients receiving Rho(D) immune globulin are included in the Nursing Practice Application for Patients Receiving Immunizations.

Drugs Similar to Rho(D) Immune Globulin (RhoGAM)

Other immunoglobulins include cytomegalovirus immune globulin, hepatitis B immune globulin, and IV immune globulin.

Cytomegalovirus immune globulin (CytoGam): About half of the U.S. adult population has been exposed to cytomegalovirus (CMV). Few people, however, have experienced symptoms because healthy immune systems prevent symptomatic, active infections. When donating organs or tissues, CMV may be inadvertently transferred to a transplant recipient with a suppressed immune system. Cytomegalovirus immune globulin (CMV-IGIV) is recommended for the prevention of CMV infections in at-risk individuals receiving kidney, liver, pancreas, and heart transplants. The drug can lower the incidence of serious CMV-associated disease by 50%. Current dosage recommendations include the IV administration of seven doses, beginning within 72 hours of the receipt of the organ and ending 30 days later. The most common adverse effects are minor and include flushing, chills, muscle cramps, back pain, fever, nausea, vomiting, arthralgia, and wheezing.

Hepatitis B immune globulin (HBIG): The goal of HBIG administration is to prevent the transmission of HBV to those who have been exposed to the virus. The administration of HBIG is recommended for the following instances:

- Nonimmunized individuals who have had acute and significant exposure to hepatitis B–infected blood. This includes unintentional needlestick, oral ingestion, or direct mucous membrane contact with infected

blood or blood products. One dose is usually given immediately after exposure and another dose 1 month later. The administration of HBIG is effective in the prevention of clinical hepatitis B infection in approximately 75% of individuals who are treated.

- Infants born to women infected with HBV. These infants should receive HBIG and start the HBV vaccine series within 12 hours of birth. This regimen is 70% to 90% effective in preventing infection in the infant.
- Sexual partners of HBV-infected patients. A single dose of HBIG is 75% effective at preventing HBV infection if the drug is administered within 2 weeks of sexual contact.
- Household exposure of infants less than 12 months of age who are born to a mother or have a primary caregiver who is infected with HBV. These infants should receive HBIG and start the HBV vaccine series before 12 months of age.

The administration of HBIG is effective in the prevention of clinical hepatitis B infection in approximately 75% of individuals who are treated, but this immune protection is temporary, lasting approximately 2 to 3 months. HBIG is usually given concurrently (different IM site) with hepatitis immunization in infants born of hepatitis B–infected mothers. Adverse reactions to HBIG are rare and include injection-site reactions, such as tenderness, redness, and swelling. Hypersensitivity reactions have also been reported. HBIG is provided in a prefilled, single-dose syringe in either pediatric or adult preparations.

Immune globulin intravenous (Carimune, Gammagard, IGIV, Octagam): Immune globulin contains pooled antibodies obtained from human plasma that is used to provide passive immunity following exposure to an organism for which no active immunization exists, when there is inadequate time to develop active immunity, and as replacement therapy for those with antibody deficiencies. IGIV contains 95% or more immunoglobulin G (IgG). The passive immunity induced by IGIV is capable of attenuating or preventing a wide range of infectious diseases and adverse effects from toxins, mycoplasma, parasites, bacteria, and viruses. IGIV may be thought of as a "generic" treatment for balancing immune systems. It contains components that strengthen immune function as well as substances that can suppress overactive immune systems. Disease protection lasts for 3 weeks or longer. Because this drug contains antibodies to live viruses, active vaccinations should not be given until 3 to 5 months after IGIV has been administered.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Immunizations

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including previous history of the actual disease (e.g., chickenpox), hepatic, renal, cardiovascular, neurologic, or autoimmune disease, HIV infection, fever or active infections, pregnancy or breastfeeding, previous allergic response to immunizations or to products contained within immunization (e.g., sensitivity to yeast, eggs, or albumin products). Obtain a drug history, especially the use of immunosuppressants or corticosteroids.
- Obtain an immunization history and any unusual reactions or responses.
- Obtain baseline vital signs, especially temperature.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], platelets, electrolytes, titers, hepatic and renal tests).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for patient adherence to the recommended immunization schedule (e.g., need for repeated immunizations, boosters in adults).
- Continue periodic monitoring of CBC, hepatic and renal function studies as appropriate to the type of immunizing agent.
- Assess vital signs, especially temperature.
- Assess for and immediately report adverse effects: fever, dizziness, confusion, muscle weakness, tachycardia, hypotension, syncope, dyspnea, pulmonary congestion, skin rashes, bruising or bleeding, anaphylactic reactions.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (The patient should adhere to the recommended immunization schedule. Periodic titers may be needed to confirm immunity, especially in individuals who are over age 60 or those who are immunosuppressed.)	• Teach the patient, family, or caregivers to keep vaccination records, to copy records if needed for school or work situations but retain the originals, and to remain current with required immunizations. • Encourage older adults to consult with the healthcare provider to arrange having titers drawn to confirm immunity.
• For patients considering overseas travel, obtain current immunization recommendations for the destination country. (Current recommendations may be found on the CDC Travelers' Health website.)	• Teach the patient to consult the CDC Travelers' Health website before planning overseas travel and to consult with the healthcare provider about risks and required immunizations.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature, and neurologic status. (Immunizations may cause dermatologic, cardiovascular, and neurologic adverse effects. Increase in temperature, localized ulcerations, signs of infection at the injection site, tachycardia, palpitations, dizziness, or changes in level of consciousness may indicate significant adverse effects.) • Report all significant adverse effects to the healthcare provider for reporting to VAERS.	• Teach the patient to immediately report any fever over 38°C (101°F) or as instructed by the healthcare provider, changes in consciousness such as drowsiness or disorientation, dyspnea, tachycardia, or palpitations.
• Treat minor adverse effects symptomatically. (Acetaminophen or the drug as ordered by the healthcare provider for low-grade fevers of less than 38°C [101°F], for localized tenderness, or for minor arthralgias and malaise, and cool compresses to the injection site may help alleviate malaise, fever, or injection-site soreness.)	• Teach the patient to treat minor symptoms as needed but to immediately report any adverse effects as noted above.
• **Lifespan and Diverse Patients:** Assess for the possibility of pregnancy, previous history of organ transplantation, significantly immunocompromised patients at home, e.g., from chemotherapy, before giving live virus immunizations. (Some live vaccinations continue to be shed from the patient in the postvaccination period and may be transmitted to immunocompromised patients in the home environment. Pregnancy is a contraindication for vaccination with live viruses, and women who become pregnant within 3 months of immunization with a live vaccine should consult their healthcare provider. For religious or other reasons, some patients may refuse to accept administration of any component derived from human blood or serum, including Rho[D] immune globulin.)	• Teach the patient to alert the healthcare provider to any home situation that may require deferral of live vaccinations before the vaccination is given. Women who are pregnant or who may become pregnant within the first 3 months after vaccination should return to the healthcare provider for follow-up. • Encourage the patient with concerns about vaccination, including those with components derived from human blood or serum, to consult with the healthcare provider in order to make an educated choice about accepting or refusing the drug.
• Avoid or defer immunizations in any patient with a fever, autoimmune disease, or who take corticosteroids. (Immune response to the vaccine may result in less than the desired immunity or an increased risk of adverse effects.)	• Explain to the patient the need to defer vaccinations under certain conditions. Ensure that follow-up appointments are made as appropriate to maintain currency with immunizations.
• Assess patients for previous use of bacillus Calmette-Guérin (BCG) vaccine and consult with the healthcare provider before giving purified protein derivative (PPD) skin testing for TB. (BCG stimulates immunity to the tuberculin, and recent vaccination may cause an adverse reaction to PPD injection or result in a false-positive reaction. Other testing may be warranted.)	• Teach the patient that previous use of BCG may result in a false-positive TB test or an unusual reaction to the PPD test, and that other testing may be required to confirm or refute current infection.
Patient understanding of drug therapy: • Use opportunities during administration of immunizations and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate scheduling, what adverse effects to observe for and when to report them.

Understanding Chapter 43

Key Concepts Summary

43.1 The eradication of smallpox was a great triumph in modern medicine.

43.2 Vaccines are used to activate the immune system for the purpose of disease prevention.

43.3 Four traditional methods are used to produce vaccines.

43.4 Vaccines should be administered by an established schedule with precautions taken for patients who are immunosuppressed or pregnant.

43.5 Active immunity can be induced to prevent bacterial infections.

43.6 Effective vaccines that prevent viral infections have been developed.

43.7 Antibodies are administered to provide passive immunity.

CASE STUDY: Making the Patient Connection

Remember the patient "Samantha Abbott" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Mr. and Mrs. Abbott arrive in the office where you work with their 4-month-old infant, Samantha, for her checkup. She is scheduled to receive the following immunizations today: DTaP, Hib, PCV, and IPV. Samantha's mother states, "I don't think these immunizations are necessary. Don't these shots usually make children sick?"

As first-time parents, Mr. and Mrs. Abbott are new to the experience of childhood immunizations and require careful teaching. While obtaining her history, you find that 4-month-old Samantha has been doing well and is in the 90th percentile for height and 89th percentile for weight. She has achieved the developmental milestones for her age, is bright, and interacts well with her environment.

Critical Thinking Questions

1. What information should you obtain from the Abbotts about Samantha's first response to immunization?
2. Why is it important to discuss the potential adverse effects of vaccines with Samantha's parents?
3. What educational information should be given to the Abbotts?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

As a nurse working in the intensive care unit, today you are assigned to care for a critically ill patient who is known to be HIV positive and hepatitis B and C positive. You are cleaning up after assisting a first-year resident with the insertion of a central line and, as you are putting the disposable drapes into the trash, you feel a sharp pain in your right hand. As you pull your hand away you see a needle pushed through the glove into your hand. You report the incident to your supervisor and report to the emergency department (ED) per exposure protocol.

The ED physician orders you to have antibody testing for anti-HBsAg, to have baseline HIV testing, and to receive gamma globulin and antiviral prophylaxis.

1. What is the rationale for the HBV testing?
2. What is the rationale for the HIV testing?
3. Why is gamma globulin ordered?
4. Why is antiviral prophylaxis appropriate?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Mary is a 4-month-old infant who is brought to the clinic for her first checkup. Her mother tells the nurse that the child has never been ill. Which factor would the nurse consider most significant in assessing the baby's likelihood of receiving immunizations?
    1. Allergies to previously administered medications
    2. Mother's preconceptions and reservations relating to vaccines
    3. Maternal and paternal allergies or reactions to vaccine administration
    4. The nurse's knowledge of the recommended pediatric immunization schedule
2. The nurse is preparing to administer an MMR vaccination to a 15-month-old child. What would cause the nurse to hold the injection and recheck this order with the provider?
    1. The mother tells the nurse that the family will be going to the beach for the next few weeks.
    2. The mother states that she was told that she had a reaction to the injection when she was a child.
    3. The mother tells the nurse that her husband is having chemotherapy for Hodgkin's lymphoma.
    4. The mother tells the nurse that the child's older brother is home with a cold virus.

3. A 7-year-old girl, who was bitten by a stray dog, is treated in the emergency department. The dog has not been tested to rule out rabies. The nurse will anticipate that this patient will receive which immunizations? (Select all that apply.)
   1. Tetanus toxoid
   2. DTaP vaccine
   3. Rabies immunoglobulin
   4. Rabies vaccine
   5. Rabies toxoid

4. The nurse determines that the patient understands the teaching given for care required after receiving a tetanus toxoid injection when the patient states:
   1. "I will keep my arm still for the next 24 hours to give the vaccine time to absorb."
   2. "I will limit my fluid intake for the next 8 hours in case I have nausea."
   3. "I will avoid crowds and people with viruses for the next 7 days."
   4. "I will take some acetaminophen (Tylenol) or ibuprofen (Advil) if my arm is sore."

5. The occupational health nurse will be administering hepatitis B vaccine to a new employee. Which assessment finding discovered by the nurse would necessitate withholding the injection? The patient is:
   1. A two-pack-per-day smoker.
   2. Known to have transient hypertension.
   3. Allergic to yeast and yeast products.
   4. Frightened by needles and injections.

6. A postpartum patient received Rho(D) immune globulin (RhoGAM) therapy after the delivery of an 8-lb baby boy. The nurse performs what important intervention during the course of this treatment?
   1. Monitors the patient for 20 minutes following the administration for hypersensitivity reaction.
   2. Evaluates the laboratory results for thrombocytopenia, anemia, and increased liver enzymes.
   3. Provides the patient with the information needed to maintain a low-saturated-fat, low-cholesterol diet.
   4. Instructs the patient to use nonmedicated sugar-free lozenges or hard candies to relieve a cough.

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the anatomic structures associated with the lower respiratory tract and their functions.
2. Explain how the autonomic nervous system regulates airway diameter.
3. Explain the role of inflammation and bronchospasm in the pathogenesis of asthma.
4. Compare the advantages and disadvantages of using the inhalation route of drug administration for pulmonary drugs.
5. Describe the types of devices used to deliver aerosol therapies via the inhalation route.
6. Explain the three basic principles of asthma management recommended by the National Asthma Education and Prevention Program.
7. Compare and contrast the indications for pharmacotherapy with the short- versus long-acting beta-adrenergic agonists.
8. Describe the nurse's role in the pharmacologic management of lower respiratory tract disorders.
9. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
10. Apply the nursing process to care for patients receiving pharmacotherapy for lower respiratory tract disorders.

status asthmaticus, 788
ventilation, 787

The flow of oxygen, carbon dioxide, and other gases in and out of the human body is in constant flux. Minute-by-minute control of the airways is necessary to bring an adequate supply of oxygen to the pulmonary capillaries and to rid the body of some of its most toxic waste products. Any restriction in this dynamic flow, even for brief periods, may result in serious consequences. This chapter examines drugs used in the pharmacotherapy of two primary pulmonary disorders: asthma and chronic obstructive pulmonary disease (COPD).

Physiology of the Lower Respiratory Tract

44.1 The physiology of the respiratory system involves two main processes: perfusion and ventilation.

The primary function of the respiratory system is to bring oxygen into the body and to remove carbon dioxide. The process by which these gases are exchanged is called respiration. The basic structures of the lower respiratory tract are shown in Figure 44.1.

Blood flow through the lung is called **pulmonary perfusion**. The bronchial tree ends in microscopic sacs called alveoli, which have no smooth muscle and inflate like balloons during inspiration. The alveoli are abundantly rich in capillaries. An extremely thin membrane in the alveoli separates the inspired air from the pulmonary capillaries, allowing gases to readily move between the internal environment of the blood and the inspired air. As oxygen crosses this membrane to enter the bloodstream, it is exchanged for carbon dioxide, which is a cellular waste product that leaves the bloodstream to enter the alveoli. The process of gas exchange is illustrated in Figure 44.1.

Ventilation is the process of moving air into and out of the lungs. As the diaphragm contracts and lowers in position, it creates a negative pressure that draws air into the lungs and inspiration occurs. During expiration the diaphragm relaxes and air leaves the lungs passively.

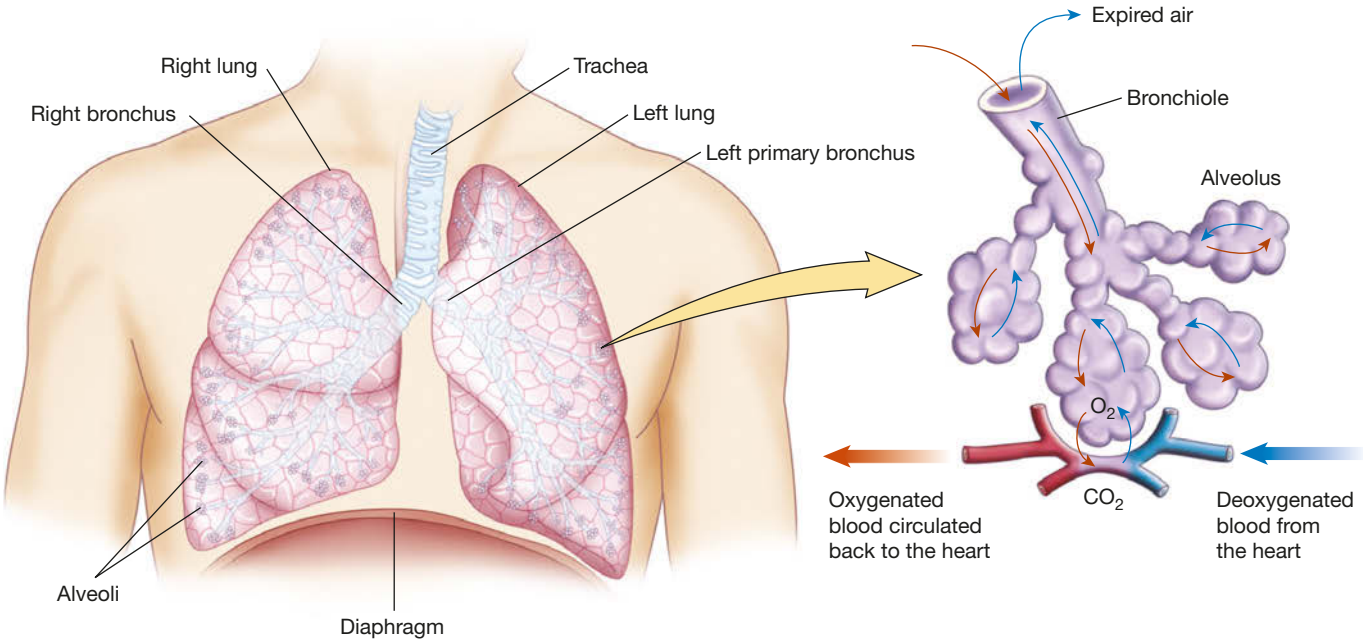

Figure 44.1 The lower respiratory tract and the process of gas exchange.

Ventilation is a purely mechanical process that occurs approximately 12 to 18 times per minute in adults. This rate is determined by neurons in the brainstem and may be modified by a number of factors, including emotions, fever, stress, and the pH of the blood.

One of the most important factors that affect ventilation is the size of the thousands of tubes or passageways leading from the outside to the alveoli, collectively known as the airways. The nervous system controls ventilation by changing the diameter of the airways, specifically the very small and abundant bronchioles.

Bronchioles are muscular, elastic, tubular structures whose diameter, or lumen, varies with the contraction or relaxation of bronchiolar smooth muscle. Bronchodilation allows air to enter the alveoli more freely, thus increasing the supply of oxygen to the body's tissues during periods of exercise. Bronchoconstriction increases airway resistance, resulting in less airflow. Bronchodilation and bronchoconstriction are largely regulated by the two branches of the autonomic nervous system:

- The sympathetic branch activates beta$_2$-adrenergic receptors, causing bronchiolar smooth muscle to relax, the airway diameter to increase, and bronchodilation to occur.
- The parasympathetic branch causes bronchiolar smooth muscle to contract, the airway diameter to narrow, and bronchoconstriction to occur.

In practical terms, drugs that enhance bronchodilation enable the patient to breathe easier. In contrast, drugs causing bronchoconstriction result in more labored breathing and shortness of breath in the patient.

Bronchoconstriction is a common indication for pharmacotherapy. Bronchoconstriction may occur through several mechanisms, and the choice of pharmacotherapy will differ depending on the mechanism. The airways may narrow due to **bronchospasm**, a sudden contraction of the smooth muscle of the airways that causes acute dyspnea. Drug treatment for bronchospasm is targeted at immediately relaxing the smooth muscle spasm. A second mechanism of bronchoconstriction is the production of thick, viscous secretions that plug up the airways. Depending on the cause, treatment may involve antibiotics for an infection or drugs that break up viscous secretions (mucolytics). A third mechanism of bronchoconstriction is edema that is caused by engorgement of the pulmonary blood vessels. Treatment may include diuretics and drugs to enhance cardiac function.

Pathophysiology of Asthma

44.2 Asthma is a chronic disease that has both inflammatory and bronchospasm components.

Asthma is one of the most common chronic conditions in the United States, and it is increasing at an alarming rate. Asthma affects almost 25 million Americans. The prevalence of asthma is higher among non-Hispanic Blacks, compared to non-Hispanic Whites, and females account for about 65% of all patients with asthma (Centers for Disease Control and Prevention, 2016). Although often considered a condition of childhood, asthma can occur at any age.

Asthma is characterized by chronic inflammation that occurs when potent mediators of the immune and inflammatory responses are released by mast cells lining the bronchial passageways. These mediators include histamine, leukotrienes, prostaglandins, and interleukins. The result of inflammation is an increase in airway edema coupled with increased mucus secretion, which narrows the airways, compromises the process of respiration, and contributes to airway obstruction. This is illustrated in Figure 44.2.

The second component in the pathogenesis of asthma is bronchospasm. The inflammatory conditions in the airway make the smooth muscle hyperresponsive to a variety of stimuli. Stimuli such as breathing smoke, pollutants, or cold air may trigger acute bronchospasm. Specific triggers are listed in Table 44.1. Some patients experience bronchospasm on exertion, a condition called exercise-induced asthma. Gastroesophageal reflux can trigger an asthma event when acid in the esophagus induces reflex bronchoconstriction.

PharmFACT

About 1 in every 12 Americans has asthma. Asthma is an associated cause of death for over 3400 people each year (American Academy of Allergy, Asthma & Immunology, n.d.).

The patient with asthma may present with a variety of symptoms, including evening cough, shortness of breath, chest tightness, and wheezing. Intervals between symptoms may vary from days to weeks to months. The severity of asthma is often graded by the frequency and intensity of acute episodes, as given in Table 44.2. **Status asthmaticus**, an emergency situation in which asthma is unresponsive to drug treatment, may lead to respiratory failure. Drugs may be given to prevent asthmatic attacks or to terminate attacks in progress.

Administration of Pulmonary Drugs via Inhalation

44.3 Inhalation is a common route of administration for pulmonary drugs because it delivers drugs directly to their sites of action.

Many drugs that are used to treat asthma are available for administration by the inhalation route. Inhalation offers a rapid and efficient mechanism for delivering drugs directly to their site of action in the lungs. The enormous

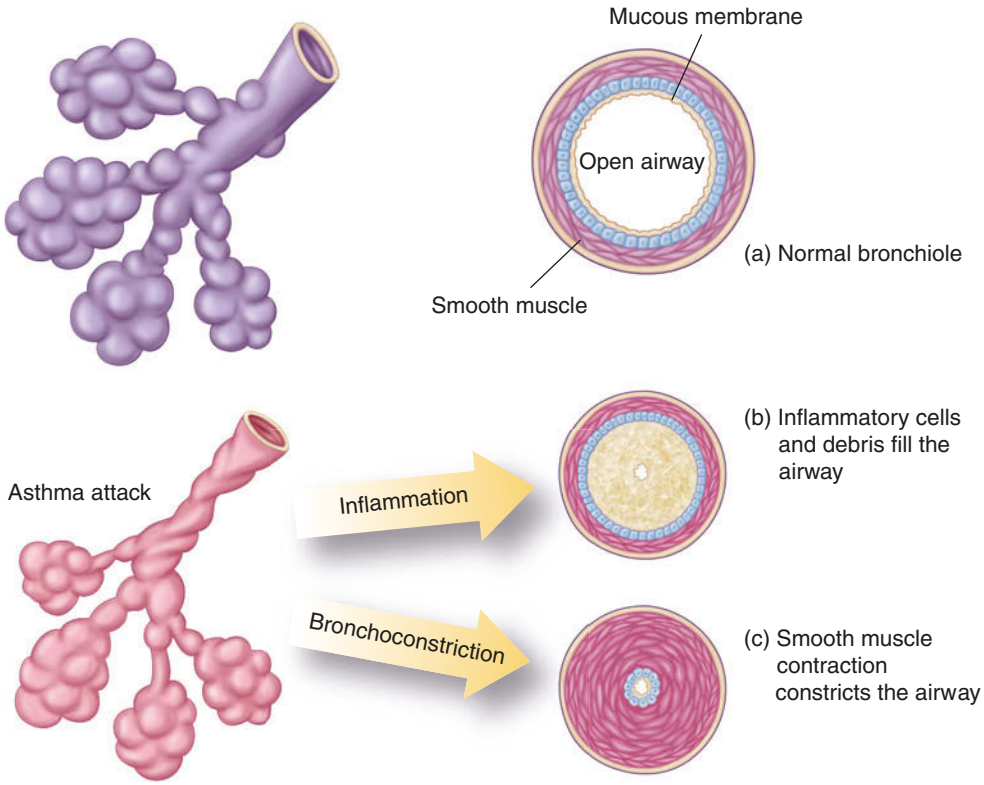

Figure 44.2 Changes in the bronchioles during an asthma attack: (a) Normal open bronchiole. (b) Inflammation plugs the airway. (c) Bronchoconstriction narrows the airway.

Table 44.1 Common Triggers of Asthma

Cause	Sources
Air pollutants	Tobacco smoke Air pollution Fumes from cleaning fluids or solvents Strong odors or sprays
Allergens	Pollen from trees, grasses, and weeds Animal dander Household dust mites Mold
Chemicals and food	Drugs, including aspirin, ibuprofen, and beta blockers Preservatives (sulfites and benzalkonium chloride) Food and condiments, including nuts, monosodium glutamate (MSG), shellfish, and dairy products
Respiratory infections	Bacterial, fungal, and viral
Stress	Emotional stress, strong emotions, anxiety, exercise in dry, cold climates

surface area of the bronchioles and alveoli and the rich blood supply to these areas result in an almost instantaneous onset of action for inhaled substances.

Medications are delivered to the respiratory system by aerosol therapy. An **aerosol** is a suspension of minute liquid droplets or fine solid particles suspended in a gas. The major advantage of aerosol therapy is that it delivers the drugs directly to the site of action. Not only does this dramatically decrease the onset of action, but it also allows for much smaller doses of a drug. The small doses of drug given by the inhalation route minimize any systemic effects that might result from absorption across pulmonary capillaries when compared to PO medications. Several devices are used to deliver drugs via the inhalation route. The most common are metered-dose inhalers, dry powder inhalers, and nebulizers.

The **metered-dose inhaler (MDI)**, often simply called an inhaler, is the most common type of aerosol delivery device. It consists of a canister that holds the medicine and a mouthpiece. To use an MDI, the patient presses the canister toward the mouthpiece to deliver a measured dose or "puff" of medication. By inhaling during drug delivery, the patient helps to ensure that the drug reaches the site of action in the lungs. Even when MDIs are used properly, however, the majority of the aerosolized drug never reaches the lungs. There are two primary reasons for this problem. One is that heavier aerosolized particles fall out by gravity and are deposited in the oropharynx. The other reason is that proper coordination of drug delivery with inhalation can be difficult for some patients. To decrease oropharyngeal deposition

Table 44.2 Assessment of Asthma

Level	Frequency of Symptoms (Cough, Wheezing, Dyspnea, Chest Tightness)	Nocturnal Attacks	Activity Limitations
Intermittent	Less than 2 times/week	Less than 2 times/month	Normal activity between flare-ups
Mild persistent	3–6 times/week	More than 3–4 times/month	Flare-ups may limit activity
Moderate persistent	Daily	More than 5 times/month	Flare-ups affect activity
Severe persistent	Continuous	Frequent	Flare-ups limit activity

and to enhance drug delivery to the lungs, many healthcare providers recommend that patients use a spacer with their MDI. A spacer is a special tube that attaches to the mouthpiece that is designed to hold the cloud of aerosolized medication. This serves two primary purposes. First, the spacer holds drops that fall out of the aerosol so that less medication is deposited on the oropharynx and in the mouth. Second, because the spacer holds the medication, the patient does not have to precisely coordinate inhalation with activation, so that more drug reaches the site of action.

A **dry powder inhaler (DPI)** delivers the medication as a fine dry powder. Whereas the MDI is activated by pressing the canister, the DPI is automatically activated when the patient inhales through the mouthpiece. Because the timing of drug delivery and inhalation does not have to be coordinated, more medication is delivered to the lung with a DPI. The DPI has no propellants in the canister (propellants can be harmful to some patients with lung problems).

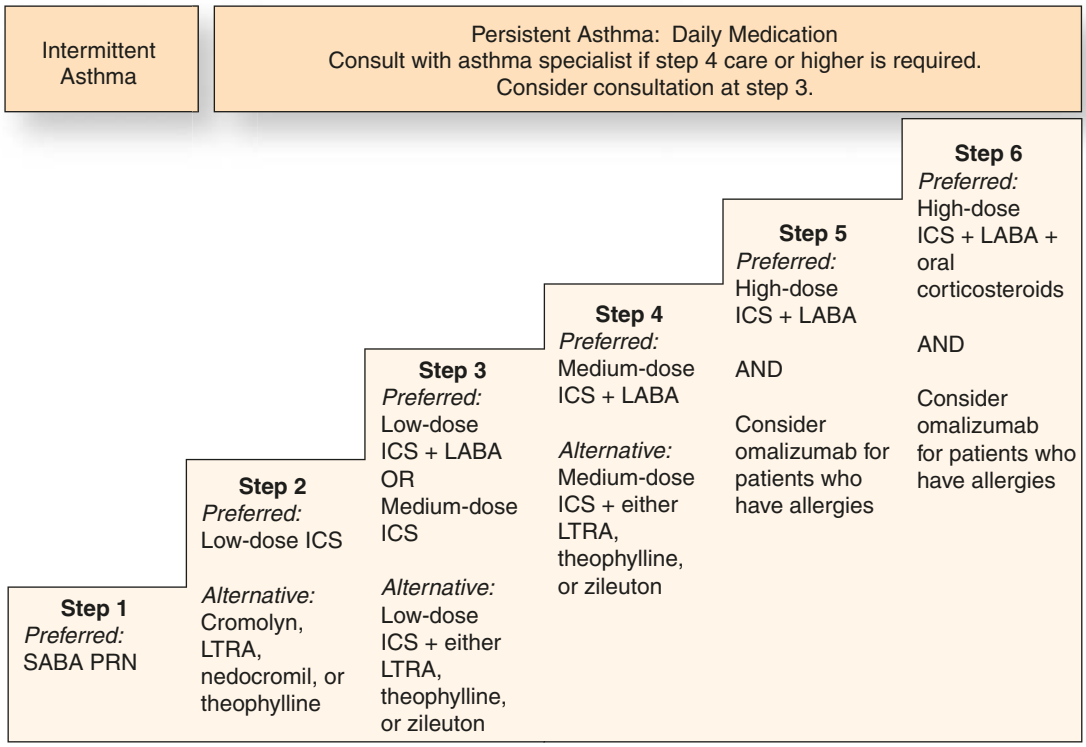
A **nebulizer** (or **small volume nebulizer**) is a machine that delivers medication as a fine mist. When using a nebulizer, the medication to be delivered is poured into a receptacle. The machine then vaporizes the liquid medication into a mist that is inhaled by using a face mask or other handheld device. These "breathing treatments" may take up to 30 minutes to administer the drug so it may not work as quickly as a drug taken from an MDI or DPI; however, medication delivered in this fashion is often more effective because it is delivered over many inhalations that occur during the period of medication delivery.

Principles of Asthma Pharmacotherapy

44.4 The goals of asthma pharmacotherapy are to terminate acute bronchospasms and to reduce the frequency of asthma attacks.

The choice of medications for asthma is determined by evidence-based guidelines coupled with the patient's response to therapy and adjusted according to each patient's situation. Evidence-based guidelines have been developed by experts in asthma management and are based on research findings. In the United States, the National Asthma Education and Prevention Program (NAEPP) issued guidelines for asthma treatment in 1991, which were subsequently updated. The NAEPP guidelines (2007) recommend a stepwise approach to asthma control based on the frequency and severity of symptoms, as shown in Figure 44.3. As patient symptoms worsen, the pharmacotherapy is adjusted accordingly by going to the next step. This provides a rational, evidence-based approach to asthma management. The three general strategies for asthma management from the NAEPP are as follows:

- Incorporate four components of care: medications, patient education, environmental control measures, and management of comorbidities.
- Initiate therapy based on asthma severity. For patients not taking long-term control therapy, select the treatment step based on severity. Patients who have persistent asthma require daily long-term control medication.
- Adjust the therapy based on asthma control. Once therapy is initiated, monitor the level of asthma control and adjust the therapy accordingly: step up if necessary and step down if possible to identify the minimum amount of medication required to maintain asthma control.



The goals of asthma pharmacotherapy are twofold: to terminate acute bronchospasms and to prevent or reduce the frequency of asthma attacks. Different medications are needed to achieve each of these goals. The NAEPP categorizes asthma drugs into two simple classes: quick-relief medications and long-term control medications. A summary of the different classes used for asthma management is given in Table 44.3.

PharmFACT

Currently, more than 6 million U.S. children have asthma. African American children and children from households earning less than $35,000 annually have the highest asthma rates (National Center for Health Statistics, 2017).

44.5 Beta$_2$-adrenergic agonists are the most effective drugs for relieving acute bronchospasm.

Beta-adrenergic agonists are some of the most frequently prescribed drugs for treating pulmonary disorders. Beta

Key: ICS, inhaled corticosteroid; LABA, long-acting inhaled beta$_2$-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$ agonist

Figure 44.3 Stepwise approach for managing asthma in adults and patients 12 years and older.
Adapted from Figure 4.5 in *Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma* by the National Asthma Education Prevention Program, coordinated by the National Heart, Lung, and Blood Institute of the National Institutes of Health, 2007. Retrieved from http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

Table 44.3 Overview of Drug Classes for Asthma Management

Class	Mechanism	Use
Quick-Relief Medications		
Short-acting beta$_2$-adrenergic agonists (SABAs)	Bronchodilators	Preferred drugs for relief of acute symptoms.
Anticholinergics	Bronchodilators	Alternate drugs for those who cannot tolerate SABAs.
Corticosteroids: systemic	Anti-inflammatory	Although not rapid acting, these PO drugs are used for short periods to reduce the frequency of acute exacerbations.
Long-Term Control		
Corticosteroids: inhaled	Anti-inflammatory	Preferred drugs for long-term asthma management. Oral doses may be required for severe, persistent asthma.
Mast cell stabilizers	Anti-inflammatory	Alternative drugs to control mild, persistent asthma or exercise-induced asthma.
Leukotriene modifiers	Anti-inflammatory	Alternative drugs to control mild, persistent asthma or as adjunctive therapy with inhaled corticosteroids.
Long-acting beta$_2$-adrenergic agonists (LABAs)	Bronchodilators	Used in combination with inhaled corticosteroids for prophylaxis of moderate to severe persistent asthma.
Methylxanthines	Bronchodilators	Used in combination with inhaled corticosteroids for prophylaxis of mild to moderate persistent asthma.
Immunomodulators	Monoclonal antibody	Used as adjunctive therapy for patients who have allergies and severe, persistent asthma.

Data from *Adults in Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma* by the National Asthma Education Prevention Program, coordinated by the National Heart, Lung, and Blood Institute of the National Institutes of Health, 2007. Retrieved from http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

agonists are drugs that activate the sympathetic nervous system, which relaxes bronchial smooth muscle, resulting in bronchodilation. They are preferred drugs for the treatment of bronchoconstriction.

Beta-agonist medications may act on either $beta_1$ receptors, which are located primarily in the heart, or on $beta_2$ receptors, which are located in smooth muscle of the lung, uterus, and other organs. Beta agonists that activate both $beta_1$ and $beta_2$ receptors are called nonselective bronchodilators. Beta agonists that activate only the $beta_2$ receptors are called selective drugs. The selective $beta_2$-adrenergic agonists have largely replaced the older, nonselective drugs such as epinephrine and isoproterenol (Isuprel) for asthma pharmacotherapy because they produce fewer adverse cardiac effects. For a review of the nonselective beta agonists and prototype features for epinephrine and isoproterenol, refer to Chapter 15.

$Beta_2$-adrenergic agonists are classified by their duration of action. Short-acting beta agonists (SABAs) have a rapid onset of action, usually several minutes, so they are effective in terminating an acute asthma attack. SABAs are recommended by the NAEPP to abort or terminate an acute asthma attack. For this reason, they are sometimes referred to as rescue medications. Their effects, however, last only 2 to 6 hours, so the use of SABAs is limited to as-needed (prn) management of acute episodes. Doses of these drugs are listed in Table 44.4.

Long-acting beta agonists (LABAs) have a duration of 12 hours, but have a relatively slow onset of action. The U.S. Food and Drug Administration (FDA) has published a public health advisory regarding an increase in deaths among patients who take LABAs. Because LABAs are not indicated to abort an asthma attack, taking the longer acting drug instead of a SABA could result in unrelieved bronchospasm and subsequent death. The LABAs are also delivered via handheld inhalers and patients may assume that they have the same actions as the SABAs. Patients must be alerted to the dangers inherent in taking these during an acute episode. Although the risk of asthma-related death is small, LABAs should only be used as additional therapy for patients who are not adequately controlled on other asthma-controller medications, such as inhaled corticosteroids, or for patients with severe asthma who clearly require two medications for disease management (see Table 44.3). They are not to be used as monotherapy for this disease.

$Beta_2$-adrenergic agonists are available in PO, inhaled, and parenteral formulations. When taken for asthma and other respiratory problems, inhalation is the most common route. Inhaled $beta_2$ agonists produce minimal systemic toxicity because only small amounts of the drugs are absorbed. When given PO a longer duration of action is achieved, but systemic adverse effects are more frequently experienced. Systemic effects may include some activation of $beta_1$ receptors in the heart, which could cause an angina attack or a dysrhythmia in patients with cardiac disease. With chronic use tolerance may develop to the bronchodilation effect and the duration of action will become shorter. Should this occur, the dose of $beta_2$ agonist may need to be increased, or a second drug may be added to the therapeutic regimen.

PROTOTYPE DRUG **Albuterol (Proventil HFA, Ventolin HFA, VoSpire ER)**

Classification **Therapeutic:** Bronchodilator
Pharmacologic: $Beta_2$-adrenergic agonist

Therapeutic Effects and Uses: Approved in 1981, albuterol is a SABA that is used to relieve and prevent the bronchospasm that is a characteristic pathophysiologic feature of asthma. Its rapid onset and excellent safety profile have made inhaled albuterol a preferred drug for the termination of acute bronchospasm. In addition to relieving bronchospasm, the drug facilitates mucus drainage and can inhibit the release of inflammatory chemicals from mast cells. When inhaled 15 to 30 minutes prior to physical activity, it can prevent exercise-induced bronchospasm for 2 to 3 hours. Inhaled albuterol is considered safe for use during pregnancy.

Oral forms of albuterol include immediate release and extended release tablets (VoSpire ER) and an oral solution. The PO forms have a longer onset of action and are not suitable for terminating acute asthma attacks. The NAEPP does not recommend the use of SABAs such as albuterol for asthma prophylaxis.

Mechanism of Action: Albuterol acts by selectively binding to $beta_2$-adrenergic receptors in bronchial smooth muscle to cause bronchodilation.

Pharmacokinetics:

Route(s)	Inhalation, PO
Absorption	Slow by the inhalation route; some of the inhaled drug is swallowed and absorbed by the gastrointestinal (GI) tract; rapid when given PO
Distribution	Delivered directly to the lungs (site of action); crosses the blood–brain barrier; may cross the placenta; unknown if secreted in breast milk
Primary metabolism	Hepatic (CYP450)
Primary excretion	Renal (less than 10% feces)
Onset of action	Inhalation: 5–15 min; PO: 30 min; peak effect: 0.5–2 h
Duration of action	Inhalation: 2–6 h; PO, sustained release: 8–12 h

Table 44.4 Bronchodilators for Asthma and COPD

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Beta Agonists/Sympathomimetics		
albuterol (Proventil HFA, Ventolin HFA, VoSpire ER)	MDI: 2 inhalations q4–6h as needed (max: 12 inhalations/day) Nebulizer: 1.25–5 mg q4–8h prn PO: 2–4 mg q12h (max: 32 mg/day)	*Headache, dizziness, tremor, nervousness, throat irritation, drug tolerance* Tachycardia, dysrhythmia, hypokalemia, hyperglycemia, paradoxical bronchoconstriction, hypomagnesemia, maternal heart problems during pregnancy (terbutaline), increased risk for asthma-related death
arformoterol (Brovana)	Nebulizer (for COPD): 15 mcg bid (max: 30 mcg/day)	
formoterol (Foradil, Perforomist)	DPI (Foradil for asthma and COPD): 12 mcg inhalation capsule bid (max: 24 mcg/day) Nebulizer (Perforomist for COPD): 20 mcg bid (max: 40 mcg/day)	
indacaterol (Arcapta Neohaler)	Inhalation (for COPD): one 75-mcg capsule/day using the Neohaler	
levalbuterol (Xopenex)	Nebulizer: 0.63 mg tid–qid MDI: 2 inhalations q4–6h Inhalation (for COPD): 2–3 inhalations/day (max: 12 inhalations/day)	
metaproterenol	PO: 20 mg q6–8h	
olodaterol (Striverdi Respimat)	Inhalation (for COPD): 2 inhalations bid	
salmeterol (Serevent)	DPI (for asthma and COPD): 1 inhalation bid	
terbutaline	PO: 2.5–5 mg tid (max: 15 mg/day) Subcutaneous: 250 mcg (may be repeated in 15 min)	
Anticholinergics		
aclidinium (Tudorza Pressair)	DPI: 2 inhalations (400 mcg) bid	*Headache, bad taste, cough, dry mouth, blurred vision, paradoxical bronchospasm, upper respiratory infection* Pharyngitis
ipratropium (Atrovent)	MDI (for COPD): 2 inhalations (50 mcg) qid (max: 12 inhalations/day) Nebulizer (for COPD): 500 mcg q6–8h as needed	
tiotropium (Spiriva)	Inhalation (for COPD): 2 inhalations of 1 capsule daily with Spiriva HandiHaler device Inhalation (for asthma and COPD): 2 inhalations daily with Spiriva Respimat device	
umeclidinium (Incruse Ellipta)	DPI (for COPD): 1 inhalation/day	
Methylxanthines		
aminophylline	PO: 380 mg/day in divided doses q6–8h (max: 928 mg/day) IV: 0.1–0.5 mg/kg/h (rate individualized based on peak drug blood levels)	*Nervousness, tremors, dizziness, headache, nausea, vomiting, anorexia* Tachycardia, dysrhythmias, hypotension, seizures, circulatory failure, respiratory arrest
theophylline	PO: 300–600 mg/day in divided doses (max: 900 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Adverse Effects: Serious adverse effects from inhaled albuterol are uncommon when taken as directed; PO forms cause more sympathomimetic adverse effects. Some patients experience palpitations, headaches, throat irritation, tremor, nervousness, restlessness, and tachycardia. Less common adverse reactions include insomnia and dry mouth. Uncommon adverse effects include chest pain, paradoxical bronchospasm, and allergic reactions.

Contraindications/Precautions: Albuterol use is contraindicated if the patient has hypersensitivity to the drug. Because albuterol may exhibit cardiovascular effects in some patients, caution is required when administering it to patients with a history of tachyarrhythmias, prolongation of the QT interval, coronary artery disease, or hypertension (HTN).

Drug Interactions: Concurrent use with beta blockers will inhibit the bronchodilation effect of albuterol and may induce bronchospasm in patients with asthma. To prevent hypertensive crisis, patients should also avoid monoamine oxidase inhibitors (MAOIs) within 14 days of beginning therapy. Concurrent use with thyroid hormone may produce additive stimulatory effects on the cardiovascular system. **Herbal/Food:** Products containing caffeine such as coffee and tea may cause nervousness, tremor, or palpitations.

Pregnancy: Category C.

Treatment of Overdose: Overdose results in an exaggerated sympathetic activation, causing dysrhythmias, hypokalemia, and hyperglycemia. Cardiac arrest and death have been reported. In severe cases, administration of a beta antagonist may be necessary.

Nursing Responsibilities: Key nursing implications for patients receiving albuterol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

Drugs Similar to Albuterol (Proventil HFA, Ventolin HFA, VoSpire ER)

Other SABAs include metaproterenol and levalbuterol. LABAs include arformoterol, formoterol, indacaterol, olodaterol, salmeterol, and terbutaline. Adverse effects are the same as those of other beta$_2$ agonists and include tachycardia, nervousness, angina, and headache.

Arformoterol (Brovana): Arformoterol was approved in 2007 for the treatment of COPD, including chronic bronchitis and emphysema. This drug is an isomer of formoterol and was the first LABA available by inhalation via nebulizer. Although it begins to relax bronchi within about 7 minutes, its maximum effects take 1 to 3 hours. Thus this drug is not suitable for terminating acute asthma attacks. Arformoterol is well tolerated and exhibits few serious adverse effects in most patients. The drug has a black box warning that it (and other LABAs) has been shown to increase the risk of asthma-related death; thus it should be prescribed only when short- and intermediate-acting drugs are unable to control symptoms. A combination drug (Dulera) containing arformoterol and mometasone (a corticosteroid) was approved in 2010. Arformoterol is pregnancy category C.

Formoterol (Foradil, Perforomist): Approved in 2001, formoterol is a LABA that is administered using a DPI. Because the drug takes 1 to 3 hours for maximum effect, it is not suitable for terminating acute bronchospasm. Due to its long duration of action, formoterol is indicated for asthma prophylaxis, including the prevention of nocturnal symptoms and exercise-induced asthma. It is also approved by the FDA for the relief of bronchospasm due to COPD. This drug is well tolerated and has the same adverse effect profile as that of other drugs in this class. Formoterol has a black box warning that it (and other LABAs) has been shown to increase the risk of asthma-related death; thus it should be prescribed only when short- and intermediate-acting drugs are unable to control symptoms. This drug is pregnancy category C.

Indacaterol (Arcapta Neohaler): Indacaterol was approved in 2011 as a maintenance bronchodilator for patients with COPD, including chronic bronchitis and emphysema. The drug comes as a capsule that is inserted into the Neohaler device for inhalation. Its once-daily dosing schedule offers an advantage over other LABAs. Indacaterol is not indicated for the termination of acute bronchospasm. Like other LABAs, indacaterol carries a black box warning that it should not be used for long-term asthma control due to the possibility of an increased risk of asthma-related death. This drug is pregnancy category C.

Levalbuterol (Xopenex): Approved in 1999, levalbuterol is an isomer of albuterol and has almost identical indications, actions, and adverse effects. This drug is administered via nebulized or aerosolized oral inhalation. It is indicated for the relief of acute bronchospasm symptoms and can be administered three to four times daily. Regular, daily use of levalbuterol is not recommended by the NAEPP as a means to prevent bronchospasm. Like other drugs in this class, levalbuterol has few serious adverse effects, with nervousness and tremor being the most frequently reported. This drug is pregnancy category C.

Metaproterenol: Approved in 1981 to treat bronchospasm, metaproterenol is a SABA available by the oral route. It has a duration of 4 to 6 hours. The actions and adverse effects are similar to those of albuterol. This drug is pregnancy category C.

Olodaterol (Striverdi Respimat): Approved in 2014, olodaterol is a LABA used to treat airflow obstruction associated with COPD. It is available by the inhalation route and can be administered once daily. Like other LABAs, olodaterol has a black box warning that it has been shown to increase the risk of asthma-related death. The warning also states that the drug is not approved to treat asthma. Adverse effects include nasopharyngitis, upper respiratory tract infection, and bronchitis. This drug is pregnancy category C.

Salmeterol (Serevent): Approved in 1994, salmeterol is a LABA given by DPI that is prescribed for asthma prophylaxis and the long-term therapy of bronchospasm associated with COPD. The LABAs salmeterol and formoterol are considered less effective at preventing asthma attacks than the inhaled corticosteroids. Salmeterol has a slow onset of action and should not be used to terminate acute bronchospasm. Pharyngitis and upper respiratory tract infections occur in patients who are taking the drug, and headache is a common adverse effect. Advair Diskus is a combination inhaler that combines salmeterol and fluticasone. Salmeterol has a black box warning that it (and other LABAs) has been shown to increase the risk of asthma-related death; thus it should be prescribed only when short- and intermediate-acting drugs are unable to control symptoms. This drug is pregnancy category C.

CONNECTIONS: Using Research in Practice

Early Exposure to Allergens May Reduce Asthma Risk

Allergen exposure has been noted to increase the risk for and severity of asthma in both children and adults (Custovic, 2015; Sheehan & Phipatanakul, 2016). What is not as clear is what roles the timing of initial exposure, ongoing exposure, types of allergens, or amount of exposure play in the development of protection from conditions such as asthma and anaphylaxis (Sheehan & Phipatanakul, 2016).

Lynch et al. (2014) noted that cumulative exposure to allergens in the first 3 years of life seemed to decrease the risk of recurrent wheezing and allergies and that such early exposure may be beneficial. A subsequent study also noted that there was no increase in allergic rhinitis or sensitization to indoor allergens such as dogs, cats, and house mites due to such early exposure (Schoos, Chawes, Jelding-Dannemand, Elfman, & Bisgaard, 2016). Recent research has demonstrated that early exposure to peanuts may dramatically reduce the development of peanut allergy, which has been linked to both asthma and anaphylaxis (Togias et al., 2017). In 2015, the American Academy of Allergy, Asthma & Immunology and the American Academy of Pediatrics published a consensus communication, encouraging the early introduction of peanut products, based on research that demonstrated an absolute risk reduction in peanut allergy in high-risk infants by 11% to 25%, and a relative risk reduction of up to 80% when peanut products were introduced between 4 and 11 months of age (DuToit et al., 2015;Fleischer et al., 2016).

Further research is needed to determine what benefits might be gained by early exposure and by what types of allergens; what dose may be appropriate to elicit a positive response; and whether other factors, such as genetics, might play a role in desensitization. Recent research offers tantalizing hope that severe allergies, asthma, and anaphylaxis may be prevented with appropriate allergen exposure early in life.

Terbutaline: An older drug approved in 1974, terbutaline is indicated for the treatment of bronchospasm associated with asthma or bronchitis. When given by the PO route, terbutaline may take 30 minutes or longer to act; thus it is too slow to be used for acute conditions. The subcutaneous form can relieve bronchospasm within 15 minutes. PO terbutaline has a shorter duration of action than albuterol or salmeterol and it must be administered 3 times daily. Terbutaline is moderately selective for $beta_2$ receptors but may produce some activation of $beta_1$ receptors in the heart. Adverse effects are similar to those observed with other drugs in this class. Terbutaline has been used off-label to delay premature labor contractions because its effects on $beta_2$ receptors in the uterus cause smooth muscle relaxation (see Chapter 69). However, in 2011 the FDA issued a black box warning that *oral* terbutaline should not be used to prevent or treat preterm labor because it has not been shown to be effective and there is a potential for serious maternal heart problems and death. In very serious conditions, the *injectable* form of the drug may still be used but treatment is limited to no longer than 48 to 72 hours to delay preterm labor. This drug is pregnancy category B.

CONNECTION Checkpoint 44.1

The medications for asthma are selective for $beta_2$-adrenergic receptors. From what you learned in Chapter 15, what are the primary indications for the drugs selective for $beta_1$-adrenergic receptors? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

44.6 The inhaled anticholinergics are used for preventing bronchospasm.

Although SABAs are the preferred drugs for treating acute bronchospasm, anticholinergics (cholinergic blockers or antagonists) are alternative bronchodilators. Although anticholinergics such as atropine have been available for many decades, their adverse effect profile made them poorly suited for the management of asthma. With the delivery of the anticholinergics by inhalation, however, they have become important drugs in the arsenal of asthma pharmacotherapy. Four inhalation anticholinergics are available for the treatment of respiratory disorders. The first to be developed was ipratropium (Atrovent), which is considered a short-acting drug. Aclidinium (Tudorza Pressair), umeclidinium (Incruse Ellipta), and tiotropium (Spiriva) are newer, long-acting anticholinergics.

Anticholinergics block the parasympathetic nervous system. Blocking the parasympathetic nervous system results in actions similar to those of stimulating the sympathetic nervous system (see Chapter 14). It is predictable then that anticholinergic drugs would cause bronchodilation and have potential applications in the pharmacotherapy of asthma and COPD. Ipratropium is the only anticholinergic with a rapid onset suitable for treating acute asthma. The others are indicated for the management of COPD and may be used off-label for chronic asthma when combined with other respiratory drugs.

Anticholinergics have actions that are similar to those of beta-adrenergic agonists, and drugs from the two classes may be combined to produce a greater and more prolonged bronchodilation than either drug used separately. This additive effect is particularly useful for patients with persistent bronchospasm for whom either drug alone is inadequate to alleviate bronchoconstriction. Taking advantage of this increased effect, the pharmaceutical companies have developed inhalants that combine both an anticholinergic and a beta agonist into a single canister.

The inhaled anticholinergics are relatively safe medications. The wide range of anticholinergic adverse effects

that is observed when drugs in this class are administered systemically rarely occurs when administered by inhalation.

PROTOTYPE DRUG **Ipratropium (Atrovent)**

Classification **Therapeutic:** Bronchodilator
Pharmacologic: Anticholinergic

Therapeutic Effects and Uses: Approved by the FDA in 1986, ipratropium is an anticholinergic medication that is delivered by the inhalation and intranasal routes. The inhalation form is approved to relieve and prevent the bronchospasm that is characteristic of asthma and COPD. It is a preferred drug for treating bronchospasms due to COPD (e.g., bronchitis and emphysema). Although it has not received FDA approval for the treatment of asthma, it is nevertheless prescribed off-label for the disorder. NAEPP guidelines state that the role of ipratropium in asthma management is as an alternative to SABAs and for patients experiencing severe asthma exacerbations. It is sometimes combined with beta agonists or corticosteroids to provide additive bronchodilation. Ipratropium is less effective than the $beta_2$ agonists at preventing exercise-induced bronchospasm.

When administered via inhalation, ipratropium can relieve acute bronchospasm within minutes of administration, although peak effects may take 1 to 2 hours. Bronchodilation action may continue for up to 6 hours.

The nasal spray formulation of ipratropium is indicated for the symptomatic relief of rhinorrhea associated with the common cold and perennial rhinitis. The drug inhibits nasal secretions but does not have decongestant action. Treatment is limited to 3 weeks.

Mechanism of Action: Ipratropium causes bronchodilation by blocking cholinergic receptors in bronchial smooth muscle. Intranasal administration blocks parasympathetic receptors, thus reducing nasal hypersecretion characteristic of the common cold.

Pharmacokinetics:

Route(s)	Inhalation, intranasal
Absorption	Minimal systemic absorption; some of the inhaled drug is swallowed but is not absorbed by the GI tract
Distribution	Small amount is secreted in breast milk; minimally bound to plasma protein
Primary metabolism	Hepatic (CYP450)
Primary excretion	Renal and feces
Onset of action	5–15 min; peak effect: 1.5–2 h
Duration of action	3–6 h; half-life: 1.5–2 h

Adverse Effects: Because it is not readily absorbed from the lungs, ipratropium produces few systemic adverse effects. Though rare, it can worsen glaucoma with sufficient systemic absorption. Typical anticholinergic adverse effects such as dry mouth, nausea, and GI distress are among the most common adverse effects but occur in less than 3% of patients. Irritation of the upper respiratory tract may cause cough, drying of the nasal mucosa, or hoarseness. Paradoxical acute bronchospasm is a rare adverse effect that may be life threatening. This drug produces a bitter taste that some patients find problematic. Intranasal administration may cause epistaxis and excessive drying of the nasal mucosa.

Contraindications/Precautions: Ipratropium is contraindicated in patients with hypersensitivity to soya lecithin or related food products such as soybean and peanut. Soya lecithin is used as a propellant in the inhaler. Ipratropium is contraindicated in patients who have demonstrated a hypersensitivity to ipratropium. All anticholinergics should be used with caution in patients with closed-angle glaucoma or urinary tract obstruction because they may worsen these conditions.

Drug Interactions: Because it has little systemic absorption, ipratropium interacts with very few drugs. Use with other anticholinergics such as atropine may lead to additive anticholinergic adverse effects. Ipratropium should not be used concurrently with pramlintide (Symlin) because both slow GI peristalsis and can cause nausea, vomiting, or constipation. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Overdose with ipratropium is unlikely because very little of the drug is absorbed.

Nursing Responsibilities: Key nursing implications for patients receiving ipratropium are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

Drugs Similar to Ipratropium (Atrovent)

The other anticholinergics currently approved for inhalation are aclidinium, tiotropium, and umeclidinium.

Aclidinium (Tudorza Pressair): Aclidinium is an anticholinergic approved in 2012 for the long-term maintenance treatment of bronchospasm associated with COPD. It is administered twice daily by DPI and is used to prevent, not terminate, bronchospasm. It has very similar actions and adverse effects to those of the other two drugs in this class. Common side effects include headache, nasopharyngitis, and cough. This drug is pregnancy category C.

Tiotropium (Spiriva): Approved in 2004, tiotropium is closely related to ipratropium and is indicated for the

long-term maintenance treatment and prophylaxis of bronchospasm in patients with COPD, including chronic bronchitis and emphysema. It is not used to terminate acute bronchospasm; SABAs are more effective for this condition. An advantage of tiotropium is its long duration of action. Unlike ipratropium, which must be taken 4 or more times a day, tiotropium needs to be taken only once a day so patients are less likely to miss doses. Another difference between the two drugs is that ipratropium is administered by MDI, whereas tiotropium is administered by DPI (HandiHaler device). For patients with COPD who have difficulty using an MDI device, tiotropium can be a viable alternative. Adverse effects are the same as those of ipratropium. This drug is pregnancy category C.

Umeclidinium (Incruse Ellipta): Approved in 2013, umeclidinium is an inhaled anticholinergic indicated for the long-term management of airflow obstruction in patients with COPD. It offers the advantage of once-daily dosing. Side effects are the same as those of other inhaled anticholinergics. This drug is pregnancy category C.

44.7 Inhaled corticosteroids are the most effective drugs for the long-term control of asthma.

Corticosteroids are the most potent natural anti-inflammatory substances known. Because asthma has a major inflammatory component, it should not be surprising that drugs in this class play a major role in the management of this disorder. *Inhaled* corticosteroids are first-line drugs for the prevention of asthmatic attacks and for the management of chronic asthma. *Oral* corticosteroids are used for the short-term management of acute asthma attacks. The therapeutic actions of the corticosteroids have resulted in their widespread use in the pharmacotherapy of allergic rhinitis (see Chapter 45) and other inflammatory disorders. Doses for the inhaled corticosteroids are given in Table 44.5.

Corticosteroids decrease inflammation of the airways by inhibiting the synthesis and release of inflammatory mediators, including histamine, leukotriene, cytokines, and prostaglandins. They also inhibit the number of circulating leukocytes and decrease vascular permeability. This results in diminished mucus production and edema, thus reducing airway obstruction. Although corticosteroids are not bronchodilators, they sensitize the bronchial smooth muscle to be more responsive to beta-agonist stimulation. In addition, they reduce the bronchial hyperresponsiveness to allergens, which is responsible for triggering many asthma attacks.

When inhaled on a daily schedule, corticosteroids suppress inflammation without producing major adverse effects. Although symptoms will improve in the first 1 to 2 weeks of therapy, 4 to 8 weeks may be required for maximum benefit. Because of the dangerous adverse effects of long-term therapy, systemic corticosteroids are generally reserved for short-term management of acute asthma exacerbations. For outpatient management in these instances, PO corticosteroids such as prednisone are given for the shortest length of time possible, usually 5 to 7 days. In the hospital setting, intravenous (IV) corticosteroids may be given. Regardless, at the end of the brief treatment period, patients are usually switched to inhaled corticosteroids for long-term management.

When taken long term, both PO and inhaled formulations of corticosteroids have the potential to affect bone physiology in adults and children. Adults who are at risk for osteoporosis should receive periodic bone mineral density tests and possibly pharmacotherapy with bisphosphonates to prevent fractures (see Chapter 72). In children, small decreases in linear bone growth have been documented. Although these effects are usually temporary, growth should be monitored and the prescriber should weigh the risks of growth suppression against the benefits of corticosteroid use. In all cases, effects on bone growth are dose and frequency dependent; thus patients should be administered the lowest doses possible to maintain adequate asthma control.

CONNECTIONS: Patient Safety

Proper Inhaler Use by Older Adults

A 73-year-old man with a history of COPD (chronic bronchitis) is brought to the emergency department of his local hospital in acute respiratory distress. On assessment, he has inspiratory and expiratory wheezing bilaterally, and his pulse oximetry value is 90%. When taking a brief drug history, the nurse notes that the patient has been managing his condition with PO roflumilast (Daliresp) and occasional low-dose corticosteroids. He tells the nurse that he has recently finished an antibiotic prescription "because I had a cold and they didn't want it to get worse." He also tells the nurse that at that time, his provider gave him a prescription for an albuterol (VoSpire ER) inhaler, which he has been using for the past 2 days, "but I've been getting worse, not better." What does the nurse suspect may be the cause of his recent respiratory distress?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

PROTOTYPE DRUG **Beclomethasone (Beconase AQ, Qvar)**

Classification **Therapeutic:** Anti-inflammatory
Pharmacologic: Corticosteroid

Therapeutic Effects and Uses: Approved in 1976, beclomethasone is a corticosteroid that is available for administration by aerosol inhalation for asthma (Qvar) or as a nasal spray (Beconase AQ) for allergic rhinitis. Guidelines from the NAEPP place beclomethasone and other

Table 44.5 Anti-Inflammatory Drugs for Asthma and COPD

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Inhaled Corticosteroids*		
beclomethasone (Beconase AQ, Qvar)	MDI: 1–2 inhalations bid (max: 20 inhalations/day)	*Hoarseness, dry mouth, cough, sore throat*
budesonide (Pulmicort)	DPI (Pulmicort Flexhaler): 1–2 inhalations (360 mcg) bid (max: 720 mcg bid) Nebulizer (Pulmicort Respules): 0.5 mg/day either once daily or bid	Oropharyngeal candidiasis, hypercorticism, hypersensitivity reactions
ciclesonide (Alvesco)	Inhalation: 1–2 inhalations (80–320 mcg/inhalation) bid	
flunisolide	MDI: 2–3 inhalations bid–tid (max: 12 inhalations/day)	
fluticasone (Flovent)	DPI (Flovent Diskus): 100–500 mcg bid (max: 1000 mcg bid) MDI (Flovent HFA): 88–220 mcg bid (max: 880 mcg bid)	
mometasone (Asmanex)	MDI: 1–2 inhalations bid (100–200 mcg) (max: 2 inhalations/day)	
Mast Cell Stabilizer		
cromolyn	Nebulizer: 1 inhalation qid	*Nausea, sneezing, cough, unpleasant taste* Anaphylaxis, angioedema, bronchospasm
Leukotriene Modifiers and Miscellaneous Drugs		
montelukast (Singulair)	PO: 10 mg/day in evening	*Headache, nausea, diarrhea, throat pain, weight loss (roflumilast)* Increased aspartate aminotransferase (AST), hepatotoxicity, psychiatric events including suicidality (roflumilast)
roflumilast (Daliresp)	PO (for COPD): 500 mcg once daily	
zafirlukast (Accolate)	PO: 20 mg bid 1 h before or 2 h after meals	
zileuton (Zyflo CR)	PO (extended release): 1200 mg bid (max: 2400 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

*For doses of systemic corticosteroids, refer to Chapter 68.

corticosteroids as first-line drugs for the long-term management of persistent asthma in both children and adults. Two inhalations, 2 to 3 times per day, usually provide adequate prophylaxis, although 3 to 4 weeks of therapy may be necessary before optimal benefits are achieved. A double strength formulation of beclomethasone (Qvar) is available with smaller drug particles that is able to deliver half the usual dose and achieve the same therapeutic effect. Beclomethasone is not a bronchodilator and should not be used to terminate asthma attacks in progress.

The intranasal formulation (Beconase AQ) is effective at reducing the symptoms of allergic rhinitis. Therapeutic effects may take 2 weeks to be fully apparent. Intranasal beclomethasone is also approved to prevent recurrence of nasal polyps following surgical removal. Very little of this drug is absorbed in the systemic circulation when it is administered by this route.

Mechanism of Action: Beclomethasone acts by reducing inflammation and immune responses, thus decreasing the frequency of asthma attacks.

Pharmacokinetics:

Route(s)	Inhalation, intranasal
Absorption	Small amounts of systemic absorption
Distribution	Delivered directly to the lungs (site of action); small amount is secreted in breast milk
Primary metabolism	Liver (CYP450: 3A substrate) and lung
Primary excretion	Mostly feces with about 10% in urine
Onset of action	1–3 weeks
Duration of action	Half-life: 15 h

Adverse Effects: Inhaled beclomethasone produces few systemic adverse effects. Because small amounts may be swallowed with each dose, the patient should be observed for signs of corticosteroid toxicity (hypercorticism) when taking this drug for prolonged periods. Local effects may include hoarseness, dry mouth, and changes in taste. Inhaled corticosteroid use has been associated with the development of cataracts in adults. Some studies have shown that long-term intranasal or inhaled corticosteroids may cause growth inhibition in children.

Like all corticosteroids, the anti-inflammatory properties of beclomethasone can mask signs of infections and the drug is contraindicated if active infection is present. A large percentage of patients taking beclomethasone on a long-term basis will develop oropharyngeal candidiasis, a fungal infection in the throat, due to the constant deposits of drug in the oral cavity. Children who have not been vaccinated for varicella should receive the vaccine because of the potential for developing serious disseminated varicella infections during treatment with corticosteroids.

Contraindications/Precautions: The only contraindication to using beclomethasone is hypersensitivity to the drug.

Drug Interactions: Because very little of the drug is absorbed, no clinically significant drug interactions occur. **Herbal/Food:** None known.

Pregnancy: Category C.

Treatment of Overdose: Overdose does not occur when taken by the inhalation route.

Nursing Responsibilities: Key nursing implications for patients receiving beclomethasone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

Drugs Similar to Beclomethasone (Beconase AQ, Qvar)

Other corticosteroids for inhalation include budesonide, ciclesonide, flunisolide, fluticasone, and mometasone.

Budesonide (Pulmicort): Budesonide is a corticosteroid that is available by the intranasal route for allergic rhinitis (Rhinocort), oral inhalation, nebulizer for asthma prophylaxis (Pulmicort), or PO capsules for Crohn's disease (Entocort). The most common adverse effects with the inhaled use of budesonide include respiratory infections, rhinitis, cough, and otitis media. Visual impairment may occur. Growth effects should be monitored in pediatric patients. This drug is pregnancy category B.

Ciclesonide (Alvesco): Approved in 2006, ciclesonide is a corticosteroid available by the oral inhalation (Alvesco) route for asthma maintenance and prophylaxis in patients over 12 years of age or by the intranasal (Omnaris) route for allergic rhinitis. Ciclesonide is a prodrug that is converted to an active metabolite following administration. Like other drugs in this class, ciclesonide is not a bronchodilator and should not be used to treat acute bronchospasm. Actions and adverse effects are the same as those of other corticosteroids administered by inhalation. This drug is pregnancy category C.

Flunisolide: Flunisolide is a corticosteroid that is available by oral inhalation for asthma prophylaxis. The most common adverse effects with inhaled use include upper respiratory infections, dry mouth, hoarseness, nausea, vomiting, and taste changes. Like other drugs in this class, visual impairment may occur and growth effects should be monitored in pediatric patients. This drug is pregnancy category C.

Fluticasone (Flovent): Fluticasone is a corticosteroid that is available by the intranasal route for allergic rhinitis (Flonase); oral inhalation for asthma prophylaxis or COPD (Flovent); or topical cream or ointment for dermatitis, eczema, and other skin conditions (Cutivate). The most common adverse effects with the inhaled use of fluticasone include headache, throat irritation, and upper respiratory tract infections. Visual impairment may occur. Growth effects should be monitored in pediatric patients. Like other inhaled corticosteroids, fluticasone is not indicated for the relief of acute bronchospasm. This drug is pregnancy category C.

Mometasone (Asmanex): Mometasone is an inhaled corticosteroid that is available for the prevention of acute asthmatic attacks. When inhaled it may take an hour or longer to produce its effects; therefore, it is not indicated for the relief of acute bronchospasm. Actions and adverse effects are the same as those of other inhaled corticosteroids. An intranasal form is available for allergic rhinitis (Nasonex), and a topical preparation (Elocon) is used to treat various inflammatory skin conditions. This drug is pregnancy category C.

CONNECTION Checkpoint 44.2

From what you learned in Chapter 42, describe strategies that could be used to limit the incidence of serious adverse effects when corticosteroids must be taken PO for prolonged periods. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

44.8 Mast cell stabilizers are used for the prophylaxis of asthma and act by preventing the release of histamine.

Mast cell stabilizers serve limited, though important, roles in the prophylaxis of asthma. Mast cells are large cells that contain inflammatory granules, such as histamine, that mediate inflammatory and allergic reactions. When these cells are sensitized, they degranulate and release the inflammatory substances into the body where they initiate an inflammatory response. Mast cell stabilizers are helpful in managing asthma and COPD because they prevent degranulation of the mast cell, preventing the release of histamine and other inflammatory mediators in the airways. Cromolyn is the only mast cell stabilizer approved for respiratory indications. The dose for this drug is given in Table 44.5. A second drug in this class, nedocromil, was formerly used to treat asthma, but is now available only as an ophthalmic solution to treat allergic conjunctivitis.

PROTOTYPE DRUG **Cromolyn**

Classification **Therapeutic:** Anti-inflammatory
Pharmacologic: Mast cell stabilizer

Therapeutic Effects and Uses: An older drug that was approved by the FDA in 1973, cromolyn prevents the inflammation that is a characteristic pathophysiologic

feature of asthma and COPD. Because it has no effect on previously released inflammatory mediators from mast cell degranulation, the effects will not be noted immediately. The NAEPP guidelines place cromolyn as an alternate drug for the treatment of mild to moderate asthma when corticosteroids are contraindicated or have not proven effective. This drug should not be used to terminate acute asthma attacks.

For asthma therapy the drug is administered via oral inhalation. An intranasal over-the-counter (OTC) formulation (NasalCrom) is available for allergic rhinitis. An ophthalmic solution (Crolom) is used to treat various allergic disorders of the conjunctiva. Gastrocrom is a PO dosage form of cromolyn that is the only FDA-approved drug to treat systemic mastocytosis, which is a rare condition in which the patient has an excessive number of mast cells. Gastrocrom is also used off-label to treat ulcerative colitis and to prevent symptoms associated with food allergies.

Mechanism of Action: By stabilizing mast cells, cromolyn helps to prevent the inflammatory response that occurs when mast cells degranulate.

Pharmacokinetics:

Route(s)	Inhalation
Absorption	Minimal systemic absorption (less than 1%)
Distribution	Delivered directly to the lungs (site of action); small amount crosses the placenta; small amount is secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Bile (and, subsequently, feces) and renal
Onset of action	Adequate effect may not be noted until 2–4 weeks of use
Duration of action	Unknown

Adverse Effects: Adverse effects are uncommon when the drug is administered by oral inhalation. The most common effects are bronchospasm, cough, and pharyngeal irritation. Intranasal and ophthalmic administration may cause local burning and stinging.

Contraindications/Precautions: As with any drug, individuals who have demonstrated a hypersensitivity to this drug should not take it. It should be discontinued if the patient develops pulmonary eosinophilia.

Drug Interactions: No significant interactions are known. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: There are no noted problems associated with overdosage. Toxicity is unlikely.

Nursing Responsibilities: Key nursing implications for patients receiving cromolyn are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

Drugs Similar to Cromolyn

Cromolyn is the only mast cell stabilizer indicated for respiratory conditions.

44.9 The leukotriene modifiers, which are primarily used for asthma prophylaxis, act by reducing the inflammatory component of asthma.

Leukotriene modifiers are a newer drug class added to the arsenal of asthma management. They are able to ease bronchoconstriction by reducing inflammation. Because of their delayed onset, leukotriene modifiers are ineffective at terminating acute asthma attacks. The NAEPP guidelines list the leukotriene modifiers as alternative drugs to be considered when inhaled corticosteroids and SABAs are unable to control asthma symptoms. Doses for these drugs are listed in Table 44.5.

Leukotrienes are mediators of the immune and inflammatory responses that are involved in allergic and asthmatic reactions. Leukotrienes are synthesized by mast cells as well as neutrophils, basophils, and eosinophils. When released in the airway, they promote edema, inflammation, and bronchoconstriction. Leukotriene modifiers reduce inflammation by either blocking the enzyme that controls leukotriene synthesis or by blocking leukotriene receptors. They are not considered bronchodilators, although they do produce some bronchodilation through indirect mechanisms. The leukotriene modifiers are only available by the PO route.

PROTOTYPE DRUG **Montelukast (Singulair)**

Classification **Therapeutic:** Drug for asthma prophylaxis and allergic rhinitis
Pharmacologic: Leukotriene modifier

Therapeutic Effects and Uses: First approved in 1998, montelukast is a PO drug that prevents the inflammation that is a characteristic feature of asthma. It is intended for the long-term control of asthma symptoms and not for the relief of an acute asthma attack. In addition to asthma, the drug is indicated for relief of symptoms associated with allergic and seasonal rhinitis. For pediatric use it is available as chewable tablets and oral granules that may be sprinkled on soft food. In 2007, montelukast was approved for the prevention of exercise-induced bronchospasm, when taken 2 or more hours prior to the expected physical activity. It is the only drug in this class approved for this indication.

Mechanism of Action: Montelukast blocks leukotriene receptors in the airways, which prevents airway edema and inflammation.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Secreted in breast milk; more than 99% bound to plasma protein
Primary metabolism	Extensive hepatic metabolism (CYP2C9, CYP3A4)
Primary excretion	Mostly bile
Onset of action	1 week
Duration of action	Unknown; half-life: up to 5.5 h

Adverse Effects: Side effects of montelukast are generally mild with headache being the most common complaint. Rhinitis, influenza, and abdominal pain have been reported by some patients. Although rare, neuropsychiatric events have been documented, including aggression, anxiety, depression, suicidal ideation, and memory impairment.

Contraindications/Precautions: The only absolute contraindication is hypersensitivity to this drug.

Drug Interactions: Montelukast is metabolized by CYP450 enzymes and has the potential to interact with substrates that inhibit this enzyme such as carbamazepine, erythromycin, and the azole antifungals. **Herbal/Food:** St. John's wort may decrease the effects of montelukast.

Pregnancy: Category B.

Treatment of Overdose: Symptoms of overdose include headache, abdominal pain, nausea, and vomiting. Treatment is supportive.

Nursing Responsibilities: Key nursing implications for patients receiving montelukast are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

Drugs Similar to Montelukast

Roflumilast, zafirlukast, and zileuton are other leukotriene modifiers and miscellaneous drugs.

Roflumilast (Daliresp): Roflumilast was approved in 2011 to prevent symptoms such as coughing and excess mucus production in patients with COPD. It is indicated for the chronic management of the disease and not for acute bronchospasms. It is available PO, administered once daily. Roflumilast acts by blocking the enzyme phosphodiesterase 4 (PDE4). PDE4 is the main enzyme that degrades cAMP in cells of the immune system. By inhibiting PDE4, roflumilast increases the levels of cAMP, which leads to reduced inflammatory cell activity in the lungs. The most common adverse effects are diarrhea, nausea, headache, back pain, influenza, insomnia, dizziness, and decreased appetite and weight loss. This drug is pregnancy category C.

Zafirlukast (Accolate): Zafirlukast was the first leukotriene modifier, approved in 1996 for the prophylaxis of persistent, chronic asthma. It is less effective than inhaled corticosteroids. Off-label uses include allergic rhinitis and prevention of exercise-induced bronchospasm. Its relatively long onset of action makes it unsuitable for the termination of acute bronchospasm. Zafirlukast produces few serious adverse effects. Headache is the most common complaint. This drug is pregnancy category B.

Zileuton (Zyflo CR): Approved in 1996, zileuton is a PO drug that acts by inhibiting the lipoxygenase, which is the first enzyme in the pathway of leukotriene synthesis. Like other leukotriene inhibitors, zileuton is considered an alternate drug in the prophylaxis of persistent, chronic asthma. An extended release formulation (Zyflo CR) allows for twice-daily dosing. Zileuton should not be used to treat acute asthma attacks. This drug is generally well tolerated, with sinusitis, nausea, and throat pain being the most common adverse effects. The most serious concern with zileuton is the potential for liver damage. Zileuton raises liver enzymes (alanine aminotransferase), and cases of jaundice and severe hepatic injury have been reported. This drug is contraindicated in patients with hepatic impairment, and liver function tests should be conducted on a regular basis during therapy. Because zileuton can increase serum warfarin levels, prothrombin time should be regularly monitored. This is a pregnancy category C drug.

44.10 Methylxanthines were once the mainstay of asthma pharmacotherapy but are now rarely prescribed for that disorder.

The **methylxanthines** were preferred drugs for treating asthma 30 years ago. Now they are primarily reserved for the long-term management of persistent asthma that is unresponsive to beta agonists or inhaled corticosteroids. One reason methylxanthines are used less often now is because their narrow therapeutic index increases the risk of toxicity, especially with prolonged use. These drugs also have significant interactions with numerous other drugs. Doses for the methylxanthines are listed in Table 44.4.

The methylxanthines are modest bronchodilators. They are chemically related to caffeine and share caffeine's stimulant effect. Methylxanthines are available in forms for PO, parenteral, and rectal administration. Because they are not available for inhalation, patients do not benefit from the smaller doses and direct effects that are provided by drugs that can be administered by the inhalation route. Interestingly, theobromine, an ingredient in chocolate, is also a methylxanthine.

Technically, theophylline is the only drug in this class. A second drug, aminophylline, consists of theophylline combined with an inert ingredient that makes it more water soluble. Other than different pharmacokinetics, the two drugs have the same actions and adverse effects.

PROTOTYPE DRUG **Theophylline**

Classification **Therapeutic:** Bronchodilator
Pharmacologic: Methylxanthine

Therapeutic Effects and Uses: Approved by the FDA in 1940, theophylline is a natural substance found in small amounts in tea. Theophylline relaxes bronchial smooth muscle and may exert some anti-inflammatory action that is beneficial to patients with asthma. It is considered an alternate drug by the NAEPP guidelines to be considered for asthma prophylaxis when more effective drugs fail to bring symptomatic relief. It may be used in combination with a corticosteroid for persistent asthma. Although FDA approved for treating acute bronchospasm, theophylline is not recommended by the NAEPP guidelines because the SABAs are more effective.

Theophylline has several off-label indications. As a respiratory stimulant, theophylline and caffeine may be used to treat sleep apnea in neonates and in adults with chronic heart failure. Given IV, theophylline has been found to reduce neurotoxicity resulting from the drug methotrexate.

Mechanism of Action: Theophylline works by two mechanisms. It relaxes bronchial smooth muscle, which promotes bronchodilation, and it suppresses airway responsiveness to stimuli that promote bronchospasm.

Pharmacokinetics:

Route(s)	PO, parenteral, suppository
Absorption	Rapid absorption
Distribution	About 40% protein bound; remainder is distributed well in fluids and less well in body lipids
Primary metabolism	Hepatic (CYP1A2, CYP2E1, CYP3A3)
Primary excretion	Renal
Onset of action	Peak: approximately 60 min (highly variable)
Duration of action	Half-life: 6–10 h (highly variable)

Adverse Effects: Theophylline has a very narrow therapeutic index. Therapeutic levels are 10 to 15 mcg/mL and the toxic level is anything above 20 mcg/mL. Serum theophylline levels should be obtained during therapy. Common adverse effects include nausea, vomiting, headache, irritability, and insomnia. More serious reactions include dysrhythmias, hypotension, and seizures.

Contraindications/Precautions: Theophylline should be used with great caution in patients who have seizure disorders, heart failure, or cardiac dysrhythmias. Theophylline has also been shown to increase the production of gastric acid so use in patients with active peptic ulcer disease is not recommended. Because of the extensive hepatic metabolism, theophylline should be closely monitored in patients with a history of liver disease. As with any drug, this drug is contraindicated in patients who have demonstrated a hypersensitivity to it.

Drug Interactions: Because theophylline is extensively metabolized by CYP450 enzymes, it is subject to numerous drug interactions, including interactions with many common antibiotics (ciprofloxacin, clarithromycin, erythromycin) and antianxiety drugs (diazepam, flurazepam, lorazepam, midazolam). When treating a patient who is receiving multiple drugs concurrently with theophylline, the nurse should consult current sources for potential drug interactions. Theophylline also has a number of IV incompatibilities, including emergency medications such as epinephrine, norepinephrine, and isoproterenol. Compatibility of any medication should be checked prior to initiating infusions in the same line. **Herbal/Food:** Foods and beverages containing caffeine will cause additive central nervous system (CNS) stimulation. St. John's wort may decrease the effectiveness of theophylline.

Pregnancy: Category C.

Treatment of Overdose: There is no specific antidote to theophylline. Gastric lavage is indicated in the event of an overdose of PO medications. Supportive measures need to be provided for hypotension, shock, dysrhythmias, and other toxic effects. Serum levels should be monitored periodically until they are within normal limits.

Nursing Responsibilities: Key nursing implications for patients receiving theophylline are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Asthma and COPD.

44.11 Monoclonal antibodies are a newer form of therapy for the prevention of asthma symptoms.

A newer approach to treating asthma and COPD is the use of monoclonal antibodies. Monoclonal antibodies are designed to attach to a specific receptor on a target cell or molecule. Most monoclonal antibodies are designed to attack cancer cells. However, two drugs have been designed to attach to inflammatory mediators that reduce allergy symptoms.

Approved in 2003, omalizumab (Xolair) was the first biologic therapy used to treat asthma. Omalizumab attaches to a receptor on immunoglobulin E (IgE). The normal function of IgE is to react to antigens and cause the release of

inflammatory chemical mediators from mast cells and basophils. By binding to IgE, omalizumab prevents inflammation and dampens the body's response to allergens that sometimes trigger asthma. This drug is approved for treating allergic rhinitis and moderate to severe, persistent asthma that cannot be controlled satisfactorily with inhaled corticosteroids. A second indication is to treat chronic idiopathic urticaria. Available by the subcutaneous route, injections are scheduled every 2 to 4 weeks. The most common adverse effects include injection-site reaction, upper respiratory tract infections, headache, and pharyngitis. The drug contains a black box warning regarding the potential for anaphylaxis. Pregnancy category has not been established.

Approved in 2016, reslizumab (Cinqair) is a monoclonal antibody that binds to interleukin-5 (IL-5). Blocking the activity of IL-5 reduces the inflammatory actions of eosinophils. The drug is reserved for severe, persistent asthma in patients ages 18 years and older and who have an eosinophilic phenotype. Eosinophilic asthma is a subtype of asthma in which the sputum contains a high percentage of eosinophils, and it is resistant to standard therapies. Reslizumab is administered by IV injections once every 4 weeks. Oropharyngeal pain is the only common adverse effect. The drug contains a black box warning regarding the potential for anaphylaxis. Pregnancy category has not been established.

CONNECTION Checkpoint 44.3

Most monoclonal antibodies are classified as immunosuppressants. From what you learned in Chapter 42, explain methods by which these drugs can be used to suppress the immune system. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Chronic Obstructive Pulmonary Disease

44.12 Chronic obstructive pulmonary disease may be treated with bronchodilators, anti-inflammatory drugs, and mucolytics.

Chronic obstructive pulmonary disease (COPD) is a progressive pulmonary disorder characterized by chronic and recurrent obstruction of airflow. The two most common examples of conditions that cause chronic pulmonary obstruction are **chronic bronchitis**, a condition in which excess mucus is produced in the lower respiratory tract, and **emphysema**, a condition in which there is loss of bronchiolar elasticity and destruction of alveolar walls.

The clinical distinction between chronic bronchitis and emphysema is sometimes unclear because patients may exhibit symptoms of both conditions concurrently. Both conditions are strongly associated with smoking tobacco products (cigarette smoking accounts for 85% to 90% of all cases of nonasthmatic COPD) and, secondarily, breathing air pollutants. In chronic bronchitis, excess mucus is produced in the lower respiratory tract due to the inflammation and irritation from cigarette smoke or pollutants. The airway becomes partially obstructed with mucus, resulting in the classic signs of dyspnea and coughing. An early sign of bronchitis is often a productive cough that occurs on awakening. Gas exchange may be impaired; thus wheezing and decreased exercise tolerance are additional clinical signs. Microbes thrive in the mucus-rich environment, and pulmonary infections are common.

Because most patients with COPD are lifelong tobacco users, they often have serious comorbid cardiovascular conditions such as heart failure and HTN. Emphysema is most often the result of years of chronic inflammation and is characterized by loss of elasticity of the bronchioles and damage and loss of alveolar wall structures. The loss of elasticity results in partial collapse of the airways on exhalation, leading to air trapping, and the destruction of alveolar walls leads to decreased perfusion and gas exchange at the alveolus. The patient with emphysema may experience extreme dyspnea from even the slightest physical activity.

Drugs may be used to bring symptomatic relief to patients with COPD, but they do not alter the progression of COPD or cure the disorder. The goals of pharmacotherapy of COPD are to relieve symptoms and avoid complications of the condition. Various classes of drugs are used to treat infections, control cough, and relieve bronchospasm. Most patients receive the same classes of bronchodilators and anti-inflammatory drugs that are prescribed for asthma. A few of the newer drugs and combination drugs are approved only for COPD. These include the following:

- Roflumilast (Daliresp) is an oral drug for severe COPD that exhibits anti-inflammatory effects on the airways by inhibiting the enzyme PDE4.
- Incruse Ellipta contains the anticholinergic umeclidinium, which relaxes bronchial smooth muscle to cause bronchodilation. It is administered once daily by oral inhalation.
- Anoro Ellipta contains umeclidinium and vilanterol (a LABA) and is given by oral inhalation.
- Breo Ellipta is a combination of vilanterol and fluticasone given once daily by oral inhalation.
- Stiolto Respimat is a combination of tiotropium and olodaterol given once daily by oral inhalation.
- Bevespi Aerosphere is a combination of glycopyrrolate (an anticholinergic) and formoterol.
- Utibron Neohaler contains indacaterol and glycopyrrolate and is given twice daily by oral inhalation.

Mucolytics, which are medications given to loosen thick viscous bronchial secretions, and expectorants, which are drugs given to aid in the removal of mucus, are sometimes prescribed (see Chapter 45). Long-term oxygen therapy is prescribed in later stages and it has been shown to

decrease mortality in patients with advanced COPD. Antibiotics may be prescribed for patients who experience multiple bouts of pulmonary infections.

Patients with COPD should not receive drugs that have beta-adrenergic antagonist activity because these drugs cause bronchoconstriction. Respiratory depressants such as opioids and barbiturates should also be avoided when possible. An important teaching point for the nurse is to strongly encourage smoking cessation in these patients. Smoking cessation has been shown to slow the progression of COPD and to result in fewer respiratory symptoms; however, it cannot undo damage that has already occurred.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Asthma and COPD

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including previous history of symptoms and association with seasons, foods, or environmental exposures; existing cardiovascular, respiratory, hepatic, renal, or neurologic disease; glaucoma; prostatic hypertrophy; difficulty with urination; presence of fever or active infections; pregnancy or breastfeeding; alcohol use; or smoking. Obtain a drug history, noting the type of adverse reaction experienced to any medications.
- If asthma symptoms are of new onset, particularly in infants and young children, assess for any recent changes in diet, soaps including laundry detergent, laundry softener, cosmetics, lotions, and environmental factors (e.g., pets, travel, or recent carpet cleaning) that may correlate with the onset of symptoms.
- Obtain baseline vital signs, noting respiratory rate and depth.
- Assess pulmonary function with pulse oximeter, peak expiratory flowmeter, and arterial blood gases to establish baseline levels.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], hepatic, and renal tests).
- Assess symptom-related effects on eating, sleep, and activity level.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased ease of breathing, improvement in pulmonary function studies, improved signs of peripheral oxygenation and increased activity levels, maintenance of normal eating and sleep periods).
- Continue periodic monitoring of pulmonary function with pulse oximeter, peak expiratory flowmeter, and arterial blood gases as appropriate.
- Assess vital signs, especially respiratory rate and depth. Assess breath sounds, noting the presence of adventitious sounds, and any mucus production.
- Assess for adverse effects: dizziness, tachycardia, palpitations, blurred vision, or headache. Immediately report fever, confusion, tachycardia, palpitations, hypotension, syncope, dyspnea, or increasing pulmonary congestion.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Increased ease of breathing, lessened adventitious breath sounds, improved signs of tissue oxygenation, and normal appetite and eating and sleeping patterns should occur.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures, such as increased fluid intake to liquefy and mobilize mucus, and to reduce exposure to allergens where possible. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating the presence of asthma or a respiratory condition, any significant allergies or anaphylaxis, and use of inhaler therapy.
• Monitor pulmonary function periodically with pulse oximeter, peak expiratory flowmeter, and arterial blood gases. (Periodic monitoring is necessary to assess drug effectiveness.)	• Teach the patient how to use the peak expiratory flowmeter or other equipment ordered to monitor pulmonary function. • Instruct the patient to immediately report symptoms of deteriorating respiratory status such as increased dyspnea, breathlessness with speech, increased anxiety, or orthopnea.
• For treatment of acute asthmatic attacks, inhaler therapy should be started at first sign of respiratory difficulty to abort the attack. For preventive therapy, long-term bronchodilation by inhaler or orally will be used to maintain bronchodilation. *LABAs and long-acting bronchodilators are not to be used to abort an acute attack.* (Acute asthmatic attacks are managed with quick-acting bronchodilation such as beta$_2$ agonists. For maintaining bronchodilation and preventing attacks, LABAs, anticholinergics, mast cell stabilizers, and glucocorticoid or methylxanthine therapy may be used. It is crucial to know and recognize the difference between quick-acting and long-acting inhalers.)	• Provide explicit instructions on the use of quick-acting versus long-acting inhalers. Teach the patient to use quick-acting inhalers at the earliest possible appearance of symptoms. Long-acting inhalers or oral therapy may be used to maintain bronchodilation but *do not discard quick-acting inhalers if on long-term maintenance therapy.* They may still be needed for periodic acute attacks.
Minimizing adverse effects: • Continue to monitor respirations, rate, depth, breath sounds, mucus production, and for increasing dyspnea, adventitious breath sounds, and signs of tissue hypoxia (e.g., cyanosis), anxiety, confusion, or decreasing pulmonary function (e.g., pulse oximeter, peak expiratory flow). Immediately notify the provider if symptoms continue to increase, especially if respiratory involvement worsens or fever is present. (Increasing dyspnea, adventitious breath sounds, diminished oxygenation, or increasing anxiety or confusion may indicate inadequate drug therapy, worsening disease process, or respiratory infection and should be reported immediately. **Diverse Patients:** Because some drugs such as theophylline metabolize through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects.)	• Instruct the patient to report immediately symptoms of deteriorating respiratory status such as increased dyspnea, breathlessness with speech, increased anxiety, or orthopnea.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Provide explicit instruction on the use of quick-acting and long-acting inhalers. Ensure that the patient is able to identify the appropriate inhaler for the treatment of acute asthmatic attacks or for preventive therapy. (Acute asthmatic attacks are managed with quick-acting bronchodilation such as beta$_2$ agonists and the patient must be able to identify the appropriate inhaler to use. Provide written instructions, including drug name and when to use, if both quick-acting and long-acting inhalers are ordered.)	• Teach the patient to use the quick-acting inhaler at the earliest possible appearance of symptoms. Long-acting inhalers or oral therapy may be used to maintain bronchodilation but *do not discard quick-acting inhalers if on long-term maintenance therapy*. They may still be needed for periodic acute attacks. • Teach the patient not to rely on the color of the inhaler to indicate quick-acting versus long-acting inhalers. Depending on the manufacturer and trade versus generic drugs, the color may change. If the patient desires to color-code, suggest individual color stickers or tape be used per patient preference. Instruct the patient not to obscure the drug name with the sticker.

• Monitor eating and sleep patterns and ability to maintain functional activities of daily living (ADLs). Provide for calorie-rich, nutrient-dense foods, frequent rest periods between eating or activity, and a cool room for sleeping. (Respiratory difficulty and fatigue associated with hypoxia and the work of breathing may affect appetite, ability to eat during dyspnea, and maintenance of required ADLs. Adequate nutrition, fluids, rest, and sleep are essential to support optimal health.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures including:
	  • Increased fluid intake to liquefy and assist in mobilizing mucus
	  • Small, frequent meals of calorie-rich, nutrient-dense foods to prevent fatigue and maintain normal nutrition
	  • Adequate rest periods between eating and activities
	  • Decreased room temperature for ease of breathing during sleep
	  • Reduced exposure to allergens where possible.
	  • Instruct the patient to immediately report any significant change in appetite, inability to maintain normal intake, inadequate sleep periods, or inability to carry out required ADLs.

• Eliminate smoking, limit exposure to secondhand smoke, and limit caffeine intake, especially if methylxanthines are prescribed. (Cigarette smoke irritates respiratory mucous membranes, increasing the risk of adverse effects and increasing bronchoconstriction. Caffeine may increase the risk of tachycardia in addition to the drugs' adverse effects, and both smoking and caffeine affect the metabolism of methylxanthines.)	• Teach the patient about smoking cessation programs, to avoid environments with secondhand smoke, and to limit or abstain from caffeine intake while taking bronchodilator therapy.
• Maintain consistent dosing of long-acting bronchodilators. LABAs, anticholinergics, mast cell stabilizers, and corticosteroids are used to prevent or limit acute bronchoconstrictive attacks. Regular, consistent dosing must be maintained for best results.	• Teach the patient the importance of continuing regular and consistent administration of all bronchodilation therapy to prevent acute attacks. Irregular use may increase the risk or severity of bronchoconstrictive events.
• Utilize the appropriate spacer between the inhaler and mouth and rinse mouth after using the inhaler, especially after corticosteroids. (Spacers between MDIs may be ordered to assist in coordination and timing of inhalation and to prevent medication being delivered to the back of the pharynx. Rinsing the mouth after the use of inhalers prevents systemic absorption or localized reactions to the drug such as ulceration.)	• Instruct the patient in the proper use of spacers if ordered, followed by return demonstration. • Teach the patient to rinse the mouth after each use of the inhaler and not to swallow after rinsing.
• Continue to monitor cardiac status, hepatic function, and ophthalmology examination findings. (Beta-adrenergic drugs given for asthma and COPD may cause cardiac adverse effects. Corticosteroids may increase the risk of cataract formation. **Lifespan:** Monitor the older adult frequently because age-related physiologic changes increase the risk of adverse effects.)	• Teach the patient about any follow-up laboratory or other testing needed, such as annual eye exams.
• Monitor for anticholinergic adverse effects in patients taking ipratropium (Atrovent) and other anticholinergic drugs. (**Lifespan:** Be aware that older adult men are at higher risk for mechanical obstruction due to an enlarged prostate. The older adult is also at increased risk of constipation due to slowed peristalsis.)	• Teach the patient about the importance of drinking extra fluids and increasing fiber intake. Instruct the patient to notify the healthcare provider if difficulty with urination occurs or if constipation is severe.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION *(continued)*

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug at the first appearance of symptoms before they are severe. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.
	• The patient recognizes the difference between quick-acting and long-acting inhalers and knows when each is to be used.
	• Instruct the patient in proper administration techniques for inhalers, followed by return demonstration, including:
	  • Use a spacer if instructed between the metered-dose inhaler and the mouth.
	  • Shake the inhaler or load it with a tablet or powder as instructed.
	  • If using a bronchodilator and corticosteroid inhalers, use the bronchodilator first, wait 5 min, then use the corticosteroid to ensure the drug reaches deeply into the bronchial area.
	  • Rinse mouth after using any inhaler.
	  • Clean the inhaler at least weekly by running warm water through the plastic mouthpiece after removing the drug canister, shaking out excess water, and allowing to air dry.
	  • **Lifespan:** Supervise children under the age of 5 to ensure proper inhaler use.

Understanding Chapter 44

Key Concepts Summary

44.1 The physiology of the respiratory system involves two main processes: perfusion and ventilation.

44.2 Asthma is a chronic disease that has both inflammatory and bronchospasm components.

44.3 Inhalation is a common route of administration for pulmonary drugs because it delivers drugs directly to their sites of action.

44.4 The goals of asthma pharmacotherapy are to terminate acute bronchospasms and to reduce the frequency of asthma attacks.

44.5 Beta$_2$-adrenergic agonists are the most effective drugs for relieving acute bronchospasm.

44.6 The inhaled anticholinergics are used for preventing bronchospasm.

44.7 Inhaled corticosteroids are the most effective drugs for the long-term control of asthma.

44.8 Mast cell stabilizers are used for the prophylaxis of asthma and act by preventing the release of histamine.

44.9 The leukotriene modifiers, which are primarily used for asthma prophylaxis, act by reducing the inflammatory component of asthma.

44.10 Methylxanthines were once the mainstay of asthma pharmacotherapy but are now rarely prescribed for that disorder.

44.11 Monoclonal antibodies are a newer form of therapy for the prevention of asthma symptoms.

44.12 Chronic obstructive pulmonary disease may be treated with bronchodilators, anti-inflammatory drugs, and mucolytics.

CASE STUDY: Making the Patient Connection

Remember the patient "Nathan Almond" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Nathan is a 12-year-old with a history of asthma, diagnosed 2 years ago. He is an outgoing, active boy and participates in a swim club and a basketball team, but he has had a difficult time adjusting to the limitations of his asthma. He has learned to control acute attacks by using an albuterol (Proventil) MDI, and because his asthma is often triggered by exercise, he has also been using a budesonide (Pulmicort) inhaler and taking montelukast (Singulair).

After competing in his swim meet at the local indoor pool, Nathan began experiencing respiratory distress. He alerted his coach, who retrieved the albuterol inhaler from Nathan's backpack. After two inhalations, Nathan was still in distress and the rescue squad was called.

On admission to the emergency department, Nathan is in obvious distress with pulse oximeter readings of 90% to 91%. He has nasal flaring and bilateral wheezing is heard in his lung fields, pulse rate is 122 beats/min, and he is orthopneic. While treatment is started, the nurse asks him questions that he can nod or shake his head to answer. He shakes his head "no" when asked if he used his budesonide inhaler today and shrugs when asked about his last dose of montelukast.

Critical Thinking Questions

1. Considering his history, medications, and the location where Nathan's asthma attack occurred, what might explain his acute attack?
2. What medications would you anticipate will be prescribed to treat Nathan's acute asthmatic attack and why?
3. What changes might be made to Nathan's medications? What teaching will Nathan and his family need prior to discharge?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

As the home health nurse, you visit with Mr. Jonas Maxwell weekly to assess his pulmonary status and his adherence to his medication regimen. Jonas has end-stage COPD. He was diagnosed with the disease many years ago and his pulmonary status has deteriorated slowly during the past few years. Despite his healthcare provider's recommendation to change to another medication, Jonas insists that theophylline is the only medication that helps him to breathe. He also uses several MDIs with spacers several times per day.

1. What symptoms would you expect to observe in Jonas if he is experiencing early signs of toxicity?
2. Create a list of things to avoid for an individual who is receiving theophylline therapy.
3. In your own words, how would you describe the function of the spacer used with Jonas's MDI?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient with asthma asks which of the prescribed medications should be used in the event of an acute episode of bronchospasm. The nurse will instruct the patient to use:
    1. Albuterol, a beta-agonist bronchodilator, by inhalation.
    2. Beclomethasone, a glucocorticoid anti-inflammatory drug, by inhalation.
    3. Ipratropium, an anticholinergic bronchodilator, by inhalation.
    4. Montelukast, a leukotriene modifier, by mouth.
2. A patient is prescribed beclomethasone (Qvar), a glucocorticoid inhaler. Education by the nurse will include:
    1. "Check your heart rate because this drug may cause tachycardia."
    2. "Limit your coffee intake while on this drug."
    3. "Rinse your mouth out well after each use."
    4. "You may feel shaky and nervous after using this drug."
3. The nurse should inform the patient who is prescribed a nebulizer treatment with albuterol (Proventil HFA, VoSpire ER) that a common adverse effect is:
    1. An increased heart rate with palpitations.
    2. A predisposition to infection.
    3. Sedation.
    4. Temporary dyspnea.
4. The nurse should monitor the patient who is taking beclomethasone (Qvar) for evidence of (select all that apply):
    1. Infection.
    2. Hyperglycemia.
    3. Urinary retention.
    4. Tachycardia.
    5. Photophobia.

5. A 4-year-old child with respiratory distress secondary to asthma has an order for a nebulizer treatment. The type of medication most likely to be given for asthma management is a:
   1. Beta agonist.
   2. Beta antagonist.
   3. Corticosteroid.
   4. Leukotriene modifier.

6. Despite repeated demonstrations of proper inhaler use by the nurse, the patient is unable to demonstrate proper technique in using the training inhaler. The patient is becoming frustrated. What is the best action for the nurse to take?
   1. Encourage the patient to keep practicing just a little longer.
   2. Notify the healthcare provider that the patient is incompetent.
   3. Provide a spacer for use with the inhaler.
   4. Switch to an oral form of a beta agonist.

"I can't stop coughing, I can't sleep, and my head hurts. I thought I had a summer cold but this is just dragging on. It's affecting my work!"
Patient "Nancy Chen"

Chapter 45
Pharmacotherapy of Allergic Rhinitis and the Common Cold

Chapter Outline

- Physiology of the Upper Respiratory Tract
- Pathophysiology of Allergic Rhinitis
- Pharmacotherapy of Allergic Rhinitis
  - H1-Receptor Antagonists (Antihistamines)
    PROTOTYPE *Fexofenadine (Allegra), p. 816*
  - Intranasal Corticosteroids
    PROTOTYPE *Fluticasone (Flonase, Veramyst), p. 818*
  - Mast Cell Stabilizers
- Decongestants
  PROTOTYPE *Pseudoephedrine (Sudafed), p. 823*
- Drugs for the Common Cold
- Antitussives
  PROTOTYPE *Dextromethorphan (Delsym, Robitussin DM, Others), p. 826*
- Expectorants and Mucolytics

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify structures of the upper respiratory tract that serve as body defenses against foreign substances.
2. Describe the common causes and symptoms of allergic rhinitis.
3. Differentiate between H_1 and H_2 histamine receptors.
4. Compare and contrast the first- and second-generation antihistamines.
5. Explain why intranasal corticosteroids are preferred drugs for the treatment of allergic rhinitis.
6. Compare and contrast the oral and intranasal decongestants.
7. Explain why it is usually better to take individual drugs for the common cold, rather than a multisymptom combination product.
8. Describe the appropriate use of cough suppressants.
9. Describe the use of drugs prescribed to treat thick bronchial secretions.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Apply the nursing process to care for patients receiving pharmacotherapy for allergic rhinitis and the common cold.

Key Terms

allergic rhinitis, 812
antitussives, 825
expectorants, 826
H_1 receptors, 814
mast cell stabilizers, 821
mucolytics, 827
rebound congestion, 822

The respiratory system begins at the nose and ends at the respiratory membrane, the dividing line between the alveoli and the pulmonary capillaries. The pharmacotherapy of asthma and chronic obstructive pulmonary disease (COPD), which are conditions of the lower respiratory tract, is discussed in Chapter 44. This chapter examines the drugs used for two conditions that are primarily associated with the upper respiratory tract: allergic rhinitis and the common cold. Because many of these medications are readily available over the counter (OTC), it is essential for the nurse to provide effective teaching for their use.

Physiology of the Upper Respiratory Tract

45.1 The upper respiratory tract acts as a defense in preventing systemic infection.

The upper respiratory tract (URT) consists of the nose, nasal cavity, pharynx, and paranasal sinuses. These passageways filter, warm, and humidify air during inhalation. The URT traps particulate matter and many pathogens, preventing them from being carried to the bronchioles and alveoli, where they would have access to the capillaries of the systemic circulation. The mucous membranes of the URT are lined with ciliated epithelium. The cilia projecting from the epithelium are found throughout the nasal passages and help to trap smaller particles. The cilia exert a wavelike motion that sweeps the pathogens and particulate matter upward toward the oropharynx, where they are swallowed when someone coughs or clears the throat. A sneeze clears the nasal passages. The basic structures of the URT are shown in Figure 45.1.

The nasal mucosa is a dynamic structure richly supplied with vascular tissue that is controlled, in part, by the autonomic nervous system. Activation of the sympathetic nervous system constricts the arterioles in the nose, reducing the thickness of the mucosal layer. This serves to widen the airway and allow air to more freely enter the URT.

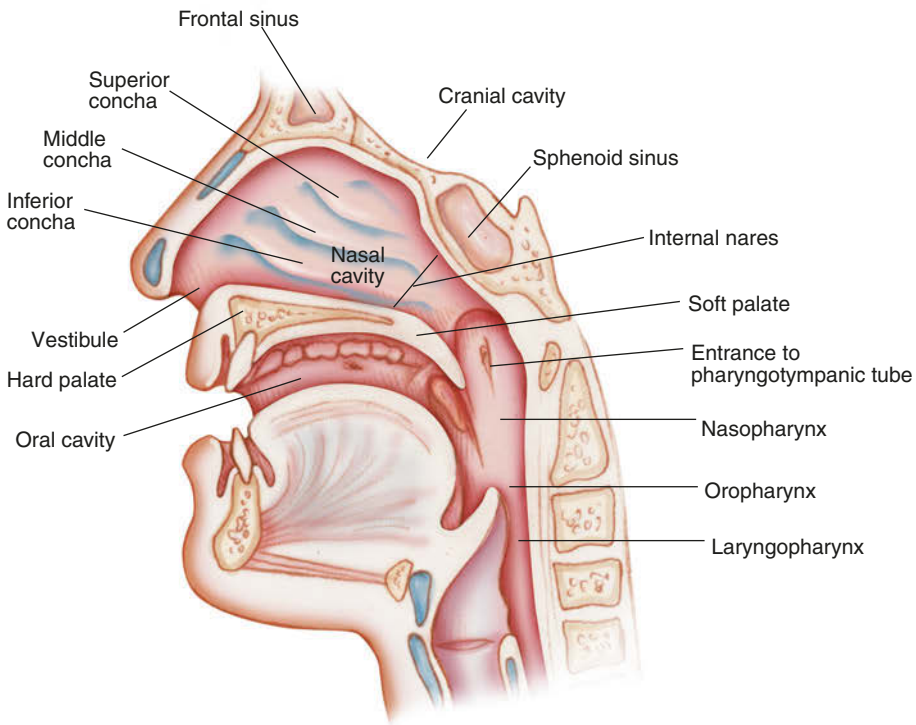

Figure 45.1 The respiratory system.

Parasympathetic activation has the opposite effect: The arterioles dilate and more mucus is produced. This difference is important during therapy with drugs that affect the autonomic nervous system. For example, administration of a sympathomimetic will shrink the nasal mucosa, relieving nasal stuffiness associated with the common cold. These drugs are classified as decongestants. On the other hand, parasympathetic drugs cause increased blood flow to the nose with increased nasal stuffiness and a runny nose as side effects.

The oral mucosa serves an important role in the body's defense against invasion by microbes. Saliva contains immunoglobulins (IgA) and lysozyme, which break down bacterial cell walls. Swallowed saliva or nasal mucus exposes microorganisms to the hostile environment of the stomach where they contact high gastric acidity and enzymes that kill them.

The nasal mucosa is also part of the first line of body defense, secreting up to a quart of mucus daily. This fluid is rich in immunoglobulins that are able to neutralize airborne pathogens. The nasal mucosa contains numerous nonspecific body defense cells that can activate complement or engulf microbes. Mast cells, which contain histamine, also line the nasal mucosa, and these play a major role in causing the symptoms of allergic rhinitis.

Pathophysiology of Allergic Rhinitis

45.2 Allergic rhinitis is caused by exposure to an environmental allergen, which leads to symptoms that resemble those of the common cold.

Allergic rhinitis is inflammation of the nasal mucosa due to exposure to allergens. Although not life threatening, allergic rhinitis is a condition that affects millions of people and one that is a common indication for pharmacotherapy.

The symptoms of allergic rhinitis resemble those of the common cold and include tearing, burning, red, swollen, or itching eyes; sneezing; nasal itching or congestion; postnasal drip; cough; and scratchy throat. In addition to the acute symptoms, complications of allergic rhinitis may include loss of taste or smell, sinusitis, hoarseness, and plugged ears. Some people may not obtain restful sleep and awaken very fatigued. Symptoms can be severe enough to cause poor performance in or absence from school or work. Because of the smaller size of their anatomic structures, children are also at increased risk for middle ear infections.

As with other types of allergies, the cause of allergic rhinitis is exposure to an antigen. An antigen, also called an allergen, is anything that is recognized as foreign and provokes a response from the body's defense system. The specific allergen responsible for a patient's allergic rhinitis is often difficult to pinpoint; however, common agents are pollens from weeds, grasses, and trees; mold spores; dust mites; certain foods; and animal dander (skin flakes). Chemical fumes, tobacco smoke, or air pollutants such as ozone are nonallergenic factors that may worsen symptoms. In addition, there is a strong genetic predisposition to allergic rhinitis.

PharmFACT

Allergic rhinitis affects about 7.8% of adults and 9% of children in the United States. The incidence of allergic conditions has been increasing worldwide for the more than 50 years (American Academy of Allergy, Asthma & Immunology, n.d.).

Some patients experience symptoms of allergic rhinitis at specific times of the year such as when pollen is at high levels in their environment. These periods are typically in the spring and fall when plants and trees are blooming; thus the name *seasonal* allergic rhinitis. Obviously, the blooming season changes with geographic location and with each species of plant. Patients may need symptom relief for only a few months during the year. When the symptoms are caused by an *outdoor* allergen, the condition is called hay fever. Others are afflicted with allergic rhinitis symptoms throughout the year because they are continuously exposed to *indoor* allergens, such as dust mites, animal dander, or mold. This variation is termed *perennial* allergic rhinitis. These patients may require a treatment plan that includes continuous pharmacotherapy.

It is often not clear whether a patient is experiencing seasonal or perennial allergic rhinitis. Patients with seasonal allergies may also be sensitive to some of the perennial allergens. It is also common for one allergen to sensitize patients to another allergen. For example, during ragweed season, a patient may become hyperresponsive to other allergens such as mold spores or animal dander. The body's response and the symptoms of allergic rhinitis are the same, however, regardless of the specific allergen(s). Allergy testing can help pinpoint the particular allergens responsible for the symptoms and help direct a treatment plan that includes avoiding allergens that cause the symptoms and treating the symptoms.

The fundamental pathophysiology responsible for allergic rhinitis is inflammation of the mucous membranes in the nose, throat, and airways. The nasal mucosa is rich with mast cells (a type of connective tissue cell) and basophils (a type of leukocyte), both of which synthesize and store histamine. The release of histamine and other substances such as leukotrienes occurs after a patient has been exposed to specific allergens. The allergen stimulates the production of high amounts of immunoglobulin E (IgE).

The IgE antibodies then bind to the outer surface of mast cells and basophils, thus sensitizing them. Sometime later, when reexposed to an antigen such as pollen, the antigen attaches to the antibody and the antigen–antibody reaction begins. This reaction stimulates a process that begins by mobilizing intracellular calcium and, eventually, the sensitized cells release chemical mediators, including histamine. In certain cases, histamine can be released from mast cells without prior exposure to an antigen (allergen). These nonallergic releases of histamine can occur with cell damage, certain drugs, plasma expanders, or radiographic contrast media.

Patients with allergic rhinitis have greater numbers of mast cells. An immediate (or Type I) hypersensitivity response releases histamine and other chemical mediators such as leukotrienes and prostaglandins from the mast cells and basophils. The body's response to the chemical mediators is to cause vasodilation of arterioles and venules, increase capillary permeability, constrict smooth muscle (bronchioles), increase secretions of glands such as the lacrimals, and act as a neurotransmitter in the central nervous system (CNS). These responses, in the case of allergic rhinitis, produce flushing of the skin, sneezing, itching nasal membranes, and watery eyes, and may cause drowsiness. A delayed hypersensitivity reaction also occurs 4 to 8 hours after the initial exposure, causing continuous inflammation of the mucosa and adding to the chronic nasal congestion experienced from the allergic response. Because histamine is released during an allergic response, many signs and symptoms of allergy are similar to those of inflammation. The mechanism of allergic rhinitis is illustrated in Figure 45.2.

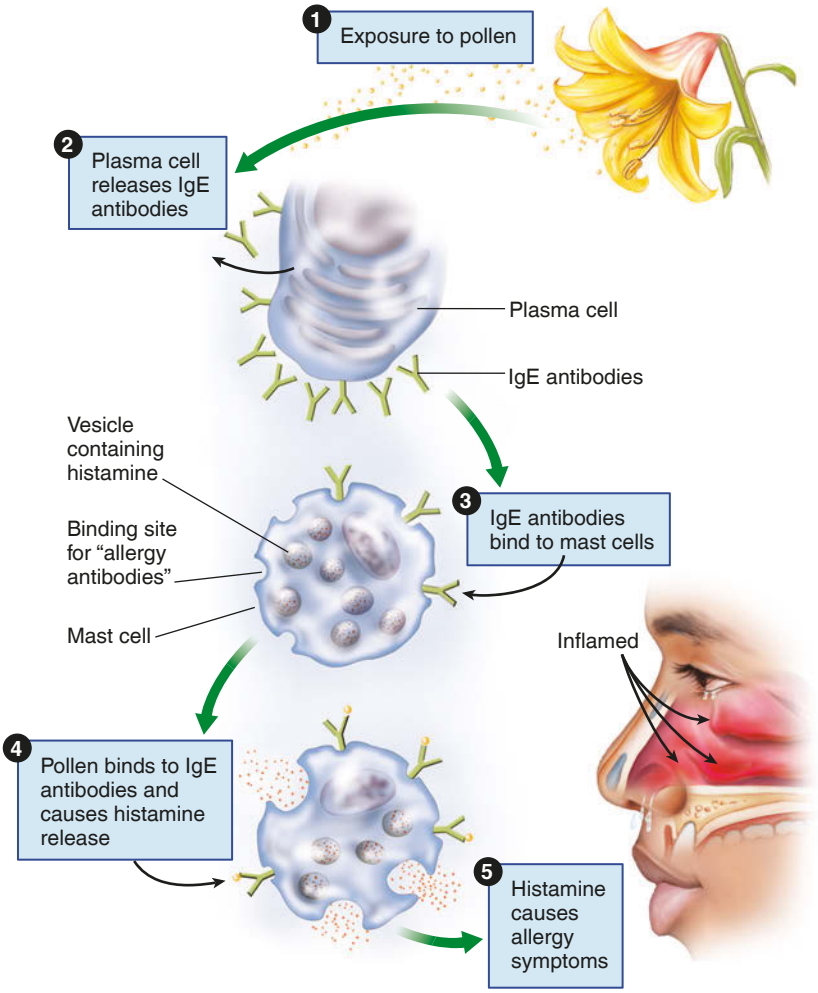

Figure 45.2 Pathophysiology of allergic rhinitis.

Pharmacotherapy of Allergic Rhinitis

45.3 Drugs for allergic rhinitis include those that prevent the disorder and those that relieve symptoms.

The therapeutic goals of treating allergic rhinitis are to prevent its occurrence and to relieve symptoms. Drugs that are used to treat allergic rhinitis may thus be grouped into two simple categories—preventers and relievers:

- Preventers are used for prophylaxis. These include antihistamines, intranasal corticosteroids, leukotriene modifiers, and mast cell stabilizers.
- Relievers are used to provide immediate, though temporary, relief for acute allergy symptoms once they have occurred. Relievers include the oral and intranasal decongestants, which usually are drugs from the sympathomimetic class but may include anticholinergics.

Nurses should help patients identify the sources of the allergy and recommend appropriate actions. These may include removing pets from the home environment or limiting their exposure (such as not allowing the pet on furniture); cleaning moldy surfaces; using and routinely cleaning or replacing microfilters on air-conditioning units; and frequent cleaning to remove dust mites from bedding, carpet, or furniture. Although dust mites can never be totally removed from mattresses, regularly decreasing their numbers can help lessen symptoms of allergic rhinitis. It may be interesting to know that dust mites feed primarily on naturally shedding human skin and that it is not the microscopic dust mite itself that a patient inhales and is allergic to, but rather its excrement.

Table 45.1 H_1-Receptor Antagonists for Allergies

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
First-Generation Drugs		
brompheniramine (Dimetapp, others)	PO: 4–8 mg q4–6h (max: 40 mg/day)	*Dry mouth, headache, dizziness, urinary retention, thickening of bronchial secretions, nausea, vomiting* Paradoxical excitation (usually in children), sedation, hypersensitivity reactions, hypotension, extrapyramidal symptoms (promethazine), agranulocytosis (brompheniramine, clemastine, promethazine)
chlorpheniramine (Chlor-Trimeton, others)	PO: 2–4 mg q4–6h (max: 24 mg/day)	
clemastine (Tavist)	PO: 1.34–2.68 mg q12h (max: 8.04 mg/day)	
cyproheptadine	PO: 4–20 mg q6–8h (max: 0.5 mg/kg/day)	
dexchlorpheniramine (Dexchlor, Poladex, Polaramine)	PO: 2 mg q4–6h (max: 12 mg/day)	
dimenhydrinate (Dramamine)	PO: 50–100 mg q4–6h	
diphenhydramine (Benadryl, others)	PO: 25–50 mg q6–8h (max: 300 mg/day)	
promethazine (Phenergan)	PO: 12.5–25 mg q6–24h (max: 100 mg/day)	
Second-Generation Drugs		
acrivastine with pseudoephedrine (Semprex-D)	PO: 1 capsule daily (8 mg acrivastine/60 mg pseudoephedrine)	*Dry mouth, headache, dizziness, nausea, drowsiness (cetirizine), bitter taste (olopatadine)* Paradoxical excitation, hypersensitivity reactions, hypotension
azelastine (Astelin, Astepro, Optivar)	Intranasal: 2 sprays per nostril q12h Ocular: 1 drop in each affected eye bid	
cetirizine (Zyrtec)	PO: 5–10 mg/day (max: 10 mg/day)	
desloratadine (Clarinex)	PO: 5 mg/day (max: 5 mg/day)	
fexofenadine (Allegra)	PO: 60 mg q12h or 180 mg once daily	
levocetirizine (Xyzal)	PO: 5 mg (1 tablet or 2 teaspoons) once daily	
loratadine (Claritin)	PO: 10 mg/day (max: 10 mg/day)	
olopatadine (Patanase, Patanol)	Intranasal (Patanase): 2 sprays per nostril bid Ocular (Patanol): 1 drop in each affected eye bid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

45.4 Antihistamines are widely used to treat allergic rhinitis and other minor allergies.

There are two types of receptors for histamine: H_1 and H_2. Activation of **H_1 receptors** produces the typical symptoms of allergy. Drugs that block H_2 receptors such as ranitidine (Zantac) reduce gastric acid secretion and are used to treat peptic ulcer disease and gastroesophageal reflux disease. This histamine receptor activity is not related to allergic responses and is covered in Chapter 59.

H_1-receptor antagonists, also called *antihistamines*, are drugs that selectively block histamine from reaching its H_1 receptors, thus alleviating allergic symptoms. Because the term *antihistamine* is nonspecific and does not indicate which of the two histamine receptors is affected, *H_1-receptor antagonist* (or *blocker*) is a more accurate name. In clinical practice, as well as in this text, the two terms are used interchangeably. Antihistamines that selectively block H_1 receptors are widely used as OTC remedies for the relief of allergy symptoms, motion sickness, and insomnia. The antihistamines are listed in Table 45.1.

The most frequent therapeutic use of antihistamines is for the treatment of allergies. These medications provide symptomatic relief from the sneezing, runny nose, and itching of the eyes, nose, and throat of allergic rhinitis. Antihistamines are often combined with decongestants and antitussives in OTC cold and sinus medicines. Common OTC antihistamine combinations that are used to treat allergies are listed in Table 45.2.

Antihistamines are most effective when taken prophylactically to *prevent* allergic symptoms. Their effectiveness in reversing allergic symptoms that have already manifested is limited. This is because antihistamines block the effect of histamine at its receptor sites. They do not prevent the release of histamine from mast cells. Their effectiveness may diminish with long-term use.

In addition to producing antihistamine effects, these drugs also easily cross the blood–brain barrier and block cholinergic receptors to cause typical anticholinergic effects. Anticholinergic effects are responsible for certain beneficial effects of antihistamines, such as drying of mucous membranes, which results in less nasal congestion and tearing.

A large number of H_1-receptor antagonists are available as medications. They all have the same basic mechanism of action and are equally effective in treating allergic rhinitis and other mild allergies. Adverse effects are similar but differ in intensity among the various antihistamines. The older, first-generation antihistamines frequently cause significant drowsiness, which can be a limiting adverse effect in some patients. After a few doses tolerance generally develops to sedation. The newer, second-generation antihistamines cause less sedation because they do not

Table 45.2 Selected Over-the-Counter Antihistamine Combinations

Trade Name	Antihistamine	Decongestant	Analgesic
Actifed Cold and Allergy tablets	chlorpheniramine	phenylephrine	—
Actifed Plus	triprolidine	pseudoephedrine	acetaminophen
Benadryl Allergy/Cold caplets	diphenhydramine	phenylephrine	acetaminophen
Chlor-Trimeton Allergy/Decongestant tablets	chlorpheniramine	pseudoephedrine	—
Dimetapp Children's Cold and Allergy	brompheniramine	phenylephrine	—
Sudafed PE Nighttime Cold	diphenhydramine	phenylephrine	acetaminophen
Sudafed PE Sinus and Allergy tablets	chlorpheniramine	phenylephrine	—
Tavist Allergy tablets	clemastine	—	—
Triaminic Cold/Allergy	chlorpheniramine	phenylephrine	—
Tylenol Allergy Multi-Symptom Gels	chlorpheniramine	phenylephrine	acetaminophen
Tylenol PM Gelcaps	diphenhydramine	—	acetaminophen

cross the blood–brain barrier. Alcohol and other CNS depressants should be used with caution when taking antihistamines, because their sedating effects may be additive, even for the second-generation drugs. Some patients (especially young children) exhibit CNS stimulation, which can cause insomnia, nervousness, and tremors, or even convulsions. Other CNS adverse effects, such as dizziness, confusion, and even fatigue, more commonly affect the older adult.

The second major adverse effect of antihistamines relates to their anticholinergic effects. Excessive drying of mucous membranes can lead to dry mouth, and urinary hesitancy may be troublesome for patients, especially those with prostatic hyperplasia. Some antihistamines produce more pronounced anticholinergic effects than others. Diphenhydramine and clemastine exhibit a significant incidence of anticholinergic adverse effects, whereas the second-generation drugs—loratadine, desloratadine, and fexofenadine—produce the least.

Although most antihistamines are given via the oral route (PO), azelastine (Astelin, Astepro) and olopatadine (Patanase) are available by the intranasal route. These drugs are as effective as the PO antihistamines, but because they are applied locally to the nasal mucosa, limited systemic absorption occurs. This may make the intranasal drugs slightly safer than PO antihistamines.

Antihistamines are used as adjuncts to the emergency treatment of anaphylaxis, which is the most severe form of allergic reaction. Although massive histamine release causes bronchoconstriction, edema, hypotension, and other symptoms of anaphylaxis, other inflammatory mediators, including leukotrienes and prostaglandins, contribute to the hypersensitivity response. Because antihistamines do not block these other mediators, antihistamines are effective only as adjunctive therapy in anaphylaxis. They are most effective if given as preventive medications before anaphylaxis for patients who are at high risk of having an allergic response. The major life-threatening symptoms of anaphylaxis are controlled with epinephrine and other vasoconstrictors.

H_1-receptor antagonists are effective in treating a number of other disorders, including the following:

- **Vertigo and motion sickness.** Nausea resulting from vertigo or motion sickness responds well to antihistamines. These drugs act by suppressing the vomiting center in the medulla and depressing the excitability of the neurons of the vestibular apparatus of the inner ear. To be effective, they must be taken prior to the onset of symptoms. Meclizine (Antivert) and dimenhydrinate (Dramamine) are the two most common antihistamines used for this purpose. Cyclizine (Marezine) is another older antihistamine that is occasionally used to reduce nausea and vertigo. The pharmacotherapy of nausea is discussed in Chapter 60.
- **Parkinson's disease.** Drugs with significant anticholinergic actions are used to treat mild forms of Parkinson's disease. They are also used to treat the tremor and extrapyramidal adverse effects from conventional antipsychotic drugs. Because diphenhydramine exerts great amounts of anticholinergic action, it is sometimes used to treat these conditions.
- **Insomnia.** Many patients become drowsy after taking first-generation antihistamines. OTC sleep aids usually include antihistamines such as diphenhydramine and doxylamine (Unisom SleepTabs). After a few days, patients will become tolerant to the drowsiness produced by these drugs; thus they should be used for 2 weeks or less.
- **Urticaria and other skin rashes.** Urticaria or hives is often caused by the release of histamine, and the condition responds well to H_1-receptor blockers. Symptomatic treatment may include any of the first- or second-generation medications, either using PO drugs or topical creams or lotions.

CONNECTIONS: Lifespan Consideration

Antihistamines and Drugs for Allergic Rhinitis in Older Adults

Although generally considered a condition of children and young and middle-aged adults, the older adult is also susceptible to allergic rhinitis. In fact, changes to nasal structure and mucous membranes in older patients may increase symptoms of rhinitis. The older adult is also more sensitive to the effects of antihistamines, and drowsiness, dizziness, and fall risk are possible with the first-generation antihistamines. Second-generation antihistamines may require a dosage adjustment due to normal physiologic changes as a patient ages. For the older adult man, the anticholinergic effects of antihistamines may exacerbate symptoms of an enlarged prostate and worsen urinary symptoms.

Studies have determined that intranasal corticosteroid sprays are preferred for the older adult with symptoms of allergic rhinitis (Nyenhuis & Mathur, 2013). They have limited systemic side effects due to the topical application; cause fewer adverse effects such as dizziness, drowsiness, or urinary problems; and are well tolerated. If an antihistamine is warranted, intranasal antihistamines or second-generation drugs are preferred over the traditional drugs. Leukotriene receptor antagonist drugs are also effective but are not considered superior to intranasal corticosteroids because of the potential for drug interactions.

At each encounter, the provider should review all current medications the patient is taking (both OTC and prescribed) to assess for any drug interactions, examine the technique of nasal instillation, and provide a written treatment plan to the patient, because memory issues may be of concern.

CONNECTION Checkpoint 45.1

Although drugs with anticholinergic action are used to treat Parkinson's disease, they are generally not the preferred drugs. From what you learned in Chapter 21, name the drug most commonly prescribed for Parkinson's disease and the neurotransmitter it replaces. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Fexofenadine (Allegra)

Classification **Therapeutic:** Drug for allergic rhinitis and minor allergies
Pharmacologic: H_1-receptor antagonist (second generation), antihistamine

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1996 for the treatment of allergic rhinitis, fexofenadine is a second-generation H_1-receptor antagonist with an effectiveness that is equivalent to that of diphenhydramine. Most effective when taken before symptoms develop, fexofenadine reduces the severity of nasal congestion, sneezing, and tearing of the eyes.

The long half-life of fexofenadine—over 14 hours—allows it to be administered once or twice daily. Fexofenadine is available in PO form as regular tablets, orally disintegrating tablets, and as a suspension. In addition to allergic rhinitis, it is also approved to treat chronic idiopathic urticaria. Allegra-D combines fexofenadine with pseudoephedrine, which is a decongestant.

Mechanism of Action: Fexofenadine acts by competing with histamine for binding to histamine (H_1) receptor sites. It does not prevent the release of histamine.

Pharmacokinetics:

Route(s)	PO (capsules, tablets, and suspension)
Absorption	Rapid
Distribution	Does not cross the blood–brain barrier; unknown if secreted in breast milk; 60–70% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	80% renal, 11% feces
Onset of action	Usually within 1 h
Duration of action	Half-life: 14.4 h; duration: 12–24 h

Adverse Effects: The major advantage of fexofenadine over first-generation antihistamines is that it does not readily cross the blood–brain barrier, so drowsiness is generally not a major adverse effect. Adverse effects are infrequent and usually minor and include headache, nausea, dyspepsia, and dysmenorrhea. Patients who are taking the drug have an increased incidence of viral infections. Anticholinergic effects such as dry mouth can occur in some patients.

Contraindications/Precautions: The only contraindication to fexofenadine is hypersensitivity to this drug. Patients with advanced chronic kidney disease (CKD) should receive reduced doses.

Drug Interactions: Although considered nonsedating, fexofenadine can still cause drowsiness in certain patients at high doses and if combined with CNS depressants, including alcohol. Concurrent administration with ketoconazole or erythromycin increases the plasma concentrations of fexofenadine. Prolongation of the QT interval has occurred with other antihistamines but is infrequent with fexofenadine. Antacids that contain aluminum or magnesium may interfere with the absorption of fexofenadine. **Herbal/Food:** Absorption may be decreased when taken with grapefruit, orange, or apple juice, thereby reducing the bioavailability of fexofenadine.

Pregnancy: Category C.

Treatment of Overdose: Overdose may cause CNS depression, dry mouth, and dizziness. There is no specific antidote for overdose, and supportive treatment of symptoms is indicated.

Nursing Responsibilities: Key nursing implications for patients receiving fexofenadine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antihistamines.

Drugs Similar to Fexofenadine (Allegra)

The second-generation H_1 antagonists include acrivastine with pseudoephedrine, azelastine, cetirizine, desloratadine, levocetirizine, loratadine, and olopatadine. Because the first-generation antihistamines are all very similar, a description of diphenhydramine is included in this section as an example of this group.

Acrivastine with pseudoephedrine (Semprex-D): Approved in 1994, Semprex-D contains acrivastine (an antihistamine) and pseudoephedrine (a decongestant). The drug is approved for the treatment of seasonal allergic rhinitis with nasal congestion in adults and children ages 12 and older. Adverse effects include headache, dry mouth, and somnolence. This drug is pregnancy category B.

Azelastine (Astelin, Astepro, Optivar): Originally approved in 2000, azelastine is a second-generation H_1 antagonist approved for relief of symptoms caused by seasonal allergic rhinitis. An intranasal formulation (Astepro) was subsequently approved to treat perennial allergic rhinitis and an ophthalmic formulation (Optivar) for allergic conjunctivitis. Dymista is a combination drug that combines azelastine with fluticasone, a corticosteroid. Adverse effects of intranasal azelastine include local effects on the nasal mucosa such as epistaxis (nosebleed), a bitter taste, and postnasal drip. The most common side effects of eyedrop therapy are headache, transient eye stinging, and a bitter taste. The drug can cause drowsiness, especially when combined with CNS depressants or alcohol. This drug is pregnancy category C.

Cetirizine (Zyrtec): Approved in 1995, cetirizine is a second-generation antihistamine that is commonly used for treating allergic rhinitis and itching due to hives. In 2017 an ophthalmic form of the drug was approved to treat ocular itching caused by allergic conjunctivitis. It may be used off-label to treat atopic dermatitis and symptoms of allergy-induced asthma. Various PO formulations are available, including tablets to be swallowed, chewable tablets, and syrup. It is well tolerated and approved for children as young as 2 years of age. Adverse effects are uncommon. Cetirizine appears to be somewhat more sedating than other second-generation drugs. Xerostomia and fatigue are additional adverse effects. The drug was moved from prescription to OTC status in 2007. Cetirizine is an active metabolite of hydroxyzine (Atarax, Vistaril), a first-generation antihistamine. This drug is pregnancy category B.

In 2007, an isomer of cetirizine was approved by the FDA. Levocetirizine (Xyzal) is a PO antihistamine that has the same indications and actions as those of cetirizine but is reported to cause less drowsiness.

Desloratadine (Clarinex): Desloratadine is a nonsedating, second-generation antihistamine that was approved in 2001 for the treatment of allergic rhinitis and itching due to hives. It is the active metabolite of loratadine (Claritin). Desloratadine is administered by the PO route and is approved to treat adults and children ages 6 months and older. Like other second-generation drugs, sedation is minimal and adverse effects are uncommon. Headache, pharyngitis, and xerostomia are the most frequently reported adverse effects. This drug is pregnancy category C.

Diphenhydramine (Benadryl, others): Diphenhydramine is a first-generation H_1-receptor antagonist that is commonly used to treat minor symptoms of allergy and the common cold such as sneezing, runny nose, and tearing of the eyes. It exhibits a strong anticholinergic drying action on mucous membranes. OTC diphenhydramine is often combined with an analgesic, decongestant, or expectorant when treating cold symptoms. Diphenhydramine is also used as a topical drug to treat rashes, and intramuscular (IM) and intravenous (IV) forms are available for severe allergic reactions. An elixir and syrup form is available for administration to young children. Other indications for diphenhydramine include Parkinson's disease, motion sickness, and insomnia. Diphenhydramine can cause significant drowsiness, although this usually diminishes with long-term use. Occasionally diphenhydramine is given to produce drowsiness as a treatment for insomnia. This drug may cause paradoxical excitement in some patients, which is an effect most commonly seen in children. This drug may cause anticholinergic adverse effects such as urinary retention, tachycardia, elevated blood pressure, xerostomia, thickening of bronchial secretions, and blurred vision. This drug is pregnancy category B.

Loratadine (Claritin): Loratadine was the first of the second-generation antihistamines, approved in 1993, to treat allergic rhinitis and itching due to hives. In 2002, the high safety record of loratadine led to the reclassification of the drug from prescription to OTC. Like other drugs in its class, loratadine causes very little drowsiness, and adverse effects are unusual. It is only available PO and may be administered to children ages 2 and older. Drowsiness and headache may occur at higher doses. This drug is pregnancy category C.

Olopatadine (Patanase, Patanol): Olopatadine is a second-generation H_1 antagonist approved in 1996. The intranasal spray (Patanase) is approved for the treatment of seasonal allergic rhinitis in adults and children 6 years of age and older. Adverse effects of olopatadine include local effects on the

nasal mucosa such as epistaxis, a bitter taste, and postnasal drip. Other adverse effects include headache, throat pain, and URT infection. Although uncommon, nasal ulceration and septal perforation are serious adverse effects. In some patients, the drug can cause drowsiness; thus it should be used with caution when combined with CNS depressants and alcohol. An ophthalmic formulation (Patanol) is approved for the treatment of allergic conjunctivitis. As eyedrops, the drug can cause local effects such as blurred vision, burning or stinging, and dry eyes. This drug is pregnancy category C.

CONNECTION Checkpoint 45.2

From what you learned in Chapter 44, what is the role of leukotriene antagonists in treating asthma? What drug classes are preferred for this condition? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

45.5 Intranasal corticosteroids are preferred drugs for allergic rhinitis because of their effectiveness and safety.

Corticosteroids, also known as glucocorticoids, may be applied directly to the nasal mucosa to prevent symptoms of allergic rhinitis. These drugs are listed in Table 45.3.

Although corticosteroids are very effective at reducing allergy symptoms, their oral and parenteral uses are limited by potentially serious adverse effects. Intranasal formulations of these drugs, however, produce virtually no serious adverse effects. Because of their effectiveness and safety, the intranasal corticosteroids have joined antihistamines as first-line drugs in the therapy of allergic rhinitis. They are now considered the most effective drug treatment for seasonal and perennial allergic rhinitis. Intranasal corticosteroids are also used for patients undergoing nasal or sinus surgery for their anti-inflammatory action.

When sprayed onto the nasal mucosa, corticosteroids act by multiple mechanisms. They decrease the secretion of inflammatory mediators, reduce tissue edema, and cause a mild vasoconstriction. All corticosteroids are administered with a metered-spray device that delivers a consistent dose of drug per spray. All have equal effectiveness. Unlike sympathomimetics, however, the benefits of inhaled corticosteroids are not immediate. To achieve peak response, 1 to 3 weeks (often longer with perennial rhinitis than seasonal rhinitis) may be required. After the patient's symptoms are controlled, the dose of intranasal corticosteroids is reduced to the lowest amount required to control the symptoms. The intranasal corticosteroids must be taken daily to produce maximum benefit. Rhinocort Aqua, Flonase, and Nasacort AQ are available OTC.

When administered appropriately, the actions of corticosteroids are limited to the nasal passages. The most frequently reported adverse effect is an intense burning sensation in the nose immediately after spraying. Excessive drying of the nasal mucosa may occur, leading to epistaxis.

PROTOTYPE DRUG **Fluticasone (Flonase, Veramyst)**

Classification **Therapeutic:** Drug for allergic rhinitis, asthma, and COPD
Pharmacologic: Intranasal corticosteroid

Table 45.3 Intranasal Corticosteroids and Miscellaneous Drugs for Allergic Rhinitis

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Intranasal Corticosteroids		
beclomethasone (Beconase AQ, Qnasl, Qvar)	Intranasal: 1 spray bid–qid	*Transient nasal irritation, burning, sneezing, dryness* Hypercorticism (only if large amounts are swallowed), nasal ulceration, *Candida* infection
budesonide (Rhinocort Aqua)	Intranasal: 2 sprays bid	
ciclesonide (Omnaris, Zetonna)	Intranasal: 2 sprays once daily (Zetonna) or bid (Omnaris) (max: 200 mcg/day)	
fluticasone (Flonase, Veramyst)	Intranasal: 1 spray in each nostril once (Veramyst) or twice (Flonase) daily	
mometasone (Nasonex)	Intranasal: 2 sprays/day	
triamcinolone (Nasacort AQ)	Intranasal: 2–4 sprays 4 times daily	
Miscellaneous Drugs		
cromolyn (NasalCrom)	Intranasal: 1 spray in each nostril tid–qid	*Nasal burning and irritation* Anaphylaxis
ipratropium (Atrovent)	Intranasal: 2 sprays per nostril tid–qid	*Transient nasal irritation, burning, sneezing or dryness, cough* Urinary retention, worsening of glaucoma
montelukast (Singulair)	PO: 10 mg/day	*Headache, nausea, diarrhea* No serious adverse effects

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Therapeutic Effects and Uses: Approved in 1990, fluticasone is an intranasal corticosteroid that is used for the management of nasal symptoms associated with seasonal and perennial rhinitis. Therapy usually begins with two sprays in each nostril, twice daily, and decreases to one dose per day. Prolonged use of corticosteroids can lead to tolerance to the drug's therapeutic effects.

Veramyst and Dymista are two newer formulations of this drug. Veramyst contains intranasal fluticasone that is approved for the treatment of both seasonal and perennial allergic rhinitis in patients 2 years and older. Veramyst offers the advantage of once-daily dosing along with improvement of both nasal and ocular symptoms associated with allergies. Dymista is a combination drug that contains fluticasone and the antihistamine azelastine. Dymista nasal spray is taken twice daily to treat allergic rhinitis.

Fluticasone is also available in oral inhalation and topical formulations. The oral inhalation product (Flovent) is administered in a metered-dose inhaler (MDI) device for the treatment of asthma and COPD (see Chapter 44). Flovent reduces bronchial inflammation that is characteristic of asthma. In 2013 Breo Ellipta, a combination of fluticasone with vilanterol (a long-acting beta$_2$ agonist), was approved to treat COPD. Topical ointments and creams are applied to the skin for various inflammatory conditions, including atopic dermatitis, eczema, exfoliative dermatitis, psoriasis, and contact dermatitis (see Chapter 73).

Mechanism of Action: Fluticasone acts to decrease local inflammation in the nasal passages through vasoconstrictor and anti-inflammatory mechanisms. It is thought to inhibit mast cells, macrophages, and inflammatory mediators such as prostaglandins, histamine, kinins, and leukotrienes.

Pharmacokinetics:

Route(s)	Intranasal spray, oral inhalation, topical
Absorption	Intranasal: drug is swallowed, with less than 2% absorbed systemically Oral inhalation: 30% reaches systemic circulation Topical: minimal absorption
Distribution	Widely distributed; 91–99% bound to plasma protein
Primary metabolism	Hepatic, extensive first-pass metabolism by CYP3A4
Primary excretion	Feces
Onset of action	12 h to several days
Duration of action	Several days

Adverse Effects: When administered by the intranasal route, adverse effects of fluticasone are uncommon and include headache, cough, nasal ulceration, epistaxis, and local burning. Swallowing large amounts increases the potential for systemic corticosteroid adverse effects (see Chapter 71).

Contraindications/Precautions: The only contraindication to fluticasone is prior hypersensitivity to the drug. Because corticosteroids can mask signs of infection, patients with known bacterial, viral, fungal, or parasitic infections (especially of the respiratory tract) should not receive these drugs until the infection has cleared. Safety has not been established in children under 4 years of age.

Drug Interactions: Concurrent use of fluticasone with an intranasal decongestant increases the risk of nasal irritation or bleeding. Use with ritonavir should be avoided, because this drug significantly increases plasma fluticasone levels. **Herbal/Food:** Use with caution with black licorice, which may potentiate the effects of corticosteroids.

Pregnancy: Category C.

Treatment of Overdose: Overdose with intranasal corticosteroids is unlikely. There is no specific treatment.

Nursing Responsibilities: Key nursing implications for patients receiving fluticasone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Symptomatic Cough and Cold Relief.

Drugs Similar to Fluticasone (Flonase, Veramyst)

All of the intranasal corticosteroids have the same indications, actions, and adverse effects. Due to individual variation, some patients experience more irritation or burning with one drug over another. All are equally effective when administered at their recommended doses. The other intranasal corticosteroids are listed in Table 45.3.

45.6 Cromolyn, ipratropium, and montelukast are alternatives to intranasal corticosteroids in the treatment of allergic rhinitis.

Although most patients with allergic rhinitis are successfully treated with intranasal corticosteroids or antihistamines, several alternatives exist. **Mast cell stabilizers** are drugs that inhibit the release of inflammatory mediators from mast cells. Mast cells contain granules that release histamine and leukotrienes during inflammatory and allergic reactions. Intranasal cromolyn (NasalCrom) is a mast cell stabilizer approved for the treatment of seasonal or perennial allergic rhinitis. Cromolyn is featured as a prototype in Chapter 44.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antihistamines

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including previous history of symptoms and association to seasons, foods, or environmental exposures; existing cardiovascular, respiratory, hepatic, renal, or neurologic disease; glaucoma; prostatic hypertrophy; difficulty with urination; presence of fever or active infections, pregnancy or breastfeeding, alcohol use, or smoking. Obtain a drug history, noting the type of adverse reaction or allergy experienced to any medications.
- If allergy symptoms are of new onset, particularly for infants and young children, assess for any recent changes in diet, soaps including laundry detergent, laundry softener, cosmetics, lotions, environmental factors (e.g., pets, travel), or recent carpet cleaning.
- Obtain baseline vital signs. An ECG may be ordered for patients with a history of cardiac conditions.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], hepatic and renal laboratory tests).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased nasal congestion and drainage, decreased eye watering or itching).
- Continue periodic monitoring of CBC and liver and renal function studies as appropriate.
- Assess vital signs, especially pulse rate and rhythm.
- Assess for adverse effects: dizziness, drowsiness, dry mouth, blurred vision, or headache. Report immediately any increasing fever, confusion, muscle weakness, tachycardia, palpitations, hypotension, syncope, dyspnea, pulmonary congestion, urinary retention, sudden severe eye pain, or rainbow halos around lights.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished nasal congestion and improvement in other signs and symptoms of allergy should begin after taking the first dose and continue to improve. Notify the provider if symptoms continue to increase, especially if respiratory involvement worsens.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures, such as increased fluid intake to liquefy and mobilize mucus, and to reduce exposure to allergens where possible. • Advise the patient to carry a wallet identification card or wear medical identification jewelry indicating any significant allergies or anaphylaxis.
• For treatment of seasonal allergies, drug therapy should be started before the beginning of the allergy season and the appearance of symptoms. (Because antihistamines competitively bind to histamine receptors, beginning drug therapy before circulating histamine increases will result in better effects.)	• Teach the patient to begin taking the drug before allergy season begins or at the earliest possible appearance of symptoms for best effects, and to maintain consistent dosing. • **Lifespan:** Teach parents or caregivers that antihistamines are not recommended for use in children under 6 years of age unless recommended by the healthcare provider.
Minimizing adverse effects: • Ensure patient safety, especially in the older adult. Observe for lightheadedness or dizziness. Monitor ambulation until the effects of the drug are known. (**Lifespan:** Drowsiness or dizziness from drug effects or orthostatic hypotension may occur and increases the risk of injury and falls, particularly in the older adult. Drowsiness tends to diminish after several doses as the patient becomes tolerant to the effects.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Continue to monitor vital signs, especially pulse rate and rhythm for patients with existing cardiac disease. ECGs may be ordered periodically for patients with a history of dysrhythmias. (Histamine plays a role in cardiac conduction and, when blocked by antihistamines, may cause dysrhythmias in patients with a history of dysrhythmias, cardiac disease, or in the sensitive patient. **Lifespan:** Undetected cardiac disease may place the older adult at greater risk for cardiovascular adverse effects.)	• Instruct the patient to immediately report dizziness, palpitations, or syncope. • Teach the patient, family, or caregiver how to monitor the pulse and blood pressure as appropriate. Ensure proper use and functioning of any home equipment obtained.
• Continue to monitor periodic hepatic and renal function laboratory values, especially in patients on long-term antihistamine use or those with previous history of hepatic impairment or CKD. (Hepatotoxicity is a potential adverse effect of antihistamines. CKD will reduce drug excretion and prolong drug effects with potentially increased adverse effects. **Lifespan:** Monitor the older adult more frequently because physiologic changes related to aging may affect the drug's metabolism or excretion.)	• Instruct the patient on the need to return periodically for laboratory work.
• Monitor for persistent dry cough, increasing cough severity, increasing congestion, or dyspnea. (Antihistamines are used with extreme caution or are contraindicated in patients with existing respiratory disease, including COPD. Thickened mucus is a potential adverse drug effect. A change in the severity of the cough may indicate increasing allergic response, worsening disease process, or respiratory infection, and should be reported immediately.)	• Instruct the patient to promptly report any change in the severity or frequency of cough. Any cough accompanied by shortness of breath, increasing congestion, fever, or chest pain should be reported immediately. • Encourage the patient to increase fluid intake to assist in liquefying mucus secretions and to ease dry mouth effects.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Assess for CNS effects including restlessness, nervousness, insomnia, headache, tremors, fatigue, or weakness. Frequently monitor for these symptoms in the patient with hyperthyroidism. Immediately report severe symptoms or any disorientation or confusion. (CNS depressant effects, such as drowsiness, fatigue, or mild weakness, are common. Paradoxical excitement, such as restlessness or nervousness, or insomnia may occur, especially in children. Patients with hyperthyroidism may experience pronounced CNS stimulatory effects. Immediately report any severe symptoms to the healthcare provider. Alcohol consumption increases the CNS depressant effects and should be avoided or eliminated.)	• Instruct the patient, family, or caregiver to immediately report increasing lethargy, disorientation, confusion, changes in behavior or mood, agitation or aggression, slurred speech, or ataxia. • Instruct the patient to avoid or eliminate alcohol consumption while on antihistamines.
• If an antihistamine is used for sleep (e.g., doxylamine), ensure patient safety, including on awakening. Avoid using antihistamines for sleep for more than 2 weeks and consult the healthcare provider if insomnia continues. (Morning or daytime grogginess, a hangover effect, may occur in some patients taking antihistamines for sleep and may impair normal activities. Patients may become tolerant to drowsiness-inducing effects within 2 weeks, and insomnia that continues beyond that time should be evaluated by a healthcare provider.)	• Caution the patient about possible morning or daytime sleepiness or grogginess, and to exercise caution with activities requiring mental alertness or physical coordination until daytime effects of the drug are known. Do not keep the medication at the bedside to prevent overdosage from occurring if additional doses are taken when drowsy. Do not take the medication concurrently with alcohol.
• Assess for changes in visual acuity, blurred vision, and immediately report any loss of peripheral vision, seeing rainbow halos around lights, acute eye pain, or pain accompanied by nausea and vomiting. (Increased intraoptic pressure in patients with closed-angle glaucoma may occur in patients taking antihistamines.)	• Instruct the patient to immediately report any visual changes or eye pain.
• Assess for urinary retention. (Antihistamines may cause urinary retention as an adverse effect. **Lifespan:** Be aware that older adult men are at higher risk for mechanical obstruction due to an enlarged prostate.)	• Instruct the patient to immediately report an inability to void, increasing bladder pressure, or pain.
• Monitor for gastrointestinal (GI) effects. Encourage the patient to take the drug with food to prevent adverse effects. (Nausea, vomiting, epigastric distress, anorexia, constipation, or diarrhea may occur and are treated symptomatically. Taking the drug with food or milk may decrease GI adverse effects.)	• Teach the patient to take the medication with food or milk. Report any significant GI symptoms (e.g., nausea with vomiting, diarrhea) to the healthcare provider for further treatment.
• Monitor for anticholinergic-related adverse effects including dry mouth, thickened mucus, nasal dryness, slightly blurred vision, or headache. (Mild anticholinergic adverse effects are common and are treated symptomatically. Significant symptoms as listed previously are reported immediately.)	• Teach the patient to increase fluid intake or suck on hard candy to relieve mouth and respiratory tract dryness. Exercise caution if blurred vision impairs normal activities and report significant visual disturbances as listed previously.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of the drug, e.g., take the drug before allergy season or before symptoms are severe. (Utilizing time during nurse administration of these drugs helps reinforce teaching.)	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Most effective when given prior to allergen exposure, cromolyn has few adverse effects and is now designated as an OTC drug for the treatment of allergy and cold symptoms. It is as effective as antihistamines but less effective than intranasal corticosteroids. This drug is safe and adverse effects are uncommon. A major disadvantage is that cromolyn must be taken 4 times daily. If a patient is experiencing nasal congestion, a topical decongestant is used prior to administration of cromolyn. When administered by the oral inhalation route, cromolyn is approved for the treatment of asthma.

Ipratropium (Atrovent) nasal spray is an anticholinergic drug indicated for the symptomatic relief of rhinorrhea associated with seasonal allergic rhinitis or the common

Table 45.4 Nasal Decongestants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
naphazoline (Privine)	Intranasal (0.05%): 2 drops or sprays q3–6h	*Intranasal: transient nasal irritation, burning, sneezing, or dryness, headache* *Oral: CNS stimulation: nervousness, insomnia, headache, dry mouth* Intranasal: rebound congestion Oral: CNS excitation (in people with coronary artery disease or HTN), tremors, dysrhythmias, tachycardia, difficulty voiding, HTN, and peripheral and visceral vasoconstriction
oxymetazoline (Afrin 12 Hour, Neo-Synephrine 12 Hour, others)	Intranasal (0.05%): 2–3 sprays bid for up to 3 days	
phenylephrine (Afrin 4–6 Hour, Neo-Synephrine 4–6 Hour, others)	Intranasal (0.1%): 1–2 sprays or drops q4h, prn, up to 3 days	
pseudoephedrine (Sudafed)	PO: 30–60 mg q4–6h (max: 240 mg/day) Sustained release: 120 mg q12h	
tetrahydrozoline (Tyzine)	Intranasal: 2–4 drops or sprays q3h	
xylometazoline	Intranasal (0.1%): 1–2 sprays bid (max: 3 doses/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

cold. Its actions are limited to decreasing nasal secretions; it does not stop the sneezing, postnasal drip, or itchy throat or eyes characteristic of allergic rhinitis or the common cold. The drug is well tolerated, with epistaxis and nasal dryness experienced by a small percentage of patients. Like other anticholinergics, it should be used with caution in patients with closed-angle glaucoma or with prostatic hyperplasia. The primary use of ipratropium is by the inhalation route as a bronchodilator in the treatment of COPD. It is presented as a prototype drug for this disorder in Chapter 44.

Montelukast (Singulair) is an oral drug that acts by blocking leukotriene receptors. Leukotrienes are associated with inflammation and are responsible for some of the sneezing, nasal itching, and congestion characteristic of allergic rhinitis. Originally approved for the treatment of asthma in 1998, allergic rhinitis was subsequently added as an indication. It is approved for both the seasonal and perennial forms of the disease and can be used in children as young as 6 months of age. Like cromolyn, montelukast is not considered as effective as the intranasal corticosteroids. A prototype for this drug is presented in Chapter 44.

Decongestants

45.7 Intranasal and oral sympathomimetics are the most effective drugs for relieving nasal congestion.

Decongestants are drugs that relieve nasal congestion. They are administered by either the PO or intranasal route and are often combined with antihistamines in the pharmacotherapy of allergies or the common cold.

Sympathomimetics (also called adrenergic agonists) with alpha-adrenergic activity are effective at relieving the nasal congestion associated with the common cold and allergic rhinitis when given by either the PO or intranasal route. The intranasal preparations such as oxymetazoline (Afrin, others) are available OTC as sprays or drops and produce a noticeable response within minutes. The nasal decongestants are listed in Table 45.4.

Intranasal sympathomimetics produce few systemic effects because only minimal amounts of these drugs are absorbed in the circulation. The most serious, limiting adverse effect of the intranasal preparations is **rebound congestion**. In almost all patients, prolonged use causes hypersecretion of mucus and worsening nasal congestion once the drug effects wear off. This leads to a cycle of increased drug use as the condition worsens to obtain the desired effect from these drugs. Because of this rebound congestion, intranasal sympathomimetics should be used for no longer than 3 to 5 days. Patients who develop dependence should be gradually switched to intranasal corticosteroids because they do not cause rebound congestion. The usual technique for switching to intranasal corticosteroids is by stopping the use of the decongestant in one nostril at a time.

When administered PO, sympathomimetics do not produce rebound congestion. Their onset of action by this route, however, is much slower than when administered intranasally, and they are less effective at relieving severe congestion. The possibility of systemic adverse effects is also greater with the PO drugs. Potential adverse effects include hypertension (HTN) and CNS stimulation that may lead to insomnia and anxiety. Pseudoephedrine and phenylephrine are common sympathomimetics found in oral OTC cold and allergy medicines.

The sympathomimetics relieve only nasal congestion and therefore are often combined with antihistamines to control sneezing and tearing. It is interesting to note that some OTC drugs having the same basic name (Neo-Synephrine, Afrin, and Vicks) may contain different sympathomimetics. For example, Neo-Synephrine decongestants with 12-hour duration contain the drug oxymetazoline; Neo-Synephrine preparations that last 4 to 6 hours contain phenylephrine.

PharmFACT

When legislation restricted the sale of products containing pseudoephedrine, the seizures of illegal methamphetamine (meth) laboratories by law enforcement agencies in the United States decreased 70% from 2003 to 2007. Since 2008, however, the number of illegal meth laboratories has been rapidly increasing, likely due to newer methods of synthesizing meth and by circumventing state laws on the purchase of pseudoephedrine (U.S. Government Accountability Office, 2013).

PROTOTYPE DRUG Pseudoephedrine (Sudafed)

Classification **Therapeutic:** Decongestant
Pharmacologic: Sympathomimetic

Therapeutic Effects and Uses: Approved in 1959, pseudoephedrine is available in tablet and elixir formulations. It is often combined with other medications in OTC preparations used to treat allergic rhinitis, sinus congestion, and the common cold symptoms. Pseudoephedrine promotes sinus drainage and can open obstructed eustachian tubes in adults and children with chronic otic inflammation. It is also used off-label to prevent otitic barotraumas, pain or damage to the tympanic membrane caused by rapid pressure changes during air travel or diving.

Pseudoephedrine deserves special attention because of its potential for misuse. Pseudoephedrine is the starting chemical for the synthesis of illegal methamphetamine by drug traffickers. As of 2004, pseudoephedrine products must be kept in a locked box behind the pharmacy counter, so that pharmacists can monitor sales and distribution. Although still considered OTC drugs, pharmacists are required to keep a log of the names and addresses and check the photo identification of anyone who buys a pseudoephedrine product. At least two states have made pseudoephedrine a prescription drug. Note that these precautions are not being taken because pseudoephedrine itself is a dangerous drug, but instead to limit the availability of the drug to illicit makers of methamphetamine. Manufacturers have reformulated their OTC cold medicines to contain phenylephrine rather than pseudoephedrine.

Mechanism of Action: Pseudoephedrine activates alpha$_1$-adrenergic receptors, which causes vasoconstriction in the nasal mucosa, resulting in shrinking of mucosal swelling. It also stimulates beta$_2$-adrenergic receptors of the respiratory tract, which may result in some bronchodilation.

Pharmacokinetics:

Route(s)	PO (tablets, elixir)
Absorption	Well absorbed orally
Distribution	Widely distributed, including in cerebrospinal fluid (CSF); crosses the placenta; secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	30 min; extended release: 60 min
Duration of action	4–8 h; extended release: 12 h

Adverse Effects: Pseudoephedrine is well tolerated at regular dosage levels. Some patients experience CNS stimulation with symptoms of insomnia, restlessness, anxiety, and dizziness. Excitability is especially a concern in infants and young children. At high doses, seizures and psychosis may occur. Other sympathomimetic effects include dysrhythmias, HTN, palpitations, tachycardia, dry mouth, and anorexia. Rebound congestion is not usually a concern with PO decongestants. Serious injury and deaths due to overdose have occurred in pediatric patients under 2 years of age who received high doses of cough and cold medicines.

Contraindications/Precautions: Pseudoephedrine should not be used by patients with severe HTN, severe coronary artery disease, or hypersensitivity to this drug or by those who take monoamine oxidase inhibitor (MAOI) drugs. Alpha-adrenergic agonists should be used with caution in patients with prostatic enlargement, because these drugs increase smooth muscle activity in the prostate gland and may diminish urinary outflow (see Chapter 71). The FDA has issued advisories that nonprescription cough and cold products (including those containing pseudoephedrine) not be used in children under 6 years of age, and that they be used with extreme caution in all children.

Drug Interactions: Pseudoephedrine interacts with MAOIs to cause a hypertensive crisis. Use with other sympathomimetic drugs, including caffeine, can lead to additive cardiovascular and CNS stimulation effects. Beta blockers and pseudoephedrine together can result in HTN or severe bradycardia. Concurrent use with tricyclic antidepressants may result in increased cardiovascular toxicity and severe headaches. Pseudoephedrine can antagonize the effects of antihypertensive drugs. Pseudoephedrine should be avoided in patients who are taking nitrates for angina due to the vasoconstriction caused by the stimulation of alpha-adrenergic receptors on systemic blood vessels. Use with digoxin may cause dysrhythmias. **Herbal/Food:** Bitter orange may increase the risk of HTN.

Pregnancy: Category C.

Treatment of Overdose: Overdose may cause coma, seizures, profuse sweating, and dysrhythmias. No specific treatment exists.

Nursing Responsibilities: Key nursing implications for patients receiving pseudoephedrine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Symptomatic Cough and Cold Relief.

Drugs Similar to Pseudoephedrine (Sudafed)

All the sympathomimetic intranasal decongestants have very similar actions and adverse effects. Additional details on this class of drugs are included in Chapter 15.

Drugs for the Common Cold

45.8 The common cold is caused by a virus and is treated with some of the same drugs as those used to treat allergic rhinitis.

The common cold is a viral infection of the upper respiratory tract that produces a characteristic array of annoying symptoms. It is fortunate that the disorder is self-limiting, because there is no cure or effective prevention for colds. Therapies used to relieve symptoms include some of the same drug classes used for allergic rhinitis, including antihistamines and decongestants. A few additional drugs, such as those that suppress cough and loosen bronchial secretions, are used for symptomatic cold treatment.

Many OTC preparations are available to treat cold symptoms. These OTC drugs are often made as combinations containing two or more drugs to treat a variety of symptoms. Some common OTC combination products are listed in Table 45.2. The most common ingredients of combination drugs for the common cold are antihistamines and decongestants; caffeine is sometimes added to combat the adverse effect of drowsiness from first-generation antihistamines. The caffeine is omitted from combination drugs if the medication is to be taken at night, for example, NyQuil. Almost all combination drugs contain some form of analgesic, such as acetaminophen, aspirin, or other nonsteroidal anti-inflammatory drug, to help with fever and muscular aches. Many combination products also contain a cough suppressant and an expectorant to help loosen congestion.

The wide variety of combination cold, flu, and sinus products that are available OTC can be confusing for consumers. Multisymptom combination products should be taken only if the patient is experiencing the indicated symptoms. For example, if cough and fever are not present, products that contain cough suppressants, expectorants, or analgesics should not be taken. Consuming combination products without appropriate symptoms can increase the risk of unnecessary adverse effects. It is usually better to take only the drugs needed to treat specific symptoms rather than a combination product.

PharmFACT

Adults average two to four colds per year, while children have six to eight per year. Colds account for more office visits per year than any other condition (American Lung Association, 2016).

CONNECTIONS: Complementary and Alternative Therapies

Ascorbic Acid (Vitamin C)

Description

Vitamin C is naturally occurring and found in a variety of foods. Citrus fruits are especially high in vitamin C, as is cranberry.

History and Claims

Vitamin C is well documented as a prevention and treatment for scurvy. In 1970, Linus Pauling, the only person to win two unshared Nobel prizes, published a book called *Vitamin C and the Common Cold* in which he asserted that the common cold could be almost completely controlled in the United States by improvement of nutrition through adequate intake of ascorbic acid. This book, more than anything else in recent times, helped the case of vitamin C as a treatment or preventive for the common cold.

Standardization

Vitamin C and the combination products can vary in the amount, strength, and quality of the vitamin found in them. The current recommended daily allowance (RDA) for vitamin C is 90 mg/day in men and 75 mg/day in women. An additional 35 mg is recommended if the adult also smokes. The upper limit of tolerance is about 2 g/day in an adult.

Evidence

Since the publication of Linus Pauling's book, many studies have been conducted to test the value of vitamin C in improving the immune system response to viruses that cause the common cold.

According to the European Food Safety Authority (EFSA) Panel on Dietetic Products, Nutrition and Allergies, there is a proven cause-and-effect relationship between the dietary intake of vitamin C and contribution to the normal functioning of the immune system (EFSA, 2015). The panel's report highlighted that the role of vitamin C in the functioning of the immune system applies to all ages, including infants and young children (from birth to 3 years) (EFSA, 2015). However, a 2013 *Cochrane Review* of 29 studies concluded that vitamin C does not actually reduce the incidence of colds in the general population, but may slightly decrease the duration of cold symptoms (Hemilä & Chalker, 2013).

Table 45.5 Selected Antitussives and Expectorants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Antitussives: Opioids		
codeine	PO: 10–20 mg q4–6h prn (max: 120 mg/day)	*Nausea, vomiting, constipation, confusion, dizziness, sedation*
hydrocodone combined with homatropine	PO: 5 mL or 1 tablet q4–6h prn (max: 30 mL/day or 6 tablets/day)	*Hypotension, seizures, hallucinations, bradycardia, respiratory depression, severe somnolence*
Antitussives: Nonopioids		
benzonatate (Tessalon)	PO: 100–200 mg tid (max: 600 mg/day)	*Drowsiness, constipation, GI upset, chest and tongue numbness (if capsules are opened or chewed)* Paradoxical excitation, tremors, euphoria, insomnia
dextromethorphan (Delsym, Robitussin DM, others)	PO: 10–20 mg q4h or 30 mg q6–8h (max: 120 mg/day)	*Drowsiness, headache, GI upset* CNS depression, paradoxical excitation, respiratory depression
Expectorant		
guaifenesin (Mucinex, Robitussin, others)	PO: 200–400 mg q4h (max: 2.4 g/day) PO (extended release): 600–1200 mg q12h (max: 2.4 g/day)	*Drowsiness, headache, GI upset* No serious adverse effects
Mucolytics		
acetylcysteine (Mucomyst)	Inhalation: 1–10 mL of 20% solution q4–6h or 2–20 mL of 10% solution q4–6h	*Unpleasant odor, nausea, local irritation, stickiness on the face* Severe nausea and vomiting
dornase alfa (Pulmozyme)	Inhalation: 1–2 of 2.5-mg ampules once daily using nebulizer	*Voice alteration, laryngitis, rash* Dyspnea

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Antitussives

45.9 Antitussives are drugs used to suppress the cough reflex.

Cough is a natural reflex mechanism that serves to forcibly remove excess secretions and foreign material from the respiratory system. In diseases such as emphysema and bronchitis, or when liquids have been aspirated into the bronchi, it is not desirable to suppress the normal cough reflex. Dry, hacking, nonproductive coughing, however, can be irritating to the membranes of the throat and trigger inflammation, depriving patients of much needed rest. It is these types of conditions in which therapy with medications that control cough, known as **antitussives**, is warranted. Although there is clear evidence that antitussives are effective against chronic, nonproductive cough, there is less certainty about their value in treating acute coughs due to the common cold (Dicpinigaitis, 2015). Antitussives are classified as opioid or nonopioid and are listed in Table 45.5.

Opioids, the most effective antitussives, act by raising the cough threshold in the CNS. Codeine and hydrocodone are the most frequently prescribed opioid antitussives. Doses needed to suppress the cough reflex are very low; thus, there is minimal potential for dependence. Most opioid cough mixtures are classified as Schedule III, IV, or V drugs and are reserved for more serious cough conditions. Though not common, overdose from opioid cough remedies may cause significant respiratory depression. Care must be taken when using these medications in patients with asthma because bronchoconstriction may occur. Codeine is usually not recommended for children. Opioids may be combined with other drugs such as antihistamines, decongestants, and nonopioid antitussives in the therapy of severe cold or flu symptoms. Some of these combinations are listed in Table 45.6.

Table 45.6 Opioid Combination Drugs for Severe Cold Symptoms

Trade Name	Opioid	Nonopioid Active Ingredients
Ambenyl Cough Syrup	Codeine	bromodiphenhydramine
Calcidrine Syrup	Codeine	calcium iodide
Codamine Syrup	hydrocodone	phenylpropanolamine
Codiclear DH Syrup	hydrocodone	guaifenesin
Codimal DH	hydrocodone	phenylephrine, pyrilamine
Hycomine Compound	hydrocodone	phenylephrine, chlorpheniramine, acetaminophen
Hycotuss Expectorant	hydrocodone	guaifenesin
Novahistine DH	codeine	pseudoephedrine, chlorpheniramine
Phenergan with Codeine	codeine	promethazine
Robitussin A-C	codeine	guaifenesin
Tega-Tussin Syrup	hydrocodone	phenylephrine, chlorpheniramine
Triaminic Expectorant DH	hydrocodone	phenylpropanolamine, pyrilamine, pheniramine, guaifenesin
Tussionex	hydrocodone	chlorpheniramine

The primary nonopioid antitussives include dextromethorphan and benzonatate (Tessalon). Dextromethorphan is available OTC as a single drug but is usually found as a component of combination, multisymptom cold medications. Benzonatate is a prescription drug. Diphenhydramine (Benadryl) is usually taken for its antihistamine effects, but it also has antitussive action.

PROTOTYPE DRUG **Dextromethorphan (Delsym, Robitussin DM, Others)**

Classification **Therapeutic:** Antitussive
Pharmacologic: Levorphanol derivative

Therapeutic Effects and Uses: Approved in 1954, dextromethorphan is the most frequently used and most effective nonopioid antitussive. Considered as effective as codeine, dextromethorphan carries no risk of dependence. Although used for over 50 years to treat cough, controlled studies examining the effectiveness of dextromethorphan have given mixed results. Its present status is that the FDA considers it a safe and effective cough suppressant when used at recommended doses. It appears to be more effective at reducing nonproductive cough due to chronic throat irritation from tobacco use or emphysema rather than acute cough due to colds.

Reports of dextromethorphan abuse began to appear in the 1990s. Dextromethorphan has been reported to cause a mild stimulant effect at lower doses and altered sensory perceptions and complete dissociative effects (mind-out-of-body–like experiences) at very high doses. The effects typically last 6 to 8 hours. To produce these effects, 10 to 30 times the antitussive dose is used. Additional information on dextromethorphan abuse is presented in Chapter 27.

Mechanism of Action: Dextromethorphan is chemically similar to the opioids and acts directly on the cough center in the medulla to elevate the cough threshold. It has no effect on opioid receptors.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily absorbed orally
Distribution	Unknown; may cross the placenta
Primary metabolism	Hepatic; metabolized by CYP2D6 and CYP3A to active metabolite
Primary excretion	Renal
Onset of action	15–30 min
Duration of action	3–8 h

Adverse Effects: Dextromethorphan has almost no adverse effects at therapeutic doses. Sedation and dizziness have occurred at moderate doses. In abuse situations the drug can cause CNS toxicity with a wide variety of symptoms, including slurred speech, ataxia, hyperexcitability, stupor, respiratory depression, seizures, coma, and toxic psychosis.

Contraindications/Precautions: This medication is extensively metabolized by the liver and should be used cautiously in patients with hepatic impairment. The FDA has issued advisories that nonprescription cough and cold products (including those containing dextromethorphan) not be used in children under 6 years of age and that they be used with extreme caution in all children.

Drug Interactions: Patients who take MAOIs, triptans, or selective serotonin reuptake inhibitors (SSRIs) should not take dextromethorphan due to the risk of serotonin syndrome (nausea, changes in blood pressure, and confusion). Dextromethorphan has an additive CNS depressant effect with alcohol, antihistamines, antidepressants, and opioids. The analgesic effect of opioids can be almost doubled by giving them with dextromethorphan. **Herbal/Food:** Grapefruit juice can raise serum levels of dextromethorphan and cause toxicity.

Pregnancy: Category C.

Treatment of Overdose: Overdose may result in significant CNS toxicity. Treatment is symptomatic.

Nursing Responsibilities: Key nursing implications for patients receiving dextromethorphan are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Symptomatic Cough and Cold Relief.

Drugs Similar to Dextromethorphan (Delsym, Robitussin DM, Others)

The other nonopioid antitussive is benzonatate.

Benzonatate (Tessalon): Approved in 1958, benzonatate is an oral, nonopioid antitussive that acts by a unique mechanism. Chemically related to the local anesthetic tetracaine (Pontocaine), benzonatate suppresses the cough reflex by anesthetizing stretch receptors in the lungs. If chewed, this drug can cause numbing of the mouth and pharynx. Adverse effects are uncommon but may include sedation, nausea, headache, and dizziness. This drug should not be used in children under 10 years of age: Death has been reported from unintentional ingestion in children. Like dextromethorphan, the effectiveness of benzonatate in treating acute cough has not been clearly established. This drug is pregnancy category C.

Expectorants and Mucolytics

45.10 Expectorants and mucolytics are used to treat thick bronchial secretions.

Several drugs are available to control excess mucus production. **Expectorants** increase bronchial secretions, and

mucolytics remove mucus by loosening thick bronchial secretions. These drugs are listed in Table 45.5.

Expectorants: Expectorants reduce the thickness or viscosity of bronchial secretions, thus increasing mucus flow that can then be removed more easily by coughing. The only commonly used OTC expectorant is guaifenesin (Mucinex). Like dextromethorphan, guaifenesin produces few adverse effects and is a common ingredient in many combination multisymptom OTC cold and flu preparations. It is most effective in treating dry, nonproductive cough but may also be of benefit for patients with productive cough. Like the antitussives, the effectiveness of guaifenesin in reducing acute cold symptoms has been questioned. The dosage range used in cold remedies is usually too low to have much positive benefit for patients. Nonprescription cough and cold products (including those containing guaifenesin) should not be used in children under 6 years of age. High doses can induce nausea, vomiting, and abdominal pain. This drug is pregnancy category C.

Mucolytics: Acetylcysteine (Mucomyst) is one of the few drugs that directly loosen thick, viscous bronchial secretions. Drugs of this type, known as mucolytics, break down the chemical structure of mucus molecules. The mucus becomes thinner and can be removed more easily by coughing. Acetylcysteine is delivered by the PO and inhalation routes and is not available OTC. It is used in patients who have cystic fibrosis, chronic bronchitis, or other diseases that produce large amounts of thick bronchial secretions. Acetylcysteine is also administered by the IV route (Acetadote) to prevent the development of hepatotoxicity in patients who have received an overdose of acetaminophen. In 2016, a new oral form of the medication (Cetylev) was approved for the same indication. Its use in the pharmacotherapy of acetaminophen toxicity is presented in Chapter 41. Adverse effects include bronchospasm, nausea, vomiting, unpleasant odor, and fever. This drug is pregnancy category B.

A second mucolytic, dornase alfa (Pulmozyme), is an enzyme that was approved in 1993 for the management of thick bronchial secretions in patients with cystic fibrosis. Dornase alfa breaks down deoxyribonucleic acid (DNA) molecules in the mucus, causing it to become less viscous. It is administered by the oral inhalation route. Adverse effects include chest pain, conjunctivitis, hoarseness, and pharyngitis. This drug is pregnancy category B.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Symptomatic Cough and Cold Relief

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including previous history and length of symptoms; existing cardiovascular, respiratory, hepatic, or renal disease; presence of fever, pregnancy or breastfeeding, alcohol use, or smoking. Obtain a drug history, including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline vital signs.
- Evaluate appropriate laboratory findings (e.g., CBC, hepatic and renal laboratory tests).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased cough, increased ease in expectorating mucus, clearer nasal passages).
- Continue periodic monitoring of CBC, liver and renal function studies as needed.
- Assess vital signs, especially pulse rate and rhythm in patients with existing cardiac disease.
- Assess for adverse effects: dizziness, drowsiness, blurred vision, headache, epistaxis. Immediately report any increasing fever, tachycardia, palpitations, syncope, dyspnea, pulmonary congestion, or confusion.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Diminished cough, thinner secretions, increased ease of expectoration, and clearing nasal passages should begin after taking the first dose and continue to improve. Improvement in other signs and symptoms of the common cold should begin after taking the first dose and continue to improve.)	• Teach the patient to supplement drug therapy with nonpharmacologic measures, such as increased fluid intake, to liquefy and mobilize mucus, and to moisten the respiratory tract. • Instruct the patient to contact the healthcare provider if symptoms worsen or if fever is present or increasing.
Minimizing adverse effects: • Ensure patient safety. Observe for lightheadedness or dizziness. (**Lifespan:** Drowsiness or dizziness from cough suppressant drug effects may occur, increasing the risk of falls, especially in the older adult.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Continue to monitor vital signs, especially pulse rate and rhythm, for patients taking decongestants, including nasal decongestants. (Adrenergic decongestants may cause tachycardia and dysrhythmias in patients with a history of dysrhythmias or cardiac disease, or in the sensitive patient. **Lifespan:** Undetected cardiac disease may place the older adult at greater risk for cardiovascular adverse effects.)	• Instruct the patient to immediately report dizziness, palpitations, or syncope. • Teach the patient, family, or caregiver how to monitor the pulse and blood pressure as appropriate. Ensure proper use and functioning of any home equipment obtained.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for persistent dry cough, increasing cough severity, increasing congestion, or dyspnea. The provider should be notified if symptoms continue to increase, especially if respiratory involvement worsens or if fever is present. (Drugs used for symptomatic relief of the common cold are used with extreme caution or are contraindicated in patients with existing respiratory disease, including COPD. A change in the severity of the cough may indicate a worsening disease process or a more serious respiratory infection and should be reported immediately.)	• Instruct the patient to promptly report any change in the severity or frequency of cough. Any cough accompanied by shortness of breath, increasing congestion, fever, or chest pain should be reported immediately. • Encourage the patient to increase fluid intake to assist in liquefying mucus secretions and to moisten the upper respiratory tract.
• Assess the color and consistency of any expectorated sputum. (Increasing thickness, color, hemoptysis, or increased quantity of sputum may indicate a serious respiratory infection and should be reported immediately.)	• Instruct the patient to report any significant change in the color, consistency, or quantity of the expectorated mucus to the healthcare provider.
• Monitor for GI effects. Encourage the patient to take tablets or capsules with a full glass of water. (Nausea, vomiting, or abdominal discomfort may occur with common cold preparations. Taking the drug with fluids or food may decrease GI adverse effects.)	• Teach the patient to take the medication with fluid or food. Report any significant GI symptoms (e.g., nausea with vomiting, diarrhea) to the healthcare provider for further treatment.
• Encourage use of single-symptom drug preparations when possible. (Many OTC formulations include a combination of drugs, increasing the risk of adverse drug effects. Drug therapy should be aimed at symptomatic relief and additional drugs that are not needed in multiuse preparations should be avoided when possible.)	• Teach the patient to consider symptoms when reading labels of OTC cold remedies and choose preparations based on current symptoms rather than multiuse remedies. • Instruct patients that multiuse cold remedies containing acetaminophen must be taken in prescribed doses, should not be taken if daily alcohol intake exceeds two glasses, and not increased to avoid acetaminophen overdose and potential liver damage.
• Do not use symptomatic cough or cold preparations in children under the age of 6 years unless instructed to do so by the provider. (FDA guidelines recommend that cough and cold preparations should not be used in children under the age of 6.)	• Instruct the parents or caregivers of children under the age of 6 years not to routinely give cold preparations to the child unless instructed to do so by the provider. • Recommend symptomatic relief measures for children under 6 years such as increased fluids and juice, ice pops, and cool or warm mist humidifiers. Frequently clean all humidifiers in use to avoid mold growth.
• Eliminate smoking and limit exposure to secondhand smoke. (Cigarette smoke irritates respiratory mucous membranes, increasing the risk of adverse effects.)	• Teach the patient about smoking cessation programs and to avoid environments with secondhand smoke.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug before allergy season begins or before symptoms are severe. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• The patient, family, or caregiver is able to discuss appropriate dosing and administration needs, including:
	  • *Cough suppressants:* Cough syrups should be swallowed without water and allowed to coat the throat for soothing effects, followed by increased fluid intake 30–60 min later. The dose should not be increased beyond the recommended dose to avoid increased risk of adverse effects.
	  • *Expectorants:* Syrups should be taken with a full glass of liquid with increased fluid intake throughout the day to assist in thinning mucus for ease of expectoration.
	  • *Nasal decongestants:* Nasal passages should be cleared by blowing, followed by the nasal spray. If a second spray is ordered, administer 5 min after the first spray. If glucocorticoid or mast cell stabilizer sprays are ordered, the decongestant spray should be used first, followed by the additional drug 5–10 min later. Spit out any additional drug that drains into the mouth. Discontinue use of decongestant nasal sprays after 3–5 days to avoid rebound congestion, unless otherwise ordered by the provider.
	  • *For all OTC cold preparations:* Single-symptom formulations should be used when possible to avoid additional drugs not needed for symptom relief or an increased risk of adverse effects.

Understanding Chapter 45

Key Concepts Summary

45.1 The upper respiratory tract acts as a defense in preventing systemic infection.

45.2 Allergic rhinitis is caused by exposure to an environmental allergen, which leads to symptoms that resemble those of the common cold.

45.3 Drugs for allergic rhinitis include those that prevent the disorder and those that relieve symptoms.

45.4 Antihistamines are widely used to treat allergic rhinitis and other minor allergies.

45.5 Intranasal corticosteroids are preferred drugs for allergic rhinitis because of their effectiveness and safety.

45.6 Cromolyn, ipratropium, and montelukast are alternatives to intranasal corticosteroids in the treatment of allergic rhinitis.

45.7 Intranasal and oral sympathomimetics are the most effective drugs for relieving nasal congestion.

45.8 The common cold is caused by a virus and is treated with some of the same drugs as those used to treat allergic rhinitis.

45.9 Antitussives are drugs used to suppress the cough reflex.

45.10 Expectorants and mucolytics are used to treat thick bronchial secretions.

CASE STUDY: Making the Patient Connection

Remember the patient "Nancy Chen" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Nancy Chen is a 32-year-old woman who is in good health except for her current problem. She has come to the urgent care center because of a stuffy nose; red, itchy eyes; and a slightly sore throat. She takes daily calcium supplements but no other medications. She is 1.68 m (5 ft 6 in.) tall and weighs 67 kg (148 lb).

Nancy is a fourth-grade teacher at a local elementary school and is worried about being able to finish her end of school term activities with the symptoms of a lingering "cold." Her vital signs are as follows: temperature, 37.4°C (99.4°F); pulse, 102 beats/min; respirations, 12 breaths/min; blood pressure, 148/88 mmHg; oxygen saturation, 98%.

After taking her vital signs, Nancy tells the nurse practitioner that her mother-in-law bought her a Neo-Synephrine nasal spray about 10 days ago. It helped, but she tells the nurse that it ran out yesterday and now her nose is even stuffier than before. She had been taking Tylenol but stopped using that, too, because she does not feel like she has a fever and it was not helping much anyway. Nancy says, "I went to the drug store after school and did not stay. I felt so miserable that I could not even figure out what medicine does what and I just wanted to get home. I need some rest so I can take care of my girls, do a good job for my students, and get my report cards done." The nurse practitioner observes that Nancy has a cough, runny nose, and inflamed eyes, which she occasionally rubs during the conversation.

Critical Thinking Questions

1. Considering the history and the initial assessment that the nurse practitioner conducted, what further data would you as the nurse want to gather that are not listed in the scenario?
2. If Nancy has no history of heart disease or HTN and takes no medicines to treat those conditions, what do you think might be the cause of her elevated blood pressure and heart rate?
3. Nancy gave her two daughters a golden retriever puppy a few weeks ago. How does this information add to your assessment findings and patient teaching?
4. The nurse practitioner diagnoses Nancy with probable allergic rhinitis and prescribes intranasal fluticasone (Flonase). In addition, the nurse practitioner suggests getting two OTC cough suppressants, one with the main ingredient dextromethorphan and the other one with the main ingredient diphenhydramine. What do you tell Nancy is the reason she is being prescribed each one?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

A 23-year-old woman arrives at the emergency department with her boyfriend. She is wheezing and short of breath. Her respiratory rate is 23 breaths/min, her heart rate is 104 beats/min, her blood pressure is 88/60 mmHg, and she has hives over most of her body. Her boyfriend says she was eating strawberries and suddenly started having trouble breathing. She has eaten strawberries for years and nothing like this has ever happened before. The healthcare provider prescribes epinephrine for her allergic response.

1. Why did the healthcare provider not prescribe an antihistamine for this allergic response?
2. A second dose of epinephrine is given and the nurse inserts an IV. With a reduction in her wheezing, the patient's respiratory rate is 18 breaths/min, heart rate is 100 beats/min, and blood pressure is 98/64 mmHg. The healthcare provider prescribes Benadryl, 10 mg IV. Describe why the provider is now prescribing an antihistamine for the patient.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Oxymetazoline (Afrin 12 Hour) has been recommended for a patient with rhinitis. Which points are appropriate to include in the teaching plan? (Select all that apply.)
   1. Take with a full glass of water.
   2. Clear the nose by blowing.
   3. Take the drug at night if drowsiness occurs.
   4. Take for no more than 5 days to prevent rebound congestion.
   5. Effects of the drug may not be noticeable for 2 to 3 weeks.
2. The nurse teaches the patient that which type of over-the-counter cough preparation is not effective on coughs associated with the common cold and allergic rhinitis?
   1. Dextromethorphan
   2. Diphenhydramine
   3. Mucolytics
   4. Pseudoephedrine
3. An older adult man informs the nurse that he is taking diphenhydramine (Benadryl) to reduce seasonal allergy symptoms. The nurse would be most concerned about an increased risk of _____ for this patient.
4. Fexofenadine (Allegra) is prescribed to treat the symptoms of allergic rhinitis for a patient with seasonal allergies. Before teaching the patient about this drug, what condition would the nurse assess for?
   1. A history of osteoporosis
   2. A history of peptic ulcer disease
   3. A history of psoriasis
   4. A history of cardiac disease
5. A patient has been prescribed fluticasone (Flonase) to use with phenylephrine (Neo-Synephrine) nasal inhalers to treat allergic rhinitis. How should the nurse teach the patient to use these drugs?
   1. Fluticasone should be used only if congestion continues after phenylephrine use.
   2. Use fluticasone first, then the phenylephrine after waiting 5 minutes.
   3. Use phenylephrine first, then the fluticasone after waiting 5 minutes.
   4. The drugs may be used in either order.
6. The nurse is teaching the patient about the use of dextromethorphan with guaifenesin (Robitussin DM) syrup for a cough accompanied by thick mucus. Which statement would be part of the patient's teaching?
   1. "Lie supine for 30 minutes after taking the drug."
   2. "Drink minimal fluids to avoid stimulating the cough reflex."
   3. "Take the drug with food for best results."
   4. "Avoid drinking fluids immediately following the syrup and then increase overall fluid intake."

Chapter 46
Basic Principles of Anti-Infective Pharmacotherapy

Chapter Outline

- Pathogenicity and Virulence
- Describing and Classifying Bacteria
- Classification of Anti-Infectives
- Mechanisms of Action of Anti-Infectives
- Acquired Resistance
- Indications and Selection of Specific Anti-Infectives
- Host Factors Affecting Anti-Infective Selection
- Superinfections

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the mechanisms by which pathogens infect the body.
2. Describe methods for classifying bacteria.
3. Explain the mechanisms by which anti-infective drugs act to kill pathogens or restrict their growth.
4. Describe the clinical significance of bacterial resistance.
5. Identify steps that the nurse can take to limit the development of resistance.
6. Describe the clinical rationale for selecting specific antibiotics.
7. Identify the role of the nurse in preventing, identifying, and treating adverse effects due to antibiotic therapy.
8. Explain how the patient's immune status, local tissue conditions, history of allergic reactions, age, pregnancy status, and genetics influence anti-infective pharmacotherapy.
9. Explain the clinical importance of selecting the correct antibiotic for the individual patient.
10. Describe the development of superinfections.

superinfections, 846
virulence, 835

The human body has adapted quite well to living in a world teeming with microorganisms (microbes). In the air, water, food, and soil, microbes have been essential components of life on the planet for billions of years. In some cases, these microorganisms coexist in intimate contact with human beings. It is estimated that 10^{14} bacterial cells reside inside or on the surface of the body, which is more than the total number of human cells in an average person. Fortunately, of the millions of species of microbes, only a relative few are harmful to human health. The purpose of this chapter is to present the fundamental principles that apply to the pharmacotherapy of infectious diseases.

PharmFACT

In 1900, 5 of the 10 most frequent causes of death in the United States were infectious diseases. Today, infectious diseases account for relatively few deaths, the most common being influenza, pneumonia, kidney infections, and septicemia (Madigan et al., 2015).

Pathogenicity and Virulence

46.1 Pathogens cause disease due to their ability to invade tissues or secrete toxins.

The first challenge in studying the pharmacotherapy of infectious disease is to understand the terminology that is used to describe the organisms and drugs. Microbes that are capable of causing human disease, or **pathogens**, include viruses, bacteria, fungi, unicellular organisms (protozoans), and multicellular animals (e.g., fleas, mites, and worms).

Some pathogens are extremely infectious and life threatening to humans, whereas others simply cause annoying symptoms or none at all. **Pathogenicity**, the ability of an organism to cause disease, depends on an organism's speed of reproduction and its skill in bypassing or overcoming body defenses. Organisms that usually infect only when the body's immune system is suppressed are called *opportunistic* pathogens.

Virulence is a quantitative measure of an organism's pathogenicity. A highly virulent microbe is one that can produce disease when present in very small numbers. Virulent pathogens produce their devastating effects through two primary characteristics: invasiveness and toxicity.

Invasiveness is the ability of a pathogen to grow extremely rapidly and cause direct damage to surrounding tissues by their sheer numbers. Because a week or more may be needed to mount an immune response against the organism, this exponential growth can rapidly overwhelm body defenses and disrupt normal cellular function. Some streptococci, staphylococci, and clostridia secrete hyaluronidase, an enzyme that digests the matrix between human cells, allowing the bacteria to penetrate anatomic barriers more easily. *Staphylococcus aureus* secretes the enzyme coagulase, which causes fibrin to be deposited on its cells, thereby protecting it from phagocytes.

The second characteristic of virulence is the production of toxins, or toxicity. **Exotoxins** are proteins released by bacteria into surrounding tissues that have the ability to inactivate or kill host cells. *Clostridium botulinum*, the organism responsible for botulism, produces one of the most potent toxins known that binds to presynaptic motor neurons to prevent the release of acetylcholine. Cholera toxin from *Vibrio cholerae* causes large amounts of fluid to be secreted into the intestinal lumen. Symptoms of exotoxin-producing bacteria are usually caused by the toxin itself, not the bacteria. For example, patients experience food poisoning by ingesting food containing the toxins produced by the organisms; growth of the bacteria in the body is not required. Most exotoxins are water soluble and can readily enter the blood to cause systemic toxemia.

Endotoxins are harmful nonprotein chemicals that are part of the outer layer of the normal cell wall of gram-negative bacteria. After the bacterial cell dies, endotoxins are liberated into the surrounding tissue and induce macrophages to release large amounts of cytokines, causing generalized inflammation, fever, and chills. Rapid decreases in the number of lymphocytes, leukocytes, and platelets

may occur. The initial doses of antibiotic therapy may actually worsen symptoms by lysing bacteria and releasing larger amounts of endotoxins. Even very small amounts of some bacterial endotoxins may disrupt normal cellular activity and, in extreme cases, result in death. Examples of organisms producing endotoxins include *Proteus*, a common cause of urinary tract infections (UTIs), and *Neisseria meningitidis*, the agent that causes meningitis.

CONNECTION Checkpoint 46.1

From what you learned in Chapter 3, if your patient has a particularly virulent infection, which route of administration would likely be used during antibiotic therapy to most rapidly kill the organisms? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Describing and Classifying Bacteria

46.2 Bacteria are described by their staining characteristics, shape, and ability to utilize oxygen.

Because of the enormous number of bacterial species, several descriptive systems have been developed to simplify their study. It is important for nurses to learn these classification schemes, because drugs that are effective against one organism in a class are likely to be effective against other pathogens in the same class. Common bacterial pathogens and their associated diseases are listed in Table 46.1.

One of the simplest methods of classifying microbes is to examine them microscopically after a crystal violet Gram stain has been applied to the microbes. Some bacteria contain a thick cell wall composed of peptidoglycan and retain the violet color after staining. These bacteria are called **gram positive** and include *Staphylococcus*, *Streptococcus*, and *Enterococcus*. Bacteria that have thinner cell walls will lose the violet stain and are called **gram negative**. Examples of gram-negative bacteria include *Bacteroides*, *Escherichia*, *Klebsiella*, *Pseudomonas*, and *Salmonella*. The distinction between gram-positive and gram-negative bacteria is a profound one that reflects important biochemical and physiologic differences between the two groups. Many antibiotics are effective against only one of the two groups. For example, gram-negative bacteria are generally susceptible to the tetracycline class but are resistant to the sulfonamides. This generalization, however, quickly breaks down when resistant strains develop.

Bacteria are often described by their basic shape, which can be readily determined microscopically. Those with rod shapes are called bacilli, those that are spherical are called cocci, and those that are spiral are called spirilla. The shape, along with the Gram stain, helps pathologists to identify organisms that are isolated from infectious specimens.

A third factor used to categorize bacteria is their ability to use oxygen. Those that thrive in an oxygen-rich environment are called **aerobic**; those that grow optimally without oxygen are called **anaerobic**. Some organisms have the ability to change their metabolism and survive in either aerobic or anaerobic conditions, depending on their external environment. Antibiotics are often selective for either aerobes or anaerobes.

Classification of Anti-Infectives

46.3 Anti-infective drugs are classified by their susceptible organisms, chemical structures, and mechanisms of action.

Anti-infective is a general term that applies to any medication that is effective against pathogens. In its broadest sense, an anti-infective drug may be used to treat bacterial, fungal, viral, or parasitic infections. To distinguish among the various anti-infectives, these medications are classified as antibacterial, antifungal, antiviral, antiprotozoan, and antihelminthic based on the type of organism they treat.

The most frequent term used to describe an antibacterial drug is *antibiotic*. Technically, **antibiotic** refers to a natural substance produced by a microorganism that can kill other microorganisms. However, many of the newer drugs that are available to treat bacterial infections are now produced synthetically. In clinical practice and in this text, the terms *antibacterial* and *antibiotic* are used interchangeably to refer to any drug that is effective against bacteria.

Classifying drugs only by their susceptible organism, such as an antibacterial, tells us nothing about the properties, actions, or adverse effects of a drug. With over 300 antibacterials available, it is helpful to group these drugs into subclasses that share similar therapeutic properties. Two means of grouping are widely used: chemical classes and pharmacologic classes.

Class names such as aminoglycoside, fluoroquinolone, and sulfonamide refer to the fundamental chemical structure shared by a group of anti-infectives. Anti-infectives that belong to the same chemical class have close structural similarities and usually share similar antibacterial properties and adverse effects. Although chemical names are sometimes long and difficult to pronounce, placing drugs into chemical classes will assist the student in mentally organizing these drugs into distinct therapeutic groups.

Pharmacologic classes are used to group anti-infectives by their mechanism of action. Like chemical classes, placing an antibiotic into a pharmacologic class allows the nurse to develop a mental framework on which to organize these medications and to predict similar actions and adverse effects. Examples of pharmacologic classes grouped by their mechanisms of action with representative

Table 46.1 Common Bacterial Pathogens

Name of Organism	Disease(s)	Description
Gram-Positive Bacilli		
Bacillus anthracis	Anthrax	Aerobe; appears in cutaneous and respiratory forms
Clostridium	Food poisoning, gas gangrene, tetanus	Anaerobe
Corynebacterium	Diphtheria	Aerobe or anaerobe
Gram-Positive Cocci		
Enterococci	Wounds, UTI, endocarditis, bacteremia	Aerobe; part of host flora of the genitourinary and intestinal tracts; common opportunistic pathogen
Staphylococcus aureus	Pneumonia, food poisoning, impetigo, wounds, bacteremia, endocarditis, toxic shock syndrome, osteomyelitis, UTI	Aerobe; some species are part of host flora on the skin and mucous membranes
Streptococci	Pharyngitis, pneumonia, skin infection, septicemia, endocarditis, otitis media, meningitis in children	Aerobe; some species are part of host flora of the respiratory, genital, and intestinal tracts
Gram-Negative Bacilli		
Bacteroides	Peritonitis, abdominal abscess	Anaerobe; part of host flora of the intestinal, respiratory, and genitourinary tracts
Campylobacter	Gastroenteritis, diarrhea	One of the most common causes of diarrheal illness in the United States
Enterobacter	UTI, blood or lung infections	Aerobe or anaerobe
Escherichia coli	Traveler's diarrhea, UTI, meningitis in children, bacteremia	Part of host flora of the intestinal tract
Haemophilus influenzae	Pneumonia, meningitis in children, bacteremia, otitis media, sinusitis	Some species are part of host flora of the upper respiratory tract
Klebsiella pneumoniae	Pneumonia, UTI	Common opportunistic pathogen; often fatal if not treated aggressively
Proteus mirabilis	UTI, skin infection	Part of host flora of the intestinal tract
Pseudomonas aeruginosa	UTI, skin infection, septicemia	Common opportunistic pathogen
Salmonella enteritides	Food poisoning	Acquired from infected animal products: raw eggs, undercooked meat or chicken
Salmonella typhi	Enteric (typhoid) fever	Acquired from contaminated food or water supplies
Serratia	Hospital-associated infections of wounds and UTI	Aerobic or anaerobic
Shigella	Dysentery	Aerobic or anaerobic; part of host flora of the gastrointestinal (GI) tract
Vibrio cholerae	Cholera	Gram-negative aerobe; acquired from contaminated food or water
Gram-Negative Cocci		
Neisseria gonorrhoeae	Gonorrhea, urethritis, anorectal infection, pelvic inflammatory disease, neonatal eye infection	Gram-negative aerobe; some species are part of host flora of the upper respiratory tract
Neisseria meningitides	Meningitis, particularly in children	Gram-negative aerobe; may result in death within hours of onset of symptoms
Spirilla/Spirochetes		
Borrelia burgdorferi	Lyme disease	Acquired from tick bites
Treponema	Syphilis	Sexually transmitted infection (STI)
Other Organisms		
Chlamydia trachomatis	STIs, eye infection	Gram-negative; most common cause of STIs in the United States
Mycobacterium leprae	Leprosy	Most cases in the United States occur in immigrants from Africa or Asia
Mycobacterium tuberculosis	Tuberculosis	Very high incidence in patients with human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS)
Mycoplasma pneumoniae	Pneumonia	Most common cause of pneumonia in patients ages 5–35
Rickettsia rickettsii	Rocky mountain spotted fever	Gram-negative; acquired from tick bites

Table 46.2 Classification of Anti-Infective Drugs

Mechanism of Action	Chemical Class	Examples
Inhibition of cell wall synthesis	Penicillins Cephalosporins Carbapenems	penicillin G cefotaxime (Claforan) imipenem (Primaxin) isoniazid (INH) vancomycin (Vancocin)
Inhibition of protein synthesis	Aminoglycosides Tetracyclines Macrolides Oxazolidinones	gentamicin (Garamycin) tetracycline (Achromycin) erythromycin (E-mycin) linezolid (Zyvox)
Disruption of plasma membrane	Azoles Polyenes	amphotericin B (Fungizone) fluconazole (Diflucan) nystatin (Mycostatin)
Inhibition of nucleic acid synthesis	Fluoroquinolones	ciprofloxacin (Cipro)
Inhibition of metabolic pathways	Sulfonamides	dapsone (DDS) trimethoprim-sulfamethoxazole (Bactrim, Septra)

drugs are listed in Table 46.2. It is important for nurses to learn both the chemical class and the pharmacologic class for each antibiotic because this will provide a deeper understanding of each drug's therapeutic action and potential adverse effects.

Mechanisms of Action of Anti-Infectives

46.4 Anti-infective drugs act by selectively targeting a pathogen's metabolism or lifecycle.

Although the immune system provides elaborate defenses against microbial invaders, there are times when the body defenses become overwhelmed by an infection. Furthermore, there are times when acquiring an infection could be a serious health challenge for a patient, and it is best to prevent it. Whether it is used for treating or preventing disease, the primary goal of anti-infective therapy is to assist the body in eliminating a pathogen. Drugs that accomplish this goal by killing bacteria are called **bactericidal**. Some drugs do not kill pathogens but instead slow their growth, allowing natural body defenses to eliminate the microorganisms. These growth-slowing drugs are called **bacteriostatic**.

Bacterial cells have distinct anatomic and physiologic differences compared to human cells. Bacteria incorporate different chemicals into their membranes and use unique biochemical pathways and enzymes to manage their rapid growth. Even the more complex pathogens such as fungi and protozoans have different cell structures and use certain metabolic pathways not found in human cells. Antibiotics exert selective toxicity by targeting these unique differences between human and bacterial, fungal, and protozoan cells. Through this selective action, these pathogens can be killed, or their growth severely hampered, without any major effects on human cells. Of course, there are limits to this selective toxicity, depending on the specific antibiotic and the dose employed. Adverse effects can be expected from all the anti-infectives. Antibacterials exert their selective toxicity via five major methods: inhibition of cell wall synthesis, inhibition of protein synthesis, disruption of the plasma cell membrane, inhibition of nucleic acid synthesis, and inhibition of metabolic pathways (antimetabolites). This is an oversimplification of antibacterial actions because some of these drugs act by multiple mechanisms and a few act by unknown mechanisms. Furthermore, as new drugs are developed, they often act by new mechanisms and become the only medication in a class. Indeed although the five major classes encompass the majority of anti-infectives, the "miscellaneous" group of anti-infectives has expanded into a large class (see Chapter 49).

Inhibition of Cell Wall Synthesis

Unlike human cells, bacteria have rigid cell walls that create a high osmotic pressure within the cells. The cell wall primarily consists of **peptidoglycan**, a strong, repeating network of carbohydrate and protein chains found only in bacteria and that contains sugars bound to peptides. Disruption of this wall causes the cell to absorb water and eventually lyse. The presence of a unique cell wall gives several means by which antibiotics may act. Fungi also have a unique cell wall that contains lipids that are not used in human cells.

The penicillins and cephalosporins bind to specific proteins that are essential to building the bacterial cell wall. Vancomycin acts by preventing the formation of peptide chains that are used in the construction of the cell wall. Several drugs that are effective against *Mycobacterium tuberculosis*, including isoniazid, act by inhibiting the incorporation of mycolic acid, an important component of the cell wall of this mycobacterium. Uses of the cell wall inhibitors are presented in Chapter 47.

Inhibition of Protein Synthesis

Both bacterial and human cells conduct protein synthesis, so this may seem an unlikely target for antibiotics. However, proteins are constructed on the surface of ribosomes, and these organelles have different structures in humans and bacteria. This difference in ribosomal structure accounts for the selective toxicity of certain antibiotics for bacterial cells.

The fact that protein synthesis occurs in several steps affords different mechanisms by which antibiotics may act. For example, the tetracyclines interfere with the transfer of ribonucleic acid (RNA), which carries the amino acids to

the ribosome. The aminoglycosides change the shape of the ribosome so that protein synthesis is impeded. Drugs that inhibit protein synthesis are discussed in Chapter 48.

Disruption of the Plasma Cell Membrane

A few antibacterial and antifungal medications act by interfering with the pathogen's plasma membrane. For example, when polymyxin B attaches to the phospholipids in bacterial plasma membranes, the permeability of the membrane changes and substances escape from the cell. The antifungal drug amphotericin B shuts down the synthesis of ergosterol, a lipid essential to the integrity of fungal plasma membranes.

Inhibition of Nucleic Acid Synthesis

Although deoxyribonucleic acid (DNA) and RNA synthesis are complex processes that occur in both human and bacterial cells, the molecular structures of the various enzymes required for these processes differ considerably. The largest group of antibiotics that inhibits DNA synthesis is the fluoroquinolones. These drugs affect bacterial DNA gyrase, an enzyme that uncoils DNA during the replication process. The fluoroquinolones are presented in Chapter 49.

Inhibition of Metabolic Pathways (Antimetabolites)

Because they divide rapidly, bacterial cells need a steady supply of nutrients and metabolites. A few drugs structurally resemble these building blocks and "fool" the bacterial cell into using them for growth. The sulfonamide antibiotics resemble para-amino benzoic acid (PABA), a precursor to folic acid. Folic acid, a B vitamin that is essential to human metabolism, is also essential to bacteria. When the bacteria attempt to use the sulfonamides, bacterial protein synthesis is blocked. The sulfonamides are presented in Chapter 50.

Other Mechanisms of Action

Anti-infectives act by a number of other miscellaneous mechanisms. The antifungal drug griseofulvin inhibits the formation of mitoticv microtubules. Antiretrovirals such as zidovudine block the synthesis of viral DNA by inhibiting the enzyme reverse transcriptase. Mebendazole kills parasitic worms by preventing their absorption of nutrients.

Many other possible mechanisms exist. As the understanding of bacterial physiology increases, it is likely that pharmacologists will develop anti-infectives with entirely new mechanisms of action. The primary mechanisms of action of antibacterial drugs are shown in Pharmacotherapy Illustrated 46.1.

PharmFACT

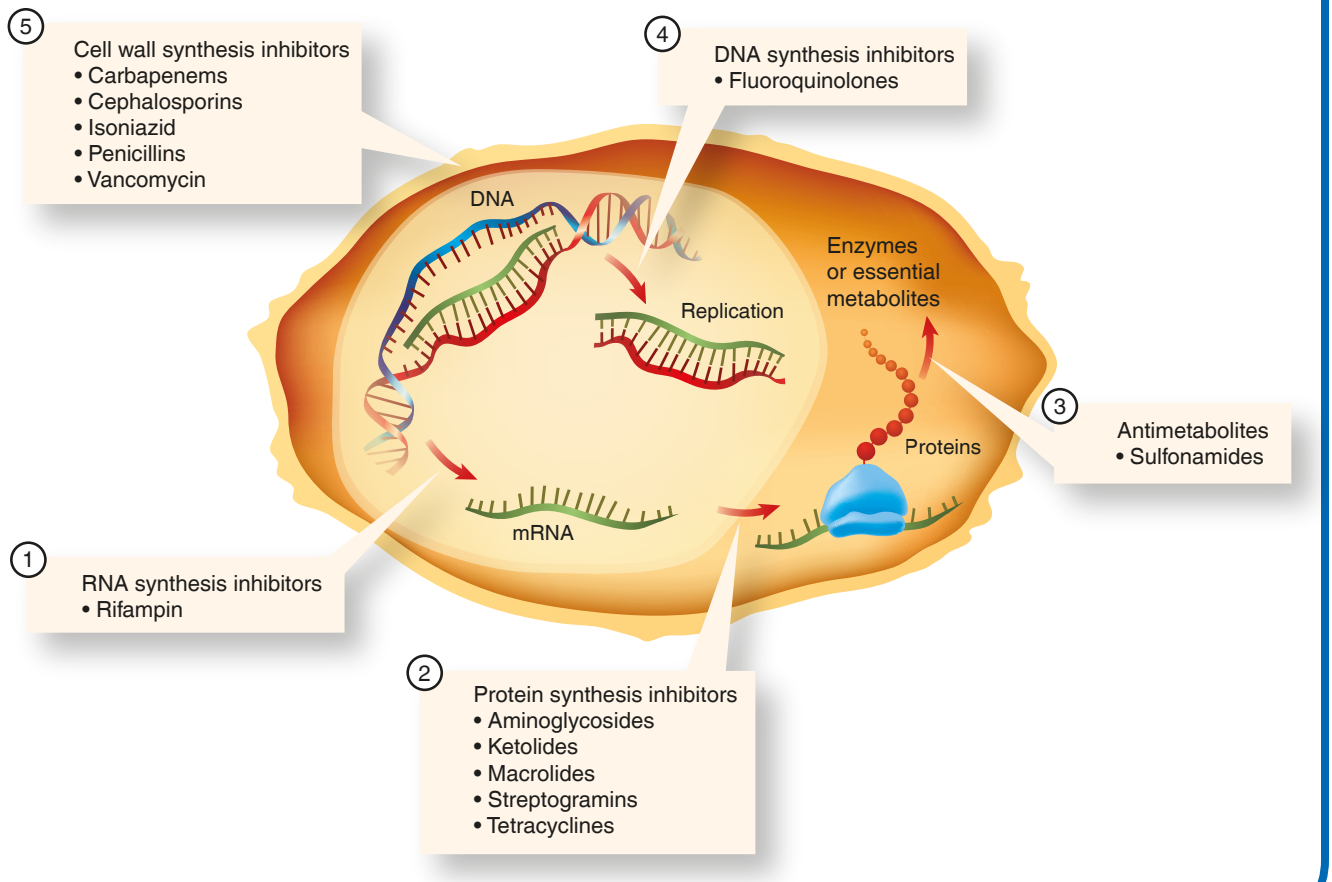
Antibiotic-resistant bacteria cause over 2 million illnesses and 23,000 deaths annually in the United States. Over half of these deaths are caused by antibiotic-resistant *Clostridium difficile* infections (Centers for Disease Control and Prevention [CDC], 2014).

Acquired Resistance

46.5 Acquired resistance is a major clinical problem that is worsened by the inappropriate use of anti-infectives.

In the 1950s, healthcare providers called antibiotics "miracle drugs" and predicted that all infectious disease would one day be eliminated. It did not take long, however, to discover that these miracle drugs were rapidly becoming ineffective. How could a drug that once killed nearly 100% of a species of bacteria soon prove to be ineffective? The answer is acquired resistance.

Acquired resistance is the ability of an organism to become unresponsive over time to the effects of an anti-infective. Resistance can occur in bacteria, fungi, viruses, and protozoans. It is a major clinical problem that is growing in importance.



Mechanisms of Resistance

How can an organism become insensitive to a drug that kills other members of its species? Medicine has discovered a number of mechanisms by which pathogens acquire resistance:

- **Destruction of the drug.** Organisms can produce an enzyme that destroys or deactivates the drug. For example, some bacteria are able to produce beta-lactamase, an enzyme that splits the active portion of the drug molecule. Organisms that produce beta-lactamase are resistant to many of the penicillin and cephalosporin antibiotics.
- **Prevention of drug entry into the pathogen.** Some antibiotics must enter the pathogen to cause their action. Some bacteria have developed enzymes that inactivate the drug as it crosses the cell wall. Others have changed the structure of the channels or pores that the antibiotic normally uses to enter the cell. Resistance to penicillins and tetracyclines can occur by these methods.
- **Removal by resistance pumps.** Some bacteria have developed a system that rapidly pumps the antibiotic out of the bacterial cell before it can reach intracellular targets such as ribosomes. Resistant bacteria have developed several types of pumps, each of which is used to remove different antibiotics.

Pharmacotherapy Illustrated 46.1

Mechanisms of Action of Antimicrobial Drugs

- **Alteration of the drug's target site.** Most antibiotics bind to a specific receptor that is located on the cell surface or inside the bacteria. Certain bacteria have changed the shape of these receptors, so they no longer bind the drug. This mechanism of resistance is common for the sulfonamides. For the macrolide antibiotics, mutations have resulted in changes to the structure of the bacterial ribosome, which is the receptor for macrolide binding.
- **Development of alternative metabolic pathways.** Some antibiotics act by depleting the pathogen of an essential substance necessary for growth. Some resistant organisms have survived antibiotic application by synthesizing larger amounts of the essential substance or by finding an alternative means of obtaining it from the environment.

How do bacteria change their physiology to become resistant to antibiotics? The answer lies in the nature of bacterial cell division. Microorganisms have the ability to replicate extremely rapidly. Under ideal conditions *E. coli* can produce a million cells every 20 minutes, or 1×10^{21} cells in only 24 hours. During exponential division, bacteria make frequent errors, or **mutations**, while duplicating their genetic code. These mutations, which occur spontaneously and randomly, occasionally result in a change in physiology that gives a bacterial cell a reproductive advantage over its neighbors. For example, the mutated bacterium may be able to survive in harsher conditions, change the shape of its organelles, or perhaps grow faster than other bacterial cells.

It is possible for such a random mutation to confer drug resistance for a microorganism. Once the mutation produces a resistant strain, the microbes permanently lose sensitivity to that specific drug and often to other drugs in the same pharmacologic and chemical class. Over several decades, these drug-resistant mutants may colonize a large segment of the human population, thus making the medication essentially useless as a first-line antibiotic.

Promotion of Resistance

The widespread and sometimes unwarranted use of antibiotics has promoted the development of drug-resistant bacterial strains. By killing strains of bacteria

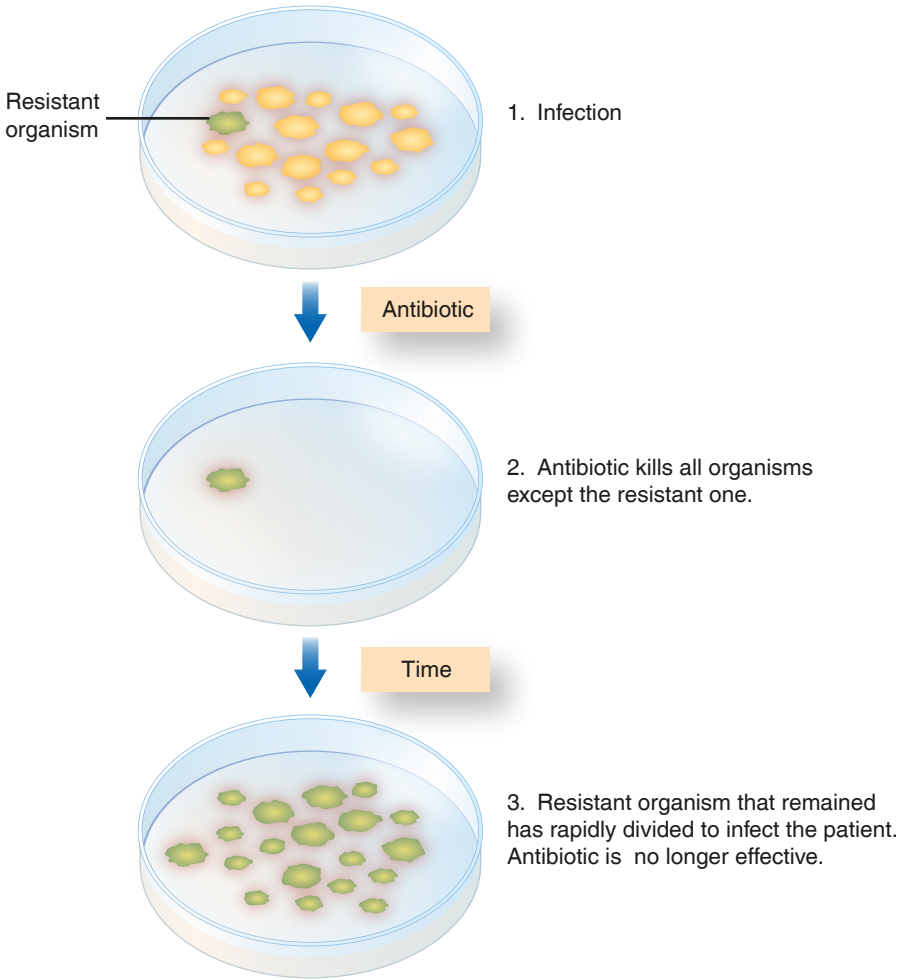


Figure 46.1 Acquired resistance.

that are sensitive to the drug, the only bacteria remaining to replicate are those that acquired the mutations that made them insensitive to the effects of the antibiotic. These drug-resistant bacteria are then free to grow, unrestrained by their neighbors that are killed by the antibiotic. Soon the patient develops an infection that is resistant to conventional drug therapy. This concept is shown in Figure 46.1.

After acquiring resistance, the mutated bacterium may pass its resistance gene to other bacteria through **conjugation**, which is the direct transfer of small pieces of circular DNA called plasmids. Through conjugation, it is quite possible for a bacterium that has never been exposed to the antibiotic to become resistant. Furthermore, because conjugation is not species specific, resistance genes may be passed from one species to a totally different species.

It is important to understand that the antibiotic itself does not cause changes in bacterial physiology, nor does the microorganism have a master plan to become resistant or to actively defeat the drug. The mutation occurs randomly—the result of accident and pure chance. The promotion and growth of the resistant strain, however, are not due to chance. The antibiotic kills the surrounding cells that are susceptible to the drug, leaving the mutated bacterium plenty of room to divide and infect. It should also be understood that it is the bacteria that become resistant, not the patient.

Prevention of Resistant Strains

Patients and their healthcare providers play important roles in delaying the emergence of resistance to antibiotics. The CDC has developed a set of guidelines for preventing antimicrobial resistance in the healthcare setting:

- **Prevent infections when possible.** Nurses must always teach their patients that it is always easier to prevent an infection than to treat one. One important aspect of prevention is getting immunizations to protect against diseases such as influenza, tetanus, polio, measles, and hepatitis B (see Chapter 43). Prevention also includes proper care and hygiene of catheters,

which are significant sources of microorganisms and provide portals of entry into the body.

- **Diagnose and treat the infection properly.** Infections should be cultured so that the offending organism can be identified and the correct drug chosen, as discussed in Section 46.7.
- **Use antimicrobials appropriately.** Antibiotics should be prescribed only when there is a clear rationale for their use. The drugs should be taken for the full length of therapy, and the prescription should not be renewed if the infection has been eliminated or prevented. The more often an antibiotic is prescribed in the population, the larger will be the percentage of resistant strains.
- **Prevent transmission.** Nurses can contain infections and stop the spread of the disease in their work settings by using proper infection control procedures. Additionally, nurses should teach their patients the methods of proper hygiene to prevent the transmission of infectious disease in the home and community settings.

CONNECTION Checkpoint 46.2

From what you learned in Chapter 27, explain the difference between resistance and tolerance. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

46.6 Several resistant strains are major clinical challenges due to the lack of therapeutic options.

Infections that are acquired in a healthcare setting, called **healthcare-associated infections (HAIs)**, are often resistant to common antibiotics. The most common site of HAIs is the urinary tract, followed by surgical wounds, respiratory tract, and the blood (bacteremia). Table 46.3 lists the organisms that are frequently responsible for HAI infections.

Table 46.3 Common Pathogens Associated with Healthcare-Associated Infections

Pathogen	Infection
Acinetobacter species (spp)	Bacteremia, pneumonia
Clostridium difficile	Colon
Enterobacter spp	Pneumonia
Enterococcus spp	Urinary tract
Escherichia coli	Bacteremia, pneumonia, urinary tract
Klebsiella pneumoniae	Pneumonia, urinary tract
Pseudomonas aeruginosa	Pneumonia, urinary tract
Staphylococci (coagulase negative)	Bacteremia
Staphylococcus aureus	Bacteremia, pneumonia, surgical wounds

The four general sources of HAIs are as follows:

- **Patient flora.** Bacteria normally residing on the skin and in the lung or genitourinary tract
- **Invasive devices.** Urinary catheters, vascular catheters, endotracheal tubes, and endoscopes
- **Medical personnel.** Infected healthcare workers or noninfectious carriers
- **Medical environment.** Contaminated instruments, air, food, or fluids.

Many times, patients are at risk for HAIs caused by resistant organisms. Resistant strains that are especially important to pharmacotherapy include methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, carbapenem-resistant Enterobacteriaceae, and *Clostridium difficile*.

Methicillin-resistant *Staphylococcus aureus* (MRSA): MRSA is a type of bacterium that is resistant to certain antibiotics such as methicillin, amoxicillin, and penicillin. At least 60% of *S. aureus* infections are now resistant to penicillin. The term *methicillin resistant* is still used for these infections despite the fact that methicillin was removed from the market many years ago.

MRSA infections are most frequently acquired in hospitals and long-term care facilities. These hospital-acquired infections (HA-MRSA) occur primarily in patients with weakened immune systems. MRSA infections that occur in nonhospitalized settings are called community-acquired infections. Community-acquired MRSA (CA-MRSA) infections occur in otherwise healthy people and are usually manifested as skin and soft tissue infections, such as pimples and boils. The strains that are responsible for HA-MRSA infections appear to be distinctly different from those that cause CA-MRSA infections; thus the pharmacotherapy of the two infections differs somewhat.

Therapeutic options for patients with serious MRSA infections are limited. In recent years, MRSA strains have developed resistance to most classes of antimicrobials, including fluoroquinolones, macrolides, aminoglycosides, tetracyclines, and clindamycin. In general, the HA-MRSA strains are resistant to more classes than the CA-MRSA infections. Until recently, vancomycin was the only antibiotic effective for treating serious MRSA infections. Unfortunately, MRSA strains that are also resistant to vancomycin have appeared. Several newer antibiotics, including linezolid (Zyvox), quinupristin-dalfopristin, and daptomycin, are now available to treat multidrug-resistant strains of MRSA.

Vancomycin-resistant enterococci (VRE): Enterococci are normal inhabitants of the human gastrointestinal (GI) tract and the female genital tract. Enterococci are also frequently found in wounds and pressure ulcers in hospitalized patients or nursing home residents. Patients with compromised immune systems are at greatest risk. Because

enterococci are hardy organisms, they can survive for prolonged periods on environmental surfaces, and healthcare workers using poor infection control techniques can easily spread them. More than 95% of VRE strains in the United States are *Enterococcus faecium*.

Like MRSA, VRE infections represent a major therapeutic challenge, and treatment options are limited. Strains that are resistant to the most commonly used classes of antibiotics have been isolated. Virtually all are resistant to high levels of ampicillin, which is the conventional treatment for enterococci infections. In the 1990s, vancomycin became the only antibiotic effective against multidrug-resistant VRE strains. Unfortunately, each year finds more VRE strains becoming resistant to vancomycin, and newer antibiotics must be used for these infections.

Carbapenem-resistant Enterobacteriaceae (CRE): Enterobacteriaceae colonize the mucosal surfaces and GI tracts of humans and include *E. coli*, *E. aerogenes*, and *K. pneumoniae*. Most members of this family are opportunistic and can cause secondary infections in numerous locations, including the lungs, urinary tract, and blood. Enteric Enterobacteriaceae are responsible for most CRE. CRE secrete carbapenemases, which are a form of beta-lactamase, to inactivate the antibiotics.

CRE have been increasingly observed in hospitals and long-term care facilities, which are the primary transmission sites for these infections. Some CRE are resistant to all drugs in the carbapenem class of antibiotics, which have been considered the drugs of last resort for treating this infection. Indeed, in 2017 a strain was isolated from a patient in the United States that was resistant to all available antimicrobial drugs (pan-resistant) (Chen, Todd, Kiehlbauch, Walters, & Kallen, 2017).

Because most Enterobacteriaceae are resistant to beta-lactam antibiotics and carbapenems, pharmacotherapy may include tigecycline, fosfomycin, aminoglycosides, and polymyxin B. The mortality rate for a CRE infection can be as high as 50%.

***Clostridium difficile* (*C. difficile*):** *C. difficile* is the most common microbial cause of HAI, resulting in 500,000 infections and associated with 29,000 deaths annually in the United States (CDC, 2015). Eighty percent of the deaths occur in patients over age 65. Those at highest risk for *C. difficile* infection are patients receiving an antibiotic while in a healthcare facility. Infection is attributed to a combination of unnecessary antibiotic use (creatine-resistant strains) and ineffective infection control procedures.

Pharmacotherapy for *C. difficile* includes vancomycin for severe cases and metronidazole and fidaxomicin for moderate or mild infections. In 2016, bezlotoxumab (Zinplava) was approved to prevent relapses, which are very common in patients with *C. difficile* infection. Bezlotoxumab is a monoclonal antibody that binds to *C. difficile* toxin B to prevent its cytotoxic effects. This drug is not an antibiotic but is an adjunct to regular antibiotic therapy for this microbe.

PharmFACT

The CDC reports that about 1 in 3 people carry staphylococci in their nose, and 2 in 100 people carry MRSA. MRSA infections in healthcare settings are declining, with 30,800 fewer severe MRSA infections and 9000 fewer deaths reported in hospital patients in 2011 versus 2005 (CDC, 2016).

46.7 Careful selection of the correct antibiotic is essential for effective pharmacotherapy and to limit adverse effects.

It is essential for the healthcare provider to select an antibiotic that will be effective against the specific pathogen that is causing the patient's infection. Selecting an incorrect drug will delay proper treatment, giving the pathogens more time to invade or secrete toxins. For acute infections, treatment delays of just a few hours or days can lead to poorer patient prognosis and even death. Prescribing ineffective antibiotics also promotes the development of resistance and may cause unnecessary adverse effects in the patient.

For the correct antibiotic to be chosen, identification of the causative agent is necessary. Although gathering data on symptoms is important, many infections produce the same signs early in their course; thus more exact laboratory means of diagnosis are necessary.

Specimens such as urine, sputum, blood, or pus are examined in the laboratory for the purpose of isolating and identifying specific pathogens. After isolation, the microbe is exposed in the laboratory to different antibiotics to determine the most effective ones. This process of isolating the infectious organism and identifying the most effective antibiotic is called **culture and sensitivity (C&S) testing**. Other laboratory techniques include examination of the blood for specific antibodies, direct antigen detection, and DNA probe hybridization.

Ideally, the pathogen should be identified before anti-infective therapy is begun. However, laboratory testing and identification may take several days and, in the case of viruses, several weeks. Indeed, some pathogens cannot be cultured at all. If the infection is severe, therapy is often begun with a **broad-spectrum antibiotic**, which is one that is effective against a wide variety of different microbial species. After C&S testing is completed, the drug may be changed to a **narrow-spectrum antibiotic**, which is one that is effective against a smaller group of microbes or only the isolated species. In general, narrow-spectrum antibiotics have less effect on **host flora**, thus causing fewer adverse effects. Host flora are microorganisms that normally inhabit the human body.

Anti-infectives should not be prescribed for infections such as the common cold or for disorders for which antibiotics serve no therapeutic advantage. Antibiotics do not affect

viral diseases such as the common cold, although many patients with this self-limiting disorder believe that these drugs will speed their recovery. Another example of anti-infective misuse is prescribing antibiotics to patients who have a cough due to chronic bronchitis. It should be understood, however, that healthcare providers may prescribe anti-infectives to prevent a secondary infection from developing. For example, an older adult patient with a severe cold may develop a weakened immune response. Thus the healthcare provider may order an antibiotic not for the viral infection, but to prevent a secondary bacterial infection from developing.

Indications and Selection of Specific Anti-Infectives

46.8 Depending on the pathogen, anti-infective therapy may be conducted with a single drug or a combination of drugs.

If C&S testing confirms that an infection is caused by only one species of microbe, antibiotic therapy is usually begun with a single drug. In some cases, combining two antibiotics may actually decrease each drug's effectiveness, a phenomenon known as *antagonism*. For example, giving a drug that slows bacterial growth may interfere with an antibiotic that depends on a high bacterial growth rate to produce its bactericidal effect. Use of multiple antibiotics can also promote the emergence of multidrug-resistant strains and produce unnecessary adverse effects.

In well-defined circumstances combination therapy with multiple antibiotics is warranted. For example, multiple anti-infective drugs are indicated if different species of pathogens are causing the infection. Patients may present with a life-threatening infection of unknown etiology and the healthcare provider may need to prescribe several antibiotics until the specific pathogens can be identified. In some cases, two antibiotics have been shown through clinical research to work synergistically, producing a greater kill rate than would be achieved by either antibiotic given alone. Examples of situations where multidrug therapy is clearly warranted are for the pharmacotherapy of tuberculosis (see Chapter 51) and HIV-AIDS (see Chapter 55).

CONNECTION Checkpoint 46.3

From what you learned in Chapter 5, why would a patient potentially experience fewer adverse effects if given two antibiotics at lower doses, rather than a single antibiotic at a higher dose? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

46.9 Anti-infectives may be administered to prevent infections.

In most cases, anti-infectives are given when there is clear evidence of infection. This is because healthcare providers have developed clear rationales for prescribing these drugs to discourage the emergence of resistant strains.

However, anti-infectives are administered to prevent infections in certain high-risk patients. In these cases, research has demonstrated that the benefits of infection prophylaxis outweigh the increased risk of adverse effects or the potential for producing resistant strains. Prophylactic anti-infectives are indicated for the following clinical situations:

- Antibiotics for patients with suppressed immune systems, including those with HIV infection, AIDS, or profound neutropenia
- Antibiotics for patients with deep puncture wounds such as from dog bites
- Antibiotics for patients with prosthetic heart valves, prior to receiving medical or dental surgery, to prevent bacterial endocarditis
- Antibiotics for patients who are undergoing specific types of surgery, such as cardiovascular, orthopedic, or alimentary canal surgery, where it has been shown that antibiotic use decreases the risk of postoperative infections
- Antimalarial drugs for patients who are entering areas of the world where malaria is endemic
- Antitubercular drugs for close personal contacts of patients who have confirmed or suspected active tuberculosis
- Antiretrovirals to prevent the transmission of HIV to newborns when the mother is HIV positive
- Antiretrovirals for healthcare workers who have a confirmed exposure to HIV-contaminated body fluids.

Prophylactic therapy with anti-infectives is usually conducted using specific protocols that designate the duration of therapy. For example, chloroquine (Aralen) is given 1 week before expected exposure to malaria and continues for 4 weeks following exposure. Zidovudine (AZT) is given to a mother who is HIV positive beginning by week 14 of pregnancy until birth, after which the drug is given to her neonate for 6 weeks. Only in rare cases are anti-infectives given prophylactically for indefinite time periods. Examples include the prevention of infections in patients with suppressed immune systems such as those with HIV infection, or those receiving immunosuppressants following an organ transplant.

Host Factors Affecting Anti-Infective Selection

46.10 Patient factors such as host defenses, local tissue conditions, history of allergic reactions, age, pregnancy status, and genetics influence the choice of anti-infective.

The most important factor in selecting an appropriate antibiotic is to be certain that the microbe is sensitive to the

bactericidal or bacteriostatic effects of the drug. Once the appropriate drug has been chosen, the nurse must consider a number of host factors that have the potential to significantly influence the success of anti-infective therapy.

Host Defenses

Remember that the primary goal of antibiotic therapy is to kill enough of the pathogen or slow its growth such that natural body defenses can overcome the invading agents. An anti-infective is rarely able to eliminate a pathogen without help from a functioning immune system. Patients with weakened immune defenses often require the administration of prophylactic antibiotics. Should an infection occur in these patients, anti-infective therapy is more aggressive and prolonged. Examples of patients who may require this type of antibiotic therapy include those with AIDS and those with neutropenia caused by immunosuppressive or antineoplastic medications.

Local Tissue Conditions

Anti-infectives must be able to reach the area of infection in sufficient concentrations to be effective; thus local conditions at the infection site are important to the success of pharmacotherapy. Infections of the central nervous system (CNS) are particularly difficult to treat because many medications are unable to cross the blood–brain barrier to reach the brain and associated tissues. Injury or inflammation at an infection site can cause tissues to become acidic or anaerobic and have poor circulation. Excessive pus formation or large hematomas can impede drugs from reaching their targets. Pathogens such as mycobacteria, salmonella, toxoplasma, and listeria can reside intracellularly and thus be resistant to antibacterial action.

Factors that hinder the drug from reaching microbes will limit therapeutic success, and adjustments in treatment may be necessary. Increasing the dosage or switching to a different route of drug administration may be indicated. Occasionally, it is necessary to switch to a different antibiotic that is more effective for conditions specific to the infection site.

Allergy History

Although not common, serious hypersensitivity reactions to antibiotics may be fatal. The penicillins are the class of antibacterials that have the highest incidence of allergic reactions: Between 0.7% and 10% of all patients who receive these drugs exhibit some degree of hypersensitivity.

Patient assessment must always include a thorough medication history. A previous acute allergic incident with a drug is highly predictive of future hypersensitivity to the same medication. Because the patient may have been exposed to an antibiotic unknowingly, such as through food products or molds, allergic reactions can occur without any apparent previous exposure. If severe allergy to a drug is established, it is best to avoid all drugs in the same chemical class.

Other Host Factors

Age, pregnancy status, and genetics are additional factors that influence anti-infective pharmacotherapy. Infants and older adults are less able to metabolize and excrete antibiotics; thus doses are generally decreased. Because of polypharmacy in older patients, this group is more likely to be taking multiple drugs that could interact with antibiotics.

Some antibiotics are readily secreted in breast milk or cross the placenta. For example, tetracyclines taken by the mother can cause teeth discoloration in the newborn, and aminoglycosides can affect hearing. Some anti-infectives are pregnancy category D, such as minocycline, doxycycline, neomycin, and streptomycin. The benefits of antibiotic use in pregnant or lactating women must be carefully weighed against the potential risks to the fetus and neonate.

A genetic absence of certain enzymes can lead to an inability of a patient to metabolize antibiotics to their inactive forms. For example, patients with a deficiency of the enzyme glucose-6-phosphate dehydrogenase should not receive sulfonamides, chloramphenicol, or nalidixic acid due to the possibility of erythrocyte rupture.

CONNECTION Checkpoint 46.4

From what you learned in Chapter 42, what classes of drugs are administered to boost immune function so that the patient is less likely to experience an opportunistic infection? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Superinfections

46.11 Superinfections can occur when an anti-infective antibiotic kills host flora.

Microorganisms that normally inhabit the human body, or host flora, are present on the surface of the skin and in the upper respiratory, genitourinary, and intestinal tracts. Some of these microbes serve useful purposes by producing natural antibacterial substances or by breaking down toxic agents. The various host flora are in competition with each other for physical space and nutrients. This **microbial antagonism** helps protect the host from being overrun by pathogenic organisms.

Antibiotics are unable to distinguish between host flora and pathogenic organisms. When an antibiotic kills the host's normal flora, additional nutrients and space are available for pathogenic microorganisms to grow unchecked. These new, secondary infections caused by

antibiotic use are called **superinfections**, or suprainfections. The appearance of a new infection while receiving anti-infective therapy is highly suspicious of a superinfection. Signs and symptoms of superinfection commonly include diarrhea, bladder pain, painful urination, or abnormal vaginal discharges.

Broad-spectrum antibiotics are more likely to cause superinfections because they kill many microbial species, which sometimes include host flora. Organisms that commonly cause superinfections are *Clostridium albicans* in the vagina, streptococci in the oral cavity, and *C. difficile* in the colon.

Understanding Chapter 46

Key Concepts Summary

46.1 Pathogens cause disease due to their ability to invade tissues or secrete toxins.

46.2 Bacteria are described by their staining characteristics, shape, and ability to utilize oxygen.

46.3 Anti-infective drugs are classified by their susceptible organisms, chemical structures, and mechanisms of action.

46.4 Anti-infective drugs act by selectively targeting a pathogen's metabolism or lifecycle.

46.5 Acquired resistance is a major clinical problem that is worsened by the inappropriate use of anti-infectives.

46.6 Several resistant strains are major clinical challenges due to the lack of therapeutic options.

46.7 Careful selection of the correct antibiotic is essential for effective pharmacotherapy and to limit adverse effects.

46.8 Depending on the pathogen, anti-infective therapy may be conducted with a single drug or a combination of drugs.

46.9 Anti-infectives may be administered to prevent infections.

46.10 Patient factors such as host defenses, local tissue conditions, history of allergic reactions, age, pregnancy status, and genetics influence the choice of anti-infective.

46.11 Superinfections can occur when an anti-infective antibiotic kills host flora.

Chapter 47
Antibiotics Affecting the Bacterial Cell Wall

Chapter Outline

- Structure of Bacterial Cell Walls
- Penicillins

  Natural Penicillins

  PROTOTYPE *Penicillin G, p. 852*

  Broad-Spectrum Penicillins (Aminopenicillins)

  PROTOTYPE *Ampicillin, p. 854*

  Extended-Spectrum (Antipseudomonal) Penicillins

  Penicillinase-Resistant (Antistaphylococcal) Penicillins
- Cephalosporins

  PROTOTYPE *Cefazolin (Ancef, Kefzol), p. 858*
- Carbapenems

  PROTOTYPE *Imipenem-Cilastatin (Primaxin), p. 860*
- Miscellaneous Cell Wall Inhibitors

  PROTOTYPE *Vancomycin (Vancocin), p. 862*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the structure of a bacterial cell wall and its importance to pharmacotherapy.
2. Identify the classes of antibiotics that act by affecting the synthesis of the bacterial cell wall.
3. Explain the mechanisms by which antibiotics affect the bacterial cell wall.
4. Compare and contrast the four classes of penicillins.
5. Compare and contrast the five generations of cephalosporins.
6. Identify similarities and differences among drugs in the carbapenem class.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy with bacterial cell wall inhibitors.

Key Terms

beta-lactamase, 851
beta-lactam ring, 851
penicillinase, 851
penicillin-binding proteins (PBPs), 849

The discovery and development of the first anti-infective drugs in the mid-1900s was a milestone in the field of medicine. Humans no longer die in massive numbers from infectious organisms such as *Yersinia pestis*, which killed 25% of the known human population in the 14th century due to the bubonic plague. This chapter examines the penicillins, cephalosporins, and other antibiotic drugs that kill bacteria by disrupting their cell walls.

Structure of Bacterial Cell Walls

47.1 Bacterial cell walls consist of layers of carbohydrate and protein chains, which are constructed by enzymes called penicillin-binding proteins.

The cell wall is a structure that sets people apart from the bacterial world. Humans do not have them, but all bacteria do. The osmotic pressure is so high within a bacterial cell that the cell would rupture without the containment of this rigid structure. The cell wall also serves as a barrier to substances that try to enter the cell, including antibiotics. Simply, it protects the bacterial cell from a hostile environment. The cell walls of gram-positive bacteria are very thick, whereas the walls of gram-negative bacteria are thinner. The structure of a bacterial cell wall is illustrated in Figure 47.1.

The primary material in a bacterial cell wall is peptidoglycan, a strong, repeating network of carbohydrate and protein chains that contains sugars bound to peptides. In gram-positive bacteria, peptidoglycan is laid down in repeated layers that are cross-linked to each other to provide greater stability to the wall. The layers may be compared to a fort that is built to provide protection from invaders. A single wall could be easily destroyed, but five or six repeated walls would provide almost impenetrable protection to those inside.

Because of the critical importance of their cell walls, bacteria spend a lot of time and energy building them. At least 30 different bacterial enzymes participate in their construction. Some of these enzymes are targets for penicillins and related antibiotics and are called **penicillin-binding proteins (PBPs)**. Most penicillins affect transpeptidase, which is the final PBP enzyme in the construction of the cell wall that adds the cross-links to the peptidoglycan layers.

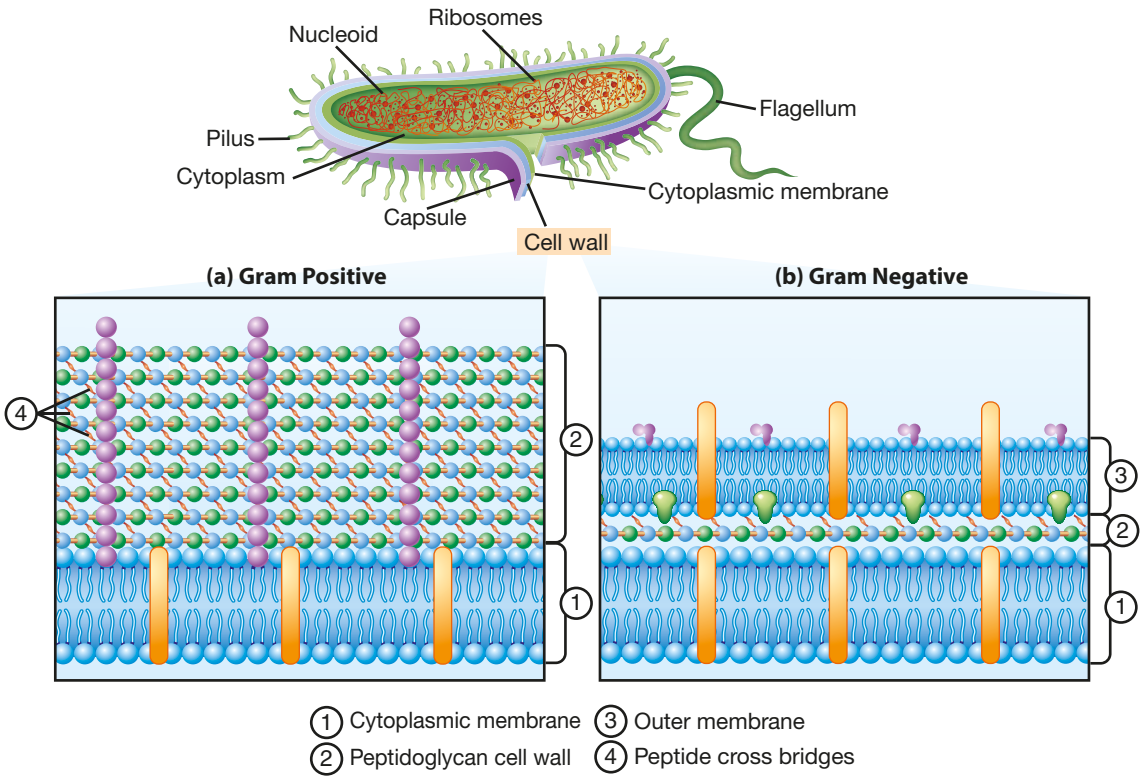

Figure 47.1 The bacterial cell wall: (a) gram-positive bacterium; (b) gram-negative bacterium.

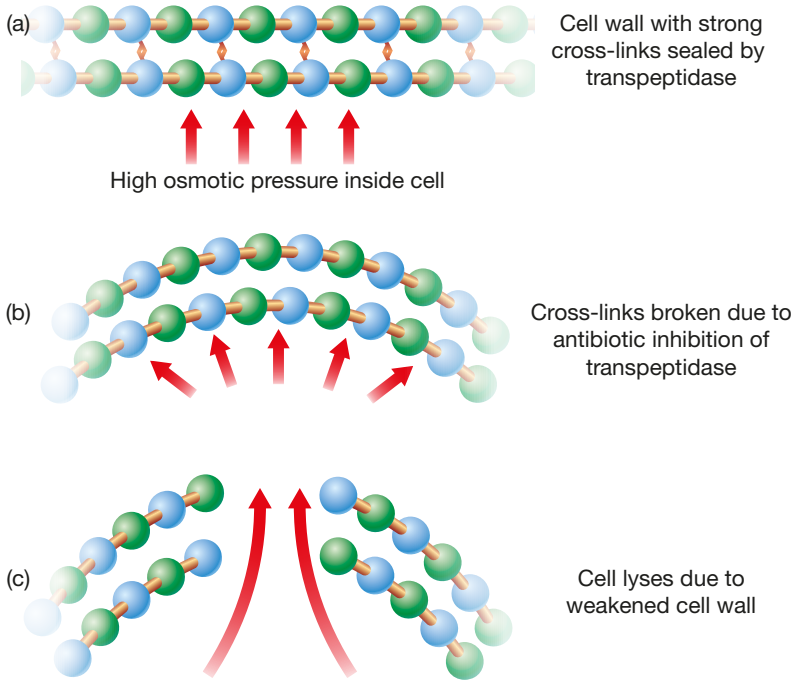

Figure 47.2 Mechanism of penicillin: (a) Bacterial cell wall strengthened by peptide cross-links. (b) Penicillin breaks cross-links. (c) Cell death due to weakened cell walls.

Without the cross-linking, the cell wall becomes weakened and bulges due to the high osmotic pressure inside the cell. The bacterial cell eventually lyses (ruptures). This process is illustrated in Figure 47.2. Because human cells do not possess cell walls, they do not have PBPs. Therefore, antibiotics that affect the cell wall have selective toxicity to bacteria.

The PBPs are located on the outside of the plasma membrane of the bacterial cell. This location allows antibiotics to exert their bactericidal effect without actually entering the cell. Although all bacteria have a cell wall, the materials and PBPs used in their construction differ among species. Even slight structural changes to a PBP can cause lack of antibiotic binding to the enzyme. This explains why penicillins are not effective against all species of microorganisms. This also provides an explanation as to how an organism develops resistance to the penicillins.

Penicillins

47.2 The penicillins, one of the oldest and safest groups of antibacterials, are primarily active against gram-positive bacteria.

Although not the first anti-infective discovered, penicillin was the first mass-produced antibiotic. Discovered in cultures of the common fungus *Penicillium* in 1929, penicillin was first administered therapeutically in 1941. The medication quickly gathered a reputation as a miracle drug by preventing thousands of deaths from what are now considered minor infections. Penicillins are the most extensively studied of all the antibiotic classes. Doses of the penicillins are listed in Table 47.1.

Table 47.1 Penicillins

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Natural Penicillins		
penicillin G benzathine (Bicillin)	IM: 1.2 million units as a single dose (max: 2.4 million units/day)	*Rash, pruritus, diarrhea, nausea, fever* Anaphylaxis symptoms including angioedema, circulatory collapse, and cardiac arrest; nephrotoxicity
penicillin G potassium	IM/IV: 2–24 million units divided q4–6h (max: 80 million units/day)	
penicillin G procaine	IM: 600,000–1.2 million units daily (max: 4.8 million units/day)	
penicillin V	PO: 125–250 mg qid (max: 7.2 g/day)	
Broad-Spectrum Penicillins (Aminopenicillins)		
amoxicillin (Amoxil)	PO: 250–500 mg tid (max: 1750 mg/day)	
amoxicillin-clavulanate (Augmentin)	PO: 250- or 500-mg tablet (each with 125 mg clavulanic acid) q8–12h	
ampicillin	PO/IV/IM: 250–500 mg q6h (max: 4 g/day PO or 14 g/day IV/IM)	
ampicillin and sulbactam (Unasyn)	IV/IM: 1.5–3 g q6h	
Extended-Spectrum (Antipseudomonal) Penicillins		
piperacillin	IM/IV: 2–4 g tid–qid (max: 24 g/day)	
piperacillin-tazobactam (Zosyn)	IV: 3.375 g qid over 30 min	
ticarcillin-clavulanate (Timentin)	IV: 3.1 g q4–6h	
Penicillinase-Resistant (Antistaphylococcal) Penicillins		
dicloxacillin	PO: 125–500 mg qid (max: 4 g/day)	
nafcillin	IV/IM: 500 mg–1 g qid (max: 12 g/day)	
oxacillin	IV: 250–500 mg/kg/day q4–6h (max: 12 g/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Penicillins kill bacteria by disrupting their cell walls. The portion of the chemical structure of penicillin that is responsible for its antibacterial activity is called the **beta-lactam ring**. The beta-lactam ring resembles one of the chemical building blocks of peptidoglycan. When the PBP enzyme attempts to add the next "link" in the peptidoglycan chain, it binds to the beta-lactam ring, and construction of the cell wall is terminated. Other antibiotic classes that contain a beta-lactam ring include the cephalosporins, monobactams, and carbapenems, as shown in Figure 47.3. These classes are sometimes grouped together and referred to as beta-lactam antibiotics.

Penicillin lyses the growing bacterial cells that are building cell walls; therefore, it is considered bactericidal. It has much less toxicity, however, on bacterial cells that have already constructed their cell walls. Like all infections, the body's immune defenses are needed to eliminate stable, slow-growing bacterial cells.

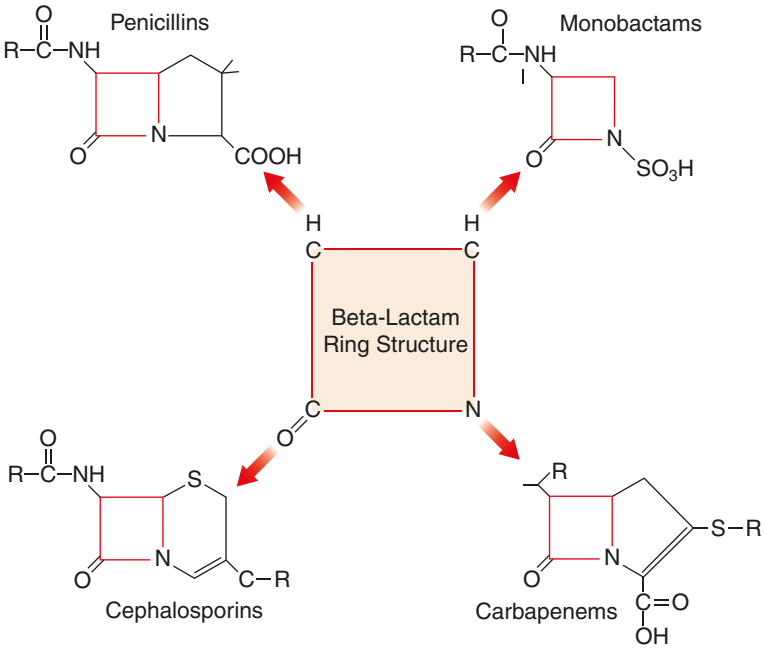

Figure 47.3 Beta-lactam antibiotics: The beta-lactam ring is common to many different classes of antibiotics.

Because of their extensive use during the past 70 years, large numbers of resistant bacterial strains have emerged to limit the therapeutic usefulness of the penicillins. There are several mechanisms by which bacteria may become resistant to penicillins. Through mutations, the structures of PBPs have changed such that they no longer bind penicillin. Indeed, many species of bacteria are inherently insensitive to penicillins because they lack the target binding protein for these antibiotics.

Another mechanism of resistance is that some bacteria secrete enzymes that split the beta-lactam ring, rendering the antibiotic ineffective. **Beta-lactamase** is the general term used for any of several enzymes produced by bacteria that can split the four-atom beta-lactam ring structure. The action of this enzyme is illustrated in Figure 47.4.

Scientists who first discovered this enzyme named it **penicillinase**, a name that is still frequently used in medicine. Although the terms are sometimes used interchangeably, it should be noted that penicillinase is only one type of beta-lactamase—that which splits the ring in penicillin

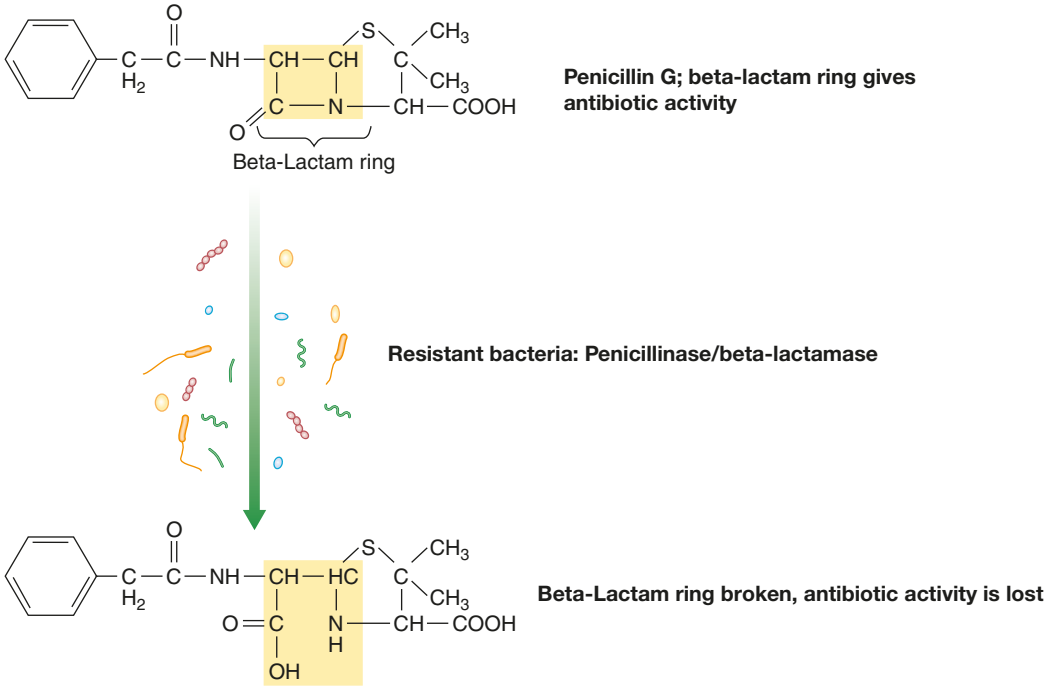

Figure 47.4 Action of penicillinase.

antibiotics. Other forms of beta-lactamase exist that can inactivate cephalosporins, carbapenems, and other antibiotics with this ring structure. In this textbook, the term *penicillinase* is used when referring to this enzyme's action on penicillins; the term *beta-lactamase* is used when referring to other antibiotics. It should be understood, however, that these are two forms of the same enzyme.

To overcome the killing effects of penicillin, some bacteria secrete larger amounts of penicillinase when exposed to antibiotics. In addition, the genes encoding for penicillinase can be transferred to other bacteria through conjugation, thus spreading the development of resistance genes.

Although each drug in this class has certain unique properties, some generalizations may be made about the penicillins:

- Most are more effective against gram-positive bacteria, although a few have activity against gram-negative bacteria.
- Most have a narrow spectrum of antimicrobial activity.
- They are widely distributed to most body tissues, although only small amounts reach the cerebrospinal fluid (CSF).
- Nearly all are rapidly excreted by the kidneys.
- Most have short half-lives.

Allergic reactions are the most common adverse effects of the penicillins and ones that require careful attention by nurses. The overall incidence of penicillin allergy ranges from 0.7% to 10%. Symptoms range from mild rash and nausea to fever or anaphylaxis. Although the incidence of anaphylaxis is low, from 0.04% to 2%, mortality is high and nurses must take every precaution to identify patients at highest risk. Allergic reactions may occur within minutes after taking the drug, or they may be delayed for several days or weeks.

Prior exposure to penicillin is necessary for an allergic reaction, although this exposure may have occurred inadvertently through exposure to mold or by eating animal products that contain small amounts of penicillin. Allergy to one penicillin increases the risk of allergy to other drugs in this class. There is also a degree of cross hypersensitivity between penicillins and cephalosporins. The nurse should not give penicillin to a patient who has a medical history of serious penicillin allergy. If penicillin must be given due to a patient's condition, and it is unknown if the patient is allergic, skin tests may be used to assess the risk of experiencing a severe allergic reaction. Giving a small amount of penicillin and waiting to see if anaphylaxis develops is not an acceptable method for assessing the probability of allergy. The size of a dose is not related to the severity of the response, because even very small amounts can elicit anaphylaxis in susceptible patients. Nurses must always be vigilant in observing for signs of allergy following penicillin administration, because there is no infallible method for predicting which patient will experience an allergy to the drug.

Chemical modifications to the original molecule have produced drugs that offer several advantages over the natural penicillins, including the following:

- Penicillinase resistance
- Broader antimicrobial spectrum
- Extended spectrum.

Natural Penicillins

The natural penicillins were the first to be isolated from the fungus *Penicillium*. They are inexpensive and the preferred drugs for susceptible infections.

PharmFACT

The U.S. Food and Drug Administration (FDA) has determined that there is no added health benefit to consumers in using products containing antibacterial ingredients, including soaps and body washes (Centers for Disease Control and Prevention, 2015).

PROTOTYPE DRUG **Penicillin G**

Classification **Therapeutic:** Antibacterial
Pharmacologic: Cell wall inhibitor, natural penicillin

Therapeutic Effects and Uses: Approved by the FDA in 1943, penicillin G has a narrow spectrum of activity that includes most gram-positive bacteria. Many gram-negative organisms are resistant to penicillin G. It is a preferred drug for the treatment of infections shown to be susceptible by culture and sensitivity (C&S) testing because it is inexpensive and exhibits few adverse effects. These include susceptible strains of *Staphylococcus*, *Streptococcus*, *Neisseria*, *Actinomyces*, *Bacillus anthracis*, *Clostridium*, *Treponema*, and *Corynebacterium*. Penicillin is given for the prophylaxis of bacterial endocarditis in patients with prosthetic heart valves or congenital heart disease and for those at risk for recurrent bouts of rheumatic fever.

Penicillin G is available as a benzathine, potassium, or a procaine salt; each has slightly different pharmacokinetics. For example, while the intramuscular (IM) administration of penicillin G potassium is rapid, the benzathine and procaine salts are absorbed from an IM site very slowly, over a 24-hour period. However, there is no difference in effectiveness among the three salts because they all dissociate to penicillin G. Penicillin G benzathine and penicillin G procaine are administered IM; penicillin G potassium may be administered by either the intravenous (IV) or IM route. Penicillin G potassium was once available by the oral (PO) route, but the drug had low bioavailability due

to destruction by gastric acid. Penicillin V and amoxicillin are more stable in acid and are used when oral penicillin therapy is desired.

Mechanism of Action: This drug inhibits bacterial wall synthesis by binding PBPs. Penicillin G is bactericidal and destroyed by penicillinase.

Pharmacokinetics:

Route(s)	IM, IV
Absorption	Rapid absorption (IM)
Distribution	Widely distributed; only small amounts cross the blood–brain barrier; secreted in breast milk; approximately 60% bound to plasma proteins
Primary metabolism	15–30% metabolized, primarily hepatic
Primary excretion	Renal
Onset of action	IM: 15–30 min; IV: immediate
Duration of action	4–6 h; half-life: 20–60 min

Adverse Effects: Penicillin G is well tolerated by most patients and adverse effects are uncommon. Urticaria and delayed skin reactions occasionally occur. The most serious adverse effect is severe hypersensitivity reaction. The anaphylactic response may include cardiovascular collapse; edema of the mouth, tongue, pharynx, and larynx; confusion; seizures; and hallucinations. While most allergic reactions to penicillin occur within minutes after administration, late hypersensitivity reactions may occur several weeks into the regimen.

Contraindications/Precautions: Penicillin G is contraindicated in patients who are allergic to any drug in the penicillin class and is used cautiously in those with hypersensitivity to cephalosporins. In cases where penicillin G is the only effective antibiotic in a patient with a known allergy to the drug, penicillin may be given via a desensitization procedure whereby the dose begins very small and gradually increases. Because 90% of a dose of penicillin G is excreted unchanged by the kidneys through tubular secretion, patients with chronic kidney disease (CKD) must be carefully monitored. Patients with heart failure should not receive the penicillin sodium salt. Hyperkalemia may result with high doses of the penicillin G potassium salt.

Drug Interactions: Penicillin G may decrease the effectiveness of oral contraceptives. Colestipol will decrease the absorption of penicillin. Probenecid decreases the excretion of penicillin G and can lead to antibiotic toxicity. Potassium-sparing diuretics such as spironolactone may cause hyperkalemia when administered with penicillin G potassium. Because penicillins can antagonize the actions of aminoglycoside antibiotics, drugs from these two classes are not administered concurrently. The bacteriostatic action of tetracyclines may inhibit the bactericidal action of penicillin G. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving penicillin G are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic.

Drugs Similar to Penicillin G

Other natural penicillins include penicillin G benzathine, penicillin G procaine, and penicillin V.

Penicillin G benzathine (Bicillin): Approved in 1943, penicillin G benzathine dissociates to form penicillin G; thus they share the same actions, indications, and adverse effects. Administered only by deep IM injection, penicillin G benzathine is absorbed very slowly, resulting in low peak serum levels with a prolonged duration of action that can last up to 26 days. Neurologic adverse effects have been reported with penicillin G benzathine, including severe agitation, confusion, hallucinations, and seizures. Injections of this drug are painful and injection-site reactions may occur. Permanent neurologic damage occurs if this drug is injected near a nerve. The drug carries a black box warning that it must not be given IV. This drug is pregnancy category B.

Penicillin G procaine: Approved in 1943, penicillin G procaine is a repository form of penicillin given only by the IM route. Like the benzathine salt, it is absorbed slowly from its injection site and has a prolonged duration of action (15–20 hours). It shares the same actions, indications, and adverse effects as penicillin G. The procaine salt is less painful on administration than penicillin G administered by the IM route. Penicillin G procaine can cause neurotoxicity if the drug is unintentionally injected near a nerve. Like the benzathine salt, neurologic adverse effects can occur with penicillin G procaine, including severe agitation, confusion, hallucinations, and seizures. Patients with allergies to the local anesthetic procaine (Novocain) should not receive this drug. This drug is pregnancy category B.

Penicillin V: Penicillin V is nearly identical to penicillin G, except that it is more acid stable, which allows it to be administered PO. However, it should be taken on an empty stomach to maximize absorption. Approved in 1956, it shares the same actions, indications, and adverse effects as penicillin G. Some patients experience nausea, vomiting, and diarrhea. This drug is pregnancy category B.

CONNECTION Checkpoint 47.1

From what you learned in Chapter 5, explain how taking a thorough medical history can eliminate some allergic reactions to antibiotics. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Broad-Spectrum Penicillins (Aminopenicillins)

A major limitation of the natural penicillins is their lack of activity against gram-negative organisms. The aminopenicillins, amoxicillin and ampicillin, are effective against gram-positive and certain gram-negative bacilli such as *Haemophilus influenzae*, *Escherichia coli*, *Salmonella*, and *Shigella*. This distinction is responsible for them being placed into a separate class called broad-spectrum penicillins.

Aminopenicillins are rapidly inactivated by penicillinase, which limits their therapeutic usefulness, particularly against *Staphylococcus aureus* infections. Despite this limitation, the aminopenicillins are some of the most widely prescribed antibiotics for sinus and upper respiratory and genitourinary tract infections. Their widespread use over many decades has resulted in the emergence of a large number of resistant strains.

Combination drugs have been developed that offer certain advantages over single-drug therapy with aminopenicillins. The fixed-dose combination of Augmentin combines amoxicillin with clavulanate, a beta-lactamase (penicillinase) inhibitor. Another fixed-dose product, Unasyn, contains ampicillin and the beta-lactamase inhibitor sulbactam. By inhibiting penicillinase, these combined drugs allow a greater percentage of the aminopenicillin molecules to reach pathogens and disrupt cell wall synthesis. The beta-lactamase inhibitors are ineffective when used alone and therefore are always used in fixed combination formulations with other drugs.

PROTOTYPE DRUG Ampicillin

Classification **Therapeutic:** Antibacterial
Pharmacologic: Cell wall inhibitor, aminopenicillin

Therapeutic Effects and Uses: Approved in 1963, the actions of ampicillin are similar to those of penicillin G except that ampicillin has a broader spectrum that includes enhanced activity over enterococci, *E. coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *H. influenzae*, *Salmonella*, *Shigella*, and *Bordetella pertussis*. Because a large percentage of resistant strains have developed, ampicillin is no longer a preferred drug for the treatment of gonococcal infections, childhood meningitis, or *Salmonella* or *Shigella* enteritis.

Mechanism of Action: Ampicillin inhibits bacterial wall synthesis by binding PBPs. This drug is bactericidal and inactivated by penicillinase.

Pharmacokinetics:

Route(s)	PO, IM, IV
Absorption	50% absorbed PO
Distribution	Widely distributed; only small amounts cross the blood–brain barrier; secreted in breast milk; plasma protein binding is about 15–20%
Primary metabolism	Largely unmetabolized, 10% hepatic
Primary excretion	Renal
Onset of action	PO: 30–60 min; IM: 15–30 min
Duration of action	Half-life: 1–2 h

Adverse Effects: Ampicillin is a safe drug that rarely produces serious adverse effects. Rash and diarrhea are the most common adverse effects, and diarrhea occurs more frequently with ampicillin than with the other aminopenicillins. Pain at the injection site is common. Like all penicillins, anaphylaxis is rare, though potentially fatal. Anaphylactic response may include cardiovascular collapse; edema of the mouth, tongue, pharynx, and larynx; confusion; seizure; and hallucinations. Pseudomembranous colitis (PMC) is an additional rare, though serious, severe adverse effect.

Contraindications/Precautions: Ampicillin is contraindicated in patients who are allergic to any drug in the penicillin class and used cautiously in those with hypersensitivity to cephalosporins. Ampicillin is excreted primarily by the kidneys; therefore, drug therapy must be monitored carefully in patients with CKD.

Drug Interactions: Ampicillin may decrease the effectiveness of oral contraceptives. Probenecid (Benemid) decreases the excretion of ampicillin and can lead to antibiotic toxicity. Penicillins can antagonize the actions of aminoglycoside antibiotics and must be administered at least 2 hours apart. The antibacterial actions of ampicillin are diminished when it is taken concurrently with chloramphenicol, erythromycin, or tetracyclines. **Herbal/Food:** Because food decreases its absorption, ampicillin should be taken on an empty stomach.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving ampicillin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic.

Drugs Similar to Ampicillin

The only other aminopenicillin is amoxicillin.

Amoxicillin (Amoxil): Approved in 1974, amoxicillin is closely related structurally to ampicillin and has many of the same characteristics. The drug is destroyed by penicillinase-producing organisms. It is more acid stable than ampicillin and offers greater gastrointestinal (GI) absorption with peak serum levels twice as high. It exhibits a lower incidence of diarrhea than ampicillin. Amoxicillin has largely replaced ampicillin, and it is one of the most frequently prescribed antibiotics. Amoxicillin should not be administered to patients with hypersensitivity to any penicillin. An extended release form of the drug (Moxatag) was approved in 2008 for treating tonsillitis or pharyngitis caused by *Streptococcus pyogenes*. This drug is pregnancy category B.

Extended-Spectrum (Antipseudomonal) Penicillins

Piperacillin and ticarcillin have broad spectrums of antimicrobial activity similar to those of the aminopenicillins. Their primary advantage is their additional activity against *Pseudomonas aeruginosa*; thus they are called extended-spectrum or antipseudomonal penicillins.

P. aeruginosa is an opportunistic pathogen found in air, soil, and water. It can persist on environmental surfaces such as soap residues and hot tubs and can even survive in some antiseptic solutions. *P. aeruginosa* infections may occur anywhere in the body, primarily causing disease in patients whose health is already compromised in some manner. It is responsible for about 10% of all healthcare-associated infections (HAIs), including serious pneumonia in debilitated patients and a large number of infections in wounds and in patients with extensive burns.

P. aeruginosa has natural resistance to most antibiotics due in part to its ability to rapidly pump out antibiotic molecules that enter its cells. Because *Pseudomonas* infections are often persistent, aggressive combination anti-infective therapy is often indicated. A typical combination includes an aminoglycoside antibiotic with an antipseudomonal penicillin. Because penicillins inactivate aminoglycosides, they must be administered at least 2 hours apart. Other antibiotics such as ceftazidime (Ceptaz, Fortaz, Tazicef), ciprofloxacin (Cipro), or imipenem (Primaxin) may be needed.

As with the other penicillins, drugs in this class inhibit bacterial wall synthesis by binding PBPs. The antipseudomonal penicillins achieve their extended spectrum because they have greater penetration through the outer membrane of gram-negative bacteria and a higher affinity for penicillin-binding proteins. The two drugs in this class are similar, and there are few differences to distinguish them. Like most penicillins, the antipseudomonal penicillins are widely distributed to tissues and rapidly excreted mostly unchanged in the urine.

Because penicillinase-producing bacteria can inactivate the antipseudomonal penicillins, they are usually combined with a beta-lactamase inhibitor. Fixed-dose combinations with beta-lactamase inhibitors include piperacillin with tazobactam (Zosyn) and ticarcillin with clavulanate (Timentin).

Rash and diarrhea are the most common adverse effects of the antipseudomonal penicillins. These drugs prevent the aggregation of platelets, which can prolong bleeding time. Caution must therefore be taken when using these medications concurrently with drugs that modify coagulation. Sodium salts of the antipseudomonal penicillins cause sodium overload in patients with heart failure. Like all penicillins, anaphylaxis is rare, though potentially fatal. PMC is an additional severe adverse effect. Very high doses may produce confusion and seizures. The antipseudomonal penicillins are pregnancy category B.

Piperacillin: Approved in 1981, piperacillin has one of the broadest spectrums of any of the penicillins and is effective against most gram-negative and many gram-positive anaerobic and aerobic microbes. It has been used to treat a variety of serious infections, including those of the skin, blood, sinuses, central nervous system (CNS), respiratory tract, and genitourinary tract. Available by the IM and IV routes, piperacillin is often used in combination with an aminoglycoside antibiotic because together they exert synergistic action on gram-negative microbes. High doses can lead to platelet dysfunction, although piperacillin seems to have less effect than other antipseudomonal penicillins. Electrolytes should be regularly monitored to prevent hypokalemia and hypernatremia. Piperacillin should not be administered to patients with hypersensitivity to any penicillin. Localized injection-site reactions include pain, inflammation, phlebitis, and hematomas. Zosyn is a fixed-dose combination of piperacillin and tazobactam.

Ticarcillin-clavulanate (Timentin): As with piperacillin, ticarcillin has one of the broadest spectrums of any penicillin. Approved in 1976, it has been used to treat moderate to severe gram-negative infections of the skin, blood, bone and joints, CNS, respiratory tract, and genitourinary tract. Available by the IV route, high doses can lead to hypernatremia, platelet dysfunction, and hypokalemia. Electrolytes should be regularly monitored to prevent hypokalemia and hypernatremia. Ticarcillin has a high sodium content that could affect patients with preexisting heart disease. Ticarcillin should not be administered to patients with hypersensitivity to any penicillin. Pain and phlebitis with thrombosis may occur at the injection site. To increase its effectiveness, it is combined with clavulanate.

Penicillinase-Resistant (Antistaphylococcal) Penicillins

This subclass of penicillins includes dicloxacillin, nafcillin, and oxacillin, which are drugs that are effective against

penicillinase-producing bacteria. These medications are less effective than penicillin G against non–penicillinase-producing strains and are ineffective against gram-negative bacteria. This narrow spectrum of activity has largely restricted their use to penicillinase-producing strains of *Staphylococcus*. Because they are often the preferred drugs for infections by this organism, they are referred to as antistaphylococcal penicillins. An older drug in this class, cloxacillin (Cloxapen), is no longer marketed in the United States.

The emergence of many methicillin-resistant *S. aureus* (MRSA) strains has severely limited the use of drugs in this class. As discussed in Chapter 46, some MRSA strains are resistant to all penicillins. The first drug developed in the penicillinase-resistant class, called methicillin, was removed from the U.S. market for producing an unacceptable incidence of interstitial nephritis.

Drugs in the penicillinase-resistant class share similar actions and properties with penicillin G. Dicloxacillin is readily absorbed by the PO route, whereas nafcillin and oxacillin are given parenterally. They are rapidly excreted by the kidneys, having a half-life of 30 to 60 minutes. As with all penicillins, hypersensitivity reactions may occur. Some of these drugs are sodium salts, which may cause sodium overload in susceptible patients. PMC has been reported in a small number of patients taking these drugs. All are pregnancy category B drugs.

Dicloxacillin: Approved in 1968, dicloxacillin is a penicillinase-resistant penicillin available by the PO route. As with other drugs in this class, its use is primarily limited to the treatment of susceptible staphylococcal infections. It is not effective against MRSA. Nausea and vomiting are commonly reported adverse effects. It should be taken on an empty stomach to enhance absorption. Other adverse effects and contraindications are the same as those of other penicillins. This drug should not be given to a patient with hypersensitivity to any penicillin.

Nafcillin: Approved in 1964, nafcillin is used to treat susceptible infections of the blood, skin, upper and lower respiratory tract, bone and joints, and urinary tract. It is ineffective against MRSA infections. Unlike most penicillins, nafcillin is excreted primarily in the bile; thus dosage adjustments for patients with hepatic disease are necessary. It is available in both oral and parenteral formulations. Because only 10% to 20% of the drug is absorbed when given PO, it is normally given parenterally. The complete blood count (CBC) must be regularly monitored because nafcillin can cause neutropenia and other blood abnormalities in 10% to 20% of the patients taking it. This drug should not be given to a patient with hypersensitivity to any penicillin.

Oxacillin: Approved in 1962, oxacillin is used to treat a variety of staphylococcal infections of the blood, skin, upper and lower respiratory tract, bone and joints, and urinary tract. It is ineffective against MRSA infections. Because oxacillin causes fewer injection-site reactions than nafcillin, it is sometimes the preferred parenteral drug for susceptible strains. Indications and adverse effects are similar to those of other penicillinase-resistant penicillins. This drug should not be given to a patient with hypersensitivity to any penicillin.

CONNECTIONS: Using Research in Practice

Seasonal Variations in Resistance to Penicillin

Seasonal variations in the prevalence of infections such as pneumonia have been noted, and infections tend to increase as the weather becomes colder. People spending more time indoors and in closer contact with each other, along with indoor air pollution, have been correlated to this increase. In a recent study, seasonal variations in the susceptibility to penicillin were also noted in children with *Streptococcus pneumoniae* infections (Tam, Madoff, O'Connell, & Pelton, 2015). The authors theorize that as the infection rate increases during winter months, there is a concurrent increase in antibiotics prescribed. While the study analyzed only susceptibility to penicillin, seasonal variations in other antibiotic resistance may also be possible.

Cephalosporins

47.3 The cephalosporins are similar in structure and function to the penicillins and are widely prescribed for gram-negative infections.

Isolated shortly after penicillin, the cephalosporins comprise the largest antibiotic class. Like the penicillins, many cephalosporins contain a beta-lactam ring that is responsible for their antimicrobial activity. In some cephalosporins, the structure of the beta-lactam ring is quite stable and resistant to enzyme destruction. The cephalosporins are bactericidal and inhibit cell wall synthesis by binding to PBPs. Growing bacterial cells are unable to build their cell walls properly, and lysis occurs in the same manner as penicillins. The cephalosporins are listed in Table 47.2.

The primary therapeutic use of the cephalosporins is for gram-negative infections and for patients who are allergic to penicillin or who have penicillin-resistant infections. Over 20 cephalosporins are available, all having similar sounding names that can challenge even the best memory. Selection of a specific cephalosporin is first based on the sensitivity of the pathogen, and secondly on possible adverse effects.

The cephalosporins are classified chronologically by their generations, which are loosely based on differences in

Table 47.2 Cephalosporins

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
First Generation		
cefadroxil (Duricef)	PO: 500 mg–1 g once or twice a day (max: 2 g/day)	*Diarrhea, abdominal cramping, nausea, fatigue, rash, pruritus, pain at injection site, oral or vaginal candidiasis* PMC, nephrotoxicity, anaphylaxis
cefazolin (Ancef, Kefzol)	IM/IV: 250 mg–2 g tid (max: 12 g/day)	
cephalexin (Keflex)	PO: 250–500 mg qid (max: 4 g/day)	
Second Generation		
cefaclor (Ceclor)	PO: 250–500 mg tid (max: 2 g/day)	
cefotetan (Cefotan)	IV/IM: 1–2 g q12h (max: 6 g/day)	
cefoxitin (Mefoxin)	IV/IM: 1–2 g q6–8h (max: 12 g/day)	
cefprozil (Cefzil)	PO: 250–500 mg 1–2 times/day (max: 1 g/day)	
cefuroxime (Ceftin, Zinacef)	PO (Ceftin): 250–500 mg bid (max: 1 g/day) IM/IV (Zinacef): 750 mg–1.5 g q8h (max: 9 g/day)	
Third Generation		
cefdinir (Omnicef)	PO: 300 mg bid (max: 600 mg/day)	
cefditoren (Spectracef)	PO: 400 mg bid for 10 days (max: 800 mg/day)	
cefixime (Suprax)	PO: 400 mg/day or 200 mg bid (max: 800 mg/day)	
cefotaxime (Claforan)	IM: 1–2 g bid–tid (max: 12 g/day)	
cefpodoxime (Vantin)	PO: 200 mg q12h for 10 days (max: 800 mg/day)	
ceftazidime (Fortaz, Tazicef)	IV/IM: 1–2 mg q8–12h (max: 6 g/day)	
ceftibuten (Cedax)	PO: 400 mg/day for 10 days (max: 400 mg/day)	
ceftriaxone (Rocephin)	IV/IM: 1–2 g/day in a single or divided dose (max: 4 g/day)	
Fourth and Fifth Generation		
cefepime (Maxipime)	IV/IM: 0.5–1 g q12h for 7–10 days (max: 6 g/day)	
ceftaroline (Teflaro)	IV: 600 mg q12h for 5–14 days	
ceftolozane and tazobactam (Zerbaxa)	IV: 1.5 g q8h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

their spectrums of microbial activity. It is important to note that the placement of a drug in a particular generation is somewhat arbitrary and has little therapeutic usefulness. Drugs within each generation have different chemical structures, routes of administration, and spectrums of activity. Scientists do not always agree on placement. The following generalizations may be made regarding the generations:

- First-generation cephalosporins contain a beta-lactam ring; bacteria that produce beta-lactamase are usually resistant to these drugs. They are the most effective cephalosporins against gram-positive bacteria, including staphylococci and streptococci and are sometimes the preferred drugs for these organisms. First-generation cephalosporins have only moderate activity against gram-negative bacteria. First-generation drugs do not cross the blood–brain barrier to any appreciable extent.
- Second-generation cephalosporins exhibit a broader spectrum against gram-negative organisms than do the first-generation drugs. They are more potent and less sensitive to beta-lactamase than the first-generation drugs. Like the first-generation cephalosporins, however, they are unable to enter the CSF in sufficient concentration to treat infections of the CNS. In general, the second-generation drugs have largely been replaced by third-generation cephalosporins.
- Third-generation cephalosporins exhibit an even broader spectrum against gram-negative bacteria than the second-generation group. They generally have a longer duration of action and are resistant to beta-lactamase. These cephalosporins are sometimes the preferred drugs against infections by *Pseudomonas*, *Klebsiella*, *Neisseria*, *Salmonella*, *Proteus*, and *H. influenzae*. Third-generation drugs are able to enter the CSF to treat CNS infections.
- Fourth-generation cephalosporins have a similar antimicrobial spectrum to third-generation drugs but are more effective against organisms that have developed resistance to earlier cephalosporins. Fourth-generation drugs are capable of entering the CSF in sufficiently high concentrations to treat CNS infections.
- Fifth-generation cephalosporins are broad-spectrum drugs with extended gram-positive effectiveness. They are designed to be effective against MRSA infections. The fifth-generation drugs include ceftaroline and ceftolozane. Ceftolozane is only available as a

combination drug with tazobactam (Zerbaxa), which appears to have enhanced activity against *P. aeruginosa* and most streptococci. It is approved to treat complicated intra-abdominal infections and complicated urinary tract infections (UTIs).

CONNECTION Checkpoint 47.2

From what you learned in Chapter 46, what is the primary difference in physiology that distinguishes a gram-positive organism from a gram-negative organism? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Over decades of use, many bacterial strains have developed resistance to the cephalosporins. Like the penicillins, the primary mechanism of resistance is the secretion of beta-lactamase enzymes (sometimes called cephalosporinases). Although third-generation drugs were initially unaffected by beta-lactamase, resistant strains that can inactivate medications in this generation have been identified. None of the cephalosporins has significant activity against MRSA or penicillin-resistant *Streptococcus pneumoniae*.

In general, the cephalosporins are safe drugs with adverse effects similar to those of the penicillins. Allergic reactions are the most common adverse effect. Although sometimes prescribed for patients who are allergic to penicillin, nurses must be aware that 5% to 10% of the patients who are allergic to penicillin will also exhibit hypersensitivity to cephalosporins. Despite this small incidence of cross-allergy, the cephalosporins offer a reasonable alternative for patients who are unable to take penicillin. Cephalosporins are contraindicated, however, for patients who have experienced anaphylaxis following penicillin exposure.

In addition to allergy, rash and GI complaints are common adverse effects of cephalosporins. Nurses should continually assess for the presence of superinfections. Because cephalosporins are secreted in small amounts in breast milk, they should be used with caution in nursing mothers.

Nearly all cephalosporins are eliminated by the kidneys. Earlier-generation cephalosporins exhibited kidney toxicity but this is diminished with the later-generation drugs in this class. Patients with CKD or those who are concurrently receiving nephrotoxic drugs should be monitored carefully during therapy with any cephalosporin. Kidney function tests should be evaluated on a regular basis.

Other adverse effects are specific to particular cephalosporins. For example, cefotetan interferes with vitamin K metabolism and increases the risk of bleeding due to hypoprothrombinemia. Nurses must carefully monitor prothrombin time (PT) in patients taking these drugs, particularly those who are concurrently taking anticoagulants. Cefotetan produces a disulfiram-like reaction when taken concurrently with alcohol. Cephalosporins cause pain at IM injection sites, and thrombophlebitis can occur when given IV. Over half of the cephalosporins are administered only parenterally.

PROTOTYPE DRUG Cefazolin (Ancef, Kefzol)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Cell wall inhibitor, first-generation cephalosporin

Therapeutic Effects and Uses: Approved in 1973, cefazolin is a beta-lactam antibiotic used for the treatment and prophylaxis of bacterial infections, particularly those that are caused by susceptible gram-positive organisms. Its effectiveness extends to non–penicillinase-producing and penicillinase-producing *S. aureus* and streptococci (except enterococci). Cefazolin is not effective against MRSA. Cefazolin has been used to treat infections of the respiratory tract, urinary tract, skin structures, biliary tract, bones, and joints. It has also been useful in the pharmacotherapy of genital infections, septicemia, and endocarditis. This drug is sometimes used for infection prophylaxis in patients who are undergoing surgical procedures. Cefazolin has a longer half-life than other first-generation cephalosporins, which allows for less frequent dosing. It is one of the most frequently prescribed parenteral antibiotics.

Mechanism of Action: Cefazolin inhibits bacterial wall synthesis by binding to specific PBPs. The drug is bactericidal, exhibits a broad spectrum, and is sensitive to beta-lactamase.

Pharmacokinetics:

Route(s)	IM, IV
Absorption	Well absorbed when given IM
Distribution	Widely distributed; only small amounts cross the blood–brain barrier; crosses the placenta; secreted in breast milk; about 85% bound to plasma protein
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	Immediate
Duration of action	Half-life: 90–135 min

Adverse Effects: Like the penicillins, the cephalosporins are well tolerated by most patients. Rash and diarrhea are the most common adverse effects, and superinfections are likely when the antibiotic is used for prolonged periods. Approximately 1% to 4% of patients will experience some kind of an allergic reaction. Severe hypersensitivity reactions are rare, though potentially fatal. Anaphylactic response may include cardiovascular collapse; edema of the mouth, tongue, pharynx, and larynx; confusion;

seizures; and hallucinations. Pain and phlebitis can occur at IM injection sites. However, cefazolin causes less pain than do other cephalosporins. Seizures are a rare, though potentially serious, adverse effect of cephalosporin therapy.

Contraindications/Precautions: Cefazolin is contraindicated in patients who are allergic to any drug in the cephalosporin class and is used cautiously in those with hypersensitivity to penicillins. Because most cefazolin is excreted unchanged by the kidneys, patients with CKD must be carefully monitored.

Drug Interactions: Probenecid decreases the excretion of cefazolin and can lead to antibiotic toxicity. Concurrent use of cefazolin with nephrotoxic drugs, such as aminoglycosides or vancomycin, increases the risk of nephrotoxicity. Cefazolin may have additive or synergistic antimicrobial action with other antibiotics such as aztreonam, carbapenems, and the penicillins. The anticoagulant effect of warfarin may be increased if given concurrently with cefazolin. **Herbal/Food:** None known.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities (includes all generations of cephalosporins): Key nursing implications for patients receiving cefazolin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic.

Drugs Similar to Cefazolin (Ancef, Kefzol)

First generation: Other first-generation cephalosporins include cefadroxil (Duricef) and cephalexin (Keflex). These drugs are administered parenterally and have the same spectrum of microbial activity. They have the same basic indications (primarily gram-positive bacteria) and are eliminated by the kidneys.

Second generation: Second-generation cephalosporins include cefaclor (Ceclor), cefotetan (Cefotan), cefoxitin (Mefoxin), cefprozil (Cefzil), and cefuroxime (Ceftin, Zinacef). All have the same spectrum of microbial activity and there is little difference among the drugs other than the route of administration (see Table 47.2). The kidneys eliminate all second-generation cephalosporins. Cefoxitin and cefotetan are the most active against *Bacteroides fragilis*.

Third generation: Third-generation cephalosporins are the largest group and include cefdinir (Omnicef), cefditoren (Spectracef), cefixime (Suprax), cefotaxime (Claforan), cefpodoxime (Vantin), ceftazidime (Fortaz, Tazicef), ceftibuten (Cedax), and ceftriaxone (Rocephin). The differences among third-generation cephalosporins are minor. Some are available by the PO route, whereas others are given only parenterally (see Table 47.2). Cefixime and ceftriaxone have longer durations that allow for once-daily dosing. Ceftazidime is one of the few third-generation drugs with significant activity against *P. aeruginosa*. Cefotaxime is a preferred drug for certain types of meningitis and for infection prophylaxis in patients who are undergoing surgical procedures. Ceftizoxime (Cefizox) is no longer available in the United States.

In 2015, Avycaz, a combination of ceftazidime and avibactam (a beta-lactamase inhibitor) was approved to treat complicated intra-abdominal infections and complicated UTIs. Given IV, Avycaz is reserved for infections proven to be susceptible to the drug to reduce the development of resistant strains.

Fourth generation: Cefepime (Maxipime) is the only drug in this generation. It is very similar to the third-generation drugs but appears to have a slightly broader spectrum of activity and is more stable against organisms that produce beta-lactamase. It has been used for the treatment of serious infections in hospitalized patients with gram-positive microorganisms such as Enterobacteriaceae and *Pseudomonas*. It is not effective against MRSA.

Fifth generation: Ceftaroline (Teflaro), the first drug in this generation, was approved by the FDA in 2010 for acute bacterial skin and skin structure infections and community-acquired bacterial pneumonia. It is effective against a broad spectrum of both gram-positive and gram-negative organisms, including MRSA. Available by the IV route, it is relatively safe, with the most common adverse effects being diarrhea, nausea, and rash. A second fifth-generation drug, ceftolozane, is a combination drug with tazobactam (Zerbaxa) for the treatment of complicated intra-abdominal infections and complicated UTIs.

Carbapenems

47.4 The carbapenems are resistant to beta-lactamase and are broad-spectrum alternatives to penicillin.

Although the penicillins and cephalosporins comprise the largest groups of drugs affecting the bacterial cell wall, several other antibacterials also act by this mechanism. Doses of these drugs are listed in Table 47.3.

Imipenem (Primaxin), ertapenem (Invanz), doripenem (Doribax), and meropenem (Merrem) belong to a class of antibiotics called carbapenems. These drugs are bactericidal and have some of the broadest antimicrobial spectrums of any class of antibiotics. They contain a beta-lactam ring and kill bacteria by inhibiting construction of the cell wall. Though similar, the ring in carbapenems has a slightly different structure than other beta-lactam antibiotics that makes

Table 47.3 Carbapenems and Miscellaneous Cell Wall Inhibitors

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Carbapenems		
doripenem (Doribax)	IV: 500 mg q8h for 5–14 days (max: 500 mg q8h)	*Nausea, diarrhea, headache* Anaphylaxis, superinfections, PMC, confusion, seizures
ertapenem (Invanz)	IV/IM: 1 g/day	
imipenem-cilastatin (Primaxin)	IV: 250–500 mg tid–qid (max: 4 g/day)	
meropenem (Merrem)	IV: 1–2 g tid (max: 2 g tid)	
Miscellaneous Cell Wall Inhibitors		
aztreonam (Azactam, Cayston)	IM (Azactam): 0.5–2 g bid–qid (max: 8 g/day) Inhalation (Cayston): one vial in nebulizer tid for 28 days	*Nausea, vomiting, rash, thrombophlebitis (Azactam); cough, nasal congestion, wheezing (Cayston)* Anaphylaxis, superinfections, bronchospasm (Cayston)
bacitracin	Topical: Apply thin layer of ointment bid or tid or as solution of 250–1000 units/mL in wet dressing	*Anorexia, nausea, vomiting* Nephrotoxicity, anaphylaxis
dalbavancin (Dalvance)	IV: 1500 mg single dose or 1000 mg followed 1 wk later by 500 mg	*Headache, nausea, diarrhea* Hypersensitivity and infusion-related reactions
fosfomycin (Monurol)	PO: 3 g sachet dissolved in 3–4 oz of water as a single dose	*Nausea, diarrhea, back pain, headache* Anaphylaxis, superinfections
oritavancin (Orbactiv)	IV: 1200 mg single dose given over 3 h	*Headache, nausea, vomiting, diarrhea* Limb and subcutaneous abscesses, hypersensitivity, infusion-related reactions
telavancin (Vibativ)	IV: 10 mg administered over 60 min, once daily for 7–10 days	*Nausea, vomiting and foamy urine* Nephrotoxicity, QT interval prolongation, infusion-related reactions, birth defects
vancomycin (Vancocin)	IV: 500 mg qid; 1 g bid PO: 500 mg–2.0 g in three to four divided doses for 7–10 days	*Nausea, vomiting* Anaphylaxis, superinfections, nephrotoxicity, ototoxicity, red man syndrome

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

it very resistant to destruction by beta-lactamase. These factors allow the carbapenems to provide better activity against serious gram-negative and multidrug-resistant infections than most cephalosporins or penicillins. A disadvantage is that they must be given parenterally. The primary role of the carbapenems is for the treatment of complicated bacterial infections. They are sometimes considered the antibiotics of "last resort" for treating multidrug-resistant infections.

All the carbapenems exhibit a low incidence of adverse effects. Diarrhea, nausea, rashes, and thrombophlebitis at injection sites are the most common adverse effects.

In recent years, bacteria have been isolated that are resistant to the carbapenems. These infections, called carbapenem-resistant Enterobacteriaceae (CRE) infections, are usually healthcare associated and can be highly lethal (see Chapter 46).

PROTOTYPE DRUG Imipenem-Cilastatin (Primaxin)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Cell wall inhibitor, carbapenem

Therapeutic Effects and Uses: Approved in 1985, imipenem is used for the treatment and prophylaxis of susceptible bacterial infections. Imipenem has a very broad antimicrobial spectrum and is the most widely used carbapenem. Because of its broad spectrum and beta-lactamase resistance, it is effective against most gram-positive and gram-negative microbes, including anaerobic bacteria. It is particularly useful for mixed infections containing both aerobic and anaerobic organisms, including those with *S. aureus*. *P. aeruginosa* and strains of MRSA are also susceptible to imipenem.

Although imipenem contains a beta-lactam ring, it is resistant to the actions of beta-lactamase. This drug, however, is rapidly destroyed by dipeptidase, an enzyme found in the kidney tubules. Concurrent administration of the drug cilastatin, a renal dipeptidase inhibitor, with imipenem prevents the destruction of imipenem and allows for higher serum levels of the antibiotic. Cilastatin possesses no antimicrobial activity of its own. Imipenem is marketed only with cilastatin in a fixed-dose combination (Primaxin).

Primaxin is sometimes combined with antibiotics from other classes, such as the aminoglycosides or cephalosporins,

when treating *P. aeruginosa* infections. Primaxin has a short half-life that requires administration every 6 hours.

Mechanism of Action: Imipenem inhibits bacterial wall synthesis by binding to specific PBPs. Cilastatin blocks renal dipeptidase, which is the enzyme primarily responsible for the excretion of imipenem. The combination of imipenem-cilastatin is bactericidal.

Pharmacokinetics:

Route(s)	IM, IV
Absorption	Not absorbed PO
Distribution	Widely distributed, including in the CSF; secreted in breast milk; both imipenem and cilastatin cross the placenta
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	IM: rapid; IV: immediate
Duration of action	Half-life: 1 h

Adverse Effects: The most frequent adverse effects of imipenem-cilastatin include nausea, vomiting, diarrhea, rash, and pain and phlebitis at the injection site. Rare, though serious, reactions include confusion, seizures, hallucinations, PMC, and anaphylaxis. Anaphylactic response may include cardiovascular collapse and edema of the mouth, tongue, pharynx, and larynx.

Contraindications/Precautions: Imipenem-cilastatin is contraindicated in patients who have experienced a severe allergic reaction to this drug, other carbapenems, cephalosporins, or penicillins. Because the kidneys excrete imipenem-cilastatin, patients with CKD must be carefully monitored and dosages lowered. This drug should be used cautiously in patients with brain lesions, head trauma, or a history of seizures due to an increased risk of seizures.

Drug Interactions: Certain other antibiotics, including penicillins, cephalosporins, and aztreonam, antagonize the antimicrobial effects of imipenem-cilastatin; therefore, they should not be given concurrently. Concurrent use with cyclosporine, tramadol, theophylline, or ganciclovir may increase the risk of seizures and other CNS effects. Imipenem-cilastatin decreases levels of valproic acid, resulting in seizures. **Herbal/Food:** None known.

Pregnancy: Category C.

Treatment of Overdose: Overdose may result in ataxia and seizures. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving imipenem-cilastatin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic.

Drugs Similar to Imipenem-Cilastatin (Primaxin)

Other carbapenems include doripenem, ertapenem, and meropenem.

Doripenem (Doribax): Approved in 2007, doripenem is similar to meropenem and acts against both gram-positive and gram-negative organisms. It is approved to treat complicated intra-abdominal infections and UTIs. It is administered by IV infusion over 60 minutes. Common adverse effects include headache, rash, nausea, vomiting, diarrhea, and phlebitis. Doripenem is contraindicated in patients who have experienced a severe allergic reaction to other carbapenems, cephalosporins, or penicillins. This drug is pregnancy category B.

Ertapenem (Invanz): Approved in 2002, ertapenem has a narrower spectrum than the other carbapenems, being active primarily against gram-negative aerobes. Its major advantage is its longer half-life, which allows for once-daily dosing. It is approved for the treatment of serious abdominopelvic and skin infections, community-acquired pneumonia, complicated UTIs, and diabetic foot infections without concomitant osteomyelitis. It is administered by the IV and IM routes. Adverse effects are similar to those of other carbapenems. Ertapenem is contraindicated in patients who have experienced a severe allergic reaction to other carbapenems, cephalosporins, or penicillins. This drug is pregnancy category B.

Meropenem (Merrem): Approved in 1996, meropenem has a similar spectrum of activity to imipenem, and is approved for peritonitis and skin and skin structure infections in adults and bacterial meningitis in children. The drug may be used off-label for other indications. The antimicrobial spectrum of activity of meropenem is similar to that of imipenem. Meropenem may be more active against Enterobacteriaceae, gonococcus, *H. influenzae*, and *P. aeruginosa*. This drug is not destroyed by renal dipeptidase, so it is not administered with cilastatin. Adverse effects are similar to those of imipenem. Meropenem is contraindicated in patients who have experienced a severe allergic reaction to other carbapenems, cephalosporins, or penicillins. It is only available by the IV route. Bolus injections are given IV over 3 to 5 minutes, and infusions over 15 to 30 minutes. This drug is pregnancy category B.

PharmFACT

About 41,000 bloodstream infections occur in hospitalized patients with central lines each year. One in four patients who get a bloodstream infection will die from it (American Nurses Association, n.d.).

Miscellaneous Cell Wall Inhibitors

47.5 Several miscellaneous cell wall inhibitors have activity against resistant microbes.

Several other cell wall inhibitors have important roles in the pharmacotherapy of infections. These drugs comprise a group of mostly unique, distinct antimicrobials.

One of the miscellaneous groups, the lipoglycopeptides, now includes several newer drugs that have similar chemical structures and act by inhibiting peptidoglycan synthesis. The lipoglycopeptides include telavancin (Vibativ), oritavancin (Orbactiv), and dalbavancin (Dalvance). All three drugs are derivatives of vancomycin and contain lipid and carbohydrate chains attached to a peptide.

PROTOTYPE DRUG **Vancomycin (Vancocin)**

Classification **Therapeutic:** Antibacterial
Pharmacologic: Cell wall inhibitor

Therapeutic Effects and Uses: Approved in 1964, vancomycin (Vancocin) is used for the treatment and prophylaxis of susceptible bacterial infections. It is effective against most gram-positive organisms, including *Streptococcus*, *Corynebacterium*, *Clostridium*, *Listeria*, and *Bacillus* species. Vancomycin is usually administered by slow IV infusion for systemic infections because it is not well absorbed from the GI tract. It has been administered off-label by the intrathecal or intraventricular route to treat meningitis. Oral vancomycin is approved for the treatment of antibiotic-induced PMC, which is caused by a toxin produced by *C. difficile*. When given orally, the drug acts locally in the intestine and very little is absorbed into the systemic circulation.

Current protocols restrict the use of vancomycin to severe infections that have become resistant to safer antibiotics. It is anticipated that this restriction will discourage or delay the appearance of resistant strains. Because vancomycin was used infrequently during the first 30 years following its discovery, the incidence of vancomycin-resistant organisms has been less than that of other antibiotics. Vancomycin is the most effective drug for treating MRSA infections. Vancomycin-resistant strains of *S. aureus*, however, have begun to appear in recent years. Vancomycin is often considered a "last resort" antibiotic. Therapeutic options for vancomycin-resistant infections are limited.

Mechanism of Action: Although vancomycin kills bacteria mainly by inhibiting bacterial cell wall synthesis, it also affects the plasma membrane and interferes with ribonucleic acid (RNA) synthesis. The fact that it has multiple mechanisms is probably responsible for the low rate of resistance from the drug. It is bactericidal and only effective against gram-positive organisms such as *S. aureus* and *S. pneumoniae*.

Pharmacokinetics:

Route(s)	IV, PO
Absorption	Poorly absorbed PO
Distribution	Oral form does not usually enter systemic circulation; IV form is widely distributed with small amounts in the CSF; secreted in breast milk; 55% bound to plasma proteins
Primary metabolism	Probably not metabolized
Primary excretion	Renal
Onset of action	IV: immediate
Duration of action	Half-life: 4–8 h

Adverse Effects: Vancomycin may cause a syndrome of flushing, hypotension, tachycardia, and rash on the upper body, a condition called red man syndrome. This syndrome can be minimized by infusing the drug over at least 60 minutes. Other common adverse effects include nausea, rash, fever, and chills. Serious adverse effects include confusion, seizures, and hallucinations. If extravasation occurs, it may lead to tissue necrosis. Ototoxicity is associated with serum concentrations of vancomycin above 60 to 80 mcg/mL. Tinnitus and high-tone hearing loss precede deafness and may progress even after this drug is discontinued. The most susceptible individuals are older adults and those on high doses. Nephrotoxicity can occur in patients with therapeutic concentrations but is more common if trough serum concentrations are kept above 10 mcg/mL. Anaphylactic response may include cardiovascular collapse or edema of the mouth, tongue, pharynx, and larynx.

Contraindications/Precautions: Vancomycin is contraindicated in patients who have experienced previous hypersensitivity to this drug. The nurse must monitor drug therapy carefully in patients with CKD and those with a history of hearing loss.

Drug Interactions: Vancomycin adds to toxicity of aminoglycosides, amphotericin B, cisplatin, cyclosporine, polymyxin B, and other ototoxic and nephrotoxic medications. Vancomycin may increase the risk of lactic acidosis when administered with metformin, especially in patients with CKD. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Because overdose may result in renal impairment, patients are treated supportively to maintain kidney function.

Nursing Responsibilities: Key nursing implications for patients receiving vancomycin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic.

Drugs Similar to Vancomycin (Vancocin)

Other miscellaneous cell wall inhibitors include aztreonam, bacitracin, dalbavancin, fosfomycin, oritavancin, and telavancin.

Aztreonam (Azactam, Cayston): Approved in 1986, aztreonam has a beta-lactam ring and belongs to a newer class of antibiotics known as monobactams. Like other cell wall inhibitors, aztreonam binds to specific penicillin-binding proteins to cause a bactericidal effect. Although considered narrow-spectrum antibiotics, monobactams are particularly useful against certain gram-negative aerobes, such as *P. aeruginosa*. Other organisms considered susceptible to aztreonam include *Citrobacter, Enterobacter*, *E. coli*, *H. influenzae*, *Neisseria*, *Proteus*, *Providencia rettgeri*, and *Shigella.* Monobactams have little or no activity against gram-positive bacteria or anaerobes. Although they have beta-lactam rings, they do not exhibit cross hypersensitivity with penicillins or cephalosporins. Azactam is administered by the parenteral route and exhibits similar adverse effects as those of other cell wall inhibitors including nausea, vomiting, diarrhea, superinfections such as vaginal candidiasis, and local pain or phlebitis at the injection site. Anaphylaxis and PMC are rare. An inhalation form of the drug, Cayston, was approved in 2010 to improve respiratory symptoms in patients with cystic fibrosis who have *P. aeruginosa* infection. This drug is pregnancy category B.

Bacitracin: Bacitracin is an older antibiotic, approved in 1948, that acts by inhibiting cell wall synthesis. It is combined with polymyxin B in over-the-counter (OTC) first aid products (Neosporin, Polysporin), and is also available as monotherapy in OTC products such as Bacitracin First Aid. It is effective against a variety of gram-positive and a few gram-negative microbes. Although an IM form is available, bacitracin is almost always used topically due to potential nephrotoxicity (black box warning). In addition to creams and ointments, bacitracin solutions may be used to soak compresses that can be applied to large areas of the skin. This drug is pregnancy category C.

Dalbavancin (Dalvance): Approved in 2014, dalbavancin is a lipoglycopeptide derived from vancomycin that is approved to treat adults with acute bacterial skin and skin structure infections. It is given in one or two IV doses. Susceptible organisms include MRSA and various streptococcus species. The drug is well tolerated, with GI complaints being the most common adverse effects. This drug has not been assigned a pregnancy category.

Fosfomycin (Monurol): Approved in 1996, fosfomycin is a cell wall inhibitor that is currently approved for the treatment of uncomplicated UTI and bladder infections in women caused by *E. coli* and *Enterococcus faecalis*. It is given as an oral powder, which is mixed with water and taken PO as a single dose. Adverse effects are minor and include asthenia, nausea, vomiting, diarrhea, headache, and vaginitis. This drug is pregnancy category B.

Oritavancin (Orbactiv): Like dalbavancin, oritavancin is a lipoglycopeptide derived from vancomycin that was approved in 2014 to treat adults with acute bacterial skin and skin structure infections. It is given as a single IV infusion. Susceptible organisms include MRSA, various streptococcus species, and *E. faecalis*. Oritavancin may interfere with coagulation blood test results and may cause higher than normal warfarin levels. The use of unfractionated heparin is contraindicated for 5 days after oritavancin administration. This drug is pregnancy category C.

Telavancin (Vibativ): Approved in 2009, telavancin is a synthetic derivative of vancomycin that acts by inhibiting the polymerization and cross-linking of peptidoglycan in bacterial cell walls. It is approved as a once-daily IV infusion for the treatment of complicated skin and skin structure infections caused by gram-negative bacteria, including MRSA. Common adverse effects include taste disturbances, nausea, vomiting, and foamy urine. Telavancin is nephrotoxic and kidney function should be monitored during therapy. Telavancin prolongs the QT interval and it should be used with caution with other medications that cause this effect. This drug is pregnancy category B.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic, or renal disease, and the possibility of pregnancy. Obtain a drug history including allergies, specific reactions to drugs, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of the current infection, noting location, characteristics (what it looks like), presence or absence of drainage and the character of drainage, duration, and the presence or absence of fever or pain.
- Evaluate appropriate laboratory findings (e.g., CBC, C&S, hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Assessment

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection and fever).
- Continue periodic monitoring of CBC, hepatic and renal function, urinalysis, and C&S as ordered.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, drowsiness, or dizziness. Severe diarrhea, especially containing mucus, blood, or pus; yellowing of the sclera or skin; decreased urine output; or darkened urine should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, or signs and symptoms of infection should begin to diminish after taking the first dose and continue to improve.)	• Teach the patient to complete the entire course of antibacterial therapy; to not share doses with other family members with similar symptoms; and to return to the provider if symptoms have not resolved after an entire course of therapy. • Teach the patient to notify the provider if fever and signs and symptoms of infection increase after 3 days.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Immediately report undiminished fever, changes in level of consciousness (LOC), or febrile seizures to the healthcare provider. (Continued fever may be a sign of worsening infection, adverse drug effects, or antibiotic resistance.)	• Teach the patient to report fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider within 3 days, increasing signs and symptoms of infection, or symptoms that remain after taking the entire course of antibacterial therapy. Immediately report febrile seizures, changes in behavior, or changes in LOC to the healthcare provider.
• Continue to monitor periodic laboratory work: renal function tests, CBC, urinalysis, and C&S as ordered. (Penicillins and cephalosporins may be nephrotoxic. Periodic C&S tests may be ordered if infections are severe or slow to resolve to confirm appropriate therapy.)	• Instruct the patient on the need for periodic laboratory work.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of the drug. Continue to monitor the patient for up to 2 weeks after completing antibacterial therapy. (Anaphylactic reactions are possible, particularly with the first dose of an antibacterial. Post-use, residual drug levels, dependent on length of half-life, may cause delayed reactions.)	• Teach the patient to immediately report any itching, rashes, swelling (particularly of tongue or face), urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing. • Instruct the patient with known antibacterial allergies to carry a wallet identification card or wear medical identification jewelry indicating allergy.
• Continue to monitor for nephrotoxicity; e.g., darkened urine, diminished urine output, or weight gain greater than 1 kg (2 lb) in 24 h. (Penicillins and cephalosporins may require frequent monitoring to prevent adverse effects. **Lifespan:** Age-related physiologic differences may place the young child or older adult at greater risk for nephrotoxicity.)	• Teach the patient to immediately report any diminished urine output, weight gain of more than 1 kg (2 lb) in a 24-h period, darkening of urine. • Advise the patient to increase fluid intake to 2–3 L/day if permitted.
• Monitor for development of superinfections, e.g., *C. difficile–associated diarrhea* (CDAD) or pseudomembranous colitis (PMC), or fungal or yeast infections. (Superinfections with opportunistic organisms may occur when normal host flora are diminished or killed by the antibacterial drug. Severe diarrhea may indicate the presence of CDAD or PMC.)	• Instruct the patient to report any diarrhea that increases in frequency or amount, or contains mucus, blood, or pus. • Instruct the patient to consult the healthcare provider before taking any antidiarrheal drugs that slow gastric motility because these may cause the retention of harmful bacteria. • Teach the patient to observe for changes in stool, white patches in the mouth, whitish thick vaginal discharge, itching in the urogenital area, or blistering itchy rash, and to immediately report severe diarrhea. • Teach the patient infection control measures such as frequent hand hygiene, allowing for adequate drying after showering or bathing, and to increase intake of live-culture dairy foods.
• Monitor for signs and symptoms of neurotoxicity, e.g., dizziness, drowsiness, severe headache, changes in LOC, or seizures. (Penicillins and cephalosporins have an increased risk of neurotoxicity. **Lifespan:** Be particularly cautious with the older adult who is at greater risk for falls.)	• Instruct the patient to immediately report increasing headache, dizziness, drowsiness, changes in behavior, LOC, or seizures. • Caution the patient that drowsiness may occur and to be cautious with driving or other activities requiring mental alertness until the effects of the drug are known. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes.
• Monitor for development of red man syndrome in patients receiving vancomycin. Report any significantly large area of reddening such as trunk, head, neck, limbs, or gluteal area, especially if associated with decreased blood pressure or tachycardia. (Vancomycin hypersensitivity may cause the release of large amounts of histamine. If a significant area is involved, vasodilation from histamine may cause hypotension and reflex tachycardia. Prevancomycin antihistamines, e.g., diphenhydramine, may be ordered. IV infusions should be given slowly and monitored closely.)	• Instruct the patient to immediately report unusual flushing, especially involving a large body area, dizziness, dyspnea, or palpitations.
• Monitor for signs and symptoms of blood dyscrasias, e.g., low-grade fevers, bleeding, bruising, or significant fatigue. (Penicillins may cause blood dyscrasias with resulting decreases in RBCs, WBCs, or platelets.)	• Teach the patient to report any low-grade fevers, sore throat, rashes, bruising, nosebleeds, increased bleeding, unusual fatigue, or shortness of breath, especially after taking the antibiotic for a prolonged period.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor electrolytes, pulse, and ECG if indicated in patients on penicillin. (Some preparations of penicillin may be based on sodium or potassium salts and may cause hypernatremia and hyperkalemia.)	• Teach the patient to promptly report any palpitations, lightheadedness, dizziness, or swelling of feet or ankles.
• **Lifespan:** Women of childbearing age taking oral contraceptives and penicillin antibiotics should use an alternative form of birth control to prevent pregnancy. (Some penicillins may significantly reduce the effectiveness of oral contraceptives.)	• Teach women of childbearing age on oral contraceptives to consult their healthcare provider about birth control alternatives if penicillin antibiotics are ordered.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Do not share with other family members, and do not stop the medicine when starting to feel better.
	  • Avoid or eliminate alcohol. Cephalosporins may cause significant reactions when taken with alcohol, and alcohol increases adverse GI effects of the drug.
	  • Take the drug with food or milk, but avoid acidic or carbonated beverages to decrease adverse GI effects.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking the antibacterial drug.
	  • Discard outdated medications or those no longer in use. Review medicine cabinet twice a year for old medications (e.g., at beginning and end of daylight saving time).

Understanding Chapter 47

Key Concepts Summary

47.1 Bacterial cell walls consist of layers of carbohydrate and protein chains, which are constructed by enzymes called penicillin-binding proteins.

47.2 The penicillins, one of the oldest and safest groups of antibacterials, are primarily active against gram-positive bacteria.

47.3 The cephalosporins are similar in structure and function to the penicillins and are widely prescribed for gram-negative infections.

47.4 The carbapenems are resistant to beta-lactamase and are broad-spectrum alternatives to penicillin.

47.5 Several miscellaneous cell wall inhibitors have activity against resistant microbes.

CASE STUDY: Making the Patient Connection

Remember the patient "Katie Dennison" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Katie Dennison is an 83-year-old retired schoolteacher. She was recently seen by her healthcare provider for removal of a noncancerous skin lesion. Now she suspects that the wound on her arm has become infected. She has attempted to report this condition to her healthcare provider. However, due to the holidays she has been unable to reach him. Ms. Dennison presents to a local urgent care center for treatment.

The physical examination and diagnostic tests reveal the following findings: Vital signs are temperature, 38°C (100.9°F); pulse, 110 beats/min; respiratory rate, 20 breaths/min; and blood pressure, 108/68 mmHg. The large dressing on her left arm is saturated with dried yellow-green exudates. She states that it is painful to move her left arm and that the pain has limited her range of motion in the affected extremity. She is pale and has "paper-thin" fragile skin.

Katie reports that she unintentionally got the dressing wet while taking a shower. She did not change the dressing because she was not told to do so by her healthcare provider when the skin lesion was removed. A series of laboratory tests was completed. A sterile dressing was applied to the wound. Ms. Dennison was given an injection of cefazolin (Ancef) and a prescription for antibiotics. She was also instructed to follow up with her healthcare provider within the next 2 to 3 days.

Critical Thinking Questions

1. What factors possibly contributed to the wound infection in this patient?
2. What laboratory tests were probably obtained during this visit to the urgent care center?
3. What information should the nurse provide to the patient concerning the antibiotic?
4. Discuss the mechanism of action for cefazolin.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Mrs. Murphy is 80 years old and lives in a retirement community for lower income older adults. You are the community health nurse visiting with her. As part of your assessment, you ask Mrs. Murphy how she obtains her prescribed medications. The patient explains that most of the time, her neighbor will pick up prescriptions for her. She further explains that in some cases, however, she has "stockpiled" medicines she has been prescribed. When you investigate, you find that the patient has multiple bottles of various types of unused antibiotics. Some of the drugs were prescribed 5 or 6 years ago.

1. Describe how you should respond to this situation.
2. Identify the health teaching needs of this patient regarding stockpiling (saving) antibiotics.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Which instruction should the nurse give a 21-year-old female patient being treated with ampicillin?
   1. Stop taking oral contraceptives because serious adverse effects could occur.
   2. Use oral contraceptives as prescribed because antibiotics do not react with birth control pills.
   3. The antibiotic may decrease the effectiveness of oral contraceptives.
   4. The antibiotic when taken with oral contraceptives causes toxicity.

2. The nurse is caring for a patient who is receiving intravenous vancomycin (Vancocin). Which symptom, if present, may indicate that the patient is experiencing drug-induced ototoxicity?
   1. Erythema of the earlobes and ear canal
   2. Inner ear pruritus after infusion is completed
   3. Tinnitus and dizziness when remaining still
   4. Ocular pain with purulent drainage

3. The patient reports abnormal vaginal discharge after completing a prescription of cefotaxime (Claforan). For which condition is the patient most likely exhibiting symptoms?
   1. Hypersensitivity reaction
   2. Superinfection
   3. Pseudomembranous colitis
   4. Antibiotic toxicity

4. The patient who has been taking cefixime (Suprax) for the past week and a half returns to the provider with reports of "explosive diarrhea, very watery, sometimes with a lot of mucus" up to eight times in the last 2 days. The patient reports significant weakness. For which condition is the patient describing symptoms?
   1. Antibiotic-induced peptic ulcer disease
   2. Antibiotic-associated malabsorption
   3. GI-associated hypersensitivity
   4. *Clostridium difficile*–associated diarrhea

5. The patient who is taking imipenem-cilastatin (Primaxin) reports shortness of breath, mouth and tongue swelling, and generalized itching. For which of the following does the nurse initially assess the patient?
   1. Hypersensitivity reaction
   2. Blood dyscrasias
   3. Beta-lactamase induction
   4. Drug toxicity
6. The nurse is teaching a patient who recently was diagnosed with an upper respiratory infection and prescribed ampicillin. The nurse would evaluate the session as being successful if the patient states which of the following?
   1. "I should take this medication on an empty stomach with a full glass of water."
   2. "I can expect my tongue to become black and furry."
   3. "Once I stop coughing, I should stop taking this medication."
   4. "If I miss a dose, I should take two doses together to catch up."

"Today is the fifth day since I started taking the medication and I'm still having chills and fever. I thought these antibiotics were supposed to get rid of this!"
Patient "John Travis"

Chapter 48
Antibiotics Affecting Bacterial Protein Synthesis

Chapter Outline

- Mechanisms of Antibiotic Inhibition of Bacterial Protein Synthesis
- Tetracyclines

  PROTOTYPE *Tetracycline (Sumycin, Others), p. 872*
- Macrolides

  PROTOTYPE *Erythromycin (EryC, Erythrocin, Others), p. 875*
- Aminoglycosides

  PROTOTYPE *Gentamicin (Garamycin, Others), p. 878*
- Miscellaneous Inhibitors of Bacterial Protein Synthesis

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the steps in the synthesis of bacterial proteins.
2. Identify the classes of antibiotics that act by inhibiting bacterial protein synthesis.
3. Explain mechanisms by which antibiotics inhibit bacterial protein synthesis.
4. Explain how protein synthesis inhibitors exert selective toxicity toward bacterial, rather than human, cells.
5. Describe means by which bacteria become resistant to protein synthesis inhibitors.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with bacterial protein synthesis inhibitors.

Key Terms

cholestatic hepatitis, 876
gray baby syndrome, 880
postantibiotic effect, 877
pseudomembranous colitis (PMC), 872
Svedberg unit, 870
translation, 869

To maintain the extreme metabolic rate required for exponential replication, bacteria must synthesize huge amounts of protein. Antibacterial drugs that inhibit this high rate of protein metabolism can either kill the bacterial cell or slow its replication rate. Tetracyclines, macrolides, and a few miscellaneous drugs are bacteriostatic inhibitors of protein synthesis. The aminoglycosides are bactericidal inhibitors.

Mechanisms of Antibiotic Inhibition of Bacterial Protein Synthesis

48.1 Antibiotics inhibit microbial protein synthesis by binding to the bacterial ribosome.

The importance of protein to a microbe is illustrated by the fact that up to 50% of the dry weight of a bacterial cell consists of protein. Bacterial proteins serve many of the same functions as human proteins. For example, the bacterial enzymes required for all biochemical reactions are proteins. Proteins are studded in the plasma membrane and serve as channels, pores, or transporters, assisting substances as they move into and out of cells. Like human proteins, bacterial proteins are composed of long chains of amino acids.

Several types of proteins, however, are unique to bacteria. Bacterial cells produce protein toxins, which kill other bacteria and can cause serious injury to human cells. The sticky gel-like substance that allows bacterial cells to cling to human epithelial cells on the skin surface, in bronchi, in the gastrointestinal (GI) tract, or in the genitourinary tract consists of proteins combined with carbohydrates. The structure of the bacterial cell wall (see Chapter 47) consists of peptidoglycan layers of protein and carbohydrates that protect the bacterium from its environment. From these examples, it is easy to understand why proteins are critical to bacterial cells.

Knowledge of how proteins are synthesized by bacterial cells is important to understanding how antibiotics act. The basic steps in protein synthesis, or **translation**, are the same in bacteria as they are in humans. Knowledge of translation, which is illustrated in Figure 48.1, is necessary to understand the mechanisms of action of antibiotics that inhibit protein synthesis.

Protein synthesis occurs in the cytoplasm and requires the following three components:

- Messenger ribonucleic acid (mRNA)
- Transfer ribonucleic acid (tRNA)
- Ribosomes, which consist of one large and one small subunit.

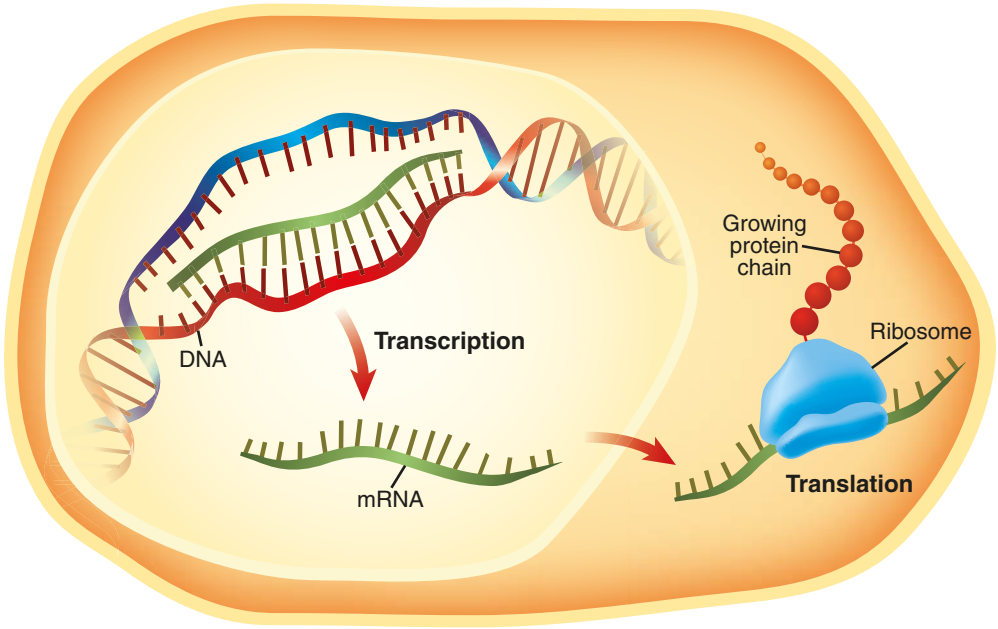

Figure 48.1 Steps in protein synthesis: The DNA is used as a template to make mRNA (transcription). The mRNA is sent to the ribosome to make the protein chain (translation).

The mRNA carries the encoded message for making a protein from the deoxyribonucleic acid (DNA) to the ribosome, which serves as the site for protein construction. The strand of mRNA squeezes between the two ribosomal subunits and begins to move through the subunits. As it does, a tRNA molecule arrives, carrying the specific amino acid that was encoded in the mRNA strand. As the mRNA proceeds through the ribosome, subsequent amino acids are added one at a time to the growing protein chain. This growing chain is known as a polypeptide. Eventually, a "stop signal" is reached on the mRNA strand, which tells the ribosome that the last amino acid has been added and the protein is ready to be released. The protein may be active immediately, or it may be processed to its active form in the Golgi body. The finished protein may be used within the bacterial cell (enzymes) or be exported outside (toxins).

All cells, including bacteria, are able to quickly increase protein synthesis to meet their growth demands or to respond to environmental challenges. For example, a bacterium may receive a message that competitive bacteria are in the vicinity. The gene coding for a toxin or antibiotic may become active, producing large amounts of mRNA and eventually protein toxin, which serves as a defense against the invaders.

If both humans and bacteria conduct continuous protein synthesis, why are antibiotics that inhibit protein synthesis not also toxic to human cells? The answer lies in differences in the structures of the bacterial and human ribosomes. Ribosomes are composed of two subunits, one of which is larger and less dense than the other. In bacteria, these ribosomal components are referred to as 30S and 50S subunits. The letter "S" is a unit of measurement, the **Svedberg unit**, which reflects the ribosome's size or sedimentation rate in a high-speed centrifuge. The entire bacterial ribosome is called a 70S ribosome (Svedberg units are not additive).

All antibiotics that target bacterial protein synthesis do so by affecting the 70S ribosome. Although humans also have ribosomes, their ribosomes are larger and denser than the 70S bacterial ribosome. The 80S human ribosome is mostly unaffected by antibiotics that bind to the bacterial 70S ribosome, thus providing a degree of selective toxicity. Interestingly, human mitochondria do contain a 70S ribosome that is affected by several of these antibiotics, thus explaining some of the adverse effects of these drugs.

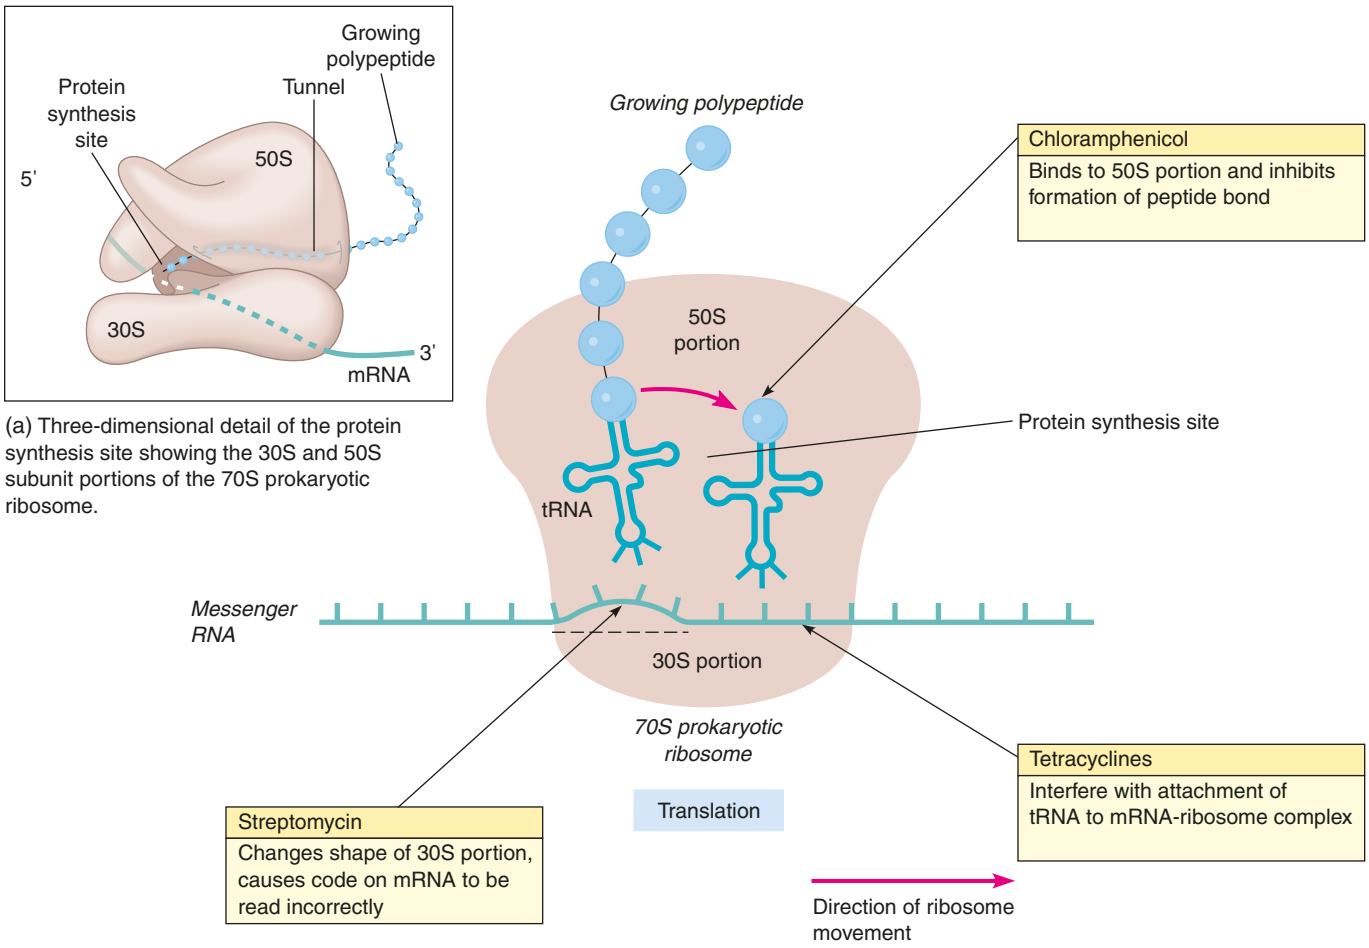
About 20 drugs that affect the synthesis of bacterial proteins have been discovered. The different steps at which antibiotics inhibit the production of bacterial proteins are shown in Figure 48.2.

Tetracyclines

48.2 Tetracyclines have broad antimicrobial activity against many gram-positive and gram-negative bacteria.

The first tetracyclines were extracted from *Streptomyces* in soil samples in 1948. Unfortunately, their widespread use in the 1950s and 1960s resulted in a large number of resistant strains, limiting the current therapeutic usefulness of these drugs.

CONNECTIONS: Using Research in Practice



Traveler's Diarrhea

Traveler's diarrhea (TD) is defined as the passage of three or more loose stools in a 24-hour period or more frequently than is normal for the individual, and is the most common travel-related illness (World Health Organization, n.d.). Depending on the destination and the season of travel, 30% to 70% of people traveling abroad will develop TD (Connor, 2015.). TD may or may not have associated symptoms such as fever, nausea, vomiting, or abdominal cramping. It is caused by ingesting contaminated food or water or by contact with contaminated surfaces. High-risk foods include raw or undercooked meats and seafood and unpeeled raw fruits and vegetables.

Bacteria are the most common cause of TD, thought to account for 80% to 90% of cases; however, viruses and parasites can also be causative agents (Connor, 2015). *Escherichia coli, Shigella, Campylobacter, Salmonella,* and noroviruses are common causes of TD.

Prophylactic antibiotics are not recommended for most travelers because they afford no protection against nonbacterial pathogens. However, early treatment with antibiotics may reduce the duration of symptoms. The antibiotic used to treat TD depends on where the patient traveled and the causative bacteria patterns in those areas. Ciprofloxacin is the most commonly prescribed antibiotic for treating TD, except when patients travel to South or Southeast Asia, where azithromycin is more effective. A single 1-g dose of azithromycin is as effective as a 3-day course of levofloxacin for TD in Thailand, where campylobacter is common (Leder, 2015). The use of an antimotility drug, such has loperamide, has been shown to be an effective and safe adjunct to antibiotics. However, when *Clostridium difficile* is suspected, loperamide should be used with an effective anticlostridial drug (Lääveri, Sterne, Rombo, & Kantele, 2016).

Travelers can try to decrease their risk of contracting TD by practicing frequent hand cleansing with hand sanitizers or antiseptic cloths; avoiding beverages with ice, not drinking water that has not been boiled, and not using tap water for brushing teeth; and not consuming raw fruits or vegetables that cannot be peeled, because they may be contaminated.

(a) Three-dimensional detail of the protein synthesis site showing the 30S and 50S subunit portions of the 70S prokaryotic ribosome.

(b) In the diagram the black arrows indicate the different points at which chloramphenicol, the tetracyclines, and streptomycin exert their activities.

Figure 48.2 Mechanisms of action of antibiotics inhibiting bacterial protein synthesis.
From *Microbiology: An Introduction* (10th ed., p. 558), by G. Tortora, B. Funke, & C. Case, 2010. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.

The five tetracyclines are effective against a large number of aerobic and anaerobic gram-negative and gram-positive organisms: They have one of the broadest antimicrobial spectrums of any class of antibiotics. They are effective against some species that are resistant to penicillins and other cell wall inhibitors. Because of widespread bacterial resistance, however, they are the preferred drugs for only a few diseases: Rocky Mountain spotted fever, typhus, cholera, Lyme disease, peptic ulcers caused by *Helicobacter pylori*, and chlamydial infections. In addition, *Treponema pallidum* (syphilis) responds well to tetracycline therapy for patients who are allergic to penicillin. Although traditionally used for gonorrhea, most strains of *Neisseria gonorrhoeae* are now resistant to tetracyclines. Drugs in this class are occasionally used for the treatment of acne vulgaris, for which they are given topically or orally (PO) at low doses. Almost all strains of *Pseudomonas aeruginosa* are resistant to tetracyclines. Once resistance develops to one tetracycline, it usually extends to all drugs in this class. Doses for the tetracyclines are listed in Table 48.1.

Table 48.1 Tetracyclines

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
demeclocycline (Declomycin)	PO: 150 mg q6h or 300 mg q12h (max: 2.4 g/day)	*Nausea, vomiting, abdominal cramping, flatulence, diarrhea, mild phototoxicity, rash, dizziness, stinging or burning with topical applications*
doxycycline (Vibramycin, others)	PO/IV: 100–200 mg bid (max: 200 mg/day)	
minocycline (Minocin, others)	PO/IV: 100–200 mg bid	
tetracycline (Sumycin, others)	PO: 250–500 mg bid–qid (max: 2 g/day)	Anaphylaxis, superinfections, hepatotoxicity, exfoliative dermatitis, permanent teeth discoloration in children
tigecycline (Tygacil)	IV: 100 mg, followed by 50 mg q12h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Tetracyclines exert a bacteriostatic effect by selectively inhibiting bacterial protein synthesis. As illustrated in Figure 48.2, the tetracyclines bind to the 30S bacterial ribosome, thereby preventing the addition of amino acids to the growing polypeptide chain. Resistance to tetracyclines develops when bacteria prevent tetracyclines from concentrating inside their cells, or when their ribosome shape is altered so the antibiotic can no longer bind. In addition to having ribosomes with different structures, human cells lack the active transport system required for tetracyclines to enter their cells. At high doses, however, tetracyclines begin to exert toxicity on human cells.

All tetracyclines have the same spectrum of antimicrobial activity and similar adverse effects. All except tigecycline may be given PO. Several have topical and parenteral formulations. They are sometimes classified by their duration of action as short acting, intermediate acting, or long acting.

Most PO tetracyclines should be taken on an empty stomach to maximize their absorption. Because gastric distress is relatively common with drugs in this class, patients will often take tetracyclines with food. However, these drugs bind metal ions such as calcium, magnesium, aluminum, and iron, and tetracyclines should not be taken with milk or iron supplements. Food, milk, or other dairy products can reduce drug absorption by 50% or more. Food does not interfere with absorption of the longer acting drugs doxycycline and minocycline.

CONNECTIONS: Patient Safety

Photosensitivity and Antibiotics

Having fun in the sun may be hazardous to some patients. Photosensitivity is a relatively common adverse reaction to some medications, especially antibiotics. Many pharmacologic therapies have photosensitivity as a possible adverse effect.

Any skin reaction to light is generally defined as photosensitivity. However, this medication-induced adverse effect can present in two categories: phototoxicity and photoallergic reactions. The more common of the two conditions is phototoxicity, which encompasses both sunburn and reactions caused by chemical photosensitizers such as medications. Both reactions are typically manifested by delayed redness and edema followed by hyperpigmentation. Phototoxicity may occur after first exposure to a drug.

Photoallergic reactions are less common. These reactions present as variations of contact dermatitis and are the result of hypersensitivity. In photoallergic reactions, the drug forms an immunogenic complex with cutaneous proteins due to the presence of light energy. Photoallergic reactions tend to become more pronounced with repeat exposures.

What role can nurses play to help patients prevent photosensitivity reactions from occurring?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Because most tetracyclines are incompletely absorbed, they remain in the GI tract in high concentrations, often killing normal flora in the colon. Tetracycline-induced diarrhea is common and could indicate toxic effects on normal flora or a bowel superinfection. The presence of diarrhea must be monitored carefully due to the possibility of **pseudomembranous colitis (PMC)**. Caused by *C. difficile*, this is a rare, though potentially severe, disorder resulting from therapy with tetracyclines, fluoroquinolones, cephalosporins, and other classes of antibiotics.

When administered parenterally or in high doses, certain tetracyclines can cause hepatotoxicity, especially in patients with preexisting liver disease. Some patients experience photosensitivity during therapy, making their skin especially susceptible to sunburn. Photosensitivity may appear as exaggerated sunburn within minutes to hours of exposure and is often accompanied by a tingling, burning sensation. Because of their broad spectrum, superinfections due to *Candida albicans* are relatively common. Women who are on oral contraceptives may be more susceptible to vaginal candidiasis. Tetracyclines are usually contraindicated in pregnant or lactating women and in children under the age of 8 because these drugs cause yellow-brown teeth discoloration and may slow the overall growth rate in fetuses or children.

PROTOTYPE DRUG Tetracycline (Sumycin, Others)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Bacterial protein synthesis inhibitor, tetracycline

Therapeutic Effects and Uses: Approved by the U.S. Food and Drug Administration (FDA) in 1953, tetracycline is used for the treatment and prophylaxis of susceptible gram-positive and gram-negative bacteria as well as chlamydiae, rickettsiae, mycoplasmas, and certain protozoa. Tetracycline has one of the broadest spectrums of any antibiotic. Its use has increased during the past decade due to its effectiveness against *H. pylori* in the treatment of peptic ulcer disease. Oral and topical preparations are available for treating inflammatory acne vulgaris.

Mechanism of Action: Tetracycline inhibits bacterial protein synthesis by binding to the 30S ribosomal subunit, interfering with the attachment of the tRNA to the mRNA-ribosome complex. The growing amino acid chain is prematurely terminated and protein synthesis is inhibited. Tetracycline is usually considered bacteriostatic, although it can be bactericidal at high concentrations.

Pharmacokinetics:

Route(s)	PO, topical
Absorption	80% is absorbed PO

Distribution	Widely distributed; only small amounts cross the blood–brain barrier; crosses the placenta; secreted in breast milk
Primary metabolism	15–30% metabolized, primarily in the liver
Primary excretion	60% renal, small amounts excreted into bile
Onset of action	1–2 h
Duration of action	Half-life: 6–12 h

Adverse Effects: Being a broad-spectrum antibiotic, tetracycline has a tendency to affect vaginal, oral, and intestinal flora and cause superinfections. Other frequent adverse effects include nausea, vomiting, epigastric burning, diarrhea, discoloration of the teeth, and photosensitivity. Serious adverse reactions include anaphylaxis; fatty degeneration of the liver, producing jaundice; and exfoliative dermatitis. Although not nephrotoxic, tetracycline can worsen kidney impairment in patients with preexisting disease.

Contraindications/Precautions: Tetracycline is contraindicated in patients who are allergic to any drug in the tetracycline class. As a pregnancy category D drug, tetracycline should not be used during pregnancy. Drug therapy must be monitored carefully in patients with impaired hepatic function or chronic kidney disease (CKD), because this drug is excreted by these routes.

Drug Interactions: Oral supplements, laxatives, or antacids that contain metal ions such as calcium, iron, magnesium, or aluminum reduce the GI absorption and serum levels of oral tetracycline. Tetracycline binds with colestipol and cholestyramine, thereby decreasing the antibiotic's absorption. Tetracyclines decrease the effectiveness of oral contraceptives. **Herbal/Food:** Dairy products interfere with tetracycline absorption. Tetracycline eliminates vitamin K–producing bacteria in the intestines; patients taking warfarin may experience an increased anticoagulant effect.

Pregnancy: Category D.

Treatment of Overdose: No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving tetracycline are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Tetracycline, Macrolide, or Aminoglycoside Antibiotic.

Drugs Similar to Tetracycline (Sumycin, Others)

Other tetracyclines include demeclocycline, doxycycline, minocycline, and tigecycline. The use of oxytetracycline (Terramycin) has been discontinued in the United States.

Demeclocycline (Declomycin): Approved in 1960, demeclocycline has the same spectrum of antimicrobial action as other tetracyclines. Unrelated to its anti-infective properties, demeclocycline is the only drug in this class used off-label to treat syndrome of inappropriate antidiuretic hormone (SIADH). Because of its blocking action on antidiuretic hormone (ADH), demeclocycline is used to produce diuresis in patients with excess ADH secretion (see Chapter 65). Photosensitivity is more severe with demeclocycline than with any other drug in this class. Demeclocycline undergoes extensive enterohepatic recirculation and is excreted in the bile; thus doses should be reduced for patients with hepatic impairment. This drug is pregnancy category D.

Doxycycline (Vibramycin, others): Approved in 1967, doxycycline is the safest tetracycline for patients with impaired renal function because it is excreted primarily by nonrenal routes. Normally administered PO, an intravenous (IV) form is available for treating severe infections. It is absorbed well, with or without food, and offers the advantage of once- or twice-daily dosing. Doxycycline is included in the Centers for Disease Control and Prevention "Sexually Transmitted Diseases Treatment Guidelines" (2015) for treating chlamydial infections, pelvic inflammatory disease, and penicillin-resistant syphilis. Doxycycline is recommended as an alternative to ciprofloxacin for the prophylactic treatment of *Bacillus anthracis* (anthrax). Adverse effects and contraindications are the same as those of other tetracyclines.

Several other formulations of doxycycline have been approved. Doryx is an extended release enteric-coated oral formulation. Oracea is a dual-release capsule, containing immediate and delayed release beads for the treatment of inflammatory lesions of the skin associated with rosacea. It is not intended for the treatment or prevention of infections. Two doxycycline products are available for the treatment of chronic periodontitis in adults. Atridox is administered as a topical, subgingival controlled release product, and Periostat is given as an oral tablet. Doxycycline is pregnancy category D.

Minocycline (Minocin, others): Approved in 1971, minocycline offers the advantage of once- or twice-daily dosing and may be administered without regard to meals or dairy products. It is the only tetracycline that can cause reversible vestibular toxicity, resulting in dizziness, vertigo, and weakness that can limit therapy. Minocycline is active against some strains of bacteria that are resistant to other drugs in the tetracycline class. Hepatic function laboratory values should be monitored during therapy to assess for hepatotoxicity. Other adverse effects and contraindications are the same as those of other tetracyclines. A microsphere powder formulation, called Arestin, is introduced subgingivally to treat periodontitis. Solodyn, an extended release

tablet, is approved for the treatment of inflammatory lesions associated with moderate to severe acne vulgaris in patients over 12 years of age. Minocycline is pregnancy category D.

Tigecycline (Tygacil): Approved in 2005, tigecycline is structurally very similar to tetracycline. Available only by the IV route, it has more limited indications than other drugs in this class: complicated skin and skin structure infections, complicated intra-abdominal infections, and community-acquired bacterial pneumonia. Tigecycline is effective against certain bacterial strains resistant to other antibiotics, including methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE). Nausea and vomiting are the most frequent adverse effects, and these may be severe enough to cause discontinuation of therapy. Life-threatening anaphylaxis and pancreatitis have been reported. Other adverse effects and contraindications are the same as those of other tetracyclines. Hepatic function laboratory values should be monitored during therapy to assess for hepatotoxicity. Tigecycline carries a black box warning that the drug is associated with an increased mortality risk and that its use should be reserved for infections not responsive to other anti-infectives. This drug is pregnancy category D.

PharmFACT

The bubonic plague caused by the bacterium *Yersinia pestis* was responsible for killing approximately 50% of the population during the 5th and 6th centuries AD, and 40% of the population between the 8th and 14th centuries. The plague still occurs sporadically, especially in Africa, but does not cause the same degree of mortality as in past centuries (Dufel, 2015).

Macrolides

48.3 The macrolides are alternatives to penicillin for many gram-positive infections.

Erythromycin (EryC, Erythrocin, others), the first macrolide antibiotic, was isolated from *Streptomyces* organisms in a soil sample in 1952. The name *macrolide* was chosen for this drug class because they all possess an unusually large 14- to 15-atom ring as part of their chemical structure. Doses for the macrolides are listed in Table 48.2.

Macrolides are considered alternative drugs for patients who are allergic to penicillin. They are widely prescribed although they are the preferred drugs for relatively few diseases. Most effective against gram-positive bacteria, common indications for macrolides include the treatment of whooping cough, diphtheria, Legionnaire's disease, and infections by streptococci, *Haemophilus influenzae, Mycoplasma pneumoniae,* and chlamydia. Clarithromycin is one of several antibiotics used to treat peptic ulcer disease due to its activity against *H. pylori* (see Chapter 59). The macrolides are preferred drugs for the prophylaxis of recurring rheumatic fever in patients who are allergic to penicillins. Fidaxomicin (Dificid) is approved for treatment of *C. difficile*–associated diarrhea (CDAD).

The macrolides inhibit bacterial protein synthesis by binding to the 50S ribosomal subunit, thus preventing movement of the ribosome along the mRNA. Macrolides do not bind to human ribosomes, thus offering a degree of selective toxicity. These drugs are usually bacteriostatic, though they may be bactericidal depending on the dose and the target organism.

The newer macrolides have a longer half-life and generally cause less GI irritation than erythromycin, which is the original drug from which macrolides were synthesized. Azithromycin (Zithromax) has an extended half-life such that it can be administered for only 5 days rather than the 10-day therapy required for most antibiotics. A single dose of azithromycin is effective against *N. gonorrhoeae*. The brief duration of therapy increases patient adherence.

Like most of the older antibiotics, macrolide-resistant strains are becoming more common. Many microbes develop resistance to macrolides by pumping them out of the cell before the antibiotic has a chance to reach an effective concentration. In some cases, bacteria have modified the shape of their 50S ribosomal subunit so that it no longer binds the drug.

The macrolides are well tolerated and considered to be one of the safest antibiotic classes. The most common

Table 48.2 Macrolides

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
azithromycin (Zithromax, Zmax)	PO (Zithromax): 500 mg for 1 dose, then 250 mg/day for 4 days PO (Zmax): 2 g single dose	*Nausea, vomiting, diarrhea, abdominal cramping, dry skin or burning (topical route)* Anaphylaxis, ototoxicity, PMC, hepatotoxicity, superinfections, dysrhythmias
clarithromycin (Biaxin)	PO: 250–500 mg bid	
erythromycin (EryC, Erythrocin, others)	PO: 250–500 mg bid or 333 mg tid	
fidaxomicin (Dificid)	PO: 200 mg bid for 10 days	*Nausea, vomiting, abdominal pain* GI bleeding, anemia, neutropenia, anaphylaxis

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

adverse effects are GI related and include nausea, vomiting, abdominal cramping, and diarrhea. These GI symptoms occur whether the drug is administered PO or IV. Taking the drug with food can significantly inhibit absorption; thus these drugs should be taken on an empty stomach.

Many macrolides have an enteric coating, which serves two purposes. First, the coating allows the drug to dissolve in the small intestine rather than the stomach, causing less gastric irritation. Second, the macrolides are inactivated in gastric acid, and the enteric coating allows it to avoid destruction and reach the small intestine where they are readily absorbed in the alkaline environment.

Macrolides are metabolized and concentrated in the liver and excreted into bile. Because macrolides decrease the hepatic metabolism of other drugs, a number of drug–drug interactions are possible. When macrolides prevent the conversion of drugs to their less active form, the serum levels of these other drugs will increase and cause potential toxicity. For example, warfarin (Coumadin) is extensively metabolized to its inactive form in the liver. If given concurrently with erythromycin, the destruction of warfarin is diminished and greater amounts of "active" warfarin remain in the blood for longer periods. Because warfarin increases bleeding time, this could result in prolonged bleeding in a patient. In general, doses of drugs that are metabolized in the liver should be reduced, or at least carefully monitored, if they are given concurrently with macrolides.

CONNECTION Checkpoint 48.1

From what you learned in Chapter 38, what type of laboratory monitoring should be done for a patient who is taking warfarin concurrently with a macrolide? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Erythromycin (EryC, Erythrocin, Others)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Bacterial protein synthesis inhibitor, macrolide

Therapeutic Effects and Uses: Erythromycin (called erythromycin base) is indicated for the treatment and prophylaxis of susceptible bacterial infections. The main application for erythromycin is for patients who are allergic to penicillins or who may have a penicillin-resistant infection. It has a spectrum similar to that of the penicillins and is effective against most gram-positive bacteria, including susceptible strains of *Staphylococcus* and *Streptococcus*. Susceptible gram-negative strains include *N. gonorrhoeae* and *H. influenzae*. It is a first-line drug for infections from *Bordetella pertussis* (whooping cough), *Legionella pneumophila* (Legionnaire's disease), *M. pneumoniae*, and *Corynebacterium diphtheriae*.

All oral forms of erythromycin are considered to have equal effectiveness. Topical and ophthalmic formulations are also available. Erythromycin is available in a number of salts:

- Erythromycin stearate (Erythrocin) and erythromycin ethylsuccinate (EryPed, Pediamycin) are acid stable and more readily absorbed in the stomach than erythromycin base. These forms are converted to the base form in the liver before they become bacteriostatic. The stearate salt should be taken on an empty stomach, whereas the ethylsuccinate salt may be taken without regard to food.
- Erythromycin lactobionate is given IV when the patient is unable to take oral medications, or when the infection is severe enough to warrant a faster onset of action.

Mechanism of Action: Erythromycin inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit. Erythromycin is considered bacteriostatic but may be bactericidal in high doses.

Pharmacokinetics:

Route(s)	PO, topical, IV
Absorption	Readily absorbed PO; enteric coated
Distribution	Widely distributed; only small amounts cross the blood–brain barrier; secreted in breast milk
Primary metabolism	Hepatic metabolism (CYP3A); concentrates in the liver and bile
Primary excretion	Bile
Onset of action	1 h
Duration of action	Half-life: 1.5–2 h

Adverse Effects: The most common adverse effects from erythromycin are nausea, vomiting, and abdominal cramping, although these are rarely serious enough to cause discontinuation of therapy. Concurrent administration with food reduces these adverse effects. When given by the IV route, phlebitis and intense pain at the injection site are common. Anaphylaxis is possible. Hearing loss, vertigo, and dizziness may be experienced when using high doses, particularly in older adults and in those with impaired hepatic or renal excretion. High doses of IV erythromycin may be cardiotoxic and pose a risk for torsades de pointes, which is a type of dysrhythmia that is potentially fatal. Like nearly all other antibiotics, PMC is possible with the use of erythromycin.

Contraindications/Precautions: Erythromycin is contraindicated in patients with hypersensitivity to drugs in the macrolide class and for those who are taking terfenadine, astemizole, or cisapride. Drug therapy must be monitored carefully in patients with impaired hepatic or biliary

function, due to the possibility of **cholestatic hepatitis**, a type of liver inflammation caused by obstruction of the bile ducts. Because macrolides have been shown to prolong the QT interval, erythromycin should be used with caution in patients with known prolongation of the QT interval, a history of torsades de pointes, bradydysrhythmias, or uncompensated heart failure.

Drug Interactions: Erythromycin inhibits hepatic CYP450 metabolic enzymes and can interact with many drugs. When used concurrently with erythromycin, the serum levels and toxicities of alfentanil, carbamazepine, cyclosporine, fentanyl, theophylline, and methadone may increase. Because erythromycin may increase the effects of digoxin or warfarin, leading to abnormal bleeding, the doses of these anticoagulants may need to be lowered. Erythromycin competes with clindamycin and chloramphenicol for binding sites on the 50S bacterial ribosomal subunit, causing an antagonistic effect. Thus these antibiotics should not be taken concurrently. The concurrent use of erythromycin with lovastatin or simvastatin is contraindicated because it increases the risk of myopathy and rhabdomyolysis. Because fluconazole also inhibits CYP3A4, especially at high dosages, its concurrent use with erythromycin is contraindicated. **Herbal/Food:** Grapefruit juice may increase the bioavailability of erythromycin.

Pregnancy: Category B.

Treatment of Overdose: No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving erythromycin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Tetracycline, Macrolide, or Aminoglycoside Antibiotic.

Drugs Similar to Erythromycin (EryC, Erythrocin, Others)

Other macrolides include azithromycin, clarithromycin, and fidaxomicin. The macrolide dirithromycin (Dynabac) is no longer available in the United States.

Azithromycin (Zithromax, Zmax): Approved in 1991, azithromycin has a long duration of action that allows for less frequent dosing. A "Tri-pak" consists of three 500-mg tablets (taken over 3 days) and a "Z-pak" contains six 250-mg tablets (taken over 5 days). For acute otitis media in children, a single dose has been found to be as effective as 3- or 5-day regimens. An IV form for infusions is available for the treatment of pelvic inflammatory disease and community-acquired pneumonia. An ophthalmic solution (AzaSite) is available for treating bacterial conjunctivitis. Azithromycin demonstrates greater activity over gram-negative organisms than erythromycin.

Azithromycin causes less nausea than erythromycin and may be taken with or without food. The extended release oral suspension should be administered on an empty stomach. Because azithromycin does not inhibit liver metabolism, it is safer for patients with hepatic impairment and causes fewer drug–drug interactions than erythromycin base. The most common adverse effects are diarrhea, nausea, and abdominal pain. Azithromycin has been shown to prolong the QT interval, which can increase the risk of cardiac dysrhythmia. The drug should be used with caution in patients with known prolongation of the QT interval, a history of torsades de pointes, bradydysrhythmias, or uncompensated heart failure. Patients with a known hypersensitivity to any macrolide should not receive azithromycin. This drug is pregnancy category B.

Clarithromycin (Biaxin): Approved in 1991, clarithromycin is similar to erythromycin but causes significantly less nausea, and the regular release tablets may be taken with or without food. The drug is commonly prescribed for infections of the respiratory tract, sexually transmitted infections, *H. pylori*–associated peptic ulcer disease, and otitis media. An extended release (XL) formulation is used to treat sinusitis, chronic bronchitis, and community-acquired pneumonia. The XL form should be administered with food because its absorption is increased. The most frequent adverse effects with clarithromycin are diarrhea, nausea, abnormal taste, dyspepsia, abdominal discomfort, and headache. Like erythromycin, clarithromycin is metabolized by CYP450 enzymes and a significant number of drug–drug interactions may occur. Patients with a known hypersensitivity to any macrolide should not receive clarithromycin. This drug is pregnancy category C.

Fidaxomicin (Dificid): A newer macrolide, fidaxomicin was approved in 2011 specifically for infections proven or strongly suspected to be caused by *C. difficile*. The drug should be prescribed only for this indication because other uses could encourage the development of resistant strains. Taken as an oral tablet, the drug is not significantly absorbed and remains in the digestive tract where it produces its effects on *C. difficile*. Fidaxomicin appears to have equal efficacy to vancomycin, the primary antibiotic used to treat CDAD. Relapses are less frequent than with vancomycin. The drug is well tolerated, with the most frequent adverse effects being nausea, vomiting, abdominal pain, and GI bleeding. This drug is pregnancy category B.

Aminoglycosides

48.4 The aminoglycosides are effective against aerobic gram-negative organisms but have the potential to cause ototoxicity and nephrotoxicity.

The first aminoglycoside, streptomycin, was named after *Streptomyces griseus*, the soil organism from which it was

Table 48.3 Aminoglycosides

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
amikacin	IV/IM: 5–7.5 mg/kg as a loading dose, then 7.5 mg/kg bid	*Pain or inflammation at the injection site, rash, fever, nausea, diarrhea, dizziness, tinnitus*
gentamicin (Garamycin, others)	IV/IM: 1.5–2 mg/kg as a loading dose, then 1–2 mg/kg bid–tid	
kanamycin	IV/IM: 5–7.5 mg/kg bid–tid	Anaphylaxis, nephrotoxicity, irreversible ototoxicity, superinfections
neomycin	PO: 4–12 g/day in divided doses	
paromomycin (Humatin)	PO: 7.5–12.5 mg/kg tid	
streptomycin	IM: 15 mg/kg up to 1 g as a single dose	
tobramycin	IV/IM: 1 mg/kg tid (max: 5 mg/kg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

isolated in 1943. Once widely used, streptomycin is now usually reserved for the treatment of tuberculosis (TB) due to the development of safer alternatives and the appearance of a large number of resistant strains. Other aminoglycosides have since been isolated, and several have been produced semisynthetically. All have a common chemical structure of two or more amino sugars with a glycosidic, or sugar, link. The differences in spelling of some of these drugs, *-mycin* and *-micin*, reflects the different organisms from which the drugs were originally isolated. Doses for the aminoglycosides are listed in Table 48.3.

Aminoglycosides bind irreversibly to the 30S ribosomal subunit of bacteria, changing its shape and preventing the initiation stage of protein synthesis. Some drugs in this class also affect the 50S subunit. In addition, these antibiotics cause mRNA to be read incorrectly, resulting in abnormal proteins that are subsequently inserted into the bacterial plasma membrane, causing it to leak. Whereas most antibiotics that affect protein synthesis are bacteriostatic, aminoglycosides are bactericidal.

Although they have the ability to kill many different bacterial species, the aminoglycosides are considered narrow-spectrum drugs because they are normally reserved for serious systemic infections caused by aerobic gram-negative organisms, such as *Pseudomonas* and members of the Enterobacteriaceae family, which includes *E. coli*, *Serratia, Proteus*, and *Klebsiella*. Aminoglycosides are ineffective against most gram-positive bacteria. Because oxygen is required for aminoglycoside antibiotics to be transported inside bacterial cells, this class of drugs does not affect anaerobes.

Most aminoglycosides are polar compounds that are poorly absorbed from the GI tract. Less than 1% of an oral dose is absorbed; therefore they must be administered parenterally to treat systemic infections. Because aminoglycosides travel through the alimentary canal unchanged, they are occasionally given PO to sterilize the bowel prior to intestinal surgery. Neomycin is available for topical infections of the skin, eyes, and ears. Paromomycin (Humatin) is given PO for the treatment of parasitic infections.

Due to their polar nature, aminoglycosides cannot enter most human cells. Although distributed to most body fluids, not enough of the drugs enter the cerebrospinal fluid (CSF) for them to treat central nervous system infections. Aminoglycosides can, however, cross the placenta. If taken late in pregnancy, streptomycin can cause hearing loss in the child. In addition, aminoglycosides concentrate in renal tissue, which leads to potential nephrotoxicity.

Resistance develops quickly when aminoglycosides are administered as monotherapy. Resistance occurs when a species acquires an ability to degrade the antibiotic. Once degraded by the bacterial enzymes, these drugs are unable to bind with the bacterial ribosome. Some resistance also occurs when mutations change the shape of the bacterial ribosome so that it no longer binds the aminoglycoside. The emergence of aminoglycoside-resistant strains of *Enterococcus faecalis* and *Enterococcus faecium* has become a serious clinical problem because there are few therapeutic alternatives to treat these infections. Once resistance develops to an aminoglycoside, the mutant strain of infection is usually resistant to the other drugs in this class. An exception is amikacin, which appears to act against gentamicin-resistant strains.

Several techniques have been used to increase the effectiveness of the aminoglycosides. Administering these drugs in one large dose per day rather than smaller divided doses results in a greater bactericidal effect and fewer resistant microbes. A second technique is to administer aminoglycosides and penicillins concurrently (though not mixed in the same IV solution). The penicillin weakens the cell wall, allowing a greater amount of aminoglycoside to enter and reach its ribosomal targets.

Aminoglycosides are excreted almost exclusively by the kidneys. Because certain tissues bind the drugs very tightly, renal excretion may be prolonged up to 20 days after discontinuation of the drug. Although serum drug levels may fall below what is considered a minimally effective concentration, some antimicrobial activity continues during this time. This is known as a **postantibiotic effect**.

The clinical applications of the aminoglycosides are limited by their potential to cause serious adverse effects. The degree and types of toxicity are similar for all drugs in

this class. For example, all aminoglycosides can impair both hearing and balance. Damage to sensory cells in the cochlea causes hearing loss. Balance is affected by damage to sensory cells in the vestibular apparatus of the inner ear. As many as 25% of patients who are taking aminoglycoside antibiotics may experience some ototoxicity. This effect is more prominent when the medications are used for longer than 10 days, or when the patient has preexisting kidney impairment, causing high serum drug levels. The damage to sensory cells is cumulative; repeated doses of the drug can damage increasing numbers of cells. Because many older adults have some degree of preexisting hearing impairment, permanent deafness may occur in this group. Signs of impending inner ear damage include high-pitched tinnitus, headache, nausea, vomiting, and vertigo. Signs of ototoxicity may continue for several weeks after the drugs are discontinued. If hearing and balance functions are not carefully monitored during therapy and proper interventions are not implemented, the ototoxicity may become irreversible.

One of the most serious adverse effects of aminoglycosides is nephrotoxicity. Aminoglycosides directly injure renal tubule cells, and this nephrotoxicity may be severe, affecting up to 26% of patients receiving these antibiotics. As expected, patients who are receiving higher doses for longer periods are most affected. Those with CKD or who are receiving concurrent therapy with other nephrotoxic drugs must be monitored carefully: Regular evaluation of urinalysis, blood urea nitrogen (BUN), and serum creatinine results is essential. Serum drug concentrations should be obtained regularly and doses adjusted accordingly to prevent permanent damage. If recognized early, renal damage caused by aminoglycosides is reversible. Impaired kidney function may cause drug serum levels to rise, thus increasing the risk or worsening of ototoxicity.

A less common though serious adverse effect of aminoglycosides is neuromuscular blockade. Aminoglycosides inhibit the release of acetylcholine at synapses. Giving other drugs that affect acetylcholine release, such as anesthetics or neuromuscular blockers (see Chapter 26), can result in profound apnea and prolonged muscle paralysis. Because they have fewer acetylcholine receptors, patients with myasthenia gravis are especially at risk. To avoid the problem, aminoglycosides may be discontinued prior to surgery. IV calcium salts have been found to reverse aminoglycoside-induced neuromuscular blockade.

CONNECTION Checkpoint 48.2

From what you learned in Chapter 14, name the prototype drugs classified as neuromuscular blockers. Is muscle paralysis occurring at a nicotinic or muscarinic synapse? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Gentamicin (Garamycin, Others)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Bacterial protein synthesis inhibitor, aminoglycoside

Therapeutic Effects and Uses: Approved in 1966, gentamicin is used for the treatment and prophylaxis of susceptible bacterial infections. It is prescribed primarily for serious infections caused by aerobic, gram-negative bacilli. Activity includes *Enterobacter*, *E. coli*, *Klebsiella*, *Citrobacter*, *Pseudomonas*, and *Serratia*. Gentamicin is effective against a few gram-positive bacteria, including some strains of MRSA. It has no activity against anaerobes. This drug is not absorbed by the PO route. A topical formulation (Genoptic) is available for infections of the external eye.

Therapy with gentamicin is generally limited to those cases in which a less toxic alternative is not available. Resistance to gentamicin is increasing, and some patients show cross-resistance to other aminoglycosides such as tobramycin. Gentamicin is sometimes given concurrently with a beta-lactam antibiotic such as a penicillin or cephalosporin to improve bacterial kill and to delay resistance.

Mechanism of Action: Gentamicin inhibits bacterial protein synthesis by binding to the 30S ribosomal subunit. Gentamicin is bactericidal in that it causes premature termination of the growing polypeptide chain.

Pharmacokinetics:

Route(s)	Intramuscular (IM), IV, topical (ophthalmic)
Absorption	Not absorbed PO; readily absorbed IM
Distribution	Distributed to most body tissues and fluids, except the CSF; concentrates in the kidney and inner ear; crosses the placenta; small amounts secreted in breast milk
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	Rapid
Duration of action	Half-life: 3–4 h

Adverse Effects: Resistance to gentamicin is increasing and some cross-resistance among aminoglycosides has been reported. Rash, nausea, vomiting, and fatigue are the most common adverse effects. **Black Box Warnings:** Adverse effects from parenteral gentamicin may be severe and include the following:

- Neurotoxicity may manifest as ototoxicity and produce a loss of hearing or balance, which may become permanent with continued use. Tinnitus, vertigo, and

persistent headaches are early signs of ototoxicity. The risk of neurologic effects is higher in patients with CKD. Other signs of neurotoxicity include paresthesias, muscle twitching, and seizures. Concurrent use with other neurotoxic drugs should be avoided.

- Neuromuscular blockade and respiratory paralysis are possible and the drug may cause severe neuromuscular weakness that lasts for several days.
- Nephrotoxicity is possible. Signs of reduced kidney function include oliguria, proteinuria, and elevated BUN and creatinine levels. Nephrotoxicity is of particular concern to patients with preexisting kidney disease and may limit pharmacotherapy. Concurrent use with other nephrotoxic drugs should be avoided.

Contraindications/Precautions: Gentamicin is contraindicated in patients who are hypersensitive to aminoglycosides. Drug therapy must be monitored carefully in patients with CKD or in those with preexisting hearing loss. Gentamicin should not be used in pregnant or breastfeeding patients.

Drug Interactions: Concurrent use with other nephrotoxic drugs such as acyclovir, amphotericin B, capreomycin, cisplatin, cyclosporine, salicylates, polymyxin B, or vancomycin increases the risk of nephrotoxicity. Other drugs affecting the eighth cranial nerve such as ethacrynic acid and furosemide will increase the risk of ototoxicity if given concurrently with gentamicin. Penicillins can inactivate aminoglycosides if they are mixed together in the same solution. Antiemetics such as dimenhydrinate, meclizine, promethazine, and scopolamine may block the nausea characteristic of vestibular toxicity or motion sickness, thus masking the signs of aminoglycoside-induced ototoxicity. **Herbal/Food:** No significant interactions are known.

Pregnancy: Category D (parenteral).

Treatment of Overdose: Overdose can result in serious kidney damage and ototoxicity. No specific therapy is available. Patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving gentamicin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with a Tetracycline, Macrolide, or Aminoglycoside Antibiotic.

Drugs Similar to Gentamicin (Garamycin, Others)

Other aminoglycosides include amikacin, kanamycin, neomycin, paromomycin, streptomycin, and tobramycin. All aminoglycosides have similar spectrums of activity and adverse effects. They all carry the same black box warning as gentamicin.

Amikacin: Approved in 1976, amikacin has the broadest spectrum in this class and is sometimes effective against organisms that have developed resistance to other aminoglycosides. Amikacin has been used to treat multidrug-resistant TB. It is administered by the IV and IM routes. Indications, contraindications, and adverse effects (including the black box warning) are nearly the same as those for gentamicin. This is a pregnancy category D drug.

Kanamycin: Approved in 1958, kanamycin is the most toxic aminoglycoside, and resistant strains are common. Its use is limited to the adjunctive treatment of hepatic coma and for the short-term treatment of serious infections. Like amikacin, kanamycin may be used to treat multidrug-resistant TB after first-line drugs have failed. Kanamycin can be delivered IV, IM, by inhalation, or by intraperitoneal instillation. Contraindications and adverse effects (including the black box warning) are the same as those for gentamicin. This is a pregnancy category D drug. Concurrent therapy with other nephrotoxic and neurotoxic drugs should be avoided due to the potential for additive adverse effects.

Neomycin: Approved in 1952, neomycin is widely used for topical infections as an over-the-counter (OTC) ointment combined with polymyxin B and bacitracin (Neosporin). It is also combined in OTC creams with hydrocortisone for minor skin irritations and insect bites. Not available in parenteral form due to its toxicity, neomycin may be used orally to sterilize the bowel. Oral neomycin can cause headache, lethargy, nausea, and vomiting. Oral neomycin carries a black box warning regarding neurotoxicity, nephrotoxicity, and ototoxicity. This is a pregnancy category C drug.

Paromomycin (Humatin): Approved in 1959, paromomycin is most active against gram-negative aerobic bacteria (with the exception of *Pseudomonas*). When administered PO, the drug is not absorbed and 100% is recovered in the feces. The primary use of this drug is for sterilizing the bowel and treating intestinal parasitic infections caused by protozoans and tapeworms. Because this drug is not absorbed systemically, it does not carry the same black box warnings as other aminoglycosides. This is a pregnancy category C drug.

Streptomycin: The use of streptomycin, the first aminoglycoside approved in 1945, has been greatly reduced since 1993, but it is still available on a case-by-case basis. It is rarely used due to a large number of resistant strains and its high risk for ototoxicity. It is most often used in combination with other drugs in the pharmacotherapy of multidrug-resistant TB. Streptomycin carries a black box warning regarding neurotoxicity and nephrotoxicity. This is a pregnancy category D drug.

Tobramycin: Approved in 1975, tobramycin has a spectrum of activity similar to that of gentamicin, but it is more effective against *P. aeruginosa* than gentamicin. Most often administered parenterally, tobramycin is also available as an ophthalmic solution (Tobrex) and in nebulizer form (TOBI) for patients with cystic fibrosis who have *Pseudomonas* infections. Adverse effects (including the black box warning) and contraindications are similar to those of gentamicin. This is a pregnancy category D drug.

PharmFACT

This chapter discusses antibiotics selective for bacterial protein synthesis. However, bacteria can fight back. *C. diphtheriae* produces a toxin that targets *human* protein synthesis and is so potent that a single molecule can kill a human cell (Madigan, Bender, Buckley, Sattley, & Stahl, 2018).

Miscellaneous Inhibitors of Bacterial Protein Synthesis

48.5 Several inhibitors of protein synthesis are effective against resistant infections but may have significant adverse effects that limit their use.

Several bacterial protein synthesis inhibitors do not belong to the tetracycline, macrolide, or aminoglycoside classes. These miscellaneous drugs, listed in Table 48.4, have varying spectrums of activity and adverse effect profiles and thus must be considered individually. One of the medications in the miscellaneous class, spectinomycin (Trobicin), has been discontinued in the United States.

Chloramphenicol: Chloramphenicol is an older, broad-spectrum antibiotic that was approved in 1960 and has been available for nearly 60 years. It binds to the 50S subunit of the bacterial ribosome and may be bacteriostatic or bactericidal, depending on species and dose. Chloramphenicol is administered IV for serious infections, and a topical form is available for ophthalmic and otic infections.

Effective in treating salmonellae, rickettsiae, streptococci, typhoid fever, and meningitis caused by *H. influenzae*, this drug was widely used before it was found to be associated with bone marrow suppression and a very small, though fatal, incidence of aplastic anemia. Chloramphenicol carries a black box warning that serious and fatal blood dyscrasias have been reported with the drug. Peak and trough serum levels should be monitored regularly during therapy to avoid serious adverse effects. Chloramphenicol is now reserved for meningitis and other infections in which the benefits of the drug clearly outweigh the risks of serious drug toxicity.

Another serious toxicity from chloramphenicol is **gray baby syndrome**. Most often seen in premature or newborn infants, this syndrome occurs when the baby's liver is unable to metabolize or excrete this drug. Symptoms include failure to feed, abdominal distention, cyanosis, and cardiovascular collapse. The syndrome is rapidly fatal and

Table 48.4 Miscellaneous Inhibitors of Bacterial Protein Synthesis

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
chloramphenicol	IV: 50 mg/kg/day divided q6h	*Nausea, vomiting, diarrhea* Anaphylaxis, superinfections, pancytopenia, bone marrow depression, aplastic anemia
clindamycin (Cleocin, others)	PO: 150–450 mg qid IV: 600–1200 mg/day in divided doses	*Nausea, vomiting, diarrhea, rash, burning, or pruritus (topical forms)* Anaphylaxis, superinfections, cardiac arrest, PMC, blood dyscrasias
lincomycin (Lincocin)	PO: 500 mg tid–qid (max: 8 g/day) IM: 600 mg q12–24h (max: 8 g/day)	*Nausea, vomiting, diarrhea* Anaphylaxis, superinfections, cardiac arrest, PMC, blood dyscrasias
linezolid (Zyvox)	PO/IV: 600 mg q12h (max: 1200 mg/day)	*Nausea, diarrhea, headache* Anaphylaxis, superinfections, PMC, blood dyscrasias
quinupristin-dalfopristin (Synercid)	IV: 7.5 mg/kg infused over 60 min q8h	*Pain and inflammation at the injection site, myalgia, arthralgia, diarrhea* Superinfections, PMC
tedizolid (Sivextro)	PO/IV: 200 mg once daily	*Nausea, vomiting, headache, diarrhea, dizziness* Anemia, hypersensitivity, *CDAD*
telithromycin (Ketek)	PO: 800 mg once daily	*Nausea, vomiting, diarrhea* Visual disturbances, hepatotoxicity, dysrhythmias

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

can cause death in just a few hours. If done early, discontinuing chloramphenicol therapy can reverse the syndrome. This is a pregnancy category C drug.

Clindamycin (Cleocin, others): Approved in 1970, clindamycin acts on the 50S bacterial ribosomal subunit in a manner similar to that of the macrolides. It is usually bacteriostatic. A first-line drug for abdominal infections caused by *Bacteroides fragilis*, it is also effective against *Fusobacterium*, *Actinomyces*, and *Clostridium*.

Three salts of clindamycin are available: clindamycin hydrochloride (PO), clindamycin palmitate (PO), and clindamycin phosphate (parenteral or topical). The topical form of 1% clindamycin (Evoclin) is approved for the treatment of acne vulgaris, and a single-dose suppository vaginal cream (Clindesse) is approved for bacterial vaginosis.

Once widely prescribed as a penicillin alternative, the use of clindamycin has become limited due to the development of resistant strains, a high incidence of diarrhea, and a potential risk of drug-induced PMC caused by *C. difficile,* which can be fatal (black box warning). It is generally used only when safer alternatives are not effective. The nurse must advise patients to report incidences of diarrhea during clindamycin therapy. If PMC is suspected, clindamycin is discontinued and the patient is placed on a drug that is effective against *C. difficile* such as vancomycin. This is a pregnancy category B drug.

Lincomycin (Lincocin): Approved in 1964, lincomycin is chemically similar to clindamycin. Lincomycin may be used for patients who cannot take penicillins or cephalosporins but it offers no therapeutic advantages over clindamycin. The drug is rarely prescribed due to a relatively high incidence of serious adverse effects, especially PMC (black box warning). It is available by both PO and parenteral routes. This is a pregnancy category B drug.

Linezolid (Zyvox): Approved in 2000, linezolid is in a class of antibiotics called oxazolidinones that act by binding to the bacterial 50S ribosome at the 23S portion. Oxazolidinones are unique among antibiotics in that they prevent the first event in protein synthesis, which is the formation of an initiation complex. Linezolid is believed to be bactericidal. Linezolid is important because it is effective against infections that have become resistant to most other antibiotics, including MRSA and VRE. It is less effective against gram-negative organisms. Oral and IV formulations are available.

Adverse effects are usually minor and related to GI distress. Because this drug can cause transient dose-related myelosuppression, laboratory blood counts should be frequently monitored during therapy. Linezolid is a nonselective inhibitor of monoamine oxidase (MAO) and may cause hypertension in some patients. Risk for hypertension and palpitations is increased if the patient is taking sympathomimetics concurrently with linezolid; thus these medications should be avoided. Patients with diabetes should be cautioned about possible hypoglycemic events while taking linezolid. Linezolid is a pregnancy category C drug.

Quinupristin-dalfopristin (Synercid): Approved in 1999, quinupristin-dalfopristin is a fixed-dose bactericidal combination used for therapy of life-threatening *E. faecium* infections that are vancomycin resistant and for complicated infections caused by MRSA or *Streptococcus pyogenes*. It belongs to a class of antibiotics called *streptogramins* that act by binding the 50S bacterial ribosome in a manner similar to that of the macrolides. The combination of the two antibiotics is truly synergistic: The combination has 16 times more antimicrobial activity compared to either drug used alone. Synercid is bactericidal and only available by the IV route.

Joint and muscle pain, diarrhea, rash, and pain at the infusion site are common adverse effects. Venous irritation may be severe. Synercid inhibits hepatic drug metabolism enzymes, resulting in numerous drug–drug interactions. The nurse should use caution when administering drugs concurrently with Synercid, because those that rely on hepatic metabolism for detoxification may build to toxic levels in the blood. In addition, some cases of PMC have been reported. Quinupristin-dalfopristin carries a black box warning that it should be reserved for serious or life-threatening vancomycin-resistant *E. faecium* infections. Despite its potential for adverse effects, quinupristin-dalfopristin serves an important role in treating multidrug-resistant gram-positive pathogens, which have become a major clinical challenge. This is a pregnancy category B drug.

Tedizolid (Sivextro): Like linezolid, tedizolid is a member of the oxazolidinone class that binds to and inhibits the 50S bacterial ribosome. Tedizolid was approved in 2014 for the treatment of skin and skin structure infections, including MRSA strains, *Streptococcus* strains, and *E. faecalis*. The drug is well tolerated, with GI complaints being the most common side effects. This drug is pregnancy category C.

Telithromycin (Ketek): Approved in 2004, telithromycin is a broad-spectrum antibiotic structurally similar to the macrolides. Telithromycin is the sole member of a class called *ketolides*. Ketolides inhibit bacterial protein synthesis by the same mechanism as the macrolides: by binding to the 50S ribosomal subunit. However, telithromycin binds more tightly to the ribosome than other protein synthesis inhibitors and is capable of causing greater bacterial kill. It also exhibits a significant postantibiotic effect in some organisms. Indications for telithromycin are similar to

those of the macrolides except it has greater activity against *S. pneumoniae*. Because of this, its primary use is to treat bronchitis, sinusitis, and community-acquired pneumonia. It is effective against many other bacterial strains, including those that show macrolide resistance. This drug is available as oral tablets.

Although most adverse effects are minor and GI related, telithromycin has the potential to cause several serious adverse effects. Hepatotoxicity has occurred in a small number of patients. Telithromycin can cause blurred vision, double vision, and difficulty focusing, which can be severe enough to cause discontinuation of therapy. Telithromycin carries a black box warning that patients with myasthenia gravis should not take this drug because life-threatening respiratory failure may occur. As with some of the macrolides, telithromycin may increase the risk for ventricular dysrhythmias such as torsades de pointes and is contraindicated in patients with prolonged QT intervals. This is a pregnancy category C drug.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with a Tetracycline, Macrolide, or Aminoglycoside Antibiotic

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic, or renal disease, and the possibility of pregnancy. Obtain a drug history including allergies, specific reactions to drugs, current prescription and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of the current infection, noting location, characteristics, presence or absence of drainage and the characteristics of drainage, duration, and presence or absence of fever or pain.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], culture and sensitivity [C&S], urinalysis, and hepatic function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection and fever).
- Continue periodic monitoring of CBC, C&S, and hepatic function as ordered.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, drowsiness, tinnitus, or dizziness. Severe diarrhea, especially that containing mucus, blood, or pus, yellowing of the sclera or skin, decreased urine output or darkened urine should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, or signs and symptoms of infection should begin to diminish after taking the first dose and continue to improve.)	• Teach the patient to complete the entire course of the antibacterial therapy; do not share doses with other family members with similar symptoms; and return to the provider if symptoms have not resolved after an entire course of therapy. • Teach the patient to notify the provider if fever and signs and symptoms of infection increase after 3 days.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Immediately report undiminished fever, changes in level of consciousness (LOC), or febrile seizures to the healthcare provider. (Continued fever may be a sign of worsening infection, adverse drug effects, or antibiotic resistance.)	• Teach the patient to report fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider. Immediately report febrile seizures, changes in behavior, or changes in LOC to the healthcare provider.
• Continue to monitor periodic laboratory work: hepatic and renal function tests, CBC, urinalysis, C&S, and peak and trough drug levels as ordered. (Tetracyclines and aminoglycosides may be nephrotoxic; macrolides may be hepatotoxic. Periodic C&S tests may be ordered if infections are severe or are slow to resolve to confirm appropriate therapy. Peak and trough drug levels will be monitored for aminoglycosides to prevent severe adverse effects.)	• Instruct the patient on the need for periodic laboratory work.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of the drug. Continue to monitor the patient for up to 2 weeks after completing antibacterial therapy. (Anaphylactic reactions are possible, particularly with the first dose of an antibacterial. Post-use, residual drug levels, dependent on the length of half-life, may cause delayed reactions.)	• Teach the patient to immediately report any itching, rashes, or swelling, particularly of the face or tongue, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing. • Instruct the patient with known antibacterial allergies to carry a wallet identification card or wear medical identification jewelry indicating the allergy.
• Continue to monitor for nephrotoxicity; e.g., diminished urine output, or weight gain greater than 1 kg (2 lb) in 24 h. (Tetracyclines and aminoglycosides may require frequent monitoring to prevent adverse effects. **Lifespan:** Age-related physiologic differences may place the young child or older adult at greater risk for nephrotoxicity.)	• Teach the patient to immediately report any diminished urine output, visible swelling of feet or ankles, or weight gain greater than 1 kg (2 lb) in 24 h. • Advise the patient to increase fluid intake to 2–3 L/day.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for the development of superinfections, e.g., CDAD or PMC, fungal or yeast infections. (Superinfections with opportunistic organisms may occur when normal host flora are diminished or killed by the antibacterial drug and no longer hold pathogens in check. Severe diarrhea may indicate the presence of CDAD or PMC, superinfections caused by *C. difficile*.)	• Instruct the patient to report any diarrhea that increases in frequency or amount, or that contains mucus, blood, or pus. • Instruct the patient to consult the healthcare provider before taking any antidiarrheal drugs, which cause the retention of harmful bacteria. • Teach the patient to observe for changes in the color, consistency, or frequency of stool, white patches in the mouth, whitish thick vaginal discharge, itching in the genital area, or blistering itchy rash. • Teach the patient infection control measures such as frequent hand hygiene, adequate drying after showering or bathing, and to increase the intake of live-culture dairy foods.
• Monitor for significant throat irritation in patients taking tetracycline. (Esophagitis or esophageal ulceration may occur secondary to tetracycline use.)	• Teach the patient taking tetracycline to immediately report any difficulty in swallowing or throat or epigastric pain.
• Monitor for signs and symptoms of neurotoxicity, e.g., dizziness, drowsiness, severe headache, tinnitus, increasing muscle weakness, paresthesias, twitching, or seizures. (Aminoglycosides have an increased risk of neurotoxicity. **Lifespan:** Be particularly cautious with the older adult who is at greater risk for falls.)	• Instruct the patient to immediately report increasing headache, dizziness, twitching, or seizures. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Monitor electrolytes, pulse, and electrocardiogram (ECG) if indicated in patients taking erythromycin and related drugs. (Erythromycin and some related drugs may prolong the QT interval and increase the risk for potentially fatal dysrhythmias.)	• Teach the patient to promptly report any palpitations, lightheadedness, or dizziness.
• Monitor for signs and symptoms of ototoxicity, e.g., dizziness, vertigo, tinnitus, or diminished hearing. (Erythromycin and aminoglycosides have an increased risk of ototoxicity.)	• Instruct the patient to immediately report dizziness, vertigo, tinnitus, or diminished hearing.
• Monitor for the effects of other drugs if the patient is on erythromycin. (**Diverse Patients:** Because erythromycin metabolizes through the CYP450 system pathways, monitor ethnically diverse patients to ensure optimal therapeutic effects and to minimize adverse effects. Erythromycin also inhibits CYP450 enzymes and is known to increase the effects of some drugs such as anticoagulants and digoxin and decrease others. Grapefruit juice taken concurrently with erythromycin may increase drug levels.)	• Teach the patient to report any unusual effects related to other drugs taken concurrently. If the patient is taking anticoagulants, an increase in bleeding should be immediately reported. • Teach the patient not to consume grapefruit or grapefruit juice while taking erythromycin.
• Continue to monitor for dermatologic effects including red or purplish skin rash, blisters, or sunburn. Immediately report severe rashes, especially when accompanied by blistering. (Tetracyclines may cause significant dermatologic effects including Stevens–Johnson syndrome.)	• Teach the patient to wear sunscreen and protective clothing for sun exposure and to avoid tanning beds. Immediately report any severe sunburn or rashes.
• **Lifespan:** Assess for the possibility of pregnancy or breastfeeding in patients prescribed tetracycline or erythromycin antibiotics. (Tetracyclines affect fetal bone growth and teeth development, causing permanent yellowish-brown staining of teeth. Tetracycline use in children under age 8 or 9 should also be avoided. Erythromycin antibiotics may significantly reduce the effectiveness of oral contraceptives, and a secondary method to prevent conception should be used.)	• Advise women who are pregnant, breastfeeding, or attempting to become pregnant to inform their healthcare provider before receiving any tetracycline antibiotic. • Teach women of childbearing age on oral contraceptives to consult their healthcare provider about birth control alternatives if erythromycin antibiotics are ordered.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Do not share with other family members and do not stop taking the medicine when starting to feel better.
	  • Take the drug with food or milk and avoid acidic or carbonated beverages to decrease GI effects.
	  • Do not take tetracycline with milk products, iron-containing preparations such as multivitamins, or with antacids. Take the tetracycline 1 h before or 2 h after consuming these products.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking the antibacterial drug.
	  • Discard outdated medications or those no longer in use. Review the medicine cabinet twice a year for old medications (e.g., at the beginning and end of daylight saving time).

Understanding Chapter 48

Key Concepts Summary

48.1 Antibiotics inhibit microbial protein synthesis by binding to the bacterial ribosome.

48.2 Tetracyclines have broad antimicrobial activity against many gram-positive and gram-negative bacteria.

48.3 The macrolides are alternatives to penicillin for many gram-positive infections.

48.4 The aminoglycosides are effective against aerobic gram-negative organisms but have the potential to cause ototoxicity and nephrotoxicity.

48.5 Several inhibitors of protein synthesis are effective against resistant infections but may have significant adverse effects that limit their use.

CASE STUDY: Making the Patient Connection

Remember the patient "John Travis" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

John Travis, a 31-year-old high school teacher, has had an upper respiratory infection for the past 2 weeks. Although he has seen his healthcare provider, he does not seem to be improving. He is convinced that if he takes the antibiotic just 1 more day, he will surely improve. However, after 5 days of drug therapy, John continues to experience chills, fever, and a productive cough. His wife insisted that he return to the clinic for further evaluation and treatment.

At the clinic the patient's physical examination and diagnostic tests reveal the following findings: temperature, 39.2°C (102.6°F); pulse rate, 112 beats/min; respiratory rate, 30 breaths/min; and blood pressure, 134/88 mmHg. He is visibly short of breath and is experiencing intermittent coughing episodes. On auscultation of his lung fields, bilateral crackles and wheezes are discovered. His white blood cell (WBC) count is 14,400 mm^3. A chest x-ray is taken to confirm a diagnosis of pneumonia and reveals right lower lobe infiltrates (white areas in the lung that indicate infection).

The patient is diagnosed with bacterial pneumonia. He is hospitalized and prescribed IV antibiotic therapy. On the second hospital day you are assigned to care for John. He and his wife have multiple questions about the drug therapy prescribed.

Critical Thinking Questions

1. Why did the first antibiotic prescribed not cure the infection?
2. The patient has been told that a sputum specimen is needed for a "C and S" and asks what that is. What will the nurse teach him about this test and why it is needed?
3. John has been told that laboratory personnel will be collecting blood for a peak and trough level this afternoon and in the morning. How would the nurse explain this laboratory test to the patient?
4. What symptoms would indicate that the patient's condition is worsening?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Mr. Klein is an 85-year-old man seen in the outpatient clinic for an acute infection. He has informed the healthcare provider that he is allergic to a variety of antibiotics and is subsequently prescribed erythromycin estolate. The patient is a recovering alcoholic who has been abstinent for 10 years.

1. What is the significance of Mr. Klein's history of alcoholism?
2. What possible adverse effect should the nurse instruct the patient to watch for?
3. What laboratory diagnostic studies may be indicated for this patient?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. While teaching the patient about taking oral tetracycline, which of the following does the nurse advise the patient to do?
    1. Consume calcium-rich products to decrease the duration of the antibacterial effect.
    2. Use a soft toothbrush and floss teeth gently to remove staining on teeth.
    3. Report any ringing in the ears or dizziness.
    4. Avoid direct exposure to sunlight and apply sun block when outdoors.
2. The nurse determines that the patient understands the use of azithromycin (Zithromax) when the patient makes which statement?
    1. "It only needs to be taken once daily because it lasts longer."
    2. "It causes more nausea than most other antibiotics in this classification."
    3. "It must be taken on an empty stomach."
    4. "It is ineffective if taken with calcium-rich foods."
3. The patient is receiving amikacin (Amikin) for a bacterial infection. Which adverse effects does the nurse include in the plan of care to monitor the patient's status?
    1. Weight gain
    2. Visual disturbances
    3. Mental depression
    4. Urinary frequency
4. The healthcare provider orders gentamicin (Garamycin) for a patient with a postoperative wound infection. Which laboratory result should prompt the nurse to consult with the prescriber about possible nephrotoxicity of this drug?
    1. Elevated serum creatinine level
    2. Decreased blood urea nitrogen (BUN) level
    3. Increased white blood cell (WBC) count
    4. Elevated serum iron level
5. The patient has received a prescription for tetracycline (Sumycin) for treatment of acne. The nurse will teach the patient to avoid taking the tetracycline concurrently with _____.
6. The patient is receiving gentamicin (Garamycin) IV for a significant infection. While the patient is receiving this drug, what assessment data will the nurse gather to monitor for adverse effects? (Select all that apply.)
    1. Serum creatinine
    2. Signs of muscle weakness
    3. Liver function studies
    4. Urine output
    5. Hearing and balance assessments

Patient "Mike Springs"

Chapter 49
Fluoroquinolones and Miscellaneous Antibacterials

Chapter Outline

- Bacterial DNA Replication
- Inhibition of DNA Replication
- Fluoroquinolones
  PROTOTYPE *Ciprofloxacin (Cipro), p. 891*
- Miscellaneous Antibacterials
  Daptomycin (Cubicin)
  Metronidazole (Flagyl)
  Polymyxin B
  Rifampin (Rifadin, Rimactane)
  Telithromycin (Ketek)

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the steps in bacterial DNA replication.
2. Identify the classes of drugs that act by affecting bacterial DNA replication.
3. Explain mechanisms by which fluoroquinolones inhibit bacterial DNA replication.
4. Describe means by which bacteria become resistant to fluoroquinolones.
5. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
6. Explain the nurse's role in the safe administration of fluoroquinolones.
7. Apply the nursing process to care for patients receiving pharmacotherapy with fluoroquinolones and miscellaneous antibacterials.

Key Terms

DNA gyrase (topoisomerase II), 888
DNA helicase, 888
DNA polymerase, 888
supercoil, 888
topoisomerase IV, 888

With resistance to other antibacterials developing rapidly, drugs in the fluoroquinolone class have become increasingly important in the pharmacotherapy of infectious diseases. Fluoroquinolones are bactericidal and are effective against many gram-positive and gram-negative microbes. They affect bacterial deoxyribonucleic acid (DNA) synthesis and are particularly useful in the management of respiratory, genitourinary, and gastrointestinal (GI) infections.

Bacterial DNA Replication

49.1 Bacterial DNA replication requires several different enzymes to uncoil, unwind, and duplicate the DNA.

Under optimal conditions, many pathogenic bacteria can divide every 1 to 3 hours. Under highly favorable conditions, *Escherichia coli* divides every 20 minutes, producing a billion cells in only 10 hours. The most critical step in bacterial reproduction is duplicating the DNA so that each daughter cell contains the same genetic material. Thus, bacteria are in the process of continuously replicating their DNA as well as constructing cell walls and synthesizing proteins.

Like human DNA, bacterial DNA uses the four bases, adenine, guanine, cytosine, and thymidine, and is arranged in a double-helical formation. Most bacteria, however, contain a single circular chromosome as illustrated in Figure 49.1. The helix is then twisted and coiled. This highly twisted arrangement is called a **supercoil**. This supercoiled arrangement is necessary for all the DNA to fit into the small bacterial cell. However, this supercoil must be relaxed and the two helices unwound immediately prior to replicating its DNA, so that duplication enzymes can reach the bases.

A large number of enzymes are needed for DNA replication, and some of these enzymes are targets for antibiotics. This is a complex process but may be simplified in four steps. The enzymes involved in this four-step process afford different sites at which drugs may act.

1. **Unwind:** The enzyme **DNA helicase** speeds down the DNA, unwinding the two strands.
2. **Relax:** Working just ahead of helicase, **DNA gyrase** (also called **topoisomerase II**) relaxes the supercoils.
3. **Replicate:** The enzyme **DNA polymerase** adds the precursor bases to replicate the original DNA and form new DNA strands.
4. **Migrate:** The two newly formed strands are interlocked until the enzyme **topoisomerase IV** frees them to migrate to opposite sides of the cell, where they are segregated into the two daughter cells.

Inhibition of DNA Replication

49.2 Drugs have been discovered that inhibit different steps in bacterial DNA replication.

Blocking the DNA replication of a pathogen is a common mechanism used by drugs across several different

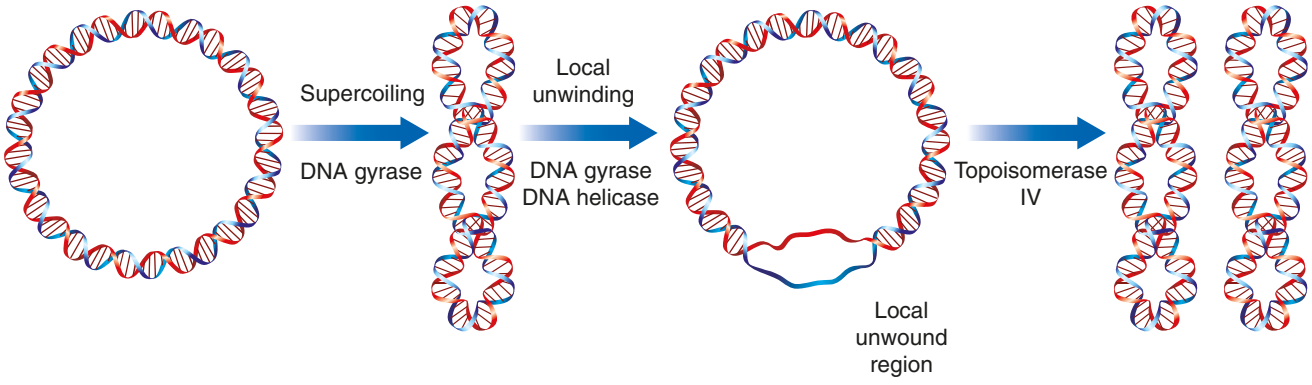

Figure 49.1 The unwinding and replication of bacterial DNA.

therapeutic classes. Drugs can block bacterial DNA replication in three basic ways:

- Drugs can inhibit the synthesis or availability of precursor bases or nucleotides.
- Drugs can bind to bacterial DNA, preventing the relaxation and uncoiling processes required for replication.
- Drugs can bind to enzymes of DNA replication, halting the formation of new DNA strands.

A number of drugs employed in cancer chemotherapy act by mimicking precursor molecules or by interacting with DNA. Cytarabine (Cytosar-U) and fluorouracil (5-FU) resemble nucleotides and are mistakenly incorporated into newly formed DNA strands. Daunorubicin (Cerubidine) and bleomycin (Blenoxane) are highly toxic antibiotics that interact with DNA to physically block replication. Although classified as antibiotics, these drugs are too toxic to be used for infections but have therapeutic indications in the chemotherapy of specific types of cancer.

Several drugs act by inhibiting enzymes involved in DNA replication. Acyclovir (Zovirax) inhibits the DNA polymerase of herpesvirus and is a leading drug for treating this infection (see Chapter 54). Teniposide (Vumon) and etoposide (VePesid) are antineoplastic drugs that act by inhibiting topoisomerase I, an enzyme that helps repair DNA damage. By binding in a complex with topoisomerase and DNA, these antineoplastics cause strand breaks that accumulate and permanently damage the DNA.

The fluoroquinolone antibiotics act on two enzymes in the DNA replication process. First, they bind to DNA gyrase, inhibiting its ability to relax the supercoiling of the bacterial DNA. When the replication enzymes reach an area still in a supercoiled state, replication terminates. A second mechanism is binding to topoisomerase IV. When this occurs, the two daughter DNA strands cannot migrate to opposite sides of the cell, and division cannot be completed. It is thought that fluoroquinolones inhibit DNA gyrase in gram-negative organisms, and inhibit topoisomerase IV in gram-positive organisms. However, this is likely an oversimplification of their exact mechanism. These drugs have no effect on human enzymes involved in DNA replication because of significant differences in the chemical structures of the human and bacterial enzymes. These differences account for their selective toxicity on bacteria and their favorable safety profile.

Fluoroquinolones

49.3 Fluoroquinolones are antibiotics whose therapeutic applications have expanded in recent years to treat many gram-positive and gram-negative infections.

The first drug in this class, nalidixic acid (NegGram), was approved by the U.S. Food and Drug Administration (FDA) in 1962. Classified as a quinolone, the use of nalidixic acid was restricted to treating urinary tract infections (UTIs). Although no longer available, nalidixic acid is important because it served as a building block for the synthesis of other drugs in this class.

In the late 1980s, the development of quinolones with a fluorine side chain resulted in drugs with wider spectrums of activity and longer durations of action. The fluoroquinolones, listed in Table 49.1, have become an increasingly important class of antibiotics in the past two decades. Fluoroquinolones are bactericidal and affect bacterial DNA synthesis by inhibiting both DNA gyrase and topoisomerase IV.

The generations of fluoroquinolones are based on their antibacterial spectrums. All fluoroquinolones have activity against gram-negative pathogens, with the newer generations being significantly more effective against gram-positive bacteria. The distinctions among the generations are listed in Table 49.2. Some of the newer fluoroquinolones were developed and approved primarily for the treatment of respiratory infections.

Clinical applications of fluoroquinolones include infections of the respiratory, GI, and genitourinary tracts, and some skin and soft tissue infections. Their effectiveness against gram-negative organisms makes them preferred drugs in the treatment of uncomplicated UTIs (see Chapter 50). Moxifloxacin (Avelox) is effective against anaerobes, a group of bacteria that are often difficult to treat. Ciprofloxacin (Cipro) is the fluoroquinolone usually selected for infections by *Pseudomonas aeruginosa*. Recent studies have suggested that some fluoroquinolones may be effective against *Mycobacterium tuberculosis*, although the FDA has not approved these drugs for this indication.

Along with doxycycline, streptomycin, and penicillin, several fluoroquinolones are indicated for pathogens that could potentially be of benefit following a bioterrorism incident. Ciprofloxacin (Cipro) is a preferred drug for postexposure prophylaxis to *Bacillus anthracis*, the causative agent of anthrax. Ciprofloxacin is also indicated for postexposure prophylaxis to other potential biologic warfare pathogens such as *Yersinia pestis* (plague), *Francisella tularensis* (tularemia), and *Brucella melitensis* (brucellosis). Details on the pharmacotherapy of bioterrorism agents are presented in Chapter 75.

Several fluoroquinolones are well absorbed orally and may be administered either once or twice a day, making them ideal for outpatient therapy. The serum levels of these drugs after oral (PO) administration are nearly equivalent to the levels achieved during IV administration. This allows for a rapid, smooth transition from IV therapy to oral therapy, potentially decreasing the length of the hospital stay. Like aminoglycosides, fluoroquinolones exhibit a postantibiotic effect. Their bactericidal actions continue after serum

Table 49.1 Fluoroquinolones

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
First Generation (no longer available)		
Second Generation		
ciprofloxacin (Cipro)	PO: 250–750 mg bid (max: 1500 mg/day) Drops (ophthalmic solution): 1–2 drops q2h while awake for 2 days, then q4h for the next 5 days	*Nausea, headache, diarrhea, rash, insomnia, pain and inflammation at injection site, local burning, stinging, corneal irritation (ophthalmic)* Anaphylaxis, tendon rupture, superinfections, photosensitivity, pseudomembranous colitis (PMC), seizure, peripheral neuropathy, hepatotoxicity, exacerbation of myasthenia gravis, toxic psychosis
ofloxacin	PO/IV: 200–400 mg bid (max: 800 mg/day) Drops (ophthalmic solution): 1–2 drops q2–4h in affected eye Drops (otic solution): 5–10 drops in affected ear daily	
Third Generation		
gatifloxacin (Zymar, Zymaxid)	Drops (ophthalmic solution): 1 drop in each affected eye q2–4h	
levofloxacin (Levaquin)	PO/IV: 250–750 mg/day (max: 750 mg/day)	
Fourth Generation		
besifloxacin (Besivance)	Drops (ophthalmic solution): 1 drop in each affected eye q8h	
delafloxacin (Baxdela)	PO: 450 mg bid IV: 300 mg bid given over 60 minutes	
finafloxacin (Xtoro)	Drops (otic solution): 4 drops in affected ear bid	
gemifloxacin (Factive)	PO: 320 mg/day (max: 320 mg/day)	
moxifloxacin (Avelox, Moxeza, Vigamox)	PO/IV (Avelox): 400 mg/day once daily (max: 400 mg/day) Ophthalmic solution: 1 drop in affected eye tid (Vigamox) or bid (Moxeza)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Table 49.2 Generations of Fluoroquinolones

Generation	Example	Route of Administration	Spectrum of Activity	Indications
First generation	nalidixic acid	Oral	Enterobacteriaceae	No longer available
Second generation	ciprofloxacin	Oral and IV	Enterobacteriaceae, atypical pathogens, *Pseudomonas aeruginosa*	Complicated UTI, gastroenteritis with severe diarrhea, sexually transmitted infections (STIs)
Third generation	levofloxacin	Oral and IV	Enterobacteriaceae, atypical pathogens, some streptococci	Complicated UTI, gastroenteritis with severe diarrhea, STIs, community-acquired pneumonia
Fourth generation	moxifloxacin	Oral	Enterobacteriaceae, atypical pathogens, some streptococci, methicillin-resistant *S. aureus* (MRSA), anaerobes	Bacterial conjunctivitis (ophthalmic drops), acute bacterial sinusitis, exacerbations of chronic bronchitis, community-acquired pneumonia, skin and skin structure infections

levels fall to below minimum inhibitory concentrations. Once available by the PO route, gatifloxacin is now formulated as an ophthalmic solution.

Adverse Effects

In the 1990s, fluoroquinolones came into widespread use because they were well tolerated and few serious adverse effects were reported. Over time, several uncommon, although very serious, adverse effects were discovered. Since that time, almost half the fluoroquinolones approved by the FDA have been discontinued in the United States due to safety concerns. As part of the black box warning for all oral and IV fluoroquinolones, the risk for serious adverse effects generally outweighs the benefits for patients with acute bacterial sinusitis, acute exacerbation of chronic bronchitis, and uncomplicated UTIs. Fluoroquinolones should only be used for these indications when there are no alternative treatment options.

Cartilage toxicity: Animal studies have suggested that fluoroquinolones can affect the extracellular matrix of cartilage during development, and tendon toxicity has been reported in children using these drugs. Although these abnormalities ceased upon termination of antibiotic therapy, fluoroquinolones are not approved for patients under age 18, and their use in children is restricted to instances where the benefits of pharmacotherapy clearly outweigh the potential risks.

Although rare, tendon abnormalities have also been reported in adults. Tendinitis and rupture of the shoulder, hand, and Achilles tendons have occurred several months after discontinuation of therapy. The FDA requires safety labeling that states patients older than 65 years are at increased risk for severe tendon disorders and that this risk is further increased by concurrent use of corticosteroids. Musculoskeletal complaints should be carefully monitored during therapy with fluoroquinolones, and patients should be advised to report unexplained joint or tendon pain.

GI toxicity: GI symptoms such as nausea, vomiting, and diarrhea occur in as many as 20% of patients taking fluoroquinolones. Although food does not affect their absorption, certain multivitamins or mineral supplements containing calcium, zinc, iron, aluminum, and magnesium can delay absorption of the antibiotic by as much as 90%. Substances containing these minerals should not be administered at the same time as fluoroquinolones.

The FDA has issued required safety labeling for certain antimicrobials to warn of the risk for *Clostridium difficile*–associated diarrhea (CDAD). This safety labeling applies to most fluoroquinolones as well as drugs from many other antibiotic classes.

Hypersensitivity reactions: Certainly not unique to fluoroquinolones, hypersensitivity may occur to any antibiotic. Although the FDA has always required label warnings on quinolones for the risk of hypersensitivity reactions that occur after the first dose, new labels warn of the rare risk for serious, and sometimes fatal, events after multiple doses.

Cardiotoxicity: Some of the most serious adverse effects of drugs in this class are dysrhythmias (moxifloxacin). Several of the drugs in this class were removed from the market due to the potential for fatal dysrhythmias. Nearly all fluoroquinolones prolong the QT interval.

Nervous system toxicity: Central nervous system (CNS) effects such as dizziness, headache, and sleep disturbances affect 1% to 8% of patients. Seizures, hallucinations, high intracranial pressure, confusion, and toxic psychoses have been reported in patients taking fluoroquinolones. These drugs should be used with caution in patients with preexisting seizure disorders. In 2013, the FDA issued a safety warning that serious nerve damage (peripheral neuropathy) caused by oral or parenteral fluoroquinolones may be permanent.

Phototoxicity: Moderate to severe phototoxicity may occur in patients exposed to direct or indirect sunlight, or to sunlamps during or following treatment with fluoroquinolones. Recovery may take several weeks.

Hepatotoxicity: Some of the fluoroquinolones elevate hepatic enzymes, which usually return to normal 1 to 2 months after completion of therapy. Liver damage, including fatal hepatic failure, is a potential risk.

Resistance: Like other antibiotics, resistance of bacterial species to fluoroquinolones has been increasing and can occur by multiple mechanisms. Mutations to DNA gyrase can alter its ability to bind fluoroquinolones, thus rendering the drug less effective. Some bacteria have developed resistance pumps that remove fluoroquinolones from inside their cells, whereas others have developed a cell wall structure that is less permeable to the drugs. Because of the large number of resistant strains, the Centers for Disease Control and Prevention no longer recommends fluoroquinolones for the treatment of gonorrhea. Resistance to one fluoroquinolone sometimes confers resistance to all drugs in this class; therefore, resistance is becoming a limiting factor in the clinical utility of these drugs.

PROTOTYPE DRUG Ciprofloxacin (Cipro)

Classification **Therapeutic:** Antibacterial
Pharmacologic: Bacterial DNA replication inhibitor, fluoroquinolone

Therapeutic Effects and Uses: Ciprofloxacin is a second-generation fluoroquinolone approved in 1987 that is the most widely used drug in this class. It is prescribed for UTI, sinusitis, pneumonia, skin infections, bone and joint infections, infectious diarrhea, and certain eye infections. It is a broad-spectrum antibiotic that is most effective against gram-negative organisms. It is active against *Enterobacter*, *Citrobacter*, *E. coli*, *Haemophilus*, *Klebsiella*, *Proteus*, *Staphylococcus*, *Shigella*, *Salmonella*, *Neisseria*, and *Serratia* species. It is poorly effective against *Streptococcus pneumoniae* and is inactive against most anaerobic bacteria. Ciprofloxacin is a preferred drug for postexposure prophylaxis of inhalational *B. anthracis* spores.

Ciprofloxacin is available by the oral, IV, ophthalmic, and otic routes. As an ophthalmic solution (Ciloxan), it is used to treat corneal ulcers and conjunctivitis due to *Staphylococcus*, *Haemophilus*, and *Pseudomonas*. An otic suspension (Ciprodex otic) is a combination of ciprofloxacin and dexamethasone to treat acute otitis media and acute otitis externa in children ages 6 months and older. Cipro HC otic combines ciprofloxacin with hydrocortisone to treat adults and children with acute otitis media.

Several extended release (XR) formulations are available that permit once-daily dosing, usually for treating UTIs. Cipro XR contains two different ciprofloxacin salts: ciprofloxacin hydrochloride and ciprofloxacin betaine. Proquin XR contains only the hydrochloride salt and has been formulated to cause less nausea, vomiting, and diarrhea than other formulations. Proquin XR is administered for only 3 days and is approved only for uncomplicated UTI (acute cystitis).

Mechanism of Action: By inhibiting bacterial DNA gyrase and topoisomerase, ciprofloxacin affects bacterial replication and DNA repair. Ciprofloxacin is usually considered bactericidal and exhibits a prolonged postantibiotic effect.

Pharmacokinetics:

Route(s)	PO, IV, ophthalmic and otic drops
Absorption	60–80% absorbed
Distribution	Widely distributed to all body fluids; crosses the placenta; secreted in breast milk; small amounts in cerebrospinal fluid; 20–40% bound to plasma proteins
Primary metabolism	Mostly unchanged; small amounts of hepatic metabolism
Primary excretion	Primarily renal; 15% by biliary route
Onset of action	Rapid
Duration of action	12 h

Adverse Effects: Ciprofloxacin is well tolerated by most patients, and serious adverse effects are uncommon. GI adverse effects, such as nausea, vomiting, and diarrhea, may occur in patients taking high doses. Ciprofloxacin may be administered with food to diminish adverse GI effects. The patient should not, however, take this drug with antacids or mineral supplements, because drug absorption will be diminished. Some patients report phototoxicity, headache, and dizziness. Like most antibiotics, ciprofloxacin can cause serious pseudomembranous colitis (PMC). Although rare, seizures and toxic psychosis have been reported in patients receiving fluoroquinolones. **Black Box Warning:** Tendinitis and tendon rupture may occur in patients of all ages. Risk is especially high in patients over age 60; in kidney, heart, and lung transplant recipients; and in those receiving concurrent corticosteroid therapy. Fluoroquinolones may cause extreme muscle weakness in patients with myasthenia gravis.

Contraindications/Precautions: Ciprofloxacin is contraindicated in patients who are hypersensitive to fluoroquinolones and in pregnant patients. Drug therapy must be monitored carefully in patients with suspected CNS disorders, because this drug can be neurotoxic at high doses and can cause seizures when given by rapid IV infusion. Although prescribed for patients with UTIs, the drug should be used with caution in patients with serious chronic kidney disease (CKD), because this drug is excreted by this route and may accumulate to toxic levels. Fluoroquinolones should be used with caution in patients with myasthenia gravis because they may greatly exacerbate muscle weakness.

Drug Interactions: Concurrent administration with warfarin may increase anticoagulant effects and result in bleeding due to the decreased metabolism of warfarin. Antacids and vitamin supplements containing calcium or aluminum, iron or zinc sulfate, and sucralfate decrease the absorption of ciprofloxacin, thus causing decreased effectiveness of the antibiotic. Ciprofloxacin slows the hepatic metabolism of xanthines, including caffeine, theophylline, and theobromine. **Herbal/Food:** Patients ingesting large quantities of caffeinated products may experience excessive nervousness, anxiety, or tachycardia. Calcium-fortified juices may interfere with absorption of the antibiotic.

Pregnancy: Category C.

Treatment of Overdose: No specific therapy is available; patients are treated symptomatically.

Nursing Responsibilities: Key nursing implications for patients receiving ciprofloxacin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Fluoroquinolones.

Drugs Similar to Ciprofloxacin (Cipro)

Other fluoroquinolones include besifloxacin, finafloxacin gatifloxacin, gemifloxacin, levofloxacin, moxifloxacin, and ofloxacin. With few exceptions, these drugs have actions and adverse effects that are very similar to those of ciprofloxacin. A black box warning regarding possible tendon rupture is included for all oral and parenteral drugs in this class. Norfloxacin was discontinued in 2014.

Besifloxacin (Besivance): Approved in 2009, besifloxacin is available as a 0.6% ophthalmic suspension for the treatment of bacterial conjunctivitis. The most frequently reported adverse reaction is conjunctival redness. If used for a prolonged time period, the patient should be examined for the possibility of overgrowth of resistant microbes. Patients should be advised to discontinue use of contact lenses during therapy. This drug is pregnancy category C.

Delafloxacin (Baxdela): Delafloxacin was approved in 2017 to treat skin and skin structure infections. It is effective against a large number of gram positive and gram negative bacteria, including MRSA. The most frequent adverse effects include nausea, diarrhea, headache, and vomiting. Delafloxacin carries black box warnings similar to the other systemic drugs in this class. The drug has no pregnancy category.

Finafloxacin (Xtoro): One of the newer drugs in this class, finafloxacin was approved in 2014 for the treatment of acute otitis externa caused by *P. aeruginosa* or *Staphylococcus aureus*. It is used for 7 days and rarely causes any adverse effects. This drug is pregnancy category C.

Gatifloxacin (Zymar, Zymaxid): Once available by the oral and parenteral routes, gatifloxacin is now approved only as an ophthalmic solution for the treatment of bacterial conjunctivitis. The most frequently reported adverse reactions

after ophthalmic administration include increased worsening of conjunctivitis, eye irritation, dysgeusia, and eye pain. Patients should be advised to discontinue use of contact lenses during therapy. This drug is pregnancy category C.

Gemifloxacin (Factive): Gemifloxacin was approved in 2003 for acute bacterial exacerbations of chronic bronchitis and community-acquired pneumonia. It is more effective against gram-positive bacteria, most importantly *S. pneumoniae* and *S. aureus*, than many other drugs in this class. To reduce the development of drug-resistant strains, the manufacturer recommends that gemifloxacin be used to treat only infections proven susceptible to the drug. Available PO, the drug undergoes minimal metabolism by the liver and is excreted almost equally by the kidneys and in the feces. Diarrhea, rash, and nausea are the most common adverse effects. It is contraindicated in patients with certain dysrhythmias, due to its effects on cardiac conduction. Other contraindications and adverse effects (including the black box warning) are similar to those of ciprofloxacin. This drug is pregnancy category C.

Levofloxacin (Levaquin): Approved in 1996, levofloxacin is prescribed for UTI, acute pyelonephritis, chronic bacterial prostatitis, hospital-acquired and community-acquired pneumonia, acute bacterial sinusitis, acute bacterial exacerbation of chronic bronchitis, skin infections, and bacterial conjunctivitis. It is available for PO, IV, and ophthalmic (Iquix, Quixin) administration. Levofloxacin has a long half-life that allows for once-daily dosing. The most common adverse effects are nausea, headache, diarrhea, insomnia, constipation, and dizziness. Adverse effects of ophthalmic levofloxacin include transient blurred vision, foreign body sensation, headache, burning, pharyngitis, and photophobia. Caution should be used for patients with certain dysrhythmias, due to its effects on cardiac conduction. Although rare, hematologic toxicity, including agranulocytosis and thrombocytopenia, and nephrotoxicity may occur after multiple doses. Other contraindications and adverse effects for the oral and IV forms (including the black box warning) are the same as those of ciprofloxacin. This drug is pregnancy category C.

Moxifloxacin (Avelox, Moxeza, Vigamox): Approved in 1999, moxifloxacin is prescribed for skin infections, intra-abdominal infections, community-acquired pneumonia, acute sinusitis, and acute bacterial exacerbation of chronic bronchitis. It is available by the oral and IV routes and as an ophthalmic preparation (Moxeza, Vigamox) for bacterial conjunctivitis. The most common adverse effects are dizziness, diarrhea, nausea, and vomiting. For the ophthalmic drops, eye irritation, pyrexia, and conjunctivitis are the common adverse effects. Like gemifloxacin, it is contraindicated in patients with certain dysrhythmias, due to its effects on cardiac conduction. Other contraindications and adverse effects for the oral and IV forms (including the black box warning) are the same as those of ciprofloxacin. This drug is pregnancy category C.

CONNECTIONS: Patient Safety

Levofloxacin (Levaquin)

Yesterday, Mrs. Rackey received the first dose of IV levofloxacin (Levaquin). While receiving the medication, she reported itching and a slight swelling of the tongue and lips (angioedema). However, later that day she had no discomfort or presence of the previous symptoms. She will receive the second dose of the medication again this morning. What should the nurse do?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Ofloxacin: Approved in 1990, ofloxacin is indicated for acute bacterial exacerbations of chronic bronchitis, community-acquired pneumonia, chlamydial infections of the reproductive tract, acute pelvic inflammatory disease, cystitis, complicated UTI, prostatitis, superficial ocular infections (ophthalmic solution), and otitis media (otic solution). The most common adverse effects are nausea, headache, insomnia, dizziness, and rash. The otic preparation can cause otic pruritus. Other contraindications and adverse effects for the oral and IV forms (including the black box warning) are the same as those of ciprofloxacin. It is available for the PO, IV, ophthalmic, and otic routes. This drug is pregnancy category C.

Miscellaneous Antibacterials

49.4 A number of miscellaneous antibacterials have specific clinical indications.

Several drugs act by miscellaneous mechanisms or are the only drugs in their class. Doses for the miscellaneous drugs are listed in Table 49.3.

Daptomycin (Cubicin): Approved in 2003, daptomycin belongs to a class of antibiotics known as the cyclic lipopeptides. The spectrum of activity of daptomycin includes a wide variety of gram-positive pathogens. It is indicated for the treatment of complicated skin infections caused by organisms such as *S. aureus*, including methicillin-resistant *S. aureus* (MRSA), *Streptococcus pyogenes*, and *Enterococcus faecalis* (vancomycin-susceptible strains only). Daptomycin is bactericidal and its mechanism of action is clearly distinct from that of any other antibiotic. When binding to bacterial membranes, daptomycin causes a rapid depolarization of membrane potential, leading to inhibition of protein, DNA, and ribonucleic acid (RNA) synthesis. It is given only by IV infusion. The most clinically significant adverse effects are abnormal liver function tests, elevated creatine phosphokinase (CPK), dyspnea, and pneumonia. Myopathy has been recorded in a small percentage of patients taking daptomycin; therefore, the nurse should carefully monitor for muscle pain or weakness. The drug

Table 49.3 Miscellaneous Antibacterials

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
daptomycin (Cubicin)	IV: 4–6 mg/kg once q24h for 7–14 days	*Insomnia, diarrhea, headache, abnormal liver function tests, elevated CPK, edema* Anaphylaxis, superinfections, renal failure, myopathy, jaundice, PMC
metronidazole (Flagyl)	Anaerobic infections: PO: 7.5 mg/kg q6h (max: 4 g/day) IV loading dose: 15 mg/kg IV maintenance dose: 7.5 mg/kg q6h (max: 4 g/day)	*Dizziness, headache, anorexia, abdominal pain, metallic taste and nausea,* Candida *infections* Seizures, peripheral neuropathy, leukopenia
polymyxin B	IV: 15,000–25,000 units/kg/day divided q12h IM: 25,000–30,000 units/kg/day divided q4–6h	*Urticaria* Nephrotoxicity, neurotoxicity (confusion, blurred vision, paresthesias, paralysis), superinfections
rifampin (Rifadin, Rimactane)	PO/IV: 600 mg/day	*Nausea, vomiting, heartburn, anorexia, diarrhea, orange discoloration of the urine, sweat, and tears* PMC, renal failure, hepatotoxicity, blood dyscrasias
telithromycin (Ketek)	PO: 800 mg once daily	*Nausea, diarrhea, dizziness, headache, blurred vision* Superinfections, PMC, hepatotoxicity, dysrhythmias, respiratory failure, loss of consciousness

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

should be withheld if the CPK becomes elevated above 1000 units/L. This drug is pregnancy category B.

Metronidazole (Flagyl): Metronidazole is an older antiinfective, approved in 1963, that is effective against a large number of anaerobes. It acts by interfering with the DNA and RNA synthesis of pathogens. Metronidazole is one of only a few drugs that have dual activity against both bacteria and multicellular parasites. It is a preferred drug for trichomoniasis, giardiasis, and amebiasis. Unlike most antibiotics, resistance to metronidazole is uncommon. When given orally, adverse effects are generally minor and include nausea, dry mouth, and headache. High doses can produce neurotoxicity.

As an antibacterial, metronidazole has two indications: serious infections due to anaerobic bacteria, and peptic ulcer disease. Few antibacterials are effective against anaerobes because the organisms reside in sites that have tissue destruction and a poor blood supply. Anaerobic bacteria are common causes of abscesses, gangrene, diabetic skin ulcers, and deep wound infections. Serious intra-abdominal infections or septicemia due to *Bacteroides* and streptococci often respond well to IV infusions of the drug. It is a preferred drug for managing CDAD. Metronidazole has found a relatively new use in the treatment of *Helicobacter pylori* infections of the stomach associated with peptic ulcer disease. The drug carries a black box warning that it causes cancer in laboratory animals. Metronidazole is featured as a prototype drug in Chapter 53. This drug is pregnancy category B.

Polymyxin B: Approved in 1951, polymyxin B is an older, bactericidal drug that acts by disrupting the bacterial cell membrane. The drug is able to penetrate the phospholipid layer, make the membrane leaky, and cause the death of the bacterium. Although parenteral formulations are available, polymyxin B is rarely prescribed by these routes due to potential nephrotoxicity and neurotoxicity (black box warnings). Its primary application is in the treatment of topical infections of the skin, mucous membranes, or eye, caused by gram-negative organisms. It is not effective against gram-positive microbes. It is combined with bacitracin and neomycin in common OTC first aid products such as Neosporin Ointment, Bactine Antibiotic, and Polysporin. Topical application, including to denuded skin, results in negligible systemic absorption. Polymyxin B is combined with neomycin and hydrocortisone in prescription otic preparations. Topical polymyxin B is pregnancy category B.

Rifampin (Rifadin, Rimactane): Approved in 1958, rifampin is administered PO or IV and is usually associated with the pharmacotherapy of tuberculosis. The drug, however, is effective against a wide range of both gram-positive and gram-negative organisms. As an antibacterial, it is used for prophylaxis in contacts of patients with *Haemophilus influenzae* type B and for the prophylaxis of asymptomatic carriers of meningococcal disease. Occasionally, it is used for Legionnaire's disease, or when therapy with other antibiotics is unsuccessful. The reason its applications are limited is because of the rapid development of resistance, which can appear after only a few days of therapy. A flulike syndrome develops in about half the patients receiving the drug. Rifampin acts by inhibiting bacterial RNA polymerase, the enzyme that makes bacterial RNA. The use of rifampin in the pharmacotherapy of tuberculosis is presented in Chapter 51. This drug is pregnancy category C.

Telithromycin (Ketek): In 2004, the FDA approved telithromycin for respiratory infections, the first in a class of antibiotics known as the ketolides. Telithromycin blocks bacterial protein synthesis by binding to two different sites on the 50S ribosomal subunit. Telithromycin is an oral drug, with the most common adverse effects being diarrhea, nausea, and headache. The primary indication for this drug is community-acquired pneumonia due to *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, or *Mycoplasma pneumoniae*. When post–market surveillance discovered several cases of hepatic failure in patients receiving this drug, the FDA withdrew its approval for the treatment of acute bacterial sinusitis and acute bacterial exacerbation of chronic bronchitis. Hepatic function tests must be monitored during therapy. Telithromycin has the potential to prolong the QT interval, which represents an increased risk for ventricular dysrhythmias. The drug may cause mild to moderate visual disturbances, including blurred vision, diplopia, and difficulty focusing. Telithromycin carries a black box warning that it should not be used in patients with myasthenia gravis because fatal respiratory depression may occur. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Fluoroquinolones

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including neurologic, cardiovascular, respiratory, hepatic, or renal disease, myasthenia gravis, and the possibility of pregnancy. Assess for previous organ transplantation surgery. Obtain a drug history including allergies, noting specific reactions to drugs, current prescriptions, particularly corticosteroids, and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Assess signs and symptoms of current infection noting location, characteristics, presence or absence of drainage and character of drainage, duration, and presence or absence of fever or pain.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], culture and sensitivity [C&S], urinalysis, and hepatic function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished signs and symptoms of infection and fever).
- Continue periodic monitoring of CBC, C&S, and hepatic function as ordered.
- Assess for adverse effects: nausea, vomiting, abdominal cramping, diarrhea, headache, calf or ankle pain, weakness, numbness, or dizziness. Severe diarrhea, especially containing mucus, blood, or pus, or decreased urine output should be reported immediately.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Fever, pain, or signs and symptoms of infection should begin to diminish after taking the first dose and continue to improve.)	• Teach the patient to complete the entire course of the antibacterial therapy; do not share doses with other family members with similar symptoms; and return to the provider if symptoms have not resolved after an entire course of therapy. • Teach the patient to notify the provider if fever and signs and symptoms of infection increase after 3 days.
Minimizing adverse effects: • Continue to monitor vital signs, especially temperature if fever is present. Immediately report undiminished fever, changes in level of consciousness (LOC), or febrile seizures to the healthcare provider. (Continued fever may be a sign of worsening infection, adverse drug effects, or antibiotic resistance.)	• Teach the patient to report fever that does not diminish below 37.8°C (100°F) or per parameters set by the healthcare provider. Immediately report febrile seizures, changes in behavior, or changes in LOC to the provider.
• Continue to monitor periodic laboratory work: renal function tests, CBC, urinalysis, and C&S as ordered. (Fluoroquinolones may be nephrotoxic. Periodic C&S tests may be ordered if infections are severe or are slow to resolve to confirm appropriate therapy.)	• Instruct the patient on the need for periodic laboratory work.
• Monitor for hypersensitivity and allergic reactions, especially with the first dose of the drug. Continue to monitor the patient for up to 2 weeks after completing antibacterial therapy. (Anaphylactic reactions are possible, particularly with the first dose of an antibacterial. Post-use, residual drug levels may cause delayed reactions, dependent on the length of half-life.)	• Teach the patient to immediately report any itching, rashes, or swelling, particularly of the tongue or face, urticaria, flushing, dizziness, syncope, wheezing, throat tightness, or difficulty breathing. • Instruct the patient with known antibacterial allergies to carry a wallet identification card or wear medical identification jewelry indicating the allergy.
• Continue to monitor for nephrotoxicity, e.g., diminished urine output, or weight gain greater than 1 kg (2 lb) in 24 h. (Fluoroquinolones may require frequent monitoring to prevent adverse effects. Increasing fluid intake will help prevent drug accumulation in the kidneys. **Lifespan:** Age-related physiologic differences may place the young child or older adult at greater risk for nephrotoxicity.)	• Teach the patient to immediately report any diminished urine output, visible swelling of feet or ankles, or weight gain greater than 1 kg (2 lb) in 24 h. • Advise the patient to increase fluid intake to 2–3 L/day.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor for development of superinfections, e.g., CDAD or PMC, fungal, or yeast infections. (Superinfections with opportunistic organisms may occur when normal host flora are diminished or killed by the antibacterial drug and no longer hold pathogens in check. Severe diarrhea may indicate the presence of CDAD or PMC, superinfections caused by *C. difficile*.)	• Instruct the patient to report any diarrhea that increases in frequency, amount, or contains mucus, blood, or pus. • Instruct the patient to consult the healthcare provider before taking any antidiarrheal drugs, which cause the retention of harmful bacteria. • Teach the patient to observe for changes in stool, white patches in the mouth, whitish thick vaginal discharge, itching in the genital area, blistering itchy rash, and to immediately report severe diarrhea. • Teach the patient infection control measures such as frequent hand hygiene, adequate drying after showering or bathing, and to increase the intake of live-culture dairy foods.
• Monitor for signs and symptoms of neurotoxicity, e.g., dizziness, severe headache, seizures, peripheral numbness, or paresthesia. (Fluoroquinolones have an increased risk of neurotoxicity. Previous seizure disorders or head injuries may increase this risk. Persistent or increasing headaches should be immediately reported. Peripheral neuropathies may be permanent. **Lifespan:** Be particularly cautious with the older adult who is at greater risk for falls.)	• Instruct the patient to immediately report persistent or increasing headache, dizziness, seizures, or numbness or tingling of the hands or feet. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Monitor for joint, tendon, leg, or heel pain, or difficulty with movement or walking in patients on fluoroquinolones. (Fluoroquinolones have been associated with tendinitis and tendon rupture, especially of the Achilles tendon. **Lifespan:** Be particularly cautious with the older adult, who is at greater risk for tendinitis and tendon rupture.)	• Instruct the patient to immediately report any significant or increasing joint, tendon, heel, lower leg or calf pain, or difficulty moving or walking to the healthcare provider.
• Monitor for anticoagulation effects if the patient is on warfarin. (Fluoroquinolones decrease the metabolism of warfarin and may increase anticoagulation effects and risk of bleeding.)	• Teach the patient to report any increase in bruising or bleeding while on warfarin. More frequent laboratory work may be needed.
• Continue to monitor for dermatologic effects including red or purplish skin rash, blisters, or sunburning. Immediately report severe rashes, especially associated with blistering. (Fluoroquinolones may cause significant dermatologic effects including Stevens–Johnson syndrome. Sunscreens and protective clothing should be used to prevent photosensitivity and photoallergic reactions.)	• Teach the patient to wear sunscreen and protective clothing for sun exposure and to avoid tanning beds. Immediately report any severe sunburn or rashes.
Patient understanding of drug therapy: • Use opportunities during administration of the medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering medications, instruct the patient, family, or caregiver in proper self-administration techniques followed by teach-back. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication as follows:
	  • Complete the entire course of therapy unless otherwise instructed. Do not share with other family members and do not stop the medicine when starting to feel better.
	  • Take the drug with food but avoid taking the drug concurrently with dairy products or calcium-fortified juices, which may decrease absorption. Take the fluoroquinolone 1 h before or 2 h after consuming these products.
	  • Do not take antacids or preparations containing iron or zinc at the same time as the fluoroquinolones dose.
	  • Avoid excess consumption of beverages or foods containing caffeine, which may increase the chance of nervousness or anxiety.
	  • Take the medication as evenly spaced throughout each day as feasible.
	  • Increase overall fluid intake while taking the antibacterial drug.
	  • Discard outdated medications or those no longer in use. Review the medicine cabinet twice a year for old medications (e.g., at beginning and end of daylight saving time).

Understanding Chapter 49

Key Concepts Summary

49.1 Bacterial DNA replication requires several different enzymes to uncoil, unwind, and duplicate the DNA.

49.2 Drugs have been discovered that inhibit different steps in bacterial DNA replication.

49.3 Fluoroquinolones are antibiotics whose therapeutic applications have expanded in recent years to treat many gram-positive and gram-negative infections.

49.4 A number of miscellaneous antibacterials have specific clinical indications.

CASE STUDY: Making the Patient Connection

Remember the patient "Mike Springs" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Mike Springs presents to the local health clinic. He is a 38-year-old man who has no history of chronic illness. His vital signs are normal with the exception of a slight increase in body temperature, 37.3°C (99.2°F). He denies shortness of breath. However, his nasal passages are congested, causing him to "mouth breathe." Until this most recent illness, Mike had started efforts toward a healthier lifestyle and weight reduction. Mike is now jogging for exercise and taking vitamin tablets. He is diagnosed with acute sinusitis, and the healthcare provider orders ciprofloxacin PO 500 mg twice daily for 10 days. Additional medications prescribed include a nasal decongestant and a mild analgesic.

As Mike is leaving the health clinic, he comments that he is responsible for multiple corporate offices and will soon be traveling. He is worried about remembering to take the medication and admits to a history of nonadherence to therapy regimens because he sometimes forgets to take medications.

Critical Thinking Questions

1. Prepare a patient teaching handout for Mike that provides him with information about the antibiotics he is being prescribed.
2. Mike asks you, the nurse, if he should continue jogging and taking vitamins. What would you advise?
3. What tips can you provide someone who forgets to take scheduled medication?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Carolyn Ijams is doing her spring cleaning. As she is arranging the contents of her medicine cabinet, she notices a bottle of ciprofloxacin ophthalmic drops that is about half-used. She wonders whether she should keep it and asks you, the nurse who lives next door, what she should do.

1. Should Carolyn keep the ciprofloxacin drops? What would you want to know before making a recommendation?
2. What would you teach Carolyn about the use of ophthalmic drops such as the ciprofloxacin?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is prescribed ciprofloxacin (Cipro) and is instructed to take each dose of medication as evenly spaced apart during the day as possible. The nurse recognizes that this instruction is essential because:
   1. The medication can cause sleep pattern disturbances.
   2. Pathogenic bacteria have extremely rapid growth and reproduction rates.
   3. Superinfections may develop if a dose of the medication is missed.
   4. Allergic reactions are more likely to occur if a dose is missed.

2. The patient is prescribed ofloxacin (Floxin) for treatment of acute bronchitis. The patient tells the nurse that he experienced an allergic reaction when he took ciprofloxacin (Cipro) previously. As reported by the patient, which of the following would be most indicative of an allergic reaction to this drug group? (Select all that apply.)
   1. Headache
   2. Nausea and vomiting
   3. Itching without visible rash
   4. Swelling of lips or tongue
   5. Nervousness or anxiety

3. The nurse is instructing a patient on a new prescription for ciprofloxacin (Cipro) and will include which instructions? (Select all that apply.)
   1. Increase fluid intake to 2–3 liters per day.
   2. Avoid consuming dairy products or antacids when you take the antibiotic.
   3. Limit vitamin C intake in both dietary and oral vitamin forms.
   4. Take the pill with an antihistamine to avoid adverse effects.
   5. Coffee or tea without milk, cream, or coffee-lightener is the preferred beverage for taking the antibiotic dose.

4. A patient has been receiving levofloxacin (Levaquin) IV for septicemia for 2 weeks and will be given the drug orally at home. Which discharge instruction would be most appropriate for the nurse to give this patient?
   1. Report any unusual joint or tendon pain or difficulty with movement or walking.
   2. Take a daily multivitamin supplement with the levofloxacin.
   3. Exposure to direct sunlight will help increase absorption of vitamin D, which is impaired by this medication.
   4. Limit fluid intake to less than 1500 mL per day.

5. A patient has been given a prescription for ciprofloxacin (Cipro). The nurse checks the patient's history because this drug should be used cautiously, or is contraindicated, in patients with what condition?
   1. A history of anxiety disorder and nervousness
   2. Patients over the age of 65
   3. A history of penicillin allergy
   4. Patients with myasthenia gravis

6. Which is the most important goal of nursing care for a patient receiving polymyxin B ointment on a laceration?
   1. Promote wound healing.
   2. Sterilize the skin and mucous membranes.
   3. Prevent allergic reaction.
   4. Maximize pain relief.

Chapter 50
Sulfonamides and the Pharmacotherapy of Urinary Tract Infections

Chapter Outline

- Pathophysiology of Urinary Tract Infections
- Pharmacotherapy of Urinary Tract Infections
- Sulfonamides

  PROTOTYPE *Trimethoprim-Sulfamethoxazole (Bactrim, Septra), p. 907*
- Urinary Antiseptics

  PROTOTYPE *Nitrofurantoin (Furadantin) and Nitrofurantoin Macrocrystals (Macrobid, Macrodantin), p. 908*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Classify types of urinary tract infections based on their anatomic location.
2. Explain the epidemiology and pathogenesis of urinary tract infections.
3. Compare and contrast the pharmacotherapy of complicated versus uncomplicated urinary tract infections.
4. Identify the classes of antibiotics used to treat urinary tract infections.
5. Describe modifications in the pharmacotherapy of urinary tract infections for infants and children, pregnant women, older adults, and those with recurring infections.
6. Explain why folic acid inhibitors exert selective toxicity toward bacterial cells.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy for urinary tract infections.

Key Terms

bacteriuria, 901
crystalluria, 906
cystitis, 901
irritative voiding symptoms, 901
para-aminobenzoic acid (PABA), 905
prostatitis, 901
pyelonephritis, 901
urethritis, 901
uropathogens, 901

Urinary tract infections (UTIs) account for an estimated 8 million office visits and 100,000 hospitalizations per year, making them the most common type of bacterial infection. Although antimicrobial therapy of these infections is often straightforward, UTI is becoming a major clinical challenge in this era of increasing antibiotic resistance. This chapter examines the types of patients most likely to acquire a UTI and the anti-infective therapy that is most effective against this disease.

Pathophysiology of Urinary Tract Infections

50.1 Infections can occur in any portion of the urinary tract.

The urinary tract consists of the kidneys, ureters, urinary bladder, and urethra. The male and female urinary tracts are identical, with the exception of the urethra, which is shorter in the female and located closer to the anus. This anatomic difference results in the periurethral region of the female being populated by bacteria that are normally restricted to the gastrointestinal (GI) tract and could cause UTIs. In addition to the male having a longer urethra, the scrotum provides a physical barrier between the urethra and the anus. These anatomic differences result in a higher risk of UTI in females.

The continuous, peristaltic flow of urine from the kidneys, down the ureters, into the bladder, and voiding through the urethra provide formidable barriers to harmful microorganisms, or **uropathogens**, attempting to invade the urinary system. Although it is indeed difficult for uropathogens to go against the flow of urine and reach beyond the proximal portion of the urethra, this is the means by which the large majority of UTIs are acquired. Infections that travel from the urethra to the bladder or kidney are known as retrograde or ascending infections. The most successful uropathogens are those that secrete sticky adhesion proteins or that have structures called fimbriae that allow them to adhere to the epithelial lining of the urinary tract. Occasionally, pathogens traveling through the blood can infect the kidney. This mode of infection is called the hematogenous route and is responsible for about 5% of all UTIs.

Any portion of the urinary tract may be infected by uropathogens. Infection of the urethra, or **urethritis**, presents as discomfort during voiding and occurs in both men and women. It is usually distinguished from a bladder infection, or **cystitis**, because it causes less voiding urgency than cystitis and has a more gradual onset of symptoms. Urethritis is often a sign of a sexually transmitted infection.

A cluster of complaints known as **irritative voiding symptoms** accompanies cystitis. Occurring in both men and women, symptoms include dysuria and increased voiding urgency and frequency. Despite the increased urgency and frequency, only small volumes of urine are voided during each attempt. During and immediately following voiding, burning or aching may occur. The patient may have suprapubic tenderness upon palpation. Urinalysis usually identifies the presence of an offending uropathogen, or **bacteriuria**, as well as other signs of infection such as pyuria, hematuria, and changes in urine pH, nitrites, or proteins.

In women, symptoms of cystitis are frequently reported following intercourse with a new sexual partner. In men, cystitis is likely to occur following anal intercourse. Cystitis in men may be accompanied by acute **prostatitis**. Normally recognized by palpating the prostate, which will be tender during manual examination, prostatitis may include fever and has the potential to cause urinary obstruction as the prostate swells.

Bacteria that ascend the ureter and reach the kidney can cause **pyelonephritis**, an inflammation of the kidney, pelvis, and other renal cells. Irritative voiding symptoms occur, along with other signs similar to cystitis. More severe symptoms are manifested as nausea, vomiting, fever, chills, and acute costovertebral angle and flank tenderness. Because acute pyelonephritis may lead to shock, aggressive anti-infective therapy may be required.

Pharmacotherapy of Urinary Tract Infections

50.2 Choice of pharmacotherapy for acute urinary tract infection depends on the severity of the infection and the presence of comorbid conditions.

In addition to describing UTIs by their location, these infections are also classified as complicated or uncomplicated. The classification is an important clinical distinction

because the pharmacotherapy for complicated UTI and uncomplicated UTI is quite different.

Acute Uncomplicated Cystitis

Acute uncomplicated cystitis (AUC) occurs in patients who have no serious or chronic health disorders that might impact the spread of the uropathogen or the treatment of the UTI. These infections occur mostly in women of reproductive age, with the highest incidence occurring from 18 to 24 years of age. Adult men rarely have AUC. Common risk factors for AUC include the following:

- Frequent sexual activity
- Use of spermicides for contraception
- Use of a diaphragm for contraception
- Estrogen deficiency.

In many cases, a diagnosis of AUC is made by the healthcare provider based on symptoms and history alone, without additional serologic or urinary testing. Women who have experienced a prior AUC are often able to self-diagnose. Rapid dipstick tests are available to examine for the presence of infection. *Escherichia coli* is the most common causative agent for AUC, being responsible for 80% to 90% of UTIs. *Staphylococcus saprophyticus* is isolated in about 10% to 15% of the cases. The most frequent uropathogens are listed in Table 50.1. Follow-up of AUC is usually by routine office visit; no additional testing or cultures are required if the symptoms promptly resolve.

Most patients with AUC begin pharmacotherapy immediately, prior to receiving the results of a urinalysis confirming the specific pathogen. The selection of an initial antibiotic and duration of therapy vary among healthcare providers. The choice may be customized to an institution or community, based on local antibiotic resistance patterns and practitioner experience. Single-dose or short-course therapy is preferred for patient convenience and to maximize adherence.

Asymptomatic bacteriuria is frequently discovered on a routine urinalysis: Estimates range from 1% to 2% of young adult women to as high as 60% of women over age 60. In general, asymptomatic bacteriuria is not treated with medications because very few of these patients will progress to symptomatic UTI. Widespread therapy would be costly and increase the number of resistant strains in the community. Certain populations of patients, however, are treated when asymptomatic bacteriuria is discovered. These include pregnant women, those undergoing urologic procedures, and patients who are immunosuppressed or in otherwise poor health.

Three drug regimens are considered first-line therapy for AUC. The traditional choice is trimethoprim-sulfamethoxazole (TMP-SMZ), a fixed-dose combination drug that is featured as a prototype in Section 50.4. Given as a 3-day regimen, TMP-SMZ is effective at eliminating most of the common species of uropathogens. The occurrence of many resistant strains, however, has begun to limit its use as a first-line drug.

In communities where TMP-SMZ resistance is high (over 20%), a urinary antiseptic such as nitrofurantoin taken for 5 to 7 days is effective. Nitrofurantoin is featured as a prototype in Section 50.5. If adherence is an issue, a single dose of fosfomycin (Monurol) has proven effective for many patients. Fosfomycin blocks cell wall synthesis, and its only indication is UTI.

An equally effective therapy for AUC is a 3-day regimen with a fluoroquinolone. An extended release form of ciprofloxacin (Cipro XR, Proquin XR) permits once-daily dosing. Other fluoroquinolones useful in treating AUC include norfloxacin (Noroxin), ofloxacin (Floxin), and levofloxacin (Levaquin). Fluoroquinolones are usually reserved for complicated UTIs but they have become preferred drugs for AUC in some communities because of the appearance of sulfonamide-resistant strains. Additional details about the fluoroquinolones are presented in Chapter 49.

Table 50.1 Most Common Uropathogens

Uncomplicated UTI	Complicated UTI
E. coli	*E. coli*
S. saprophyticus	Enterobacteriaceae
Klebsiella	*Klebsiella*
Proteus mirabilis	Group B streptococci
Enterobacter	*Enterococcus*
	Pseudomonas
	Proteus mirabilis

CONNECTION Checkpoint 50.1

From what you learned in Chapter 49, what black box warning accompanies the oral and parenteral fluoroquinolones? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Complicated Urinary Tract Infection

Complicated urinary tract infections (C-UTIs) are defined as infections that occur in a patient who has an underlying comorbid condition that increases the risk of treatment failure. C-UTIs may require aggressive pharmacotherapy, often involving more toxic drugs, higher doses, or prolonged therapy. Comorbid conditions include the following:

- Structural or functional abnormalities in the genitourinary tract such as neurogenic bladder, benign prostatic hyperplasia (BPH), renal tumor, or urinary stones
- Indwelling urinary catheters
- Older patients with generally ill health

- Recurring urinary infections
- Identification of resistant uropathogens
- Patients with poor toileting or periurethral hygiene
- All UTIs in men.

Although nearly all uncomplicated UTIs are caused by *E. coli* and *S. saprophyticus*, C-UTIs are caused by a wider variety of uropathogens (see Table 50.1). Hospital-acquired C-UTIs are sometimes caused by organisms such as *Klebsiella*, *Enterobacter*, *Proteus*, and *Pseudomonas*. When treating C-UTIs, a urine culture should be obtained to identify the specific microbe and the most effective antibiotic based on culture and sensitivity (C&S) testing. Therapy is sometimes begun with a broad-spectrum anti-infective, then adjusted based on C&S results. Patients who have mild or moderate C-UTIs can be treated with the same medications used for AUC: fluoroquinolones, TMP-SMZ, or nitrofurantoin (Furadantin, Macrobid, Macrodantin). A newer treatment approved in 2017 is Vabomere, a combination that contains meropenem and vaborbactam, a beta-lactamase inhibitor. Therapy for C-UTI is often continued for 14 days to be certain that all uropathogens have been eliminated. Severe disease requires hospitalization with parenteral administration of fluoroquinolones, aminoglycosides, cephalosporins, or ampicillin, depending on the sensitivity of the microbe. Follow-up urine cultures are performed several weeks after completion of therapy to ensure that the uropathogen has been eliminated.

PharmFACT

Although men have a much lower overall incidence of UTI than women, the presence of prostatic hyperplasia or catheterization in men over age 50 dramatically increases the risk of UTI (Brusch, 2016).

50.3 Infants, children, pregnant women, older adults, and those with recurring urinary tract infections require modifications to standard pharmacotherapy.

Certain populations require special consideration when selecting and initiating a course of pharmacotherapy to treat UTI. These include infants, children, pregnant women, older adults, and those with recurring infections.

Infants and Children

Although UTIs occur most frequently in sexually active adult women, they are also relatively common in infants and children. More than 2% of boys have a UTI before 12 months of age, a higher percentage than girls of the same age. As many as 3% of all girls and 1% of boys experience a UTI during their school-age years. A concern with pediatric patients is that repeated UTIs may cause scarring of the kidneys, resulting in hypertension later in life. With this possibility in mind, healthcare providers have a goal of preventing recurring infections in children.

As in adults, *E. coli* causes most pediatric UTIs. Therapeutic options, however, are more limited in children. TMP-SMZ and nitrofurantoin are effective in children. However, fluoroquinolones are contraindicated in children under age 18 because they have been found to affect cartilage development. The safety and efficacy of fosfomycin has not been established in children younger than 12 years old. Recurring UTIs in infants and children may require prolonged, prophylactic antibiotic therapy.

Pregnancy

During pregnancy, the enlarging uterus creates pressure on the urinary bladder, which increases the size of the ureters and promotes urinary stasis and reflux. UTIs in pregnant women are a risk factor for prematurity and newborn low birth weight. In addition, pyelonephritis is one of the most frequent reasons for hospitalization during pregnancy.

Urinary screening is routinely performed by the 16th week of pregnancy. Discovery of high levels of bacteria in the urine is an indication for antimicrobial therapy, even if the patient is asymptomatic at the time of testing. A follow-up culture is performed 1 to 2 weeks after therapy is completed. Continued asymptomatic bacteriuria is predictive of the development of symptomatic UTI later in pregnancy. Therapy for asymptomatic bacteriuria is continued until cultures are negative, or until delivery.

During pregnancy, C&S testing is generally conducted to identify the appropriate antibiotic. Pharmacotherapy, however, is limited to drugs that are pregnancy category B, unless the patient is gravely ill. Category B drugs include cephalosporins, ampicillin, and nitrofurantoin. Ceftriaxone (Rocephin) is sometimes a preferred drug. Fluoroquinolones are contraindicated during pregnancy due to possible growth inhibition in the fetus, and TMP-SMZ is contraindicated during the first trimester. Asymptomatic patients are sometimes given a shorter treatment of 1 to 3 days, whereas those with clear symptoms of UTI receive a 7-day regimen.

CONNECTION Checkpoint 50.2

From what you learned in Chapter 47, if a pregnant patient has a history of allergy to ampicillin, should the nurse administer a cephalosporin such as ceftriaxone for UTI? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Older Adults

UTIs are common in the geriatric population, especially for those in long-term care (LTC) facilities. Factors that predispose older adults to UTI are BPH, increased postvoid residual urine, and urinary incontinence. Residents of LTC

facilities may have chronic diseases that require the use of indwelling catheters or IV lines. The large percentage of patients receiving antibiotics in these facilities promotes the emergence of multidrug-resistant strains, which can be difficult to eliminate in the LTC setting.

Pharmacotherapy in the geriatric population is conducted in the same manner as for younger adults, if the patient is otherwise healthy. Asymptomatic bacteriuria is generally not treated unless the patient has an underlying comorbid condition. Asymptomatic bacteriuria is present in 30% to 50% of older adults, and such widespread therapy would promote the emergence of resistant strains.

Older adults in generally poor health and those with a comorbid condition receive more aggressive pharmacotherapy. These patients may exhibit atypical symptoms, such as altered mental status, sudden incontinence, nausea, or vomiting. If immunosuppressed, an antibiotic may be prescribed for prophylaxis against pneumonia, UTIs, and skin and soft tissue infections, which are the three most common infections in LTC facilities. Because of the prevalence of resistant strains, patients in an LTC setting with symptomatic UTI should undergo C&S testing to determine the most effective course of therapy. Pharmacotherapy may be prolonged and continue until urine cultures are negative.

By providing a direct route of entry to the bladder for uropathogens, catheter-associated UTI is one of the common hospital-acquired infections. Because the risk of infection increases over time, the catheter should be removed as soon as feasible. Patients with catheters should be carefully monitored for signs of UTI. Periodic urinalysis testing should be conducted to check for bacteriuria. A positive urine culture, with or without urinary tract symptoms, is an indication for removal of the catheter (if feasible) and initiation of pharmacotherapy.

Patients with Recurring Urinary Tract Infections

One in five patients with a UTI will experience a subsequent UTI within 6 months. Recurring UTIs are classified as either relapses or reinfections. A *relapse* occurs when the patient experiences a second UTI within 2 weeks after completing pharmacotherapy for the original infection. Normally, a relapse is caused by failure of the initial treatment to totally eliminate the uropathogen. A *reinfection* occurs when the patient recovers from the original infection but acquires another infection weeks or months later. Reinfections may be caused by the original microbe or by a different uropathogen.

Recurrent UTIs require extended antimicrobial therapy, either with the original antibiotic or with a different medication. It is necessary to identify the pathogen in order to examine for resistant strains.

Women who experience two or more UTIs within 6 months, or three or more UTIs over the course of a year, are candidates for prophylactic therapy. Choices for prophylaxis include administration of antibiotics at low doses either on a daily or three-times-per-week schedule. Another option is to allow the woman to initiate therapy herself. With this type of treatment, the patient is provided with a single-dose or 3-day course of therapy, which is initiated by the woman after each act of coitus, or when symptoms first develop. Patients should be advised to see their healthcare provider if symptoms worsen, or if they do not resolve during prophylactic therapy, because this may be a sign of a more serious infection.

Sulfonamides

50.4 Sulfonamides are the traditional preferred drugs for urinary tract infections, but resistance limits their usefulness.

The discovery of the sulfonamides, also called sulfa drugs, in the 1930s heralded a new era in the treatment of infectious disease. Effective against both gram-positive and gram-negative bacteria, the sulfonamides significantly reduced mortality from susceptible microbes and earned its discoverer a Nobel Prize in medicine in 1938. Doses for the sulfonamides are listed in Table 50.2.

Sulfonamides are active against a broad spectrum of microorganisms including some staphylococci, many streptococci (except *Enterococcus faecalis*), *Haemophilus influenzae*, *Nocardia*, most Enterobacteriaceae, *Neisseria*, and *Chlamydia*. Sulfonamides have also been used to treat mycobacterial infections and some protozoans such as *Toxoplasma gondii*. Drugs in this class are also given for treatment and prophylaxis of *Pneumocystis jiroveci* pneumonia and *Shigella* infections of the small bowel. The nurse should keep in mind that although these drugs are approved by the U.S. Food and Drug Administration (FDA) to treat many different species of bacteria, the sensitivity of specific strains to sulfonamides in a particular community setting must be confirmed, due to widespread resistance.

Sulfonamides suppress bacterial growth by inhibiting the synthesis of folic acid, or folate. In human physiology, folic acid is a water-soluble vitamin that serves a critical role as a coenzyme in the synthesis of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). But if folic acid is essential to both humans and bacteria, why are the sulfonamides not acutely toxic to humans? The answer lies in differences in the metabolic pathways in humans and bacteria.

Humans must obtain "premade" folic acid by eating foods rich in this vitamin. Humans are unable to synthesize this essential nutrient "from scratch." Bacteria, on the other hand, make their own folic acid using simpler precursor molecules. The basic steps in this pathway are shown in Figure 50.1. Sulfonamides inhibit the enzyme in step 1; the

Table 50.2 Drugs Used for Urinary Tract Infections

Drug	Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Sulfonamides		
silver sulfadiazine	Topical: Apply 1% cream 1–2 times per day to burn wounds to a thickness of 1.5 mm	*Nausea, vomiting, anorexia, rash, crystalluria* Anaphylaxis, Stevens–Johnson syndrome (SJS), blood dyscrasias, fulminant hepatic necrosis, hyperkalemia
sulfadiazine	PO: Loading dose: 2–4 g Maintenance dose: 2–4 g/day in four to six divided doses	
sulfadoxine-pyrimethamine (Fansidar)	PO: 1 tablet weekly (500 mg sulfadoxine, 25 mg pyrimethamine)
