Fourth Edition

Pharmacology

Connections to Nursing Practice

Michael Patrick Adams
Carol Quam Urban
Rebecca E. Sutter

Brief Contents

Unit 1 Fundamental Principles of Pharmacology

1 Introduction to Pharmacology: Concepts and Connections 2
2 Drug Regulations 13
3 Pharmacokinetics 26
4 Pharmacodynamics 45
5 Adverse Drug Effects and Drug Interactions 55
6 Medication Errors and Risk Reduction 70
7 The Role of Complementary and Alternative Therapies in Pharmacotherapy 84

Unit 2 Pharmacology and the Nurse–Patient Relationship

8 Pharmacotherapy During Pregnancy and Lactation 98
9 Pharmacotherapy of the Pediatric Patient 110
10 Pharmacotherapy of the Geriatric Patient 123
11 Individual Variations in Drug Responses 133

Unit 3 Pharmacology of the Autonomic Nervous System

12 Review of Neurotransmitters and the Autonomic Nervous System 142
13 Cholinergic Agonists 155
14 Cholinergic Antagonists 170
15 Adrenergic Agonists 185
16 Adrenergic Antagonists 201

Unit 4 Pharmacology of the Central Nervous System

17 Review of the Central Nervous System 218
18 Pharmacotherapy of Anxiety and Sleep Disorders 227
19 Pharmacotherapy of Mood Disorders 253
20 Pharmacotherapy of Psychoses 281
21 Pharmacotherapy of Degenerative Diseases of the Central Nervous System 304
22 Pharmacotherapy of Seizures 330
23 Pharmacotherapy of Muscle Spasms and Spasticity 358
24 Central Nervous System Stimulants and Drugs for Attention-Deficit/Hyperactivity Disorder 375
25 Pharmacotherapy of Severe Pain and Migraines 392
26 Anesthetics and Anesthesia Adjuncts 422
27 Pharmacology of Substance Abuse 447

Unit 5 Pharmacology of the Cardiovascular System

28 Review of the Cardiovascular System 474
29 Pharmacotherapy of Hyperlipidemia 488
30 Pharmacotherapy with Calcium Channel Blockers 510
31 Drugs Affecting the Renin-Angiotensin-Aldosterone System 523
32 Diuretic Therapy and the Pharmacotherapy of Chronic Kidney Disease 539
33 Pharmacotherapy of Fluid Imbalance, Electrolyte, and Acid–Base Disorders 561
34 Pharmacotherapy of Hypertension 582
35 Pharmacotherapy of Angina Pectoris and Myocardial Infarction 602
36 Pharmacotherapy of Heart Failure 622
37 Pharmacotherapy of Dysrhythmias 641
38 Pharmacotherapy of Coagulation Disorders 661
39 Pharmacotherapy of Hematopoietic Disorders 691

Unit 6 Pharmacology of Body Defenses

40 Review of Body Defenses and the Immune System 714
41 Pharmacotherapy of Inflammation and Fever 723
42 Immunostimulants and Immunosuppressants 741
43 Immunizing Agents 762

Unit 7 Pharmacology of the Respiratory System and Allergy

44 Pharmacotherapy of Asthma and Other Pulmonary Disorders 786
45 Pharmacotherapy of Allergic Rhinitis and the Common Cold 810

Unit 8 Pharmacology of Infectious and Neoplastic Diseases

46 Basic Principles of Anti-Infective Pharmacotherapy 834
47 Antibiotics Affecting the Bacterial Cell Wall 848
48 Antibiotics Affecting Bacterial Protein Synthesis 868
49 Fluoroquinolones and Miscellaneous Antibacterials 887
50 Sulfonamides and the Pharmacotherapy of Urinary Tract Infections 900
51 Pharmacotherapy of Mycobacterial Infections 915
52 Pharmacotherapy of Fungal Infections 934
53 Pharmacotherapy of Protozoan and Helminthic Infections 952
54 Pharmacotherapy of Non-HIV Viral Infections 975
55 Pharmacotherapy of HIV Infection and AIDS 996
56 Basic Principles of Antineoplastic Therapy 1020
57 Pharmacotherapy of Neoplasia 1036

Unit 9 Pharmacology of the Gastrointestinal System

58 Review of the Gastrointestinal System 1074
59 Pharmacotherapy of Peptic Ulcer Disease 1082
60 Pharmacotherapy of Bowel Disorders and Other Gastrointestinal Conditions 1103
61 Vitamins and Minerals 1130
62 Enteral and Parenteral Nutrition 1147
63 Weight Reduction Strategies and the Pharmacotherapy of Obesity 1162

Unit 10 Pharmacology of the Endocrine System

64 Review of the Endocrine System 1176
65 Hypothalamic and Pituitary Drugs 1183
66 Pharmacotherapy of Diabetes Mellitus 1200
67 Pharmacotherapy of Thyroid Disorders 1229
68 Corticosteroids and Drugs Affecting the Adrenal Cortex 1245
69 Estrogens, Progestins, and Drugs Modifying Uterine Function 1262
70 Drugs for Modifying Conception 1287
71 Drugs for Disorders and Conditions of the Male Reproductive System 1307

Unit 11 Additional Drug Classes

72 Pharmacotherapy of Bone and Joint Disorders 1328
73 Pharmacotherapy of Dermatologic Disorders 1364
74 Pharmacotherapy of Eye and Ear Disorders 1389
75 Emergency Preparedness: Bioterrorism and Management of Poisoning 1409

Appendices

A Answers to Chapter Review 1425
B ISMP List of *High-Alert* Medications in Acute Care Settings 1457

Glossary 1458

Credits 1477

Index 1478

Notice: Care has been taken to confirm the accuracy of information presented in this book. The authors, editors, and the publisher, however, cannot accept any responsibility for errors or omissions or for consequences from application of the information in this book and make no warranty, express or implied, with respect to its contents.

The authors and publisher have exerted every effort to ensure that drug selections and dosages set forth in this text are in accord with current recommendations and practice at time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package inserts of all drugs for any change in indications of dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new and/or infrequently employed drug.

About the Authors

Michael Patrick Adams, PhD, is an accomplished educator, author, and national speaker. The National Institute for Staff and Organizational Development in Austin, Texas, named Dr. Adams a Master Teacher. He has published two other textbooks with Pearson Education: *Core Concepts in Pharmacology* and *Pharmacology for Nurses: A Pathophysiologic Approach*.

Dr. Adams obtained his master's degree in pharmacology from Michigan State University and his doctorate in education from the University of South Florida. Dr. Adams was on the faculty of Lansing Community College and St. Petersburg College, and was Dean of Health Professions at Pasco-Hernando State College for over 19 years. He is currently Adjunct Professor of Anatomy and Physiology at Hillsborough Community College.

I dedicate this book to nursing educators, who contribute every day to making the world a better and more caring place.

—MPA

Carol Quam Urban, PhD, RN, Associate Professor, is the Director of the School of Nursing and an Associate Dean in the College of Health and Human Services at George Mason University in Fairfax, Virginia. She has been on the faculty in the School of Nursing for over two decades and has worked with Dr. Rebecca Sutter to open three nurse-managed health clinics, academic–community partnerships that care for uninsured patients and provide educational opportunities for Mason nursing students. She has published the Pearson textbook *Pharmacology for Nurses: A Pathophysiologic Approach* with Dr. Adams and Dr. Holland.

To my daughter, Joy, an extraordinary and resilient woman who continues to change the world for the better, and in memory of my son, Keith, and my husband, Mike.

—CQU

Rebecca E Sutter, DNP, BC-FNP, is Assistant Professor in the School of Nursing and one of the directors of an academic nurse-managed clinic within the College of Health and Human Services at George Mason University in Fairfax, Virginia. She has been on the nursing faculty for over 15 years at community colleges and universities, and has practiced for over 20 years as a pediatric ICU nurse and a board-certified family nurse practitioner.

To my husband, Lee, and my parents, Jane and Ellis, who have given me the foundation to reach for my dreams, and to my amazing children Andrew, Sarah, and Emily, who have made me stronger, better, and more fulfilled than I could have ever imagined. I love you to the moon and back.

—RES

Thank You

First Edition Contributors

We extend a heartfelt thanks to our contributors, who gave their time, effort, and expertise so tirelessly to the development and writing of chapters and resources that helped foster our goal of preparing student nurses for evidence-based practice.

Diane Benson, RN, EdD
Humboldt State University, Arcata, California

Third Edition Reviewers

Our heartfelt thanks go out to our colleagues from schools of nursing across the country who have given their time generously to help create this exciting new edition of our pharmacology textbook. These individuals helped us plan and shape our book and resources by reviewing chapters, art, design, and more. *Pharmacology: Connections to Nursing Practice* has reaped the benefit of your collective knowledge and experience as nurses and teachers, and we have improved the materials due to your efforts, suggestions, objections, endorsements, and inspiration. Among those who gave their time generously to help us are the following:

Wanda Barlow, MSN, RN, FNP-BC
Instructor
Winston-Salem State University
Winston-Salem, North Carolina

Carole Berube, MA, MSN, BSN, RN
Professor Emerita
Bristol Community College
Fall River, Massachusetts

Sophia Beydoun, MSN, RN
Instructor
Henry Ford College
Dearborn, Michigan

Staci M. Boruff, PhD, RN
Professor
Walters State Community College
Morristown, Tennessee

Sharon Burke, EdD, MSN, RNC
Assistant Professor
The Pennsylvania State University
Abington, Pennsylvania

Judy Callicoatt, RN, MS, CNS
ADN Instructor
Trinity Valley Community College
Kaufman, Texas

Katrina Coggins, MSN, RN, CEN
Assistant Professor
Western Carolina University
Cullowhee, North Carolina

Tamara Condrey, DNP, RN, ACNS-BC, CCRN, CNE
Assistant Professor
Columbus State University
Columbus, Georgia

Rebecca A. Crane, MSN, RN, CHPN, CLNC
Assistant Professor
Ivy Tech Community College
Bloomington, Indiana

Lynette DeBellis, RN, MA
Assistant Professor
Westchester Community College
Valhalla, New York

Debra Dickman, MS, RN, CNE
Assistant Professor
Blessing-Rieman College of Nursing
Quincy, Illinois

Teresa Dobrzykowski, PhD, APRN, BC
Assistant Professor
Indiana University
South Bend, Indiana

Deborah Dye, RN, MSN
Department Chair and Assistant Professor
Ivy Tech Community College
Lafayette, Indiana

Nancy W. Ebersole, PhD, RN
Direct-Entry MSN Program Coordinator
Salem State University
Salem, Massachusetts

Anita Fitzgerald, RN, A/GNP
Lecturer, Director, Learning Center
California State University
Long Beach, California

Suzanne Franzoni-Kleeman, MSN, RN, CEN
Assistant Professor
American International College
Springfield, Massachusetts

Lola Goodson, RN, MSN, CRNI
Instructor
Ivy Tech Community College
Sellersburg, Indiana

Amy C. Graham, RN, MSN, FNP-BC
Assistant Professor
James Madison University
Harrisonburg, Virginia

Crystal Graham, RN, CHSE, MSN-Ed
Simulation Lab Director/Instructor of Nursing
Francis Marion University
Florence, South Carolina

Yolanda J. Green, RN, MSN
Associate Professor
Chattanooga State Community College
Chattanooga, Tennessee

Susan Growe, DNP, RN
Lecturer

Owner
Professional Nurse Consultants, LLC
Aurora, Colorado

Antonie Hiemer, MS, RN
Assistant Professor
Morrisville State College
Morrisville, New York

Susan Holland, MSN, APRN, GNP-BC
Clinical Assistant Professor
Sam Houston State University
Huntsville, Texas

Molly Jackson, RN, MSN APRN, NP-C
Instructor
Case Western Reserve University
Cleveland, Ohio

Sara K. Kaylor, EdD, RN
Assistant Professor
The University of Alabama
Tuscaloosa, Alabama

Amy Mitchell Kennedy, MSN, RN
Adjunct Faculty, RN and PN Program
ECPI University
Newport News, Virginia

Alice Kindschuh, DNP, RN, APRN-CNS, CNE
Adjunct Instructor
Nebraska Methodist College
Omaha, Nebraska

Vicky J. King, RN, MS, CNE
Nursing Faculty
Cochise College
Sierra Vista, Arizona

Julie Ann Koch, DNP, RN, FNP-BC
Assistant Professor and DNP Program Coordinator
Valparaiso University
Valparaiso, Indiana

Angela M. Koller, DNP, MSN, RN
Dean
Ivy Tech Community College
Indianapolis, Indiana

Stephen D. Krau, PhD, RN, CNE
Associate Professor
Vanderbilt University Medical Center, School of Nursing
Nashville, Tennessee

Elizabeth L. Law, MSN, NP-C, RN
Assistant Professor
Ivy Tech Community College
Indianapolis, Indiana

Connie Lawrence, MS, FNP-BC, DNP
Director of RN-BSN Program
The College at Brockport
Brockport, New York

Dr. Euphemia Marlene C. Lazarus
Professor
Camden County College
Blackwood, New Jersey

Carol Isaac MacKusick, PhDc, RN, CNN, CNE
Assistant Professor
Western Carolina University
Cullowhee, North Carolina

Shayne A. Mason, RN, BSN, PMHNP(BC)
Instructor
University of San Francisco
San Francisco, California

Vicki McCalmont RN, MS, ANP-BC, CNS, CCTC
Professor
San Diego State University
San Diego, California

Bethany Mello, DNP, MS, NP-C
Assistant Professor
University of Jamestown
Jamestown, North Dakota

James Mendez, MSN, CRNP
Adjunct Instructor
Villanova University
Villanova, Pennsylvania

Toby Nishikawa, MSN, RN
Assistant Professor
Weber State University
Ogden, Utah

Nola Ormrod, RN, MSN
Department Chair
Centralia College
Centralia, Washington

Mechelle Perea-Ryan, MS, FNP-BC, PHN
Associate Professor
California State University, Stanislaus
Turlock, California

Beth Rowlands, DNP, GNP-BC
Clinical Professor
University of Massachusetts
Boston, Massachusetts

Janet Czermak Russell, APN-BC
Professor
Essex County College
Newark, New Jersey

Jennifer Brindisi Sipe, MSN, RN
Assistant Professor
LaSalle University
Philadelphia, Pennsylvania

Michelle Taylor Skipper, DNP, FNP-BC
Clinical Associate Professor
Director, A/GNP and FNP Concentrations
East Carolina University
Greenville, North Carolina

Sabra H. Smith, DNP, MS, FNP-BC
Clinical Assistant Professor
University of South Carolina
Columbia, South Carolina

Rebecca E. Sutter, DNP, APRN, BC-FNP
Assistant Dean and Assistant Professor
George Mason University
Fairfax, Virginia

Nanci Swan, RN, MSN, CCRN
Instructor
The University of Alabama
Birmingham, Alabama

Valerie Taylor, RN, C, MEd, MSN
Assistant Professor
Lorain County Community College
Elyria, Ohio

Angela Trawick, MSN, RN
Clinical Coordinator
Florida SouthWestern State College
Fort Myers, Florida

Diana White, RN, MS
Professor
Tuskegee University
Tuskegee, Alabama

Carol S. Whiteman, MSN, RN, CCRN
Assistant Professor
Ivy Tech Community College
South Bend, Indiana

Toni C. Wortham, RN, BSN, MSN
Part-time Instructor
Madisonville Community College
Madisonville, Kentucky

Benson Kar Leung Yeung, MSN, RN
Full-time Instructor
California State University
Los Angeles, California

Preface

Pharmacology is one of the most challenging and dynamic subjects for professional nurses. Each month new drugs are being introduced, and new indications are continually being developed for existing medications. Some medications that were considered preferred drugs only a decade ago are now rarely prescribed. Current knowledge of drug actions, mechanisms, interactions, and legislation is mandatory for nurses to provide safe and effective patient care in all healthcare settings. Pharmacotherapeutics remains a critical and ever-changing component of patient care.

The subtitle of this text, *Connections to Nursing Practice*, has guided its continued development. At a fundamental level, pharmacology is a series of interrelated essential concepts. Some key concepts are shared with the natural and applied sciences. Prediction of drug action requires a thorough knowledge of anatomy, physiology, chemistry, and pathology as well as the social sciences of psychology and sociology. This interdisciplinary nature of pharmacology makes the subject difficult to learn but fascinating to study.

However, the discipline of pharmacology is far more than a collection of isolated facts. To effectively learn this discipline, the student must make connections to nursing practice and, ultimately, connections to patient care. Patients expect to receive effective and safe medication administration from a nurse who is competent in the study of pharmacology. *Pharmacology: Connections to Nursing Practice* identifies key pharmacologic concepts and mechanisms and clearly connects them to current nursing theory and practice for providing optimal patient care.

Pharmacology: Connections to Nursing Practice recognizes that pharmacology is not an academic discipline to be learned for its own sake but is a critical tool to prevent disease and promote healing. This connection to patients, their assessment, diagnoses, and interventions supports basic nursing practice. Like other core nursing subjects, the focus of pharmacology must be to teach and promote wellness for patients.

Structure of the Text

This text is organized according to body systems (units) and diseases (chapters). Unit 1, the first seven chapters, identifies fundamental pharmacologic principles that are applied throughout the text. Although new drugs are constantly being developed, these chapters build the structural framework for understanding the applications of all drugs. The role of complementary and alternative therapies, which are used by many patients, is included in the context of holistic care.

Unit 2 connects pharmacology, the nurse, and the patient, with an emphasis on positive patient outcomes. The four chapters in this unit recognize the essential role of nurse–patient interactions in providing optimal patient care throughout the lifespan. The fact that individuals vary in their responses to drug action is an important theme introduced in this unit.

Units 3 through 11 provide the concepts and connections that are necessary to understand the actions and adverse effects of individual drugs on different body systems. Many of the units begin with a chapter that briefly reviews relevant anatomy and physiology, which is a useful feature for the student when studying drug actions. Each chapter clearly identifies the concepts and connections necessary for safe and effective pharmacotherapy. Pharmacology is intimately related to the study of disease processes. The connections between pharmacology and pathophysiology are clearly established for each drug class in every chapter.

Resources for Faculty and Student Success

Resources for Faculty

Pearson is pleased to offer a suite of resources to support teaching and learning, including:

- **TestGen Test Bank**
- **Lecture Note PowerPoints**
- **Instructor's Resource Manual**

Resources for Students

Online Resources for students that are available include:

- Making the Patient Connection case studies and answers
- Additional Case Studies and answers
- Answers to Patient Safety Questions
- Suggested answers to Connection Checkpoints, and more!

A Practical Approach to Learning Pharmacology

UNIT 4	Pharmacology of the Central Nervous System	
CHAPTER 17	Review of the Central Nervous System	218
CHAPTER 18	Pharmacotherapy of Anxiety and Sleep Disorders	227
CHAPTER 19	Pharmacotherapy of Mood Disorders	253
CHAPTER 20	Pharmacotherapy of Psychoses	281
CHAPTER 21	Pharmacotherapy of Degenerative Diseases of the Central Nervous System	304
CHAPTER 22	Pharmacotherapy of Seizures	330
CHAPTER 23	Pharmacotherapy of Muscle Spasms and Spasticity	358
CHAPTER 24	Central Nervous System Stimulants and Drugs for Attention-Deficit/Hyperactivity Disorder	375
CHAPTER 25	Pharmacotherapy of Severe Pain and Migraines	392
CHAPTER 26	Anesthetics and Anesthesia Adjuncts	422
CHAPTER 27	Pharmacology of Substance Abuse	447

◀ **Disease and Body System Approach.** The organization by body systems (units) and diseases (chapters) places the drugs in context with how they are used therapeutically. This organization connects pharmacology and pathophysiology to nursing care.

▶ **Updated! Prototype Approach.** The vast number of drugs that the practicing nurse must learn is staggering. To facilitate learning, this text uses a prototype approach in which the most representative medications in each classification are introduced in detail. This edition features 194 prototype drugs that include detailed information on therapeutic effects, mechanism of action, pharmacokinetics, adverse effects, contraindications, drug interactions, pregnancy category, and treatment of overdose.

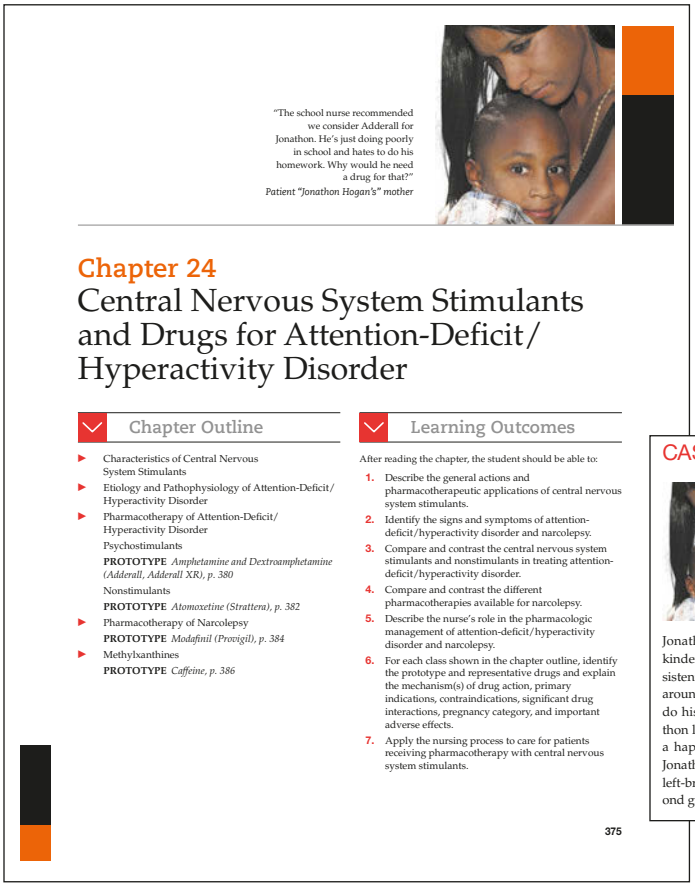
PROTOTYPE DRUG **Amiodarone (Pacerone)**

Classification **Therapeutic:** Antidysrhythmic, Class III
Pharmacologic: Potassium channel blocker

Therapeutic Effects and Uses: Approved in 1985, amiodarone is the most frequently prescribed Class III antidysrhythmic. It is considered a broad-spectrum antidysrhythmic because it is effective in terminating both atrial and ventricular dysrhythmias. It is approved for the treatment of resistant ventricular tachycardia and recurrent fibrillation that may prove life threatening, and it has become a preferred medication for the treatment of atrial dysrhythmias in patients with HF.

Adverse Effects: Potentially serious adverse effects limit the use of amiodarone. Amiodarone may cause nausea, vomiting, anorexia, fatigue, dizziness, and hypotension. Visual disturbances are common in patients taking this drug for extended periods and include blurred vision due to cornea deposits, photophobia, xerostomia, cataracts, and macular degeneration. Rashes, photosensitivity, and other skin reactions occur in 10% to 15% of patients taking the drug. Certain tissues concentrate this medication; thus, adverse effects may be slow to resolve, persisting long after the drug has been discontinued. **Black Box Warning (oral form only):** Amiodarone causes a pneumonia-like syndrome in the lungs. Because the pulmonary toxicity may be fatal, baseline and periodic assessments of lung function are essential. Amiodarone has prodysrhythmic action and may cause bradycardia, cardiogenic shock, or AV block. Mild liver injury is frequent with amiodarone.

◀ **Updated! Black Box Warnings.** The latest black box warnings issued by the U.S. Food and Drug Administration are clearly identified for all prototype medications.



▶ **Updated! Drug Tables.** Easy-to-understand tables reflect the latest FDA-approved drugs and provide average dosages for most medications. Unique to this text is a listing of the most common and the most serious adverse effects for each drug or drug class. This allows the student to immediately recognize important safety information regarding the drug(s) he or she is administering.

Table 38.5 Antiplatelet Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
anagrelide (Agrylin)	PO: 0.5 mg qid or 1 mg bid (max: 10 mg/day)	*Nausea, vomiting, diarrhea, abdominal pain, dizziness, headache*
aspirin (ASA, acetylsalicylic acid)	PO: 80 mg daily to 650 mg bid	
dipyridamole (Persantine)	PO: 75–100 mg qid as adjunct to warfarin therapy	Increased bleeding, central nervous system (CNS) effects (dipyridamole), anaphylaxis (aspirin), interstitial lung disease (anagrelide)
vorapaxar (Zontivity)	PO: 2.08 mg/day	
ADP Receptor Blockers		
clopidogrel (Plavix)	PO: 75 mg/day (max: 300 mg/day for life-threatening cases)	*Minor bleeding, dyspepsia, abdominal pain, headache, rash, diarrhea*
prasugrel (Effient)	PO: 60-mg loading dose followed by 10 mg/day	
ticagrelor (Brilinta)	PO: 180-mg loading dose followed by 90 mg bid	Increased clotting time, GI bleeding, blood dyscrasias, angina
Glycoprotein IIb/IIIa Receptor Antagonists		
abciximab (ReoPro)	IV: 0.25 mg/kg initial bolus over 5 min, then 0.125 mcg/kg/min for 12 h (max: 10 mcg/min)	*Dyspepsia, dizziness, pain at injection site, hypotension, bradycardia, minor bleeding*
eptifibatide (Integrilin)	IV: 180 mcg/kg initial bolus over 1–2 min, then 2 mcg/kg/min for 24–72 h (max: 180 mcg/kg bolus, 2 mcg/kg/min infusion)	Major hemorrhage, thrombocytopenia
tirofiban (Aggrastat)	IV: 0.4 mcg/kg/min for 30 min, then 0.1 mcg/kg/min for 12–24 h	
Drugs for Intermittent Claudication		
cilostazol (Pletal)	PO: 100 mg bid	*Dyspepsia, nausea, vomiting, dizziness, myalgia, headache*
pentoxifylline (Trental)	PO: 400 mg tid (max: 1200 mg/day)	Tachycardia and palpitations (cilostazol), CNS effects (pentoxifylline), heart failure, MI

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Connections to Nursing Practice

"The school nurse recommended we consider Adderall for Jonathon. He's just doing poorly in school and hates to do his homework. Why would he need a drug for that?"
Patient "Jonathon Hogan's" mother

Chapter 24
Central Nervous System Stimulants and Drugs for Attention-Deficit/ Hyperactivity Disorder

Chapter Outline

- Characteristics of Central Nervous System Stimulants
- Etiology and Pathophysiology of Attention-Deficit/ Hyperactivity Disorder
- Pharmacotherapy of Attention-Deficit/ Hyperactivity Disorder
  - Psychostimulants
    - **PROTOTYPE** *Amphetamine and Dextroamphetamine (Adderall, Adderall XR), p. 380*
  - Nonstimulants
    - **PROTOTYPE** *Atomoxetine (Strattera), p. 382*
- Pharmacotherapy of Narcolepsy
  - **PROTOTYPE** *Modafinil (Provigil), p. 384*
- Methylxanthines
  - **PROTOTYPE** *Caffeine, p. 386*

Learning Outcomes

After reading the chapter, the student should be able to:

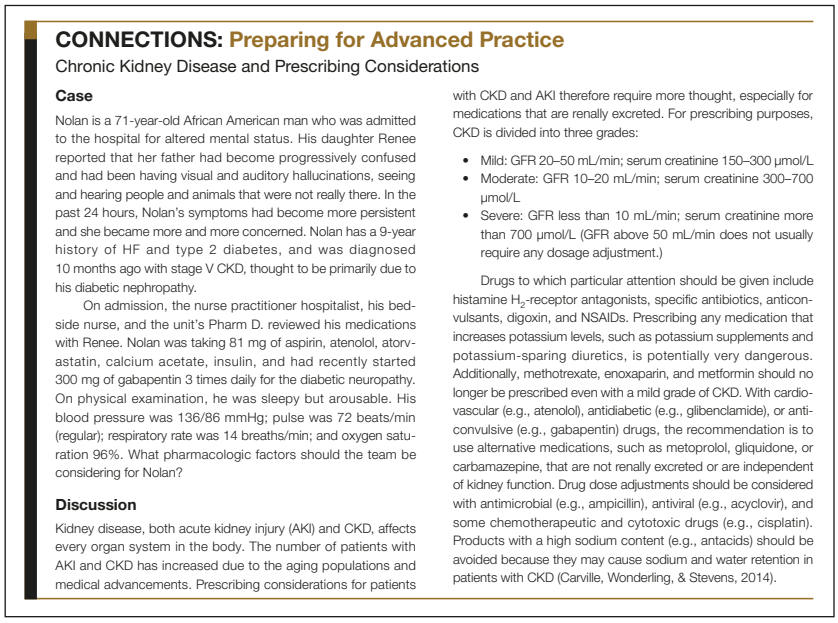
1. Describe the general actions and pharmacotherapeutic applications of central nervous system stimulants.
2. Identify the signs and symptoms of attention-deficit/hyperactivity disorder and narcolepsy.
3. Compare and contrast the central nervous system stimulants and nonstimulants in treating attention-deficit/hyperactivity disorder.
4. Compare and contrast the different pharmacotherapies available for narcolepsy.
5. Describe the nurse's role in the pharmacologic management of attention-deficit/hyperactivity disorder and narcolepsy.
6. For each class shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with central nervous system stimulants.

375

◀ **Making the Patient Connection** is a feature that opens each chapter with a quote and a photo of a patient. It reinforces to the student that the focus of pharmacology must always be on the patient. To drive this important message home, the patient who is introduced at the start of the chapter is revisited at the end with critical thinking exercises. These questions assist the student to apply the content learned in the chapter to a realistic patient scenario. An additional case study is also included for further application of knowledge learned.

CASE STUDY: Making the Patient Connection

Remember the patient "Jonathon Hogan" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.



Jonathon Hogan has had trouble at school beginning in kindergarten and for the past year. His teachers have consistently reported that he is easily distracted and wanders around the classroom even during a lesson. Getting him to do his homework after school has been a struggle. Jonathon loves art and does well at video games. Because he is a happy-go-lucky child, his parents have assumed that Jonathon's right-brain dominance has created trouble with left-brain logical work. With more homework now in second grade, Jonathon is struggling to keep up in school. The school nurse suspects he may have ADHD. She has recommended an appointment with Jonathon's healthcare provider and told his parents that Adderall may help Jonathon focus on his schoolwork.

Critical Thinking Questions

1. What is ADHD and why would Jonathon be experiencing more difficulty as he becomes older?
2. How might amphetamine sulfate and dextroamphetamine (Adderall) help Jonathon with his ADHD?
3. What caregiver education would be appropriate regarding dextroamphetamine and amphetamine sulfate (Adderall)?
4. What are other nonpharmacologic treatments for ADHD?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

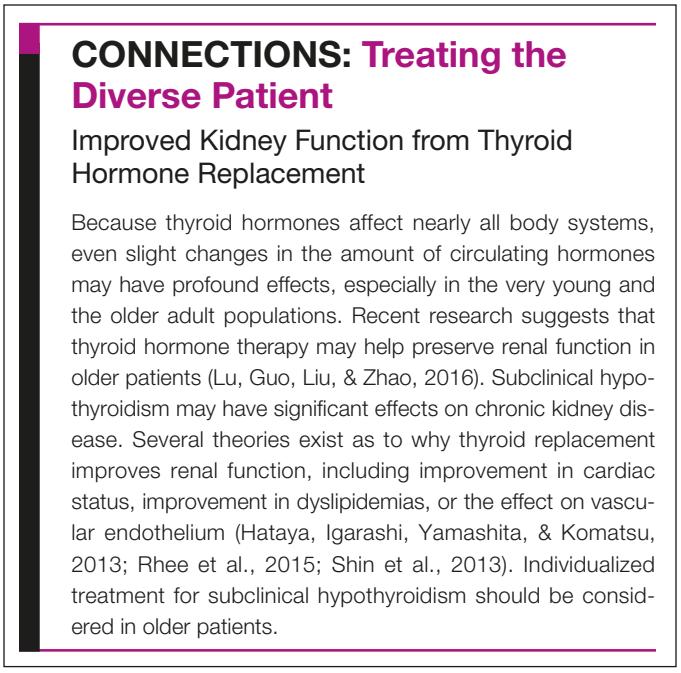
► **New! Connections: Preparing for Advanced Practice.** Dramatic changes in the delivery of healthcare have placed an increased emphasis on developing the critical thinking skills and clinical decision-making abilities of nurses at both the undergraduate and graduate levels. Through case studies, the authors use strategies that promote the clinical decision-making skills of advanced practice nurses. Particular attention is paid to advanced practice nurses who are preparing to work within specialty practice settings and with vulnerable populations.

CONNECTIONS: Preparing for Advanced Practice

Chronic Kidney Disease and Prescribing Considerations

Case

Nolan is a 71-year-old African American man who was admitted to the hospital for altered mental status. His daughter Renee reported that her father had become progressively confused and had been having visual and auditory hallucinations, seeing and hearing people and animals that were not really there. In the past 24 hours, Nolan's symptoms had become more persistent and she became more and more concerned. Nolan has a 9-year history of HF and type 2 diabetes, and was diagnosed 10 months ago with stage V CKD, thought to be primarily due to his diabetic nephropathy.



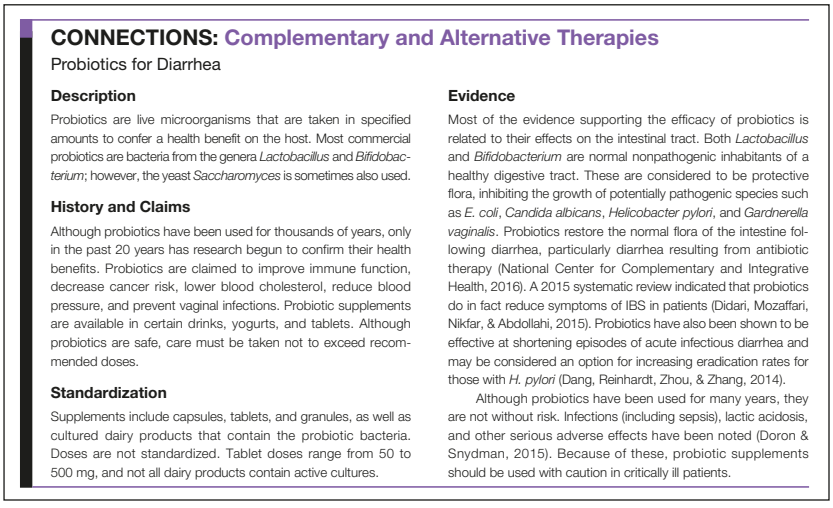
On admission, the nurse practitioner hospitalist, his bedside nurse, and the unit's Pharm D. reviewed his medications with Renee. Nolan was taking 81 mg of aspirin, atenolol, atorvastatin, calcium acetate, insulin, and had recently started 300 mg of gabapentin 3 times daily for the diabetic neuropathy. On physical examination, he was sleepy but arousable. His blood pressure was 136/86 mmHg; pulse was 72 beats/min (regular); respiratory rate was 14 breaths/min; and oxygen saturation 96%. What pharmacologic factors should the team be considering for Nolan?

Discussion

Kidney disease, both acute kidney injury (AKI) and CKD, affects every organ system in the body. The number of patients with AKI and CKD has increased due to the aging populations and medical advancements. Prescribing considerations for patients with CKD and AKI therefore require more thought, especially for medications that are renally excreted. For prescribing purposes, CKD is divided into three grades:

- Mild: GFR 20–50 mL/min; serum creatinine 150–300 µmol/L
- Moderate: GFR 10–20 mL/min; serum creatinine 300–700 µmol/L
- Severe: GFR less than 10 mL/min; serum creatinine more than 700 µmol/L (GFR above 50 mL/min does not usually require any dosage adjustment.)

Drugs to which particular attention should be given include histamine H_2-receptor antagonists, specific antibiotics, anticonvulsants, digoxin, and NSAIDs. Prescribing any medication that increases potassium levels, such as potassium supplements and potassium-sparing diuretics, is potentially very dangerous. Additionally, methotrexate, enoxaparin, and metformin should no longer be prescribed even with a mild grade of CKD. With cardiovascular (e.g., atenolol), antidiabetic (e.g., glibenclamide), or anticonvulsive (e.g., gabapentin) drugs, the recommendation is to use alternative medications, such as metoprolol, gliquidone, or carbamazepine, that are not renally excreted or are independent of kidney function. Drug dose adjustments should be considered with antimicrobial (e.g., ampicillin), antiviral (e.g., acyclovir), and some chemotherapeutic and cytotoxic drugs (e.g., cisplatin). Products with a high sodium content (e.g., antacids) should be avoided because they may cause sodium and water retention in patients with CKD (Carville, Wonderling, & Stevens, 2014).



CONNECTIONS: Treating the Diverse Patient

Improved Kidney Function from Thyroid Hormone Replacement

Because thyroid hormones affect nearly all body systems, even slight changes in the amount of circulating hormones may have profound effects, especially in the very young and the older adult populations. Recent research suggests that thyroid hormone therapy may help preserve renal function in older patients (Lu, Guo, Liu, & Zhao, 2016). Subclinical hypothyroidism may have significant effects on chronic kidney disease. Several theories exist as to why thyroid replacement improves renal function, including improvement in cardiac status, improvement in dyslipidemias, or the effect on vascular endothelium (Hataya, Igarashi, Yamashita, & Komatsu, 2013; Rhee et al., 2015; Shin et al., 2013). Individualized treatment for subclinical hypothyroidism should be considered in older patients.

◄ **Connections: Treating the Diverse Patient** features identify gender, cultural, and ethical influences that are important modifiers of drug action.

► **Connections: Complementary and Alternative Therapies** features present herbal therapies and dietary supplements that may be considered as alternatives to conventional drugs. These features include a description of the herb or supplement, history of use, standardization of dose, and brief description of the scientific evidence supporting (or not supporting) the use of the product.

CONNECTIONS: Complementary and Alternative Therapies

Probiotics for Diarrhea

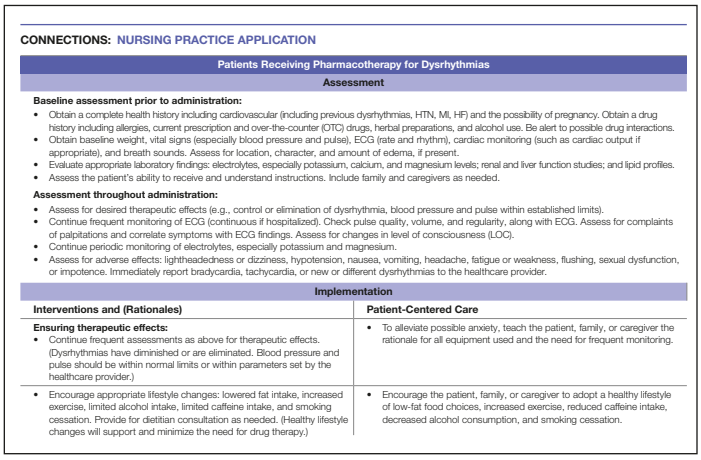
Description

Probiotics are live microorganisms that are taken in specified amounts to confer a health benefit on the host. Most commercial probiotics are bacteria from the genera *Lactobacillus* and *Bifidobacterium*; however, the yeast *Saccharomyces* is sometimes also used.

History and Claims

Although probiotics have been used for thousands of years, only in the past 20 years has research begun to confirm their health benefits. Probiotics are claimed to improve immune function, decrease cancer risk, lower blood cholesterol, reduce blood pressure, and prevent vaginal infections. Probiotic supplements are available in certain drinks, yogurts, and tablets. Although probiotics are safe, care must be taken not to exceed recommended doses.

Standardization



Supplements include capsules, tablets, and granules, as well as cultured dairy products that contain the probiotic bacteria. Doses are not standardized. Tablet doses range from 50 to 500 mg, and not all dairy products contain active cultures.

Evidence

Most of the evidence supporting the efficacy of probiotics is related to their effects on the intestinal tract. Both *Lactobacillus* and *Bifidobacterium* are normal nonpathogenic inhabitants of a healthy digestive tract. These are considered to be protective flora, inhibiting the growth of potentially pathogenic species such as *E. coli*, *Candida albicans*, *Helicobacter pylori*, and *Gardnerella vaginalis*. Probiotics restore the normal flora of the intestine following diarrhea, particularly diarrhea resulting from antibiotic therapy (National Center for Complementary and Integrative Health, 2016). A 2015 systematic review indicated that probiotics do in fact reduce symptoms of IBS in patients (Didari, Mozaffari, Nikfar, & Abdollahi, 2015). Probiotics have also been shown to be effective at shortening episodes of acute infectious diarrhea and may be considered an option for increasing eradication rates for those with *H. pylori* (Dang, Reinhardt, Zhou, & Zhang, 2014).

Although probiotics have been used for many years, they are not without risk. Infections (including sepsis), lactic acidosis, and other serious adverse effects have been noted (Doron & Snydman, 2015). Because of these, probiotic supplements should be used with caution in critically ill patients.

► **Connections: Nursing Practice Applications** features concisely connect the nursing process to the major drug class(es) in each drug chapter and incorporate outcomes from the Quality and Safety Education for Nurses (QSEN) competencies of patient-centered care, teamwork and collaboration, patient safety, and evidence-based practice. Each nursing intervention is patient centered and includes the rationale and associated patient and family teaching. Collaboration with other disciplines, such as social support services or dietary services, is also included in the interventions. Important lifespan and diverse patient considerations are noted throughout. The Nursing Practice Applications are organized to help students learn to think like a nurse as they take students through the processes of drug administration, nursing care, and teaching that are necessary in pharmacotherapy.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Dysrhythmias

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular (including previous dysrhythmias, HTN, MI, HF) and the possibility of pregnancy. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline weight, vital signs (especially blood pressure and pulse), ECG (rate and rhythm), cardiac monitoring (such as cardiac output if appropriate), and breath sounds. Assess for location, character, and amount of edema, if present.
- Evaluate appropriate laboratory findings: electrolytes, especially potassium, calcium, and magnesium levels; renal and liver function studies; and lipid profiles.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., control or elimination of dysrhythmia, blood pressure and pulse within established limits).
- Continue frequent monitoring of ECG (continuous if hospitalized). Check pulse quality, volume, and regularity, along with ECG. Assess for complaints of palpitations and correlate symptoms with ECG findings. Assess for changes in level of consciousness (LOC).
- Continue periodic monitoring of electrolytes, especially potassium and magnesium.
- Assess for adverse effects: lightheadedness or dizziness, hypotension, nausea, vomiting, headache, fatigue or weakness, flushing, sexual dysfunction, or impotence. Immediately report bradycardia, tachycardia, or new or different dysrhythmias to the healthcare provider.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Dysrhythmias have diminished or are eliminated. Blood pressure and pulse should be within normal limits or within parameters set by the healthcare provider.)	• To alleviate possible anxiety, teach the patient, family, or caregiver the rationale for all equipment used and the need for frequent monitoring.
• Encourage appropriate lifestyle changes: lowered fat intake, increased exercise, limited alcohol intake, limited caffeine intake, and smoking cessation. Provide for dietitian consultation as needed. (Healthy lifestyle changes will support and minimize the need for drug therapy.)	• Encourage the patient, family, or caregiver to adopt a healthy lifestyle of low-fat food choices, increased exercise, reduced caffeine intake, decreased alcohol consumption, and smoking cessation.

CONNECTIONS: Patient Safety

Incorrect Insulin Dose

A patient with diabetes has 30 units of Humulin R (regular) insulin ordered for the morning dose. There are several patients with diabetes on the unit and the nurse has given many doses of insulin that morning. The nurse prepares the insulin but draws up Humalog 30 units instead. The patient begins experiencing symptoms of hypoglycemia within 15 minutes and is treated successfully.

What errors occurred and how could they be prevented in the future?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

◄ **Connections: Patient Safety,** a QSEN competency, is a feature that presents a brief patient–nurse scenario that illustrates potential pitfalls encountered by nurses that can lead to medication errors. Most scenarios end with a question asking the student to identify what went wrong, what the nurse should do in the situation, what the nurse should question about the order, or what the nurse should do differently in order to prevent medication administration errors.

► **New! Connections: Using Research in Practice** features illustrate connections to nursing or pharmacology research and discuss the short- and long-term directions of pharmacotherapeutics. A critical thinking question is presented at the end of each feature to challenge the student to connect scientific evidence to nursing practice.

CONNECTIONS: Using Research in Practice

Early Exposure to Allergens May Reduce Asthma Risk

Allergen exposure has been noted to increase the risk for and severity of asthma in both children and adults (Custovic, 2015; Sheehan & Phipatanakul, 2016). What is not as clear is what roles the timing of initial exposure, ongoing exposure, types of allergens, or amount of exposure play in the development of protection from conditions such as asthma and anaphylaxis (Sheehan & Phipatanakul, 2016).

Lynch et al. (2014) noted that cumulative exposure to allergens in the first 3 years of life seemed to decrease the risk of recurrent wheezing and allergies and that such early exposure may be beneficial. A subsequent study also noted that

CONNECTIONS: Lifespan Considerations

Miscarriage Prevention with Anticoagulants

Miscarriage in pregnancy is devastating, and recurrent miscarriage even more so. Autoimmune diseases are related to poorer obstetric outcomes than that of the general population, especially in mothers with undiagnosed thrombophilias (genetic hypercoagulability disorders) such as antiphospholipid syndrome (APS). Antiphospholipid antibodies are present in 15% of women with recurrent miscarriage, and there is a potential 90% risk of future fetal loss in those women if left untreated (Chetty & Duncan, 2015). Other obstetric and neonatal complications related to APS include preeclampsia; eclampsia; hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; early delivery and subsequent prematurity; intrauterine growth restriction (IUGR); and placental insufficiency (Begum, Ganguly, & Islam, 2015; de Jesús, Rodrigues, de Jesús, & Levy, 2014).

Due to discrepancies in the research on treatment recommendations for the use of heparin, LMWH, or aspirin for recurrent spontaneous abortion before 10 weeks of pregnancy, it is recommended that a woman experiencing such loss discuss the situation with her provider and whether genetic testing should be conducted. If genetic coagulation abnormalities are found, heparin or LMWH may be considered as an option (Andreoli et al., 2013).

◄ **Connections: Lifespan Considerations** features clearly identify important considerations to ensure safe and effective pharmacotherapy in the older adult and pediatric populations.

CONNECTION Checkpoint 38.1

Coagulation occurs by intrinsic and extrinsic pathways. From what you learned in Chapter 28, which pathway is activated when blood leaks from a vessel? Which is more complex and takes several minutes? Which results in the formation of fibrin? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

▲ **Connection Checkpoints** ask the student to recall past concepts from previous chapters that are related to current study. Unique to this text, these reinforce material learned in previous chapters that has direct application to the current chapter.

► **PharmFacts** connect relevant statistics to the presented material. They add interest to the subject and place it in perspective with other nursing concepts.

PharmFACT

In the United States, over 13 million units of whole blood and red blood cells are donated each year. About 36,000 units of red blood cells are needed every day (American Red Cross, n.d.).

CONNECTIONS: Community-Oriented Practice

Calcium Channel Blockers and Effects on Minerals

Patients may be concerned about taking calcium supplements for osteoporosis prevention while taking CCBs. Calcium and magnesium supplements may actually help maintain a normal blood pressure or a lower high blood pressure, and as long as normal doses are taken, do not appear to affect the antihypertensive effects of CCBs. More recent research suggests that CCBs may affect the body's mineral content (Suliburska, Bogdanski, Szulinska, & Pupek-Musialik, 2014). CCBs, along with other antihypertensive drugs such as beta blockers and angiotensin-converting enzyme (ACE) inhibitors, were found to decrease serum zinc levels. Because depletion of some minerals such as zinc may have long-term effects on glucose and lipid metabolism, adequate mineral intake through diet or supplementation should be considered when a patient is taking CCBs or other antihypertensives.

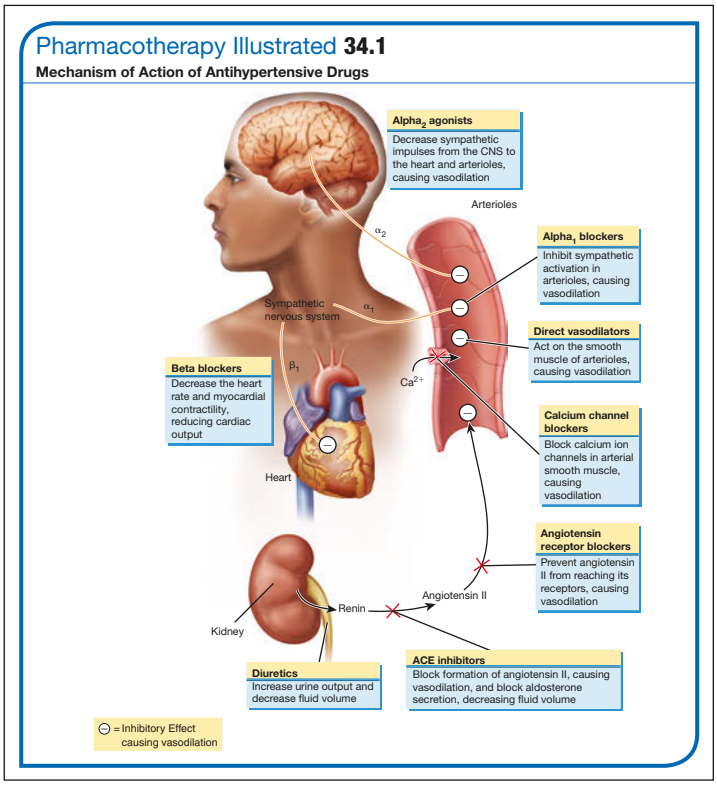
◄ **Connections: Community-Oriented Practice** features provide important information that nurses need to convey to their patients to ensure that they receive effective pharmacotherapy after leaving the hospital or clinical setting.

Nursing Responsibilities:

- Notify the prescriber prior to administration if the patient has a history of leukemia, multiple myeloma, or other myeloid malignancies.
- Monitor for and immediately report signs and symptoms of fluid overload, hypokalemia, and cardiac dysrhythmias.
- Monitor patients with preexisting fluid retention conditions carefully, such as HF, pleural effusion, or ascites, for worsening of symptoms.
- This drug has a black box warning for possible anaphylaxis. Promptly report any signs and symptoms of allergic reaction to the provider and discontinue the drug.

Lifespan and Diversity Considerations:

- Tachycardia, cardiomegaly, papilledema, conjunctival redness, and bone changes may occur more frequently in children taking oprelvekin than in adults. Carefully monitor heart rate and heart sounds, changes in visual acuity or eye pain, and for complaints of bone pain or changes in gait. Further cardiac testing (e.g., echocardiography) and frequent eye exams may be warranted.



Patient and Family Education:

- Do not take any other prescription or nonprescription drugs, dietary supplements, or herbal products without the approval of the healthcare provider.

◀ **Nursing Responsibilities** specific to some prototype drugs are provided in a bulleted list format. Nursing Responsibilities include important lifespan and diversity considerations and patient and family education needs. When a prototype drug does not have a correlating Nursing Practice Application, a more complete Nursing Responsibilities section follows the prototype drug section.

Learning Through Visuals

▶ **Updated and Expanded! Pharmacotherapy Illustrated** features visually present the mechanism of action for many of the prototype drugs, showing students specifically how drugs counteract the effects of disease.

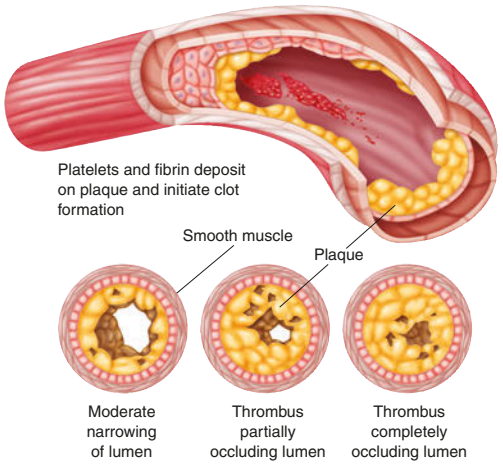


Figure 35.1 Atherosclerosis in the coronary arteries.

◄ **Vivid, Colorful, and Effective Illustrations** help students review the anatomy, physiology, and pathophysiology of a body system to better understand the impact of disease on that system.

Understanding the Chapter

The most comprehensive chapter review in its class! **Understanding the Chapter** begins with a **Key Concepts Summary**, which quickly identifies the numbered key concepts from the chapter.

► **Making the Patient Connection** reconnects the student to the patient presented in the scenario at the chapter opening. The student learns additional details about the patient's health history and participates in critical thinking questions about the scenario. This allows application of knowledge obtained in the chapter.

CASE STUDY: Making the Patient Connection

Remember the patient "Jonathon Hogan" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Jonathon Hogan has had trouble at school beginning in kindergarten and for the past year. His teachers have consistently reported that he is easily distracted and wanders around the classroom even during a lesson. Getting him to do his homework after school has been a struggle. Jonathon loves art and does well at video games. Because he is a happy-go-lucky child, his parents have assumed that Jonathon's right-brain dominance has created trouble with left-brain logical work. With more homework now in second grade, Jonathon is struggling to keep up in school. The school nurse suspects he may have ADHD. She has recommended an appointment with Jonathon's healthcare provider and told his parents that Adderall may help Jonathon focus on his schoolwork.

Critical Thinking Questions

1. What is ADHD and why would Jonathon be experiencing more difficulty as he becomes older?
2. How might amphetamine sulfate and dextroamphetamine (Adderall) help Jonathon with his ADHD?
3. What caregiver education would be appropriate regarding dextroamphetamine and amphetamine sulfate (Adderall)?
4. What are other nonpharmacologic treatments for ADHD?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Anna Steinmetz has graduated from nursing school and is working nights. She is having difficulty adjusting to her night schedule. Her healthcare provider suggested she utilize a medication to assist with her adjustment to shift work. She has been prescribed modafinil (Provigil).

1. What effect does modafinil (Provigil) have on the patient's ability to maintain alertness during shift work?
2. What teaching will you provide to the patient regarding this medication?
3. The patient reports feelings of lightheadedness with position changes. What interventions will assist in maintaining patient safety?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

◄ An **Additional Case Study** gives students another opportunity to apply their knowledge to patient care.

► **Chapter Review** prepares students for course exams on chapter content and gives exposure to NCLEX-RN®-style questions. Answers and rationales are provided in Appendix A.

Chapter Review

1. An elementary school nurse is providing education to the faculty on the use of central nervous system stimulants to treat attention-deficit/hyperactivity disorder. Of the following, which is most important for the nurse to convey to the faculty?
   1. Have the child bring the drug dose in a lunch bag and come to the office to take it to avoid being teased.
   2. Request that the parents leave an extra copy of the prescription at the school in case the dose runs out.

   The world would be better off without me." Which action would the nurse take for this patient?
   1. Tell the patient to stop taking atomoxetine immediately and not to take it until checking with the provider.
   2. Assure the patient that these are normal symptoms because the drug may take 3 or 4 weeks to work.
   3. Alert the family or caregiver that immediate attention and treatment are needed for these symptoms.

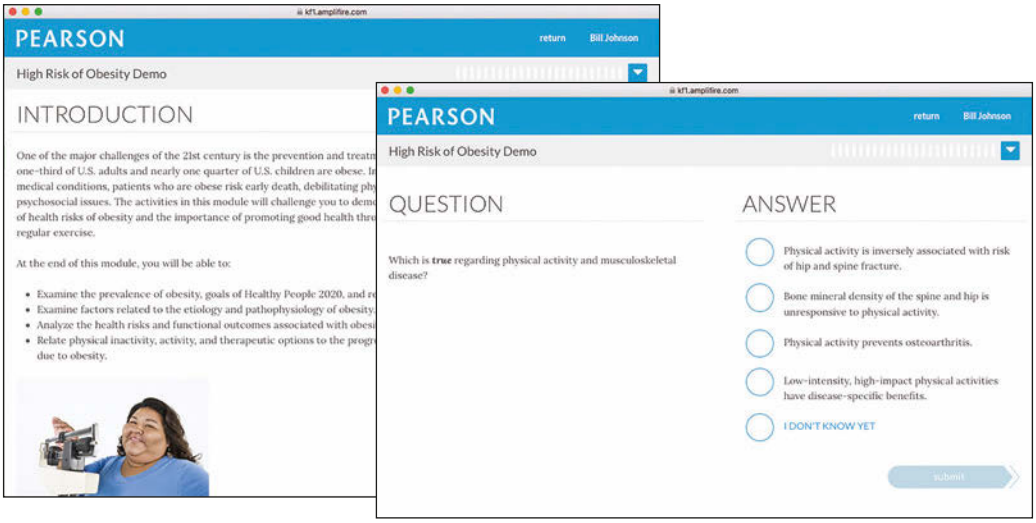
◀ Detailed **References** and a **Selected Bibliography** provide the foundation for evidence-based nursing practice and support the currency and accuracy of the textbook content.

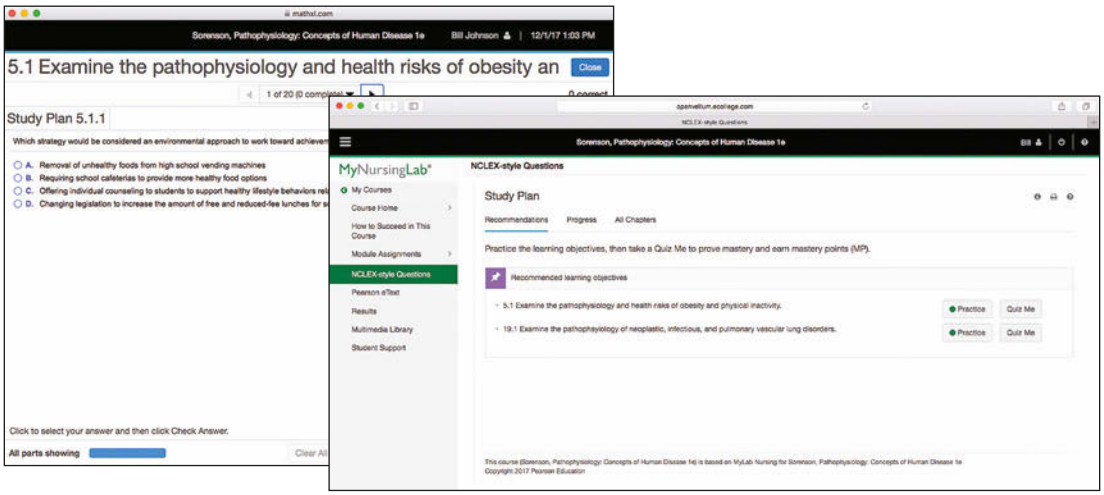
New to the Fourth Edition



- Updated Connections features cover current topics that nurses will face in practice.
- **New** Connections: Preparing for Advanced Practice features help students develop critical thinking and clinical decision-making skills.
- **New** Connections: Using Research in Practice features illustrate connections to nursing or pharmacology research.
- More than 30 new drugs have been added to update medications approved by the FDA since the previous edition.
- Revised art program: More than 10 figures have been added or revised in this edition to enhance the clarity of difficult pharmacologic concepts.

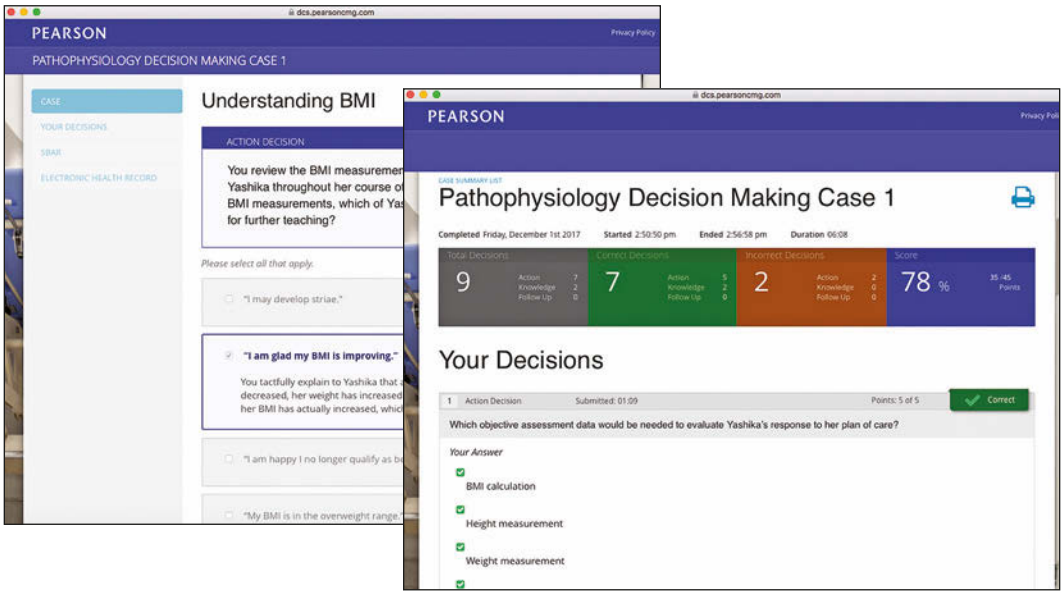
MyLab Nursing

MyLab Nursing is an online learning and practice environment that works with the text to help students master key concepts, prepare for the NCLEX-RN exam, and develop clinical reasoning skills. Through a new mobile experience, students can study *Pharmacology: Connections to Nursing Practice* anytime, anywhere. New adaptive technology with remediation personalizes learning, moving students beyond memorization to true understanding and application of the content. MyLab Nursing contains the following features:



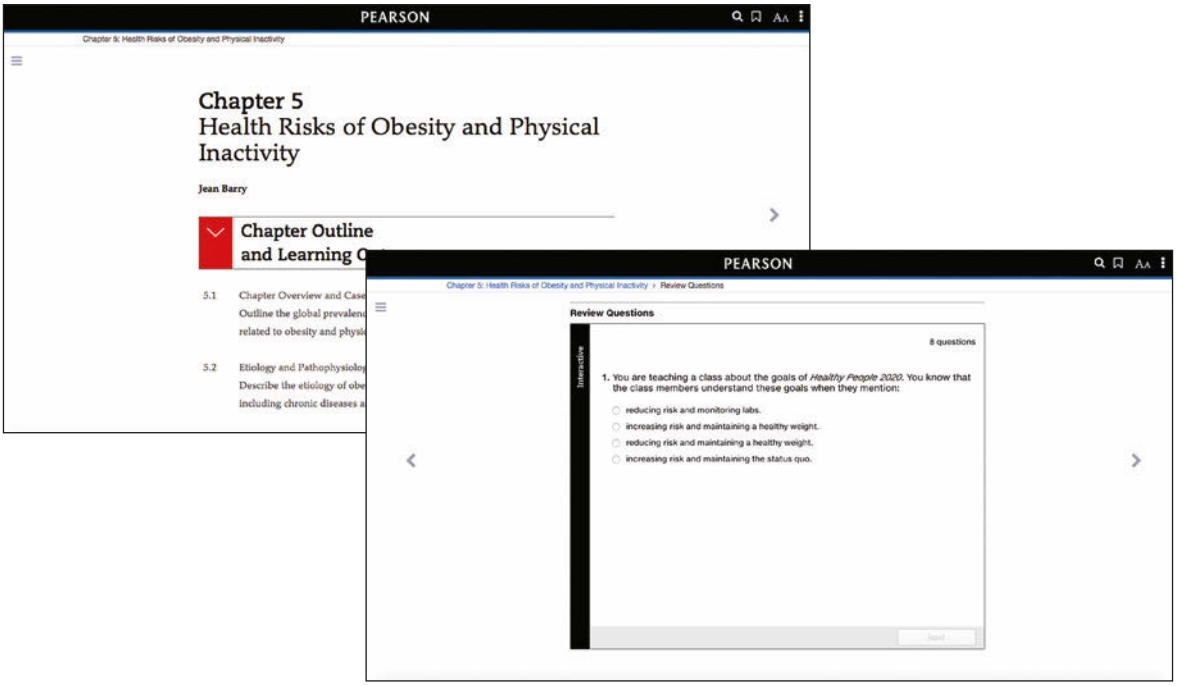
Dynamic Study Modules

New adaptive learning modules with remediation that personalize the learning experience by allowing students to increase both their confidence and their performance while being assessed in real time.



NCLEX-Style Questions

Practice tests with more than 1000 NCLEX-style questions of various types build student confidence and prepare them for success on the NCLEX-RN exam. Questions are organized by Chapter.



Decision Making Cases

Clinical case studies that provide opportunities for students to practice analyzing information and making important decisions at key moments in patient care scenarios. These 10 unfolding case studies are designed to help prepare students for clinical practice.

Pearson eText

Enhances student learning both in and outside the classroom. Students can take notes, highlight, and bookmark important content, or engage with interactive and rich media to achieve greater conceptual understanding of the text content. Interactive features include audio clips, pop-up definitions, figures, questions and answers, the nursing process, hotspots, and video animations.

- CONNECTIONS: Nursing Practice Application Patients Receiving Pharmacotherapy with Adrenergic Antagonists 213

Unit 4 Pharmacology of the Central Nervous System

17 Review of the Central Nervous System 218

Scope of Central Nervous System Pharmacology 219
Neurons and Neurotransmission 220
Structural Divisions of the Central Nervous System 222
Functional Systems of the Central Nervous System 224

18 Pharmacotherapy of Anxiety and Sleep Disorders 227

Anxiety Disorders 228
Sleep Disorders 231
Management of Anxiety and Sleep Disorders 234
Pharmacotherapy of Anxiety and Insomnia 237
- PROTOTYPE DRUG: Lorazepam (Ativan) 238

PROTOTYPE DRUG: Zolpidem (Ambien, Edluar, Others) 241
PROTOTYPE DRUG: Phenobarbital (Luminal) 246
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders 248

19 Pharmacotherapy of Mood Disorders 253

Categories of Mood Disorders 254
Major Depressive Disorder 254
Pathophysiology of Depression 255
Assessment of Depression 256
Nonpharmacologic Therapies for Depression 257
Pharmacotherapy of Depression 258
Selective Serotonin Reuptake Inhibitors 259
PROTOTYPE DRUG: Fluoxetine (Prozac) 261
Atypical Antidepressants 263
PROTOTYPE DRUG: Venlafaxine (Effexor) 264
Tricyclic Antidepressants 267
PROTOTYPE DRUG: Imipramine (Tofranil) 268
Monoamine Oxidase Inhibitors 269
PROTOTYPE DRUG: Phenelzine (Nardil) 270
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antidepressants 272
Bipolar Disorder 273
Drugs for Bipolar Disorder 274
PROTOTYPE DRUG: Lithium Carbonate (Eskalith, Lithobid) 274

20 Pharmacotherapy of Psychoses 281

Characteristics of Psychoses 282
Symptoms of Schizophrenia 283
Etiology of Schizophrenia 284
Management of Psychoses 284
Antipsychotic Drugs 286
First-Generation Antipsychotics 288
PROTOTYPE DRUG: Chlorpromazine 290
PROTOTYPE DRUG: Haloperidol (Haldol) 291
Second-Generation (Atypical) Antipsychotics 293
PROTOTYPE DRUG: Risperidone (Risperdal) 293
PROTOTYPE DRUG: Aripiprazole (Abilify) 297
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antipsychotics 299

21 Pharmacotherapy of Degenerative Diseases of the Central Nervous System 304

Degenerative Diseases of the Central Nervous System 305
Parkinson's Disease 306
Pharmacotherapy of Parkinson's Disease 307
PROTOTYPE DRUG: Levodopa and Carbidopa (Sinemet, Parcopa) 308
PROTOTYPE DRUG: Pramipexole (Mirapex) 311
PROTOTYPE DRUG: Benztropine (Cogentin) 314
Alzheimer's Disease 315
Pharmacotherapy of Alzheimer's Disease 317
PROTOTYPE DRUG: Donepezil (Aricept) 319
Multiple Sclerosis 320
PROTOTYPE DRUG: Interferon Beta-1b (Betaseron, Extavia) 322
Amyotrophic Lateral Sclerosis 325
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Neurodegenerative Disorders 325

22 Pharmacotherapy of Seizures 330

Characteristics of Seizure Disorders 331
Classification of Seizure Disorders 334
Generalized Seizures 334
Partial Seizures 335
Antiepileptic Drugs 339
PROTOTYPE DRUG: Diazepam (Valium) 342
PROTOTYPE DRUG: Phenytoin (Dilantin, Phenytek) 344
PROTOTYPE DRUG: Carbamazepine (Carbatrol, Tegretol, Others) 346
PROTOTYPE DRUG: Ethosuximide (Zarontin) 347
PROTOTYPE DRUG: Gabapentin (Neurontin) 348
PROTOTYPE DRUG: Valproic Acid (Depacon, Depakene, Depakote) 349
Other Miscellaneous Drugs 350
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Seizures 353

23 Pharmacotherapy of Muscle Spasms and Spasticity 358

Etiology and Pathophysiology of Muscle Spasms and Spasticity 359
Nonpharmacologic Therapies for Muscle Spasms and Spasticity 360
Pharmacotherapy of Muscle Spasms 361
PROTOTYPE DRUG: Cyclobenzaprine (Amrix) 363
Pharmacotherapy of Muscle Spasticity 366
PROTOTYPE DRUG: Dantrolene (Dantrium, Revonto) 366
Skeletal Muscle Relaxants as Surgical Adjuncts 370
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Muscle Spasms and Spasticity 370

24 Central Nervous System Stimulants and Drugs for Attention-Deficit/Hyperactivity Disorder 375

Characteristics of Central Nervous System Stimulants 376
Etiology and Pathophysiology of Attention-Deficit/Hyperactivity Disorder 377
Pharmacotherapy of Attention-Deficit/Hyperactivity Disorder 378
PROTOTYPE DRUG: Amphetamine and Dextroamphetamine (Adderall, Adderall XR) 380
PROTOTYPE DRUG: Atomoxetine (Strattera) 382
Pharmacotherapy of Narcolepsy 384
PROTOTYPE DRUG: Modafinil (Provigil) 384
Methylxanthines 386
PROTOTYPE DRUG: Caffeine 386
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Central Nervous System Stimulants 387

25 Pharmacotherapy of Severe Pain and Migraines 392

General Principles of Pain Management 393
Pain Management with Opioids 398
PROTOTYPE DRUG: Morphine Sulfate (Astramorph PF, Duramorph RF, Roxanol, Others) 402
Pain Management with Nonopioids 406
PROTOTYPE DRUG: Tramadol (Ultram, Others) 406
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Pain 408
Pharmacotherapy with Opioid Antagonists 412
Pharmacotherapy of Migraines 413
PROTOTYPE DRUG: Sumatriptan (Imitrex, Onzetra) 415
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Migraines 417

26 Anesthetics and Anesthesia Adjuncts 422

Types of Anesthesia 423
Principles of General Anesthesia 423
Intravenous Anesthetics 424
PROTOTYPE DRUG: Fentanyl (Sublimaze) 425
PROTOTYPE DRUG: Midazolam (Versed) 427
PROTOTYPE DRUG: Propofol (Diprivan) 428
Inhalation Anesthetics 430
PROTOTYPE DRUG: Nitrous Oxide 430
PROTOTYPE DRUG: Isoflurane (Forane) 432
Local Anesthetics 433
CONNECTIONS: Nursing Practice Application
Patients Receiving General Anesthesia 434
PROTOTYPE DRUG: Procaine (Novocaine) 438
PROTOTYPE DRUG: Lidocaine (Anestacon, Xylocaine, Zingo, Others) 439
Adjuncts to Anesthesia 441
CONNECTIONS: Nursing Practice Application
Patients Receiving Local Anesthesia 442

27 Pharmacology of Substance Abuse 447

Fundamental Concepts of Substance Abuse 448
Legislation of Controlled Substances 449
Addiction and Dependence 449
Tolerance 451
Central Nervous System Depressants 452
Sedatives and Antianxiety Drugs 452
Opioids 453
PROTOTYPE DRUG: Buprenorphine with Naloxone (Suboxone, Zubsolv, Others) 454
Alcohol (Ethanol) 455
PROTOTYPE DRUG: Disulfiram (Antabuse) 457
Marijuana and Related Substances 458
Hallucinogens 459
LSD and Similar Hallucinogens 459
Club Drugs and Miscellaneous Hallucinogens 460
Central Nervous System Stimulants 461
Amphetamines and Methylphenidate 461
Cocaine 462
Caffeine 463
Nicotine 463
PROTOTYPE DRUG: Varenicline (Chantix) 464
Inhalants 465
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Substance Abuse Disorders 466
Anabolic Steroids 467

Unit 5 Pharmacology of the Cardiovascular System

28 Review of the Cardiovascular System 474

Structure and Function of the Cardiovascular System 475
Functions and Properties of Blood 475
Cardiac Structure and Function 478
Hemodynamics and Blood Pressure 483

29 Pharmacotherapy of Hyperlipidemia 488

Types of Lipids and Lipoproteins 489
Measurement and Control of Serum Lipids 492
Drugs for Dyslipidemias 494
PROTOTYPE DRUG: Atorvastatin (Lipitor) 496
PROTOTYPE DRUG: Cholestyramine (Questran) 500
PROTOTYPE DRUG: Gemfibrozil (Lopid) 502
Miscellaneous Drugs for Dyslipidemias 503

CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Hyperlipidemia 505

30 Pharmacotherapy with Calcium Channel Blockers 510

Physiologic Role of Calcium Channels in Muscle Contraction 511
Types of Calcium Channels 512
Consequences of Calcium Channel Blockade 513
Classification of Calcium Channel Blockers 513
PROTOTYPE DRUG: Nifedipine (Adalat CC, Procardia XL) 515
PROTOTYPE DRUG: Verapamil (Calan, Isoptin, Verelan) 517
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Calcium Channel Blockers 519

31 Drugs Affecting the Renin-Angiotensin-Aldosterone System 523

Components of the Renin-Angiotensin-Aldosterone System 524
Physiologic Actions of the Renin-Angiotensin-Aldosterone System 526
Drugs Affecting the Renin-Angiotensin-Aldosterone System 527
PROTOTYPE DRUG: Lisinopril (Prinivil, Zestril) 529
PROTOTYPE DRUG: Losartan (Cozaar) 532
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers 534

32 Diuretic Therapy and the Pharmacotherapy of Chronic Kidney Disease 539

Review of Renal Physiology 540
Pharmacotherapy for Patients with Chronic Kidney Disease 541
Diuretic Therapy 543
Loop (High-Ceiling) Diuretics 545
PROTOTYPE DRUG: Furosemide (Lasix) 546
Thiazide and Thiazide-Like Diuretics 548
PROTOTYPE DRUG: Hydrochlorothiazide (Microzide) 549
Potassium-Sparing Diuretics 550
PROTOTYPE DRUG: Spironolactone (Aldactone) 551
Osmotic Diuretics 552
PROTOTYPE DRUG: Mannitol (Osmitrol) 553
Carbonic Anhydrase Inhibitors 554
PROTOTYPE DRUG: Acetazolamide (Diamox) 554
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Diuretics 555

33 Pharmacotherapy of Fluid Imbalance, Electrolyte, and Acid–Base Disorders 561

Principles of Fluid Balance 562
Fluid Replacement Agents 563
PROTOTYPE DRUG: Normal Serum Albumin (Albuminar, Plasbumin, Others) 565
PROTOTYPE DRUG: 5% Dextrose in Water (D_5W) 566
PROTOTYPE DRUG: Dextran 40 (Gentran 40, Others) 567
Physiology of Electrolytes 568
Pharmacotherapy of Electrolyte Imbalances 569
PROTOTYPE DRUG: Sodium Chloride (NaCl) 571
PROTOTYPE DRUG: Potassium Chloride (KCl) 572
PROTOTYPE DRUG: Magnesium Sulfate ($MgSO_4$) 574
Pharmacotherapy of Acid–Base Imbalances 575
PROTOTYPE DRUG: Sodium Bicarbonate 576
PROTOTYPE DRUG: Ammonium Chloride 577
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Fluid and Electrolyte Imbalances 578

34 Pharmacotherapy of Hypertension 582

Etiology and Pathogenesis of Hypertension 583
Nonpharmacologic Management of Hypertension 584
Guidelines for the Management of Hypertension 584
Pharmacotherapy of Hypertension 585
Drugs for Initial Hypertension Therapy 586
Adding Drugs to the Antihypertensive Regimen 587
Enhancing Patient Adherence 587
Antihypertensives in African Americans 588
Drug Classes for Hypertension 588
PROTOTYPE DRUG: Hydralazine 593
Management of Hypertensive Emergency 594
PROTOTYPE DRUG: Nitroprusside Sodium (Nitropress) 595
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Direct Vasodilators 596

35 Pharmacotherapy of Angina Pectoris and Myocardial Infarction 602

Pathophysiology of Myocardial Ischemia 603
Myocardial Oxygen Supply 603
Myocardial Oxygen Demand 603
Etiology of Coronary Artery Disease 604
Pathophysiology of Angina Pectoris 604
Nonpharmacologic Therapy of Coronary Artery Disease 605
Pharmacologic Management of Angina Pectoris 606

Drug Classes for Angina Pectoris 607
PROTOTYPE DRUG: Nitroglycerin (Nitrostat, Nitro-Bid, Nitro-Dur, Others) 609
PROTOTYPE DRUG: Atenolol (Tenormin) 611
Pathophysiology of Myocardial Infarction 612
Pharmacologic Management of Myocardial Infarction 613
Aspirin 614
Anticoagulants and Antiplatelet Drugs 614
Nitrates 616
Beta-Adrenergic Antagonists 616
Angiotensin-Converting Enzyme Inhibitors 616
Pain Management 617
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Organic Nitrates for Angina and Myocardial Infarction 617

36 Pharmacotherapy of Heart Failure 622

Etiology of Heart Failure 623
Pathophysiology of Heart Failure 623
Ventricular Hypertrophy 624
Activation of the Sympathetic Nervous System 625
Increased Plasma Volume and Preload 625
Natriuretic Peptides and Neurohumoral Factors 625
Pharmacologic Management of Heart Failure 626
Drugs for Heart Failure 627
PROTOTYPE DRUG: Digoxin (Lanoxin, Lanoxicaps) 632
PROTOTYPE DRUG: Milrinone (Primacor) 635
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Heart Failure 635

37 Pharmacotherapy of Dysrhythmias 641

Etiology of Dysrhythmias 642
Phases and Measurement of the Cardiac Action Potential 642
Classification of Dysrhythmias 645
General Principles of Dysrhythmia Management 646
Drugs for Dysrhythmias 646
Sodium Channel Blockers: Class I 647
PROTOTYPE DRUG: Procainamide 649
Beta-Adrenergic Antagonists: Class II 652
Potassium Channel Blockers: Class III 653
PROTOTYPE DRUG: Amiodarone (Pacerone) 653
Calcium Channel Blockers: Class IV 655
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Dysrhythmias 656
Miscellaneous Antidysrhythmics 656

38 Pharmacotherapy of Coagulation Disorders 661

Disorders of Hemostasis 662
Overview of Coagulation Modifiers 664
Anticoagulants 665
PROTOTYPE DRUG: Heparin 666
PROTOTYPE DRUG: Warfarin (Coumadin) 669
PROTOTYPE DRUG: Dabigatran (Pradaxa) 671
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Anticoagulants 672
Antiplatelet Drugs 674
PROTOTYPE DRUG: Clopidogrel (Plavix) 675
PROTOTYPE DRUG: Abciximab (ReoPro) 677
Drugs for Intermittent Claudication 679
Thrombolytics 680
PROTOTYPE DRUG: Alteplase (Activase) 681
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Thrombolytics 682
Hemostatics 684
PROTOTYPE DRUG: Aminocaproic Acid (Amicar) 684
Drugs for Hemophilia 686

39 Pharmacotherapy of Hematopoietic Disorders 691

Physiology of Hematopoiesis 692
Hematopoietic Growth Factors 692
PROTOTYPE DRUG: Epoetin Alfa (Epogen, Procrit) 693
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Erythropoietin 696
PROTOTYPE DRUG: Filgrastim (Granix, Neupogen, Zarxio) 697
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Colony-Stimulating Factors 699
PROTOTYPE DRUG: Oprelvekin (Neumega) 700
Classification of Anemias 702
Antianemic Drugs 703
PROTOTYPE DRUG: Ferrous Sulfate (Feosol, Feostat, Others) 705
PROTOTYPE DRUG: Cyanocobalamin (Nascobal) 708

Unit 6 Pharmacology of Body Defenses

40 Review of Body Defenses and the Immune System 714

Organization of the Lymphatic System 715
Innate (Nonspecific) Body Defenses 715
Inflammation 718
Specific (Adaptive) Body Defenses 719
Humoral Immune Response 720
Cell-Mediated Immune Response 720

41 Pharmacotherapy of Inflammation and Fever 723

Pathophysiology of Inflammation and Fever 724
Pharmacotherapy of Inflammation 724
Nonsteroidal Anti-Inflammatory Drugs 725
Salicylates 725
PROTOTYPE DRUG: Aspirin (Acetylsalicylic Acid) 728
Ibuprofen-Like Drugs 730
PROTOTYPE DRUG: Ibuprofen (Advil, Motrin, Others) 731
Cyclooxygenase-2 Inhibitors 733
PROTOTYPE DRUG: Celecoxib (Celebrex) 734
Antipyretic and Analgesic Drugs 735
PROTOTYPE DRUG: Acetaminophen (Tylenol) 735
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Inflammation and Fever 737

42 Immunostimulants and Immunosuppressants 741

Immunostimulants 743
PROTOTYPE DRUG: Interferon Alfa-2b (Intron A) 743
PROTOTYPE DRUG: Aldesleukin (Proleukin) 746
Immunosuppressants 747
PROTOTYPE DRUG: Cyclosporine (Gengraf, Neoral, Sandimmune) 751
PROTOTYPE DRUG: Azathioprine (Azasan, Imuran) 753
PROTOTYPE DRUG: Basiliximab (Simulect) 755
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Immunomodulators 757

43 Immunizing Agents 762

Discovery of Vaccines 763
Vaccines and the Immune System 763
Types of Vaccines 764
General Principles of Vaccine Administration 765
Active Immunity: Bacterial Immunizations 766
Diphtheria 766
Pertussis (Whooping Cough) 766
Tetanus 768
Pneumococcus 768
Meningococcus 769
Active Immunity: Viral Immunizations 769
Hepatitis B 769
PROTOTYPE DRUG: Hepatitis B Vaccine (Engerix-B, Recombivax HB) 770
Hepatitis A 771
Influenza 771
Rabies 772
Measles, Mumps, and Rubella 772
Polio 773
Varicella Zoster 774
Human Papillomavirus 775
Rotavirus 776
Passive Immunity 776
PROTOTYPE DRUG: Rho(D) Immune Globulin (RhoGAM) 776
CONNECTIONS: Nursing Practice Application
Patients Receiving Immunizations 779

Unit 7 Pharmacology of the Respiratory System and Allergy

44 Pharmacotherapy of Asthma and Other Pulmonary Disorders 786

Physiology of the Lower Respiratory Tract 787
Pathophysiology of Asthma 788
Administration of Pulmonary Drugs via Inhalation 788
Principles of Asthma Pharmacotherapy 790
PROTOTYPE DRUG: Albuterol (Proventil HFA, Ventolin HFA, VoSpire ER) 792
PROTOTYPE DRUG: Ipratropium (Atrovent) 796
PROTOTYPE DRUG: Beclomethasone (Beconase AQ, Qvar) 797
PROTOTYPE DRUG: Cromolyn 799
PROTOTYPE DRUG: Montelukast (Singulair) 800
PROTOTYPE DRUG: Theophylline 802
Chronic Obstructive Pulmonary Disease 803
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Asthma and COPD 804

45 Pharmacotherapy of Allergic Rhinitis and the Common Cold 810

Physiology of the Upper Respiratory Tract 811
Pathophysiology of Allergic Rhinitis 812
Pharmacotherapy of Allergic Rhinitis 813
PROTOTYPE DRUG: Fexofenadine (Allegra) 816
PROTOTYPE DRUG: Fluticasone (Flonase, Veramyst) 818
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antihistamines 819
Decongestants 822
PROTOTYPE DRUG: Pseudoephedrine (Sudafed) 823
Drugs for the Common Cold 824
Antitussives 825
PROTOTYPE DRUG: Dextromethorphan (Delsym, Robitussin DM, Others) 826
Expectorants and Mucolytics 826
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Symptomatic Cough and Cold Relief 827

Unit 8 Pharmacology of Infectious and Neoplastic Diseases

46 Basic Principles of Anti-Infective Pharmacotherapy 834

Pathogenicity and Virulence 835
Describing and Classifying Bacteria 836
Classification of Anti-Infectives 836
Mechanisms of Action of Anti-Infectives 838
- Inhibition of Cell Wall Synthesis 838
- Inhibition of Protein Synthesis 838
- Disruption of the Plasma Cell Membrane 839
- Inhibition of Nucleic Acid Synthesis 839
- Inhibition of Metabolic Pathways (Antimetabolites) 839
- Other Mechanisms of Action 839

Acquired Resistance 839
- Mechanisms of Resistance 839
- Promotion of Resistance 840
- Prevention of Resistant Strains 841

Indications and Selection of Specific Anti-Infectives 844
Host Factors Affecting Anti-Infective Selection 844
- Host Defenses 845
- Local Tissue Conditions 845
- Allergy History 845
- Other Host Factors 845

Superinfections 845

47 Antibiotics Affecting the Bacterial Cell Wall 848

Structure of Bacterial Cell Walls 849
Penicillins 850
- Natural Penicillins 852
- PROTOTYPE DRUG: Penicillin G 852
- Broad-Spectrum Penicillins (Aminopenicillins) 854
- PROTOTYPE DRUG: Ampicillin 854
- Extended-Spectrum (Antipseudomonal) Penicillins 855
- Penicillinase-Resistant (Antistaphylococcal) Penicillins 855

Cephalosporins 856
- PROTOTYPE DRUG: Cefazolin (Ancef, Kefzol) 858

Carbapenems 859
- PROTOTYPE DRUG: Imipenem-Cilastatin (Primaxin) 860

Miscellaneous Cell Wall Inhibitors 862
- PROTOTYPE DRUG: Vancomycin (Vancocin) 862
- CONNECTIONS: Nursing Practice Application Patients Receiving Pharmacotherapy with a Penicillin, Cephalosporin, or Vancomycin Antibiotic 863

48 Antibiotics Affecting Bacterial Protein Synthesis 868

Mechanisms of Antibiotic Inhibition of Bacterial Protein Synthesis 869
Tetracyclines 870
- PROTOTYPE DRUG: Tetracycline (Sumycin, Others) 872

Macrolides 874
- PROTOTYPE DRUG: Erythromycin (EryC, Erythrocin, Others) 875

Aminoglycosides 876
- PROTOTYPE DRUG: Gentamicin (Garamycin, Others) 878

Miscellaneous Inhibitors of Bacterial Protein Synthesis 880
- CONNECTIONS: Nursing Practice Application Patients Receiving Pharmacotherapy with a Tetracycline, Macrolide, or Aminoglycoside Antibiotic 882

49 Fluoroquinolones and Miscellaneous Antibacterials 887

Bacterial DNA Replication 888
Inhibition of DNA Replication 888
Fluoroquinolones 889
- Adverse Effects 890
- PROTOTYPE DRUG: Ciprofloxacin (Cipro) 891

Miscellaneous Antibacterials 893
- CONNECTIONS: Nursing Practice Application Patients Receiving Pharmacotherapy with Fluoroquinolones 895

50 Sulfonamides and the Pharmacotherapy of Urinary Tract Infections 900

Pathophysiology of Urinary Tract Infections 901
Pharmacotherapy of Urinary Tract Infections 901
- Acute Uncomplicated Cystitis 902
- Complicated Urinary Tract Infection 902
- Infants and Children 903
- Pregnancy 903
- Older Adults 903
- Patients with Recurring Urinary Tract Infections 904

Sulfonamides 904
- Adverse Effects 906
- PROTOTYPE DRUG: Trimethoprim-Sulfamethoxazole (Bactrim, Septra) 907

Urinary Antiseptics 908
- PROTOTYPE DRUG: Nitrofurantoin (Furadantin) and Nitrofurantoin Macrocrystals (Macrobid, Macrodantin) 908
- CONNECTIONS: Nursing Practice Application Patients Receiving Pharmacotherapy for Urinary Tract Infection 910

51 Pharmacotherapy of Mycobacterial Infections 915

Types of Mycobacterial Infections 916
Pathogenesis and Diagnosis of Tuberculosis 916
Pharmacotherapy of Tuberculosis 918
Standard Regimen 919
Patients Who Are HIV Positive 921
Pregnant Patients 921
Chemoprophylaxis Patients 921
PROTOTYPE DRUG: Isoniazid (INH) 922
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Tuberculosis 927
Drugs for Leprosy 928
PROTOTYPE DRUG: Dapsone (DDS) 929
Drugs for *Mycobacterium avium* Complex Infections 930

52 Pharmacotherapy of Fungal Infections 934

Characteristics of Fungi and Fungal Infections 935
Drugs for Systemic Fungal Infections 938
PROTOTYPE DRUG: Amphotericin B Deoxycholate (Fungizone) 939
Drugs for Both Systemic and Superficial Fungal Infections 941
PROTOTYPE DRUG: Fluconazole (Diflucan) 941
Drugs for Superficial Fungal Infections 943
PROTOTYPE DRUG: Nystatin (Nystop) 947
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antifungals 948

53 Pharmacotherapy of Protozoan and Helminthic Infections 952

Classification and Pathogenesis of Protozoan Infections 953
Drugs for Malaria 954
PROTOTYPE DRUG: Chloroquine (Aralen) 956
Drugs for Nonmalarial Protozoan Infections 958
PROTOTYPE DRUG: Metronidazole (Flagyl) 960
PROTOTYPE DRUG: Pyrimethamine (Daraprim) 964
Classification and Pathogenesis of Helminthic Infections 965
Drugs for Helminthic Infections 968
PROTOTYPE DRUG: Mebendazole (Vermox) 968
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy for Protozoan and Helminthic Infections 970

54 Pharmacotherapy of Non-HIV Viral Infections 975

Characteristics of Viruses 976
Pharmacotherapy of Non-HIV Viral Infections 978
Drugs for Herpesviruses 979
PROTOTYPE DRUG: Acyclovir (Zovirax) 980
Drugs for Influenza Viruses 982
PROTOTYPE DRUG: Amantadine (Symmetrel) 984
Drugs for Hepatitis Viruses 985
PROTOTYPE DRUG: Tenofovir (Vemlidy, Viread) 989
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antivirals for Non-HIV Viral Infections 992

55 Pharmacotherapy of HIV Infection and AIDS 996

Pathogenesis of HIV Infection 997
General Principles of HIV Pharmacotherapy 999
Classification of Antiretroviral Drugs 1001
Antiretroviral Drugs 1003
PROTOTYPE DRUG: Zidovudine (AZT, Retrovir) 1004
PROTOTYPE DRUG: Efavirenz (Sustiva) 1006
PROTOTYPE DRUG: Lopinavir with Ritonavir (Kaletra) 1008
Prophylaxis of HIV Infections 1010
CONNECTIONS: Nursing Practice Application
Patients Receiving Pharmacotherapy with Antiretrovirals 1011
Pharmacotherapy of Opportunistic Infections Associated with HIV and AIDS 1015

56 Basic Principles of Antineoplastic Therapy 1020

Characteristics of Cancer 1021
Etiology of Cancer 1022
Detection and Prevention of Cancer 1023
Goals of Chemotherapy 1023
Staging and Grading of Cancer 1024
The Cell Cycle and Growth Fraction 1025
Cell Kill Hypothesis 1027
Improving the Success of Chemotherapy 1028
Combination Chemotherapy 1028
Dosing Schedules 1028
Route of Administration 1028
Toxicity of Antineoplastic Drugs 1029
Hematologic System 1029
Gastrointestinal Tract 1030
Cardiopulmonary System 1031
Urinary System 1031
Reproductive System 1031
Nervous System 1031
Skin and Soft Tissue 1032
Other Effects 1032

57 Pharmacotherapy of Neoplasia 1036

Classification of Antineoplastic Drugs 1037
Antineoplastic Medications 1037
Alkylating Agents 1037

PROTOTYPE DRUG: Cyclophosphamide (Cytoxan) 1038
Antimetabolites 1043
PROTOTYPE DRUG: Methotrexate (MTX, Rheumatrex, Trexall) 1044
Antitumor Antibiotics 1048
PROTOTYPE DRUG: Doxorubicin (Adriamycin) 1048
Hormones and Hormone Antagonists 1051
PROTOTYPE DRUG: Tamoxifen 1053
Natural Products 1056
PROTOTYPE DRUG: Vincristine (Marqibo, Oncovin) 1057
CONNECTIONS: Nursing Practice Application Patients Receiving Cancer Chemotherapy 1060
Biologic Response Modifiers and Targeted Therapies 1063
Miscellaneous Antineoplastics 1066
Drugs for Reducing Adverse Effects 1069
Preparing and Administering Antineoplastics 1069

Unit 9 Pharmacology of the Gastrointestinal System

58 Review of the Gastrointestinal System 1074

Overview of the Digestive System 1075
Physiology of the Upper Gastrointestinal Tract 1075
Physiology of the Lower Gastrointestinal Tract 1077
Physiology of the Accessory Organs of Digestion 1077
Regulation of Digestive Processes 1079
Nutrient Categories and Metabolism 1080

"Wow, I just left my first pharmacology class and my head is swirling. How will I ever remember all this?"
Student "Josh Remming"

Chapter 1
Introduction to Pharmacology: Concepts and Connections

Chapter Outline

- Brief History of Pharmacology
- Pharmacology: The Study of Medicines
- Characteristics of an Ideal Drug
- Classification of Drugs
- Prototype Drugs
- Naming Drugs
- Connecting Pharmacology to Clinical Nursing Practice

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify key events in the history of pharmacology.
2. Compare and contrast the terms *drug*, *pharmacology*, and *pharmacotherapy*.
3. Explain the importance of pharmacotherapy to clinical nursing practice.
4. Using specific examples, explain the difference between the pharmacologic and therapeutic methods of classifying drugs.
5. Identify the advantages of using prototype drugs to study pharmacology.
6. Classify drugs by their chemical, generic, and trade names.
7. Discuss the rationale for a pharmaceutical company receiving exclusivity for the marketing of a new drug.
8. Analyze possible differences between generic drugs and their trade-name equivalents.
9. Explain how a biosimilar drug differs from its reference product.
10. Identify the responsibilities of the nurse in drug administration as part of an interprofessional team.

Key Terms

bioavailability, 8
biosimilar drug, 9
chemical names, 7
combination drugs, 8
drug, 4

generic name, 7
indications, 5
pharmacologic classification, 6
pharmacology, 4
pharmacotherapy, 4
prototype drug, 7
therapeutic classification, 6
trade name, 7

More drugs are being administered to consumers than ever before. Over 3.6 billion prescriptions are dispensed each year in the United States, and the number is rapidly approaching 4 billion. Sales of prescription medications at retail pharmacies in the United States exceeded $286 billion in 2015 (Kaiser Family Foundation, 2016). The applications of pharmacology to medicine have expanded over the centuries and the nurse serves a key role in ensuring the success of pharmacotherapy. The purpose of this chapter is to introduce fundamental concepts of pharmacology and to emphasize the connections between drug therapy and clinical nursing practice.

PharmFACT

From 1999 to 2014, deaths from prescription opioids such as methadone and oxycodone quadrupled. More than 165,000 Americans died from overdoses from these prescription drugs during this period (Centers for Disease Control and Prevention, 2016).

Brief History of Pharmacology

1.1 The practice of applying products to relieve suffering has been recorded throughout history by virtually every culture.

The story of pharmacology is rich and exciting, filled with accidental discoveries and landmark events. Its history likely began when a human first used a plant to relieve symptoms of disease. One of the oldest forms of healthcare, herbal medicine has been practiced in virtually every culture dating to antiquity. The Babylonians recorded the earliest surviving "prescriptions" on clay tablets in 3000 BC, although magic and the art of reading omens were probably considered just as legitimate to healing as the use of herbal remedies. At about the same time, the Chinese recorded the *Pen Tsao* (Great Herbal), a 40-volume compendium of plant remedies dating to 2700 BC. The Egyptians followed in 1500 BC by archiving their remedies on a document known as the Eber's papyrus, which contains over 700 magical formulas and remedies. Galen, the famous Greek physician, described over 1000 healing preparations using plant products before his death in AD 201.

Little is known about pharmacology during the Dark Ages. Although it is likely that herbal medicine continued to be practiced, especially in monasteries and in centers of Arabic culture, few historical events related to drug therapy were recorded. Pharmacology, and indeed medicine, could not advance until the discipline of science was eventually viewed differently than magic and superstition.

The first recorded reference to the word *pharmacology* was found in a text titled "Pharmacologia sen Manuductio and Materiam Medicum" by Samuel Dale in 1693. Before this date, the study of herbal remedies was called "Materia Medica." The term *Materia Medica* likely originated from a Latin term meaning "medical matters," although use of this term continued into the early 20th century.

Although the exact starting date is obscure, modern pharmacology is thought to have begun in the early 1800s. At that time, chemists were making remarkable progress in separating specific substances from complex mixtures. This enabled chemists to isolate the active agents morphine, colchicine, curare, cocaine, and other early drugs from their natural plant products. Pharmacologists could then study their effects in animals more precisely, using standardized amounts. Some of the early researchers even used themselves as test subjects. Friedrich Sertürner, who first isolated morphine from opium in 1805, injected himself and three of his friends with a huge dose of 100 mg of his new product. He and his cohorts experienced acute morphine intoxication for several days afterward.

Pharmacology as a distinct discipline was officially recognized when the first Department of Pharmacology was established in Estonia in 1847. John Jacob Abel, who is considered the father of American pharmacology due to his many contributions to the field, founded the first pharmacology department in the United States at the University of Michigan in 1890.

In the 20th century, the pace of change in all areas of medicine became exponential. Pharmacologists no longer needed to rely on the slow, laborious process of isolating active agents from scarce natural products. They could synthesize drugs "from scratch" in the laboratory. Hundreds of new drugs could be synthesized and tested in a relatively short time span. More importantly, it became

possible to understand how drugs produced their effects, right down to their molecular mechanism of action.

The current practice of pharmacology is extremely complex and has progressed far beyond its early, primitive history. The nurses and other health professionals who administer medications, however, must never forget the early roots of pharmacology: the application of products to relieve or prevent human suffering. Whether a substance is extracted from the Pacific yew tree, isolated from a fungus, or created in a laboratory, the central purpose of pharmacology is focused on the patient and improving the quality of life.

CONNECTION Checkpoint 1.1

Some modern drugs used in the treatment of diabetes, cardiovascular disorders, and other conditions have unique sources. Using an online dictionary or search engine, what are the natural sources for exenatide (Byetta), captopril (Capoten), and hyaluronic acid? What conditions are they used to treat? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacology: The Study of Medicines

1.2 Pharmacology is the study of medicines.

The word *drug* has already been used numerous times in this text. What exactly is a drug? Is everything a drug, including water, vitamin C, or perhaps a can of cola? What about substances naturally found in the body, such as estrogen or testosterone? Is it even possible to define a drug?

The definition of a drug is indeed difficult but is nevertheless important to the healthcare profession. There are many definitions, but perhaps the clearest is that a **drug** is any substance that is taken to prevent, cure, or reduce symptoms of a medical condition. Considering the substances listed earlier, which, then, are drugs? Although it may seem vague, the correct answer is "it depends."

- The caffeine consumed in a cup of coffee is not considered a drug. Yet caffeine is included in several therapies for headache pain, including Excedrin and Fioricet. For the patient trying to get pain relief, caffeine is a drug.
- Vitamin C, if ingested as part of an orange or tomato, is food. Food is not a drug. However, someone with a vitamin C deficiency may be administered vitamin C to cure scurvy. For this patient, vitamin C is then considered a drug.
- A can of cola is certainly not listed in any drug guide. However, if a patient with diabetes is experiencing a hypoglycemic reaction, the glucose in a can of soda may raise the patient's blood sugar and prevent a coma; thus, the glucose in the cola may be considered a drug in this example.
- Substances normally found in the body are not considered drugs unless they are administered to treat a condition. For example, the hormone estrogen circulating in the blood is not a drug. However, when it is taken as an oral contraceptive to prevent a condition (pregnancy), estrogen is considered a drug.

Once the meaning of the term *drug* is understood, the next essential term is *pharmacology*. The word *pharmacology* is derived from two Greek words, *pharmakon*, which means "medicine" or "drug," and *logos*, which means "study." Thus, **pharmacology** is most simply defined as the study of medicines. Pharmacology is an expansive subject, ranging from understanding how drugs are administered, to where they travel in the body, to the actual responses they produce. **Pharmacotherapy**, or pharmacotherapeutics, is the application of drugs for the purpose of disease prevention and treatment of suffering.

Drugs are a form of medical intervention given to improve a patient's condition or to prevent harm. Pharmacotherapy often begins when the patient experiences signs or symptoms that cause dissatisfaction with current or future health status. A major role of the nurse is to design interventions that meet the desired health goals of the patient. Pharmacotherapy is a critical intervention for many conditions. The rationale for pharmacotherapy is illustrated in Figure 1.1.

Over 11,000 trade-name and generic drugs and combination agents are currently available for pharmacotherapy. Each has its own characteristic set of therapeutic applications, interactions, adverse effects, and mechanism of action. Many drugs are prescribed for more than one disease and most produce multiple effects on the body. Further complicating the study of pharmacology is the fact that drugs may elicit different responses depending on individual patient factors such as age, gender, race, body mass, health status, and genetics. Indeed, learning the applications of existing medications and staying current with new drugs introduced every year can be an enormous challenge for the nurse. The task, however, is a critical one for both the patient and the healthcare provider. When applied properly, drugs can dramatically improve patients' quality of life. If applied improperly, the consequences of drug action can cause permanent disability and even death.

There are important exceptions to the drug definition mentioned earlier. What about crack cocaine, ecstasy, LSD, or the fumes in glues and paint thinners? These are certainly drugs, but they are not taken "to prevent, cure, or reduce symptoms of a medical condition." In fact, they are taken to produce a biologic effect viewed as desirable or pleasurable by the user (see Chapter 27). Other exceptions to this definition of the term *drug* will become apparent as the student studies pharmacology.

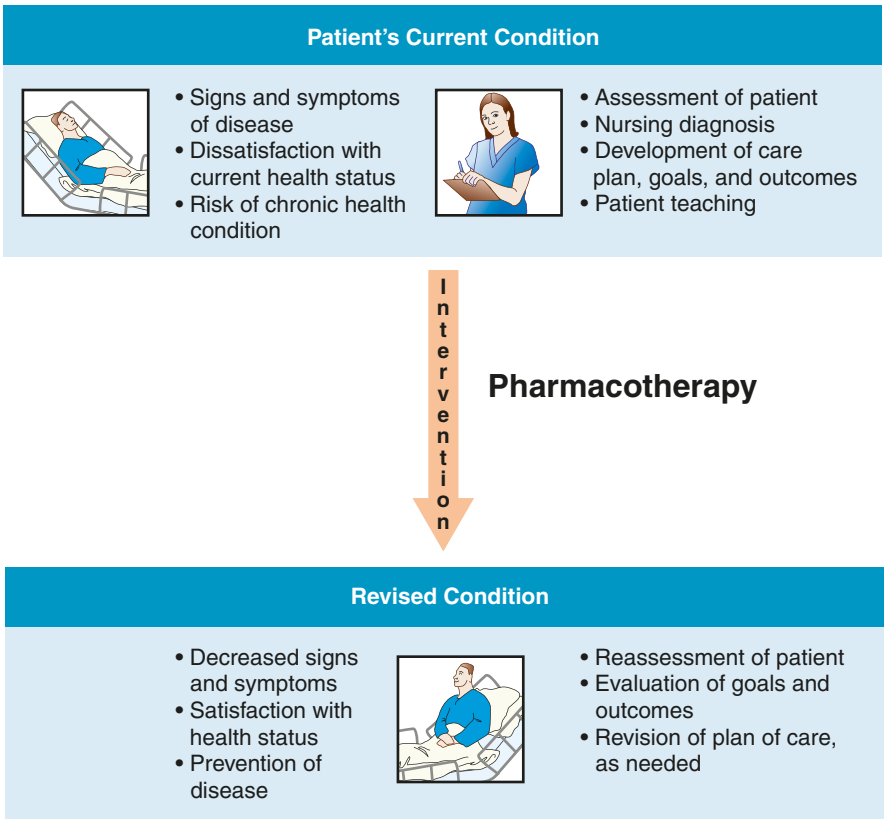

Figure 1.1 Rationale for pharmacotherapy: a partnership between the patient and the healthcare provider.

drug. Some drugs meet most of the criteria, whereas others meet very few. At the very least, all prescription drugs are expected to have some degree of effectiveness at treating or preventing a health condition. The conditions for which a drug is approved are its **indications**. Every medication has at least one indication, and most have multiple indications. Some drugs are used for conditions for which they have not been approved; these are called unlabeled or off-label indications.

As a general rule, the more a medicine strays from the perfect drug profile, the less commonly it is used. This is because whenever possible, healthcare providers strive to prescribe the most effective, safest, and most convenient medication for the patient. In the home care setting, drugs that cause annoying adverse effects, have inconvenient dosing schedules, or are expensive are often not taken by patients, potentially worsening their condition and causing failure of treatment outcomes. Of course, some essential drugs do produce serious adverse effects or must be given by invasive routes, such as intravenously. In these cases, the drug is either administered in a clinical setting by a nurse, or the patient receives careful instructions and regular monitoring on an outpatient basis.

Characteristics of an Ideal Drug

1.3 The perfect drug is safe and effective.

As they begin their journey in mastering pharmacology, nursing students should start with a notion of the ideal or "perfect drug." Learning the characteristics of an ideal drug gives a basis for comparison to "real drugs." It is always the goal of pharmacotherapy to select the perfect or ideal drug for the patient. Just what is a perfect drug? It is one that:

- Effectively treats, prevents, or cures the patient's condition.
- Produces a rapid, predictable response at relatively low doses.
- Produces no adverse effects.
- Can be taken conveniently, usually by mouth.
- Can be taken infrequently, usually once a day, and for a short length of time.
- Is inexpensive and easily accessible.
- Is quickly eliminated by the body after it produces its beneficial effect.
- Does not interact with other medications or food.

After reading this description, it should appear clear to the student that there is really no such thing as a perfect

CONNECTIONS: Patient Safety

Preventing Interactions

A patient has tried to manage symptoms of depression naturally with St. John's wort, an herbal over-the-counter product. This has not been successful and the patient has decided to visit the healthcare provider. After a thorough assessment, the provider gives the patient a prescription for the antidepressant paroxetine (Paxil). Before teaching this patient about the new prescription, the nurse consults a drug reference guide. Based on that content, what will this patient need to know about St. John's wort and paroxetine to ensure safe and effective medication therapy? (Refer to this textbook or a drug reference guide for information about paroxetine [Paxil] and potential interactions.)

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Classification of Drugs

1.4 Drugs may be organized by their therapeutic classification or pharmacologic classification.

The U.S. Food and Drug Administration (FDA, 2016) document *Approved Drug Products with Therapeutic Equivalence Evaluations*, informally called the "Orange Book," lists over 11,000 approved drugs. With the vast number of drugs available, it is essential that methods be used to group similar agents to aid in their study and understanding. The two basic classifications of drugs are therapeutic and pharmacologic. Both categories are widely used in classifying prescription and nonprescription drugs. The key difference is that the **therapeutic classification** describes what is being treated by the drug, whereas the **pharmacologic classification** describes how the drug acts.

Drugs are placed into therapeutic classes based on their usefulness in treating a specific disease. Table 1.1 shows the method of therapeutic classification, using cardiovascular drugs as an example. Many different types of drugs affect cardiovascular function. Some drugs influence blood coagulation, whereas others lower cholesterol levels or prevent the onset of stroke. Drugs may be used to treat hypertension, heart failure, abnormal cardiac rhythm, chest pain, myocardial infarction (MI), or circulatory shock. Thus, drugs that treat cardiovascular disorders may be placed in several therapeutic classes, for example, anticoagulants, antihyperlipidemics, and antihypertensives. The key to therapeutic classification is to simply state what condition is being treated by the particular drug. Other examples of therapeutic classifications include antidepressants, antipsychotics, drugs for erectile dysfunction, and antineoplastics. Notice how the prefix *anti-* often refers to a therapeutic classification.

The pharmacologic classification addresses a drug's mechanism of action or how a drug produces its effect in the body. Table 1.2 illustrates the use of pharmacologic classification, using hypertension as an example. A diuretic treats hypertension by lowering plasma volume. Calcium channel blockers treat this disorder by decreasing the force of cardiac contractions. Other drugs block components of the renin-angiotensin system. Notice that each example describes how hypertension might be controlled. A drug's pharmacologic classification is more specific than its therapeutic classification and requires an understanding of biochemistry and physiology. Pharmacologic classifications may use a drug's chemical name.

Although classifications help to organize drugs, the process is by no means easy or standardized. Most drugs have multiple classifications. For example, the drug epinephrine is classified as a vasoconstrictor, an autonomic nervous system agent, an adrenergic agonist, a sympathomimetic, a bronchodilator, an agent for anaphylaxis, an ocular mydriatic, an antiglaucoma agent, a catecholamine, and a topical hemostatic. This is clearly a mix of therapeutic (e.g., antiglaucoma) and pharmacologic (e.g., catecholamine) classifications. Which one(s) should the student remember? Unfortunately for nursing students, the answer is all of them. The classification chosen primarily depends on the specific clinical use of the drug (What condition is being treated?). Sometimes the classification of choice is simply a preference of the healthcare provider. Although challenging, remembering the different classifications will pay dividends as the student's pharmacology course progresses.

Table 1.1 Organizing Drug Information by Therapeutic Classification

THERAPEUTIC FOCUS: DRUGS AFFECTING CARDIOVASCULAR DISEASE

Therapeutic Usefulness	Therapeutic Classification
Influence blood clotting	Anticoagulants
Lower blood cholesterol	Antihyperlipidemics
Lower blood pressure	Antihypertensives
Restore normal cardiac rhythm	Antidysrhythmics
Treat angina	Antianginals

Table 1.2 Organizing Drug Information by Pharmacologic Classification

FOCUS ON HOW A DRUG WORKS: PHARMACOTHERAPY OF HYPERTENSION

Mechanism of Action	Pharmacologic Classification
Lowers plasma volume	Diuretic
Blocks heart calcium channels	Calcium channel blocker
Blocks hormonal activity	Angiotensin-converting enzyme inhibitor
Blocks physiologic reactions to stress	Adrenergic antagonist (or blocker)
Dilates peripheral blood vessels	Vasodilator

CONNECTION Checkpoint 1.2

State whether each of the following classifications for aspirin is therapeutic or pharmacologic: anticoagulant, salicylate, central nervous system agent, analgesic, antipyretic. Use a drug guide, if needed. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Prototype Drugs

1.5 A prototype drug is the agent to which all other medications in a class are compared.

As discussed in Section 1.4 learning thousands of drugs is simplified, at least somewhat, by grouping similar drugs together into broad classifications. Just knowing its therapeutic or pharmacologic classification can reveal important information about a drug. An additional strategy is helpful when learning pharmacology. One common and useful

Figure 1.2 Obtained from the deadly nightshade plant *Atropa belladonna*, atropine remains a traditional prototype drug.
Courtesy of Heike Falkenberg/Fotolia.

practice is to select a single drug from a class and compare all other medications in the class to this representative medication. This is called a **prototype drug**. By learning about the prototype drug in depth, the actions and adverse effects of other drugs in the same class can be predicted. For example, by learning the actions and effects of penicillin V, students can extend this knowledge to all other drugs in the penicillin class of antibiotics. In this textbook, the drug prototypes are clearly identified, and detailed information regarding their therapeutic effects, mechanism of action, adverse effects, contraindications, precautions, and nursing responsibilities, including patient and family education, is presented.

Selecting a drug to serve as the prototype for a class is not always a simple matter; healthcare providers and textbooks sometimes disagree. The traditional prototype approach uses the oldest and best understood drug in the class. For example, atropine has been used for thousands of years and still remains a prototype drug for certain indications (see Figure 1.2). Sometimes, however, newer drugs are developed in the same class that are more effective or have a more favorable safety profile. Over time, an older prototype drug may be infrequently prescribed and a different, more clinically useful prototype may be chosen for the class. This textbook uses a practical approach to prototype drugs, selecting a combination of traditional drugs and those most widely used. Regardless of the approach, the student must remember that the prototype is the drug to which all others in a class are compared.

Naming Drugs

1.6 Drugs have chemical, generic, and trade names.

Despite the utility of using drug classes and prototypes when studying pharmacology, learning thousands of drug names remains a challenge. Adding to this difficulty is that most drugs have multiple names. The three basic types of drug names are chemical, generic, and trade names.

Chemical names are assigned using standard nomenclature established by the International Union of Pure and Applied Chemistry (IUPAC). A drug has only one chemical name. This chemical name is sometimes helpful in predicting a drug's physical and chemical properties. Although chemical names convey a clear and concise meaning about the nature of a drug to the chemist, these names are often complicated and difficult to remember or pronounce. For example, it is unlikely that the nurse would remember that the chemical name for alprazolam (Xanax) is 8-chloro-1-methyl-6-phenyl-4H-s-triazolo[4,3-α][1,4]-benzodiazepine. In only a few cases, usually when the name is brief and easily remembered, will nurses use chemical names. Examples of easy to remember chemical names of common drugs include lithium carbonate, calcium gluconate, and sodium chloride.

Drugs are sometimes named and classified by a portion of their chemical structure, known as the chemical group name. In the Xanax example, a portion of the chemical name, benzodiazepine, is used as a drug class. Other examples include the fluoroquinolones, aminoglycosides, phenothiazines, and thiazides. Although these names may seem complicated when first encountered, knowledge of chemical group names will become invaluable as the nursing student begins to learn and understand the actions of the drugs in the major drug classes.

The **generic name** of a drug is assigned by the United States Adopted Names Council. With few exceptions, generic names are less complicated and easier to remember than chemical names. Many organizations, including the FDA, the United States Pharmacopeial Convention, and the World Health Organization, routinely describe a medication by its generic name. Because each drug has only one generic name, healthcare providers often use this name, and students must memorize it. Fortunately, sometimes components of a generic name can help a student recognize other drugs in that same class. For example, the ending *-lol* is used in the generic name of beta-adrenergic blockers, and the ending *-statin* denotes a lipid-lowering drug.

A drug's **trade name**, sometimes called the proprietary, product, or brand name, is assigned by the pharmaceutical company marketing the drug. The trade name is intentionally selected to be short and easy to remember so that patients will remember it (and ask for it by name). The term *proprietary* suggests ownership. In the United States, the FDA grants the pharmaceutical company exclusive rights to name and market a drug for a certain number of years after it approves a new drug application. During the period of **exclusivity**, competing companies are not allowed to market generic versions of the product. The rationale for exclusivity is that the developing pharmaceutical company needs sufficient time to recoup the millions of dollars in research and development costs involved in designing and testing a new drug. Without the guarantee of exclusivity, pharmaceutical companies have little incentive to develop new and unique drugs. When

exclusivity expires, competing companies may sell a generic equivalent drug, sometimes using a different name, which the FDA must approve. The typical length of exclusivity for a new drug is 5 years; however, this may be extended by 3 additional years if the drug is determined to have a new indication, can be delivered by a different route, or is made available in a different dosage form. If, for example, a pharmaceutical company completes pediatric studies and determines the dosage and safety of a drug in this population, the FDA adds 6 months of exclusivity. Orphan drugs (see Chapter 2) have 7 years of exclusivity. Pharmaceutical companies can make millions of dollars in sales from exclusivity; thus, they usually make great efforts to receive extensions from the FDA. Expiration dates for the exclusivity of specific drugs are listed by the FDA in its *Approved Drug Products with Therapeutic Equivalence Evaluations* publication.

Trade names are a challenge for students to learn because there may be dozens of products that contain the same drug. In addition, many products contain more than one active ingredient. Drugs with more than one active generic ingredient are called **combination drugs**. This poses a problem when trying to match one generic name with one product name. As an example, refer to Table 1.3 and consider the drug diphenhydramine (generic name), also called Benadryl (one of many trade names). Low doses of diphenhydramine may be purchased over the counter (OTC). Higher doses require a prescription. If the nurse is looking for diphenhydramine, it may be listed under many trade names such as Benadryl, Nytol QuickCaps, Sominex, and Unisom, formulated alone or in combination with other active ingredients. Acetaminophen and aspirin are additional examples of agents that appear in many combination drugs with dozens of different trade names. To avoid this confusion, generic names should be used when naming the active ingredients in a combination drug. When referring to a drug, it is conventional to write the generic name in lowercase first, followed by the trade name in parentheses with the first letter capitalized. Examples include alprazolam (Xanax) and acetaminophen (Tylenol).

Table 1.3 Examples of Generic Drugs Contained in Trade-Name Products

Generic Drugs	Trade Names
Aspirin	Acetylsalicylic Acid, Acuprin, Anacin, Aspergum, Bayer, Bufferin, Ecotrin, Empirin, Excedrin, Maprin, Norgesic, Salatin, Salocol, Salsprin, Supac, Talwin, Traphen-10, Vanquish, Verin, ZORprin
Diphenhydramine	Allerdryl, Benadryl, Benahist, Bendylate, Caladryl, Compoz, Diahist, Diphenadril, Eldadryl, Fenylhist, Fynex, Hydramine, Hydril, Insomnal, Noradryl, Nordryl, Nytol, Tusstat, Wehdryl
Ibuprofen	Advil, Amersol, Apsifen, Brufen, Haltran, Medipren, Midol 200, Motrin, Nuprin, Pamprin-IB, Rufen, Trendar

1.7 Generic drugs are less expensive than trade-name drugs, but they may differ in bioavailability.

During the years of exclusivity for a new drug, the pharmaceutical company determines the price of the medication. Because there is no competition, the price is relatively high. Once the exclusive rights end, competing companies market the generic equivalent drug for less money, and consumer savings may be considerable. In many states, pharmacists may routinely substitute a generic drug when the prescription calls for a trade name. In other states, the pharmacist must dispense drugs directly as written by a healthcare provider or obtain approval before providing a generic substitute.

PharmFACT

Nine out of every 10 prescriptions dispensed in the United States are for generic drugs. The greatest cost savings are for generic drugs prescribed for mental health indications and for hypertension (Generic Pharmaceutical Association, 2015).

Pharmaceutical companies marketing trade-name drugs often lobby aggressively against laws that might restrict the routine use of certain trade-name drugs. The lobbyists claim that there are significant differences between a trade-name drug and its generic equivalent and that switching to the generic drug may be harmful to the patient. Consumer advocates on the other hand argue that generic substitutions should always be permitted because of the cost savings to patients.

Are there really significant differences between a trade-name drug and its generic equivalent? The answer is unclear. Despite the fact that the dosages may be identical, drug formulations are not always the same. The two drugs may have different inert ingredients. If in tablet form, the active ingredients may be more tightly compressed in one of the preparations. Liquid drugs may use different solvents such as water or alcohol.

The key to comparing trade-name drugs and their generic equivalents lies in measuring the **bioavailability** of the two agents. Bioavailability is defined by the Federal Food, Drug, and Cosmetic Act (see Chapter 2) as the rate and extent to which the active ingredient is absorbed from a drug product and becomes available at the site of drug action to produce its effect. Bioavailability may be affected by many factors, including inert ingredients and tablet compression. Anything that affects the absorption of a drug or its travel to the target cells can certainly affect drug action. Measuring how long a drug takes to exert its effect (onset time) gives pharmacologists a crude measure of bioavailability. If the trade and generic products have the same rate of absorption and have the same onset of therapeutic action, they are said to be *bioequivalent*.

The importance of bioavailability differences between a trade-name drug and its generic equivalent depends on the specific circumstances of pharmacotherapy. For example, if a patient is in circulatory shock and the generic equivalent drug takes 5 minutes longer to produce its effect, that may indeed be significant. However, if a generic medication for arthritis pain relief takes 45 minutes to act, compared to the trade-name drug, which takes 40 minutes, it probably does not matter which drug is used, and the inexpensive product should be prescribed to provide cost savings to the consumer. As a general rule, bioavailability is of most concern when using critical care drugs and those with a narrow safety margin. In these cases, the patient should continue taking the trade-name drug and *not* switch to a generic equivalent, unless approved by the healthcare provider. For most other drugs, the generic equivalent may be safely substituted for the trade-name drug.

In the age of internet pharmacies, the issue of exclusive marketing rights has drastically changed. Other countries are not bound by U.S. drug laws, and it is easy for patients to obtain medications through the mail at a fraction of the cost in the United States. For example, a pharmaceutical company may have exclusivity for selling Cialis in the United States, but companies in India and China can sell the identical drug through internet pharmacies and ship it to customers in the United States. In some cases, they may sell the drug to consumers without a prescription. Some countries do not have the same high quality control standards as the United States, and the patient may be purchasing a useless or even harmful product. Furthermore, although some internet sites may appear to be based in the United States, they may instead be obtaining their medications from sources outside the United States. Nurses must urge their patients not to purchase drugs from overseas pharmacies because there is no assurance that the drugs are safe or effective.

1.8 Biosimilar drugs are very closely related to biologic medications that have already received FDA approval.

Biologic drugs are medicines made by living cells, such as bacteria or yeast. Because of their natural origin, biologics are often complex molecules that require many years of research to develop and gain status as FDA-approved drugs. In recent years, biologics have become important treatments for rheumatoid arthritis, multiple sclerosis, and cancer. They are effective medications, but are usually very expensive. For example, some of the newer biologics for hepatitis C cost thousands of dollars per dose.

Biosimilar drugs have comparable effectiveness and safety to FDA-approved biologic products. Because a biosimilar is not an exact, duplicate copy of the original medication (known as the *reference product*), it should not be called a generic medication. Biosimilars are not required to undergo the same rigorous preclinical and clinical testing as their reference products; therefore, they are less expensive. To be approved as a biosimilar, the manufacturer must demonstrate to the FDA that the drug differs very little from the approved reference product. This includes having the same route of administration, dosage forms, and mechanism of action. The first biosimilar, Zarxio, was approved by the FDA with the same indications as filgrastim (Neupogen), the original biologic product (FDA, 2015). Inflectra was approved in 2016 as a biosimilar to infliximab (Remicade). Many other biosimilars are expected to reach the market in the coming years.

Connecting Pharmacology to Clinical Nursing Practice

1.9 Effective pharmacotherapy depends on a nurse's understanding of pharmacology as well as interprofessional practice with other members of the healthcare team.

Pharmacotherapy has become a mainstay of modern medical treatment, and a thorough understanding of expected drug effects, the associated monitoring required, and the care and teaching associated with drugs that are prescribed in patient care is crucial to effective nursing practice. As a member of an interprofessional team, nurses, physicians, advanced practice nurses, pharmacists, and, most importantly, the patient work together to achieve optimal therapeutic outcomes from drug therapy. The importance of pharmacology to clinical nursing practice cannot be overstated, and the connection between pharmacology and nursing practice is emphasized throughout this entire textbook.

A major goal of this textbook is to provide a solid foundation in the knowledge of pharmacology and pharmacotherapeutics. Chapters 2 through 4 provide the legal and scientific bases for pharmacotherapeutics. As a member of an interprofessional healthcare team, it is most often the nurse who serves as the connection between a prescription and the patient's safe use of the prescribed drug. Monitoring the patient's condition before and during drug use, evaluating drug effects, teaching the patient about self-administration, and conducting a medication reconciliation are key nursing responsibilities. A medication reconciliation is the process of keeping track of the patient's medications as the patient's care proceeds from one healthcare provider to another. For the advanced practice nurse, an understanding of the pathophysiology underlying the patient's current condition, excellent assessment skills, and clinical decision-making skills aimed at choosing the best treatment options are required.

A major goal in studying pharmacology is to eliminate medication errors and to limit the number and severity of adverse drug events. Many adverse effects are preventable. Nurses can routinely avoid many serious adverse drug

effects in their patients by applying their experience and knowledge of pharmacotherapeutics to clinical practice. Some adverse effects, however, are not preventable. It is vital that the nurse be prepared to recognize and respond to potential adverse effects of medications. The nursing management of adverse effects and medication errors are discussed in Chapters 5 and 6, respectively.

Before any drug is administered, the nurse must obtain and process pertinent information regarding the patient's medical history, physical assessment, disease processes, and learning needs and capabilities. Growth and developmental factors must always be considered. It is important to remember that a large number of variables influence a patient's response to drugs throughout the lifespan. Having a firm understanding of these variables can increase treatment success. Chapters 8 through 11 of this textbook address these aspects of pharmacotherapy.

For a nurse, knowledge of pharmacology is an ongoing, lifelong process that builds as a nurse is in practice and chooses specific clinical areas. Early in practice, learning prototype drugs that represent a specific classification of drugs, recognizing key similarities in generic names, and always looking up unknown or new drugs will help build this knowledge base. As the nurse's experience grows, anticipating drug effects and care and teaching needs becomes integrated into nursing practice. For an advanced practice nurse working as a nurse practitioner, this clinical experience helps to enhance the new information acquired to prepare for prescriptive authority. Chapters 12 through 75 present the foundational knowledge needed for effective pharmacotherapy. Each unit begins with a review of the anatomy and physiology underlying the mechanism of action of drugs discussed in the unit, followed by detailed information about specific classifications of drugs and nursing responsibilities for those classifications.

Despite its essential nature, the study of pharmacology should be viewed in the proper perspective. Drugs are just one of many tools available to the nurse for preventing or treating human suffering. Although pharmacology is a key intervention in many cases, nurses must use all the healing sciences in treating their patients. The effectiveness of a drug in treating disease can never substitute for skilled, compassionate nursing care. Too much reliance on drug therapy can diminish the importance of the nurse–patient relationship.

Understanding Chapter 1

Key Concepts Summary

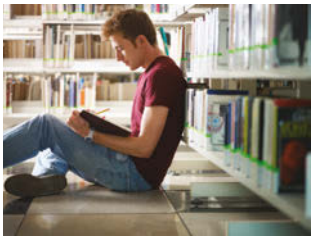
1.1 The practice of applying products to relieve suffering has been recorded throughout history by virtually every culture.

1.2 Pharmacology is the study of medicines.

1.3 The perfect drug is safe and effective.

1.4 Drugs may be organized by their therapeutic classification or pharmacologic classification.

1.5 A prototype drug is the agent to which all other medications in a class are compared.



1.6 Drugs have chemical, generic, and trade names.

1.7 Generic drugs are less expensive than trade-name drugs, but they may differ in bioavailability.

1.8 Biosimilar drugs are very closely related to biologic medications that have already received FDA approval.

1.9 Effective pharmacotherapy depends on a nurse's understanding of pharmacology as well as interprofessional practice with other members of the healthcare team.

CASE STUDY: Making the Patient Connection

Remember the student "Josh Remming" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Josh Remming, a 23-year-old student, is in his first semester of nursing school. He thought that nursing would provide him with a great career and lots of opportunity. He enjoys helping people and has always been fascinated with healthcare. However, after the first pharmacology class, Josh is worried because there seems to be an overwhelming amount of content to learn in just one semester.

At the end of the class, Josh talks with other students who are concerned and a bit anxious. Much of the

conversation centers around lecture content provided by the professor. Following are some of the questions from Josh's classmates. How would you respond?

Critical Thinking Questions

1. What is the difference between therapeutic classification and pharmacologic classification?
2. What classification is a barbiturate? Macrolide? Birth control pills? Laxatives? Folic acid antagonist? Antianginal agent?
3. What is a prototype drug, and what advantages does a prototype approach to studying pharmacology offer?
4. Why do nurses need to know all this pharmacology?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Sarah Hawkins, an older woman who lives on a fixed income, is on multiple medications. She says that all her friends are taking the generic form of their medications. While you are visiting her, she asks, "What do you think of generic medicines? Are they safe? Are they as good? Are they worth it?"

1. How do generic equivalent drugs differ from a proprietary (trade-name) drug?
2. What would you recommend that Sarah do about accepting generic drugs?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is using a drug handbook to determine the indications for the drug furosemide (Lasix). The term *indications* is defined as the:
    1. Way a drug works on the target organs.
    2. Amount of the drug to be administered.
    3. Conditions for which a drug is approved.
    4. Reason that the drug should not be given.
2. The nurse is reviewing the patient's medication record and does not recognize the medication, filgrastim-sndz (Zarxio). Consulting a drug guide, the nurse finds it is listed as a "biosimilar" to filgrastim (Neupogen). Which of the following best describes the definition of a biosimilar drug?
    1. It is another term for a "generic" drug when the two drugs exert similar biologic effects.
    2. It is a drug that has similar effects on the body, but belongs in a different chemical and therapeutic classification.
    3. It is a drug that is derived from living cells, such as yeast, and has comparable effectiveness and safety to the reference product drug.
    4. It is a drug that is identical to the reference product drug and thus, does not require FDA approval.
3. As a member of an interprofessional team, what key responsibilities does the nurse have to ensure effective pharmacotherapy? (Select all that apply.)
    1. Monitoring the patient's condition before and during pharmacotherapy
    2. Teaching the patient about self-administration and any required monitoring of drug effects
    3. Ensuring that all drug and treatment options have been considered before beginning pharmacotherapy
    4. Frequently conducting a medication reconciliation to verify current medications in use
    5. Determining the ideal drug to be prescribed to the patient to treat the current condition
4. Which patient characteristics, if noted in the patient's medical record, would the nurse consider important information that may affect the physiologic response to various types of drug therapy? (Select all that apply.)
    1. 82-year-old and female
    2. Asian and obese
    3. Past medical history of kidney disease
    4. Mother and sister with diabetes
    5. Has no medical insurance
5. The nurse is looking up a drug that has been prescribed and wants to know the therapeutic classification for the drug. Which of the following would indicate a therapeutic classification?
    1. Beta-adrenergic antagonist
    2. Antihypertensive
    3. Diuretic
    4. Calcium channel blocker

6. The nurse is asked by a family member: "They're giving mom Motrin and she takes Advil. Hasn't the wrong drug been ordered?" The nurse will respond, knowing that:
   1. There has been an error in the order and the nurse will contact the healthcare provider.
   2. There may be a reason for the healthcare provider to order a different drug.
   3. Not all healthcare agencies buy the same generic drugs and that may account for the difference.
   4. Motrin and Advil are trade names for the same generic drug, ibuprofen.

Chapter 2
Drug Regulations

Chapter Outline

- Patent Medicines
- Brief History of Drug Legislation
- Drug Standards
- The U.S. Food and Drug Administration
- Drug Approval
- Changes to the Drug Approval Process
- Prescription and Over-the-Counter Drugs
- Drug Schedules
- Prescriptive Authority for Nurses

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain the role of patent medicines in the history of pharmacology and the legislation of drugs.
2. Outline the key U.S. drug regulations and explain how each has contributed to the safety and effectiveness of medications.
3. Describe how the *United States Pharmacopeia-National Formulary* (USP-NF) controls drug purity and standards.
4. Evaluate the role of the U.S. Food and Drug Administration in the drug approval process.
5. Categorize the four stages of new drug approval.
6. Explain the role of a placebo in new drug testing.
7. Discuss how changes to the approval process have increased the speed at which new drugs reach consumers.
8. Compare and contrast prescription and over-the-counter drugs.
9. Explain how scheduled drugs are classified and regulated.
10. Discuss the requirements and regulations needed for nurses to have the ability to prescribe drugs.

Key Terms

Laws govern all aspects of the drug approval, labeling, marketing, manufacturing, and distribution process. The primary purpose of this legislation is to protect the public from unsafe and ineffective products. This chapter examines standards and legislation regulating drugs in the United States.

Patent Medicines

2.1 Early American history saw the rise of patent medicines and the lack of adequate drug regulations.

People have an expectation that the medication they are taking is effective at treating their condition, whether it is asthma, diabetes, or a headache. They expect the label to contain clear and accurate instructions on how the product should be taken. They expect that the drug will be safe when the instructions are correctly followed. Are these reasonable assumptions? In the United States and Canada, the answer is yes. But Americans have not always had this reassurance. Although drugs have been used for thousands of years, it was not until the 20th century that extensive standards and regulations were developed to protect the public from unsafe and ineffective products.

In early America, there were few attempts to regulate drugs. This period saw the rise of **patent medicines**. Although the term *patent* implies a legal right to manufacture or sell a drug, this was not the case. Patent medicines contained a trade name that clearly identified the product, such as William Radam's Microbe Killer, Stanley's Snake Oil, Dr. Kilmer's Swamp Root, or Dr. Moore's Indian Root Pills. Because there were no laws to the contrary, these products went untested and could claim to cure nearly any symptom or disease. Dr. William's Pink Pills for Pale People, which contained iron oxide and magnesium sulfate, claimed to cure rheumatism, nervous headache, palpitations, grippe, neuralgia, locomotor ataxia, partial paralysis, sallow complexion, and all forms of weakness in men or women. A typical advertisement from this era is shown in Figure 2.1.

Figure 2.1 Patent medicines contained a trade name that clearly identified the product and claimed to cure just about any symptom or disease.
Courtesy of Library of Congress/Corbis/VCG/Getty Images.

Patent medicines were often harmless (and ineffective), containing coloring, flavoring, and an aromatic substance that "smelled like medicine." At their worst, some contained hazardous levels of dangerous or addictive substances. In fact, cocaine, heroin, and morphine were freely distributed in patent medicines; some elixirs contained up to 50% morphine, which indeed caused many painful disorders to "disappear." Addictive ingredients were purposely added to guarantee repeat customers for their products. (Note the similarity with nicotine added to tobacco and caffeine added to soft drinks.) In the late 1800s, the familiar Coca-Cola soft drink was a patented beverage that contained an estimated 9 mg of cocaine per serving and was claimed to cure headache, dyspepsia, hysteria, morphine addiction, and impotence. The need for stricter regulation became more apparent in the 1860s as cocaine was synthesized, and the use of opiates as painkillers during the Civil War caused thousands of soldiers to become addicted.

Although the marketing and use of patent medicines may seem humorous and even unbelievable to modern consumers, a few of these products are still available over the counter (OTC). Examples of patent medicines that survived the drug regulations of the 1900s include Smith Brothers Throat Drops, Fletcher's Castoria, Doan's Pills, Vick's VapoRub, and Phillip's Milk of Magnesia. Of course,

the ingredients of these products have changed over time so that they conform to modern regulations regarding labeling, safety, and effectiveness.

Brief History of Drug Legislation

2.2 In the 1900s, drug legislation was enacted to make drugs safer and more effective.

Although individual states attempted to regulate drugs, the first national law was the Drug Importation Act, passed in 1848, which attempted to stop the entry of unsafe drugs into the United States. In the early 1900s, the United States began to develop and enforce tougher drug legislation to protect the public. This was spurred, in part, by the tragic deaths of 13 children in St. Louis in 1901 who were given diphtheria antitoxin that was contaminated with tetanus. In 1902, the Biologics Control Act was passed to standardize the quality of sera, antitoxins, and other blood-related products. Passed shortly thereafter, the Pure Food and Drug Act (PFDA) of 1906 was a significant and powerful piece of drug legislation that gave the government authority to regulate the labeling of medicines. Essentially, this law required that drug labels accurately reflect the contents. Prior to this date, many labels did not contain any indication of the active ingredient within the bottle or its amount. Although the ingredients had to be accurately labeled, a drug could still be marketed for any disease.

In 1912, the Sherley Amendment to the PFDA prohibited the sale of drugs labeled with false therapeutic claims that were intended to defraud the consumer. A major weakness, as borne out in subsequent legal battles, was the difficulty of proving that the false claim made by the seller was intentional.

It is surprising that up to this point in American history no attempt had been made to legislate the use of addictive drugs. The Harrison Narcotic Act of 1914 was passed to require prescriptions for high doses of narcotic drugs and to mandate that pharmacists and healthcare providers keep narcotic records. Since 1914, hundreds of additional state and federal laws have been passed to regulate drugs with abuse potential, including the landmark Comprehensive Drug Abuse Prevention and Control Act (see Section 2.8). Additional details on the history of the regulation of controlled substances are included in Chapter 27.

Unfortunately, two essential components were still missing from the regulation of drugs in the early 20th century. Although the PFDA and other legislation required that ingredients be listed on the label and prohibited intentional false claims, manufacturers did not have to prove that the drug was effective. Furthermore, product safety did not have to be tested before the drug was marketed. Bringing the issue to the forefront was an incident in 1937 in which an elixir of sulfanilamide containing a poisonous chemical (diethylene glycol) killed 107 people, mostly children.

In 1938, Congress passed the landmark Food, Drug, and Cosmetic Act (FDCA), which corrected certain loopholes in previous laws. This was the first law preventing the sale of newly developed drugs that had not been thoroughly tested for safety. Drug labels were required to contain instructions for safe use. The FDCA was also the first attempt at regulating cosmetics and medical devices. Unfortunately, the FDCA did not clearly define "prescription" or specify which drugs required a prescription. Most drugs, including many addictive and harmful substances, were sold by the corner druggist, sometimes legally, other times illegally. In 1951, the Durham-Humphrey Amendment to the FDCA delineated the difference between safer drugs, which were allowed to be sold OTC, and more dangerous drugs, which required prescriptions.

In the late 1950s, the drug thalidomide was found to produce severe birth defects in the children of women taking the drug as a sleeping pill and to treat morning sickness during pregnancy. Although the drug was not approved in the United States, it is estimated that over 20,000 Americans received the drug, because it was widely distributed to healthcare providers without U.S. Food and Drug Administration (FDA) approval. As with other drug legislation, it took a tragedy to convince Congress to pass tougher regulations. Passage of the Kefauver-Harris Amendment to the FDCA in 1962 mandated that manufacturers prove their drugs were effective for specific purposes, as well as safe, through the conduct of "adequate and well-controlled" studies. This law was applied retroactively to all drugs introduced since the passage of the FDCA. This amendment also required that all significant adverse reactions be reported to the FDA and that complete information about adverse effects be included in literature distributed to healthcare providers. For the first time, informed consent was required from patients participating in experimental drug research.

The emphasis on effectiveness continued as the FDA contracted with the National Academy of Sciences and the National Research Council in 1966 to evaluate the effectiveness of 4000 drugs that were approved between 1938 and 1962 based only on their safety. Approximately 40% of all drugs introduced between 1938 and 1962 were found to be ineffective and were subsequently removed from the market. In 1972, a review of OTC drugs began to examine the safety and effectiveness of these products.

In the 1980s, the public placed considerable political pressure on the FDA to find drugs to treat rare or unusual disorders. Pharmaceutical companies were reluctant to develop drugs for these disorders because there would not

be enough sales to recoup their research and development costs. To encourage development of such drugs, the Orphan Drug Act became law in 1983. An **orphan product** is a drug or biologic for treating rare diseases that affect fewer than 200,000 people in the United States. Drug manufacturers are now offered development grants, tax credits for clinical investigation expenses, and 7 years of exclusivity to market an orphan drug. Over 400 medications have been approved as orphan drugs since the passage of this act.

A major focus in the 1990s was to speed the drug approval process, which was often prolonged for many years. The Prescription Drug User Fee Act (PDUFA) of 1992 assessed fees from drug manufacturers to be used specifically for reducing the review time for new drug applications. From 1992 to 2002, the number of full-time equivalent employees examining new drug applications at the FDA increased from 1277 to 2337. The PDUFA was reauthorized in 1997 with the passage of the Food and Drug Administration Modernization Act, which also included provisions to accelerate the review of medical devices, regulate the advertising of unapproved uses of drugs, and regulate health claims for foods. The PDUFA has been reauthorized with the added goal of improving communication between the FDA and new drug sponsors. PDUFA fees collected in 2015 amounted to over $855 million, which supported 4133 full-time positions to support the drug application process at the FDA (FDA, 2016a).

In reaction to the rising popularity of dietary supplements, Congress passed the Dietary Supplement Health and Education Act of 1994 to control misleading industry

Table 2.1 Historical Timeline of Regulatory Acts, Standards, and Organizations

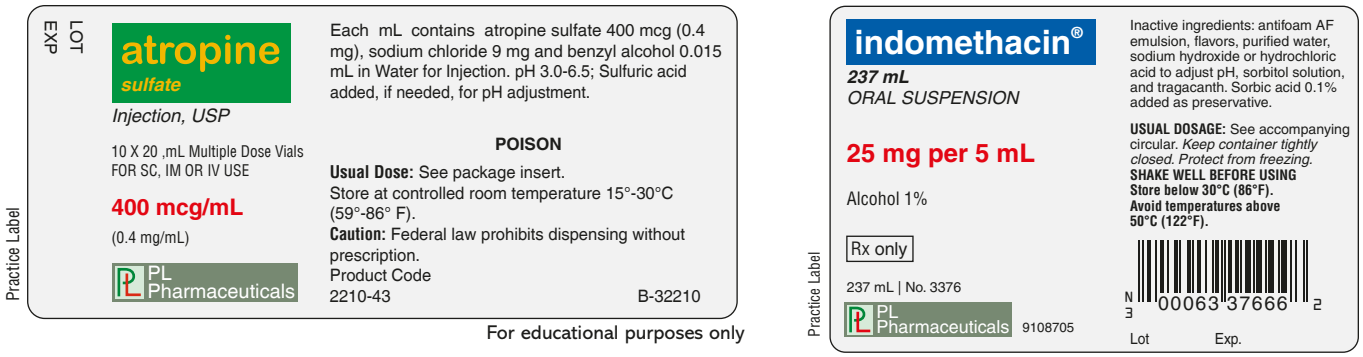
Year	Regulatory Acts, Standards, and Organizations
1820	Physicians establish the first comprehensive publication of drug standards, the *United States Pharmacopeia* (USP).
1848	The Drug Importation Act requires that all drugs (as defined by the newly established pharmacopeia) entering the United States be inspected and analyzed for "quality, purity, and fitness for medical purposes."
1852	Pharmacists found the American Pharmaceutical Association (APhA). The APhA establishes the *National Formulary* (NF), a standardized publication focusing on pharmaceutical ingredients. The USP continues to catalog all drug-related substances and products.
1862	The Federal Bureau of Chemistry, established under the administration of President Lincoln, eventually becomes the Food and Drug Administration (FDA).
1902	The Biologics Control Act controls the quality of sera and other blood-related products.
1906	The Pure Food and Drug Act prohibits the manufacture and sale of adulterated or misbranded foods, drugs, and medications.
1912	The Sherley Amendment makes medicines safer by prohibiting the sale of drugs labeled with false therapeutic claims.
1914	The Harrison Narcotics Act requires those who dispense opium, cocaine, and related substances to keep records of the drugs they dispense and makes it illegal to possess narcotics without a prescription. This act allows physicians to prescribe narcotics only for treatment, not to addicts.
1938	The Food, Drug, and Cosmetic Act is the first law preventing the marketing of drugs not thoroughly tested.
1944	The Public Health Service Act is enacted and covers many health issues, including biologic products and the control of communicable diseases.
1970	The Comprehensive Drug Abuse Prevention and Control Act (also known as the Controlled Substances Act) organizes regulated drugs (including opiates, cocaine, cannabis, stimulants, depressants, and hallucinogens) into five schedules and imposes restrictions and penalties.
1975	The *United States Pharmacopeia* and *National Formulary* become a single standardized publication, the USP-NF.
1986	The Anti-Drug Abuse Act increases sentences and imposes mandatory minimum sentences for those convicted of illegal drug activity based on the type and quantity of drug involved.
1986	The Childhood Vaccine Act authorizes the FDA to acquire information about patients taking vaccines, to recall biologics, and to recommend civil penalties if guidelines regarding biologic use were not followed.
1988	The FDA is officially established as an agency of the U.S. Department of Health and Human Services.
1992	The Prescription Drug User Fee Act requires that nongeneric drug and biologic manufacturers pay fees to be used for improvements in the drug review process.
1994	The Dietary Supplement Health and Education Act requires clear labeling of dietary supplements and gives the FDA the power to remove supplements that cause a significant public risk.
1997	The FDA Modernization Act reauthorizes the Prescription Drug User Fee Act, representing the largest reform effort of the drug review process since 1938.
2002	The Best Pharmaceuticals for Children Act improves the safety and efficacy of medicines for children and continues the exclusivity provisions for pediatric drugs as mandated under the Food and Drug Administration Modernization Act of 1997.
2003	The Medicare Prescription Drug, Improvement, and Modernization Act provides older adults and those with disabilities a prescription drug benefit and better benefits under Medicare.
2007	The FDA Amendments Act (FDAAA) of 2007 reauthorizes and expands the Prescription Drug User Fee Act, the Modernization Act, the Best Pharmaceuticals for Children Act, and the Pediatric Research Equity Act.
2012	The FDA Safety and Innovation Act (FDASIA) of 2012 reauthorizes the Prescription Drug User Fee Act. This requires the FDA to implement a structured benefit-risk framework in the new drug approval process.

claims. Due in part to intense lobbying from the dietary supplement industry, the regulation of these products remains less stringent than that for prescription or OTC drugs. The regulation of herbal products and dietary supplements is discussed in detail in Chapter 7.

In early 2000, the focus of drug regulation turned to access. Advocacy groups claimed that the high cost of drugs caused unequal access to adequate healthcare for the poor, the uninsured, the underinsured, and older adults. In 2003, the Medicare Prescription Drug, Improvement, and Modernization Act was passed. The benefits are adjusted periodically. In 2016, the act provided a benefit that pays 75% of prescription drug spending up to the first $3310 (after a $360 deductible). Those qualifying for the low-income criteria may have their premiums and cost subsidized by the government. Participants pay a maximum out-of-pocket threshold of $7062.50 per year, after which Medicare will pay 95% of the prescription costs. A brief timeline of major events in U.S. drug regulation is shown in Table 2.1.

Drug Standards

2.3 The standardization of drug purity and strength is specified by the *United States Pharmacopeia-National Formulary*.



Until the 1800s, drugs were prepared from plants that were available in the natural environment. The strength and purity of the products varied considerably because they were entirely dependent on the experience (and integrity) of the druggist preparing the product and the quality of the local ingredients. Potency and safety varied from region to region and, indeed, from batch to batch. Consider the simple analogy of baking. If 100 people across the world were asked to bake a loaf of bread, the final products would vary considerably in size, taste, and nutritional value. It is likely that no two loaves would be the same. It is obvious that a standard recipe must be followed. Similarly, to obtain consistency in the preparation and potency of drugs, standards (recipes) are needed.

Among the first standards used by pharmacists was the **formulary**, or list of pharmaceutical products and drug recipes. In the United States, the first comprehensive publication of drug standards, the *United States Pharmacopeia* (USP), was established in 1820. A **pharmacopeia** is a medical reference summarizing standards of drug purity, strength, and directions for synthesis. From 1852 until 1975, two major compendia maintained drug standards in the United States, the USP and the *National Formulary* (NF), which were established by the American Pharmaceutical Association (APhA). All drug products were covered in the USP, whereas the NF focused on nondrug ingredients. In 1975, the two were merged into a single publication named the *United States Pharmacopeia-National Formulary* (USP-NF). The current document consists of more than 300 chapters and 4900 drug monographs. The USP-NF is published annually, with two supplements being issued throughout the year. Today, the USP label can be found on many medications verifying the purity and exact amounts of ingredients found within the container. Drugs marketed in the United States must conform to USP-NF standards to avoid possible charges of adulteration and misbranding. Sample labels are illustrated in Figure 2.2. The USP also provides a voluntary program for verifying the label accuracy of dietary supplements (see Chapter 7).

The U.S. Food and Drug Administration

2.4 The regulatory agency responsible for ensuring that drugs and medical devices are safe and effective is the U.S. Food and Drug Administration.

The establishment of a regulatory agency for food and drugs in the United States began with a single chemist appointed by President Lincoln in 1862. The **U.S. Food and Drug Administration (FDA)** was established by the PFDA of 1906 and later expanded to carry out the provisions of the FDCA of 1938. It is one of the oldest drug regulatory

For educational purposes only

Figure 2.2 Medication with the USP label (left) and without USP label (right). Practice labels "for educational purposes only."

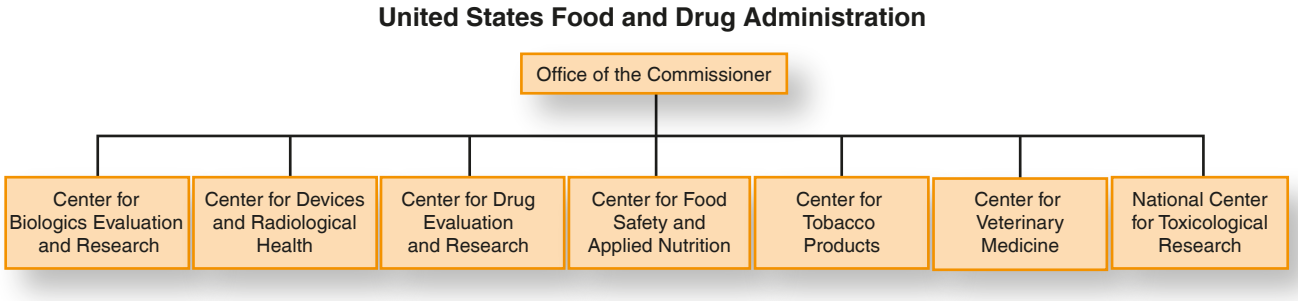


Figure 2.3 Organization of the Food and Drug Administration showing the seven centers that regulate human and veterinary drugs, biologic products, medical devices, the nation's food supply, cosmetics, tobacco, and products that emit radiation.

agencies in the world. The FDA states its mission as follows:

- Protecting the public health by ensuring the safety, efficacy, and security of human and veterinary drugs, biologic products, medical devices, the nation's food supply, cosmetics, and products that emit radiation
- Advancing the public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable
- Helping the public get the accurate, science-based information they need to use medicines and foods to improve their health.

With such an important and vast mission, the FDA is organized around seven branches, as shown in Figure 2.3. The Center for Drug Evaluation and Research (CDER) states its mission as facilitating the availability of safe, effective drugs; keeping unsafe or ineffective drugs off the market; improving the health of Americans; and providing clear, easily understandable drug information for safe and effective use. All new drugs must be approved by the CDER before they can be marketed. This includes prescription drugs, OTC drugs, and all generic equivalents. After marketing, the CDER is responsible for continued monitoring of safety and may issue additional warnings to healthcare providers or consumers as additional information becomes available.

The Center for Biologics Evaluation and Research (CBER) regulates the use of biologics (drugs derived from living sources), including sera, vaccines, and blood products. One historical achievement involving biologics is the 1986 Childhood Vaccine Act. This act authorizes the FDA to acquire information about patients taking vaccines, to recall biologics, and to recommend civil penalties if guidelines regarding biologics are not followed. The mission of the CBER was recently expanded to include the regulation of gene therapy and treatment with human cells or tissue-based products.

The FDA also oversees the administration of herbal products, dietary supplements, and cosmetics through the Center for Food Safety and Applied Nutrition (CFSAN). Although it does not require testing of herbal or dietary supplements prior to marketing, the CFSAN is responsible for taking action against any supplement that is deemed to be unsafe.

The CFSAN also regulates cosmetics, which are legally defined by the FDCA of 1938 as "articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body . . . for cleansing, beautifying, promoting attractiveness, or altering the appearance." Examples of products considered cosmetics are skin moisturizers, perfumes, lipsticks, fingernail polishes, eye and facial makeup preparations, shampoos, toothpastes, and deodorants. Can a product be both a cosmetic and a drug? In most cases, cosmetics are not drugs; however, it depends on a product's intended use. For example, if a shampoo is marketed to treat a condition such as dandruff, the active ingredient is considered a drug. If a skin cream claims to provide sunscreen protection, it may be considered a drug. Cosmetics do not require approval by the CFSAN prior to marketing, and regulations are much less restrictive compared to drug approval. Manufacturers of cosmetics are generally careful not to promote unwarranted therapeutic claims, such as that a product prevents or treats a condition or disease. This would cause the product to be considered a drug by the FDA, and it would be subject to tighter regulations.

In 2009, the FDA was given the authority to regulate the manufacture, marketing, and distribution of tobacco products. To carry out this legislative mandate, the FDA created a seventh branch, the Center for Tobacco Products.

Drug Approval

2.5 The drug approval process established by the U.S. Food and Drug Administration ensures that drugs sold in the United States are safe and effective.

Drugs are discovered in any number of ways. Penicillin was discovered purely by accident while the scientist was studying an unrelated topic. Many drugs have been isolated from natural substances, including plants and bacteria. Some medications are "me too" drugs, whereby the pharmacologist simply took a well-known drug and slightly modified

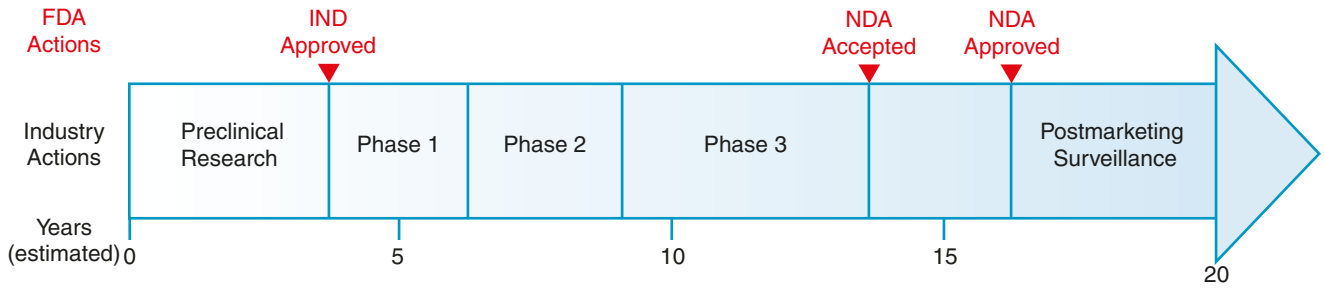

Figure 2.4 Drug development timeline.

the chemical structure to produce a very similar agent. As molecular biology and genetics have progressed into the modern era, drugs have been purposefully designed to fit into specific receptor sites on enzymes or cells.

Regardless of the path to discovery, all drugs must be approved by the FDA before they can be sold in the United States. (Medical marijuana, discussed in Chapter 27, has become an exception to this approval process.) The FDA drug review and approval process follows a well-developed and organized plan, as summarized in Figure 2.4.

The first stage of drug development is **preclinical research**, which involves extensive laboratory testing by the pharmaceutical company. Scientists perform testing on human and microbial cells cultured in the laboratory. Studies are performed in several species of animals to examine the drug's effectiveness at different doses and to look for adverse effects. The goals of this extensive testing on cultured cells and in animals are to determine drug action and to predict whether the drug will cause harm to humans. Because laboratory tests do not accurately reflect the precise way the human body will respond to the drug, preclinical research results are always inconclusive. Most drugs do not proceed past the preclinical research stage because they are either too toxic or simply not effective. The FDA does not regulate preclinical testing.

If a drug appears promising, the pharmaceutical company submits an **Investigational New Drug (IND)** application to the FDA that contains all the animal and cell testing data. Scientists at the FDA study the data and must be convinced that the drug is safe enough to allow human testing. Approval from the FDA is necessary before the next stage can begin.

Clinical investigation, the second stage of drug testing, takes place in three different stages termed **clinical phase trials**. These clinical trials are the longest part of the drug approval process and occur in sequential stages.

- **Phase 1.** Testing is conducted on 20 to 80 healthy volunteers for several months to determine proper dosage and to assess for adverse effects. The focus of the phase 1 trial is on safety. If unacceptable levels of toxicity are noted, the clinical trials are stopped.
- **Phase 2.** Several hundred patients with the disease to be treated are given the drug. The primary focus of the phase 2 trial is on effectiveness, although safety data continue to be recorded. In most cases, the effectiveness of the new drug is compared to an inert substance, or **placebo**, which serves as a control "nontreatment" group. In other cases the new drug is compared to a standard drug used for the same condition. For example, a new drug for reducing fever may be compared to acetaminophen (Tylenol). If the new drug is found to have the same (or less) effectiveness and safety profile compared to the standard drug, the pharmaceutical company may stop the clinical trials. This phase may take several years.
- **Phase 3.** Large numbers of patients with the disease are given the drug to determine patient variability. Potential drug–drug interactions are examined. Patients with chronic conditions such as cardiac, renal, or hepatic impairment are given the drug to determine safety in these important populations. Assessment of effectiveness and safety continues for several years, and thousands of patients may be given the new drug during phase 3.

If the drug continues to show promise through the clinical phase trials, a **New Drug Application (NDA)** is submitted to the FDA. The NDA signals that the pharmaceutical company is ready to sell the new drug. During the NDA review, the FDA examines all preclinical and clinical data to assess whether the proposed new drug is safe and effective. By law, the CDER is obligated to act on at least 90% of the NDAs for standard drugs within 10 months of submission. For priority drugs, the benchmark is 6 months. If the NDA is approved, the manufacturer may begin selling the new drug. If the NDA is rejected, the FDA indicates whether the drug is "approvable" or "not approvable." "Approvable" means that the drug will likely be approved if the pharmaceutical company conducts additional testing or addresses specific issues identified by the FDA. A designation of "not approvable" indicates that the drug has significant barriers to approval.

The number of new drugs approved each year during the past decade has ranged from 78 to 101. Many of the new drugs, however, closely resembled existing medications. A better way to track advances in drug therapy is to monitor how many of the approved drugs are **new molecular entities**, those medications that are truly unique and

structurally different from existing drugs. The number of new molecular entities has ranged from 20 to 30 per year.

Postmarketing surveillance, stage 4 of the drug approval process, begins after the NDA review has been completed. The purpose of stage 4 testing is to survey for harmful drug effects in a larger population. Some adverse effects are very subtle, take longer to appear, and are not identified until a drug is prescribed for large numbers of people. Adverse drug reactions are reported by the manufacturers, healthcare providers, and patients to the FDA Adverse Event Reporting System (FAERS), a computerized database designed to support the FDA's postmarketing surveillance program.

The FDA holds public meetings annually to receive comments from patients, professional organizations, and pharmaceutical companies regarding the effectiveness and safety of new drug therapies. If the FDA discovers a serious problem, it will mandate that a drug be withdrawn from the market. Examples of successful postmarketing surveillance include the removal of two cholesterol-lowering drugs in 2016. Advicor (approved in 2001) and Simcor (approved in 2008) were withdrawn because long-term clinical trials revealed that the medications were ineffective at reducing adverse cardiovascular events. In these cases, the withdrawals were not prompted by serious safety concerns. The benefits of the drugs were found to no longer outweigh their risks.

The drug approval process has several important limitations. Historically, drug trials have used Caucasian men as their test population. Because gender and racial differences may affect how drugs are handled by the body, data obtained during clinical trials may not be representative of the population as a whole. Pharmaceutical companies are now including a more diverse population in their clinical trials. Most drugs have not been tested in children: Pediatric doses and responses are often based on experience rather than research data. Although clinical trials test drugs in pregnant laboratory animals and examine for possible birth defects, these data may not be representative of how drugs affect pregnant women or their fetuses. Finally, adverse effects may occur at such a low level that they are statistically insignificant in clinical trials using a few thousand patients. Several million patients may need to take the drug before these effects can be identified.

Another limitation of the drug approval process relates to off-label uses. A new drug is developed by a pharmaceutical company for a specific indication and patient population at doses that are demonstrated to be safe and effective. FDA approval is based on this indication, based on strong scientific data. After several years of clinical experience, however, healthcare providers may find that the drug is also useful for indications not approved by the FDA. Or, the prescriber may find that the drug works better at a different dosage level or by a different route of administration. Once initially approved by the FDA for any indication, healthcare providers may legally prescribe the drug for other indications they feel are appropriate, despite the fact that the drug was never tested or approved for these additional conditions. How widespread is off-label prescribing? It is estimated that over 20% of prescriptions are for indications not approved by the FDA. The use of off-label drugs is particularly prevalent in cancer treatment and in pediatric patients. Although the FDA does not regulate off-label uses of drugs, laws prohibit pharmaceutical companies from advertising or promoting their drugs for off-label uses. It has not been clearly established whether or not off-label prescriptions increase risks to patients.

PharmFACT

It takes about 12 years of research and development, costing about $350 million, for a new drug to move from initial laboratory testing to the pharmacy shelf (Drugs.com, n.d.).

CONNECTION Checkpoint 2.1

In 2016, granisetron (Sustol), an antiemetic drug, and daclizumab (Zinbryta), an interleukin-2 blocking monoclonal antibody for treating relapsing multiple sclerosis, were approved. Are these considered therapeutic or pharmacologic classifications? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Changes to the Drug Approval Process

2.6 The U.S. Food and Drug Administration has sped up the process of drug review.

The process of synthesizing a new drug and testing it in cells, experimental animals, and humans takes many years. The NDA can include dozens of volumes of experimental and clinical data that must be examined during the FDA drug review process. Some NDAs contain over 100,000 pages of data. Even after all experiments have been concluded and clinical data have been gathered, the FDA review process can take several years.

Expenses associated with development of a new drug can cost the drug developer millions of dollars. Pharmaceutical companies are often critical of the regulatory process and are anxious to get the drug marketed to recoup their high research and development expenses. The public is also anxious to receive new medications, particularly for diseases that have a high mortality rate. Although the criticisms of government regulatory agencies are certainly understandable, and sometimes justified, the fundamental priority of the FDA is to ensure the safety of medications. Without an exhaustive review of scientific data, the public could be exposed to dangerous or ineffective drugs.

In the early 1990s, due to pressures from consumer groups and various drug manufacturers, government

officials began to plan how to speed up the drug review process. Reasons identified for the delay in the FDA drug approval process included outdated guidelines, poor communication, and not enough staff to handle the workload.

In 1992, the PDUFA was passed, requiring drug and biologic manufacturers to provide yearly product user fees. This added revenue allowed the FDA to hire more employees and to restructure its organization to more efficiently handle the processing of a greater number of drug applications. As part of the FDA modernization, priority drugs now receive accelerated approval. These are drugs intended to treat serious and life-threatening conditions, such as cancer and AIDS, that lack effective treatments. In some cases, the FDA may grant accelerated approval before the drug has completed phase 3 trials. The FDA usually requires the pharmaceutical company to file subsequent reports confirming the effectiveness of the drug.

PharmFACT

The number of new molecular entities approved in 2015 was 45. Thirty-six percent of these approvals were for first-in-class drugs that have mechanisms that differ from those of existing therapies (FDA, 2016b).

Prescription and Over-the-Counter Drugs

2.7 Over-the-counter drugs are usually safe and effective when used according to label instructions.

The 1951 Durham-Humphrey Amendment to the FDCA clearly established the difference between prescription and OTC drugs. To obtain a prescription drug, an order must be given authorizing the patient to receive the medication. Prescription medications are judged by the FDA to be potentially addictive or too harmful for self-administration. In some cases, they are used to treat conditions too complex for self-diagnosis by the consumer or the drug may require a skilled nurse or healthcare provider to administer it.

The advantages of requiring a prescription are numerous. The healthcare provider has an opportunity to examine the patient and determine a specific diagnosis. The prescriber can maximize therapy by ordering the proper drug for the patient's condition and by controlling the amount and frequency of the drug to be dispensed. In addition, the healthcare provider has an opportunity to teach the patient proper use of the drug and its expected adverse effects.

In contrast to prescription drugs, OTC drugs do not require an order from a healthcare provider. In most cases, patients may treat themselves safely if they carefully follow instructions included with the medication. A key point to remember is that no drug is without risk; if patients do not follow the guidelines on the label, serious adverse effects may result.

Patients prefer to take OTC medications for many reasons. OTC drugs are obtained more easily than prescription drugs. No appointment with a healthcare provider is required, thus saving time and money. Without the assistance of a healthcare provider, however, choosing the proper medication for a specific problem can be challenging for a patient. OTC drugs may interact with foods, herbal products, prescription drugs, or other OTC drugs. Patients may not be aware that some OTC medications can impair their ability to function safely. Self-treatment is sometimes ineffective, and the potential for harm may increase if the disease is allowed to progress.

During the past decade, consumer groups have pushed for the reclassification of certain drugs from prescription to OTC in cases whereby a high margin of safety exists with the medicines. For example, prior to 1996, substances that were used to assist in smoking cessation, such as nicotine patches and gum, were available by prescription only but are now available OTC. Other switches from prescription

CONNECTIONS: Lifespan Considerations

The Association of Cost-Related Medication Nonadherence and Food Insecurity in Older Adults

It is known that the cost of prescription drugs may be a major cause for medication nonadherence in the older adult, but are there other factors that impact nonadherence? Studies suggest that food insecurity, that is, the lack of access to sufficient, nutritious, and affordable food, may also predict nonadherence (Afulani, Herman, Coleman-Jensen, & Harrison, 2015; Herman, Afulani, Coleman-Jensen, & Harrison, 2015). Afulani et al. (2015) found that as the severity of food insecurity increased, nonadherence also increased. Older adult women and older adults with chronic conditions were more likely to report nonadherence. However, having insurance coverage, particularly Medicare and Medicaid, decreased nonadherence. Food security-related nonadherence is not just a problem for the older adult. Herman et al. (2015) found a similar relationship in the nonelderly adult population. In that study, female adults and adults with chronic conditions, low income, no or insufficient health insurance, severe mental illness, or functional limitations had an increased risk of cost-related medication nonadherence.

When assessing a patient's adherence to the prescribed medication regimen, nurses should assess factors other than cost that may increase the risk of nonadherence, particularly food insecurity. Recognizing that patients who are unable to afford or access adequate and nutritious food places them at risk for medication nonadherence may help the healthcare team improve health.

Table 2.2 U.S. Drug Schedules and Examples

Drug Schedule	Abuse Potential	Examples	Therapeutic Use
I	Highest	Heroin, GHB, LSD, marijuana, MDMA, mescaline, methaqualone, methcathinone, peyote, and psilocybin	No currently acceptable medical use; no prescriptions may be written
II	High	Potent opioids (such as codeine in high doses, fentanyl, methadone, morphine, oxycodone, meperidine), amphetamine, cocaine, methamphetamine, methylphenidate, PCP, and short-acting barbiturates	Have currently accepted medical use but use may be severely restricted; normally no refills are permitted (but there are exceptions)
III	Moderate	Anabolic steroids, buprenorphine ketamine, codeine (lower doses compounded with aspirin or acetaminophen), hydrocodone (lower doses compounded with aspirin or acetaminophen), and intermediate-acting barbiturates	Have currently accepted medical use; less stringent controls than Schedule II drugs; five refills allowed in a 6-month period
IV	Low	Benzodiazepines (such as alprazolam, diazepam, midazolam, temazepam), long-acting barbiturates, meprobamate, pentazocine, tramadol, and zolpidem	Have currently accepted medical use; similar controls to Schedule III drugs; five refills allowed in a 6-month period
V	Lowest	Cough medicines with codeine, antidiarrheal medicines with small amounts of opioids	Have currently accepted medical use; similar controls to Schedule III and IV drugs

From *Controlled Substance Schedules*, U.S. Department of Justice, n.d. Retrieved from http://www.deadiversion.usdoj.gov/schedules

to OTC include famotidine (Pepcid AC), cimetidine (Tagamet HB), omeprazole (Prilosec), cetirizine (Zyrtec), budesonide (Rhinocort), fluticasone (Flonase), and loratadine (Claritin). Over the past 25 years, 700 products have been changed from prescription to OTC. The decision to reclassify a drug may be initiated by the manufacturer or mandated by the FDA during its review process.

Herbal products and dietary supplements are also widely available OTC. Herbal products and dietary supplements are not considered drugs; they are not marketed to treat any disease, and they are not subject to the same regulatory process as medications. Yet some of these products can cause adverse effects and interact with medications. Nurses should always inquire about their patients' use of herbal products and dietary supplements and caution them that the FDA has not tested these products for effectiveness or safety. In some cases, herbal products are contraindicated. For example, St. John's wort should not be taken concurrently with antidepressant medications.

PharmFACT

An estimated 23,000-plus emergency department visits each year are attributed to adverse events related to dietary supplements. The two largest categories of supplements are energy drinks and weight loss supplements (Geller et al., 2015).

Drug Schedules

2.8 Drugs with a potential for abuse are categorized into schedules.

Dependence is a powerful physiologic or psychologic need for a substance. Some drugs are frequently abused or have a high potential for dependence; thus, the selling and distribution of these drugs are highly restricted. Drugs that have a significant potential for abuse are placed into five categories called *schedules*. These **scheduled drugs** are classified and regulated according to their potential for abuse, as shown in Table 2.2. Concepts of dependence and drug schedules are discussed in detail in Chapter 27.

In the United States, **controlled substances** are drugs whose use is restricted by the Comprehensive Drug Abuse Prevention and Control Act of 1970 and its later revisions. Hospitals and pharmacies must register with the Drug Enforcement Administration (DEA) and use their registration numbers to purchase scheduled drugs. They must maintain complete records of all quantities purchased and sold. Drugs with the highest abuse potential have additional restrictions. For example, providers must use a special order form to obtain Schedule II drugs, and orders must be written and signed by the provider. Telephone orders to a pharmacy are not permitted. Refills for Schedule II drugs are not permitted; patients must visit their healthcare provider to receive a new prescription. Healthcare providers convicted of unlawful manufacturing, distributing, and dispensing of controlled substances face severe penalties.

CONNECTION Checkpoint 2.2

Once a new drug is approved, it is assigned names. What are the two basic types of drug names and who assigns them? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Prescriptive Authority for Nurses

2.9 Advanced practice nurses are allowed to prescribe drugs under state regulations.

Historically, prescribing drugs was the responsibility of the physician or dentist. With the growth of advanced nursing degrees at the master's and doctoral levels, nurses began to specialize and to obtain certification as certified nurse midwives (CNMs), certified registered nurse anesthetists

(CRNAs), nurse practitioners (NPs), and clinical nurse specialists (CNSs). These advanced practice registered nurses (APRNs) complete graduate-level education that includes advanced pharmacology content, and they obtain certification by exam in one of the four above specialties.

The ability to prescribe drugs is regulated by state law, and each state has different requirements for prescriptive authority. As of 2016, APRNs were authorized to prescribe drugs independently of physician collaboration, delegation, or supervision in about one third of the United States. In approximately another third, the APRN must have some level of physician collaboration or delegation and may not prescribe independently (National Council of State Boards of Nursing [NCSBN], 2016). The specialty of the APRN may also affect prescriptive authority; for example, a CRNA may be subject to additional requirements compared to an NP. Controlled substance prescriptive authority may also vary from state to state. As the demand for primary care providers increases, and healthcare organizations such as the Veterans Health Administration recognize the full scope of practice for an APRN, the ability to practice independently is rapidly changing. The APRN is viewed as an essential member of the healthcare system's ability to deliver affordable care. The ability to prescribe drugs, a key component of most treatment plans, will ensure that patients are provided the best and most cost-effective care possible by APRNs and other healthcare providers. This text includes a focus on preparing for prescriptive authority, and Connections features detail specific information the APRN needs to know to prepare for this authority.

Understanding Chapter 2

Key Concepts Summary

2.1 Early American history saw the rise of patent medicines and the lack of adequate drug regulations.

2.2 In the 1900s, drug legislation was enacted to make drugs safer and more effective.

2.3 The standardization of drug purity and strength is specified by the *United States Pharmacopeia-National Formulary*.

2.4 The regulatory agency responsible for ensuring that drugs and medical devices are safe and effective is the U.S. Food and Drug Administration.

2.5 The drug approval process established by the U.S. Food and Drug Administration ensures that drugs sold in the United States are safe and effective.

2.6 The U.S. Food and Drug Administration has sped up the process of drug review.

2.7 Over-the-counter drugs are usually safe and effective when used according to label instructions.

2.8 Drugs with a potential for abuse are categorized into schedules.

2.9 Advanced practice nurses are allowed to prescribe drugs under state regulations.

CASE STUDY: Making the Patient Connection

Remember the patient "Gertrude Stone" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Gertrude Stone lives alone in the house she has owned for 46 years. Although she is seldom sick, when she needs to see a healthcare provider she must ride the public bus system. The trip requires two bus transfers and can be tiring.

Because Gertrude lives only one block from a grocery store, she often self-medicates using OTC drugs. She strongly believes in the use of herbs, vitamins, and home remedies.

As a parish nurse, you are organizing a community health fair at the church where Gertrude is an active member.

Critical Thinking Questions

1. How would you counsel Gertrude about the safety of OTC drugs?
2. What are the advantages and disadvantages of OTC medications?
3. How can Gertrude be certain that OTC medications are safe for her?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Your 12-year-old nephew is preparing a report for school about the FDA and the drug approval process. You, the nurse in the family, are often called on by family members to answer questions about anything health related. Following are his questions. How would you respond?

1. What is the role of the FDA?
2. What role does the FDA play in regulating herbal and dietary supplements?
3. How quickly can a new drug be approved by the FDA?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse knows that governmental drug legislation requires the drug manufacturer to prove that a drug is both safe and:
    1. Free of adverse effects and potential reactions.
    2. Effective for a specified purpose.
    3. Reasonable in cost and easily accessible.
    4. Beneficial to various population groups.
2. The drug research participant with a particular disease is taking part in an investigative study to examine the effects of a new drug. Previously, this drug was tested using healthy volunteers. The next phase of the clinical trial investigation in which the patient will be participating is:
    1. Phase 1
    2. Phase 2
    3. Phase 3
    4. Phase 4
3. When considering various drug therapies, the nurse knows that most drug testing and approval occurs with which population?
    1. Multiple population types and is usually safe for all patients
    2. Caucasian men and may not be safe for other populations
    3. Older adults, and may be harmful to children and adolescents as well
    4. Animals, which verifies the drug's effectiveness in humans
4. The patient requests that a refill prescription of a Schedule II controlled substance be telephoned to the drug store. When responding to the patient, the nurse would consider which factor? Refills of Schedule II drugs:
    1. Are less costly than the original prescription.
    2. Must be listened to by at least two people.
    3. Are verified through the local DEA office.
    4. Are not permitted under federal law.
5. The nurse knows that drugs that are subject to stricter regulations are those:
    1. With a high potential for abuse or dependency.
    2. That are most costly and difficult to produce.
    3. With adverse effects and high occurrence of drug or food interactions.
    4. That have taken years to be proven effective in the laboratory.
6. A nurse notes that multiple patients had a reaction to the same medication, a drug that has been available for several years. Which action should the nurse take? (Select all that apply.)
    1. File an Adverse Event Report with the FDA.
    2. Note the reaction in the patient's chart.
    3. Notify the healthcare provider who ordered the drug.
    4. Wait until the FDA sends a notification of the drug's recall before informing the patient.
    5. Compare each patient's reaction to determine if it is the same.

"I'm terribly worried about my father, John Kessler. He's been so ill for so long. I don't know if his body can take much more."
Patient's daughter, "Emily Kessler Myers"

Chapter 3
Pharmacokinetics

Chapter Outline

- Introduction to Pharmacokinetics
- Primary Processes of Pharmacokinetics
  - Absorption
  - Distribution
  - Metabolism
  - Excretion
- Time–Response Relationships
  - Drug Plasma Levels
  - Drug Half-Life
  - Loading and Maintenance Doses

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the four primary processes of pharmacokinetics.
2. Explain mechanisms by which drugs cross plasma membranes.
3. Discuss factors affecting drug absorption.
4. Discuss how drugs are distributed throughout the body.
5. Describe how plasma proteins affect drug distribution.
6. Explain the metabolism of drugs and its applications to pharmacotherapy.
7. Identify major processes by which drugs are excreted.
8. Explain how enterohepatic recirculation affects drug activity.
9. Explain how a drug reaches and maintains its therapeutic range in the plasma.
10. Explain the applications of a drug's plasma half-life ($t_{1/2}$) to pharmacotherapy.
11. Differentiate between loading and maintenance doses.

Key Terms

absorption, 28
affinity, 35
blood–brain barrier, 35
diffusion, 28
distribution, 34
drug-protein complexes, 35
enteral route, 29
enteric-coated, 29
enterohepatic recirculation, 39
enzyme induction, 37
excretion, 38

substrate, 36
therapeutic drug monitoring, 40
therapeutic range, 40
topical route, 31
toxic concentration, 40
transdermal patches, 31

Most drugs produce their effects by causing a physiologic or chemical change in specific target cells in the body. To produce a therapeutic effect, a drug must reach its target cells in sufficient quantities. For many medications, such as topical agents used to treat superficial skin conditions, this is an easy task. For most medications, however, the process of reaching target cells to cause a physiologic change is challenging. Drugs are exposed to a myriad of different barriers and destructive processes after they enter the body. The purpose of this chapter is to examine factors that act on the drug as it attempts to reach its target cells and to provide examples of how the nurse can use this information to optimize pharmacotherapeutic outcomes.

Introduction to Pharmacokinetics

3.1 Pharmacokinetics focuses on what the body does to drugs after they are administered.

The term **pharmacokinetics** is derived from the root words *pharmaco*, which refers to medicines, and *kinetics*, which means "movement" or "motion." Pharmacokinetics is thus the study of drug movement throughout the body. In practical terms, it describes what the body does to the medication after it is administered. Pharmacokinetics is a core subject in pharmacology, and a firm grasp of this topic allows nurses to better understand and predict the actions and adverse effects of medications in their patients.

Drugs face numerous obstacles in reaching their target cells. For most medications, the greatest barrier is crossing the many membranes that separate the drug from its target cells. A drug taken by mouth, for example, must cross the plasma membranes of the mucosal cells of the gastrointestinal (GI) tract and the endothelial cells of the capillaries to enter the bloodstream. To leave the bloodstream, it must again cross capillary cells, travel through interstitial fluid, and perhaps enter target cells by passing through their plasma membranes. Depending on the mechanism of action, the drug may also need to enter cellular organelles such as nuclei, which are surrounded by additional membranes. Some of the membranes and barriers that many drugs must successfully penetrate before they can elicit a response are illustrated in Figure 3.1.

While seeking their target cells and attempting to cross membrane barriers, drugs are subjected to numerous physiologic processes. For medications given by the oral route, stomach acid and digestive enzymes often break down the drug molecules. Enzymes in the liver and other organs may chemically change the drug molecule, making it less active. If seen as foreign by the body, phagocytes may attempt to remove the drug, or an immune response may be triggered. The kidneys, large intestine, and other organs attempt to rapidly excrete the drug from the body.

The preceding examples all illustrate pharmacokinetic processes: how the body handles drugs. The many processes of pharmacokinetics are grouped into four categories: absorption, distribution, metabolism, and excretion, which are illustrated in Figure 3.2. All four of these processes have drug movement in common. Whether it involves movement to its target site or movement out of the body, kinetics is certainly an appropriate name for this important branch of pharmacology.

3.2 Drugs use diffusion and active transport to cross plasma membranes to reach their target cells.

With few exceptions, drugs must cross plasma membranes and enter cells to produce their effects. Plasma membranes are composed of a lipid bilayer, with proteins and other molecules interspersed in the membrane. Like other chemicals, drugs use two primary processes to cross membranes: diffusion and active transport.

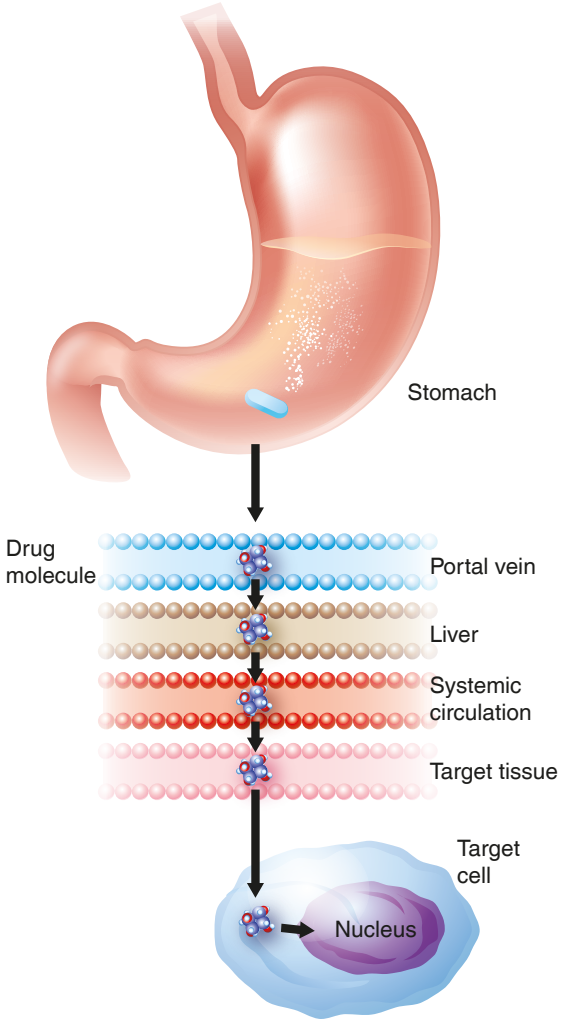

Figure 3.1 Barriers that a drug administered by the oral route must cross before interacting with a target cell.

Simple **diffusion**, or passive transport, is the movement of a chemical from an area of higher concentration to an area of lower concentration. This is best explained by the use of an example. When first administered, a drug given by the intravenous (IV) route is in high concentration in the blood but has not yet entered the tissues. The drug will move quickly by passive diffusion from its region of high concentration (blood) to a region of low concentration (tissues) to produce its action. With time the drug will be inactivated (metabolized) by the tissue and more doses of the drug may be administered, creating a continual concentration gradient from blood to tissue.

Diffusion assumes that the chemical is able to freely cross the plasma membrane. This, however, is not the case for all drugs. Passage across the lipid-rich plasma membrane is dependent on the physical characteristics of the drug molecule. Drug molecules that are small, nonionized, and lipid soluble will usually pass through plasma membranes by simple diffusion and easily reach their target cells. This process is illustrated in Figure 3.3. Drugs may also enter through open channels in the plasma membrane; however, the molecule must be very small, such as urea, alcohol, and water.

Large molecules, ionized drugs, and water-soluble agents have difficulty crossing plasma membranes by simple diffusion. These agents may require carrier, or transport, proteins to cross membranes. A drug that moves into a cell along its concentration gradient utilizing a membrane carrier protein is using the process of facilitated diffusion. This process does not require energy expenditure from the cell, but it does require that a specific carrier protein be present on the plasma membrane. Transport proteins are selective and only carry molecules that have specific structures.

Some drugs cross membranes against their gradient, from low concentration to high concentration, through the process of active transport. This requires expenditure of energy on the part of the cell and a carrier protein. Carrier proteins that assist in active transport are sometimes called pumps.

Primary Processes of Pharmacokinetics

3.3 Absorption is the process of moving a drug from the site of administration to the bloodstream.

For most medications the first step toward reaching target cells is **absorption**, the process by which drug molecules move from their site of administration to the blood. With the exception of a few topical medications, local anesthetics, anti-infectives for intestinal parasites, and some radiologic contrast agents, the majority of drugs must be absorbed in order to produce an effect. Of course, drugs administered directly into blood vessels by IV or intra-arterial routes are not absorbed because they are placed directly in the bloodstream.

Absorption is the primary pharmacokinetic factor determining the onset of drug action—the length of time it takes a drug to produce its effect. In general, the more rapid the absorption, the faster the onset of drug action. Drugs used in critical care are designed to be absorbed within seconds or minutes, or they are given intravenously. At the other extreme are drugs such as the contraceptive Mirena, which is a polyethylene tube placed in the uterus. The drug inside Mirena, levonorgestrel, is absorbed slowly from the tube and provides contraceptive protection for up to 5 years.

In addition to onset time, absorption determines the intensity of drug action. For any given drug, a specific percentage of the drug is absorbed, ranging from 0% to 100%. Everything else being equal, drugs with higher absorption rates produce a more effective response than those with lower absorption rates. The degree of absorption is conditional on many factors.

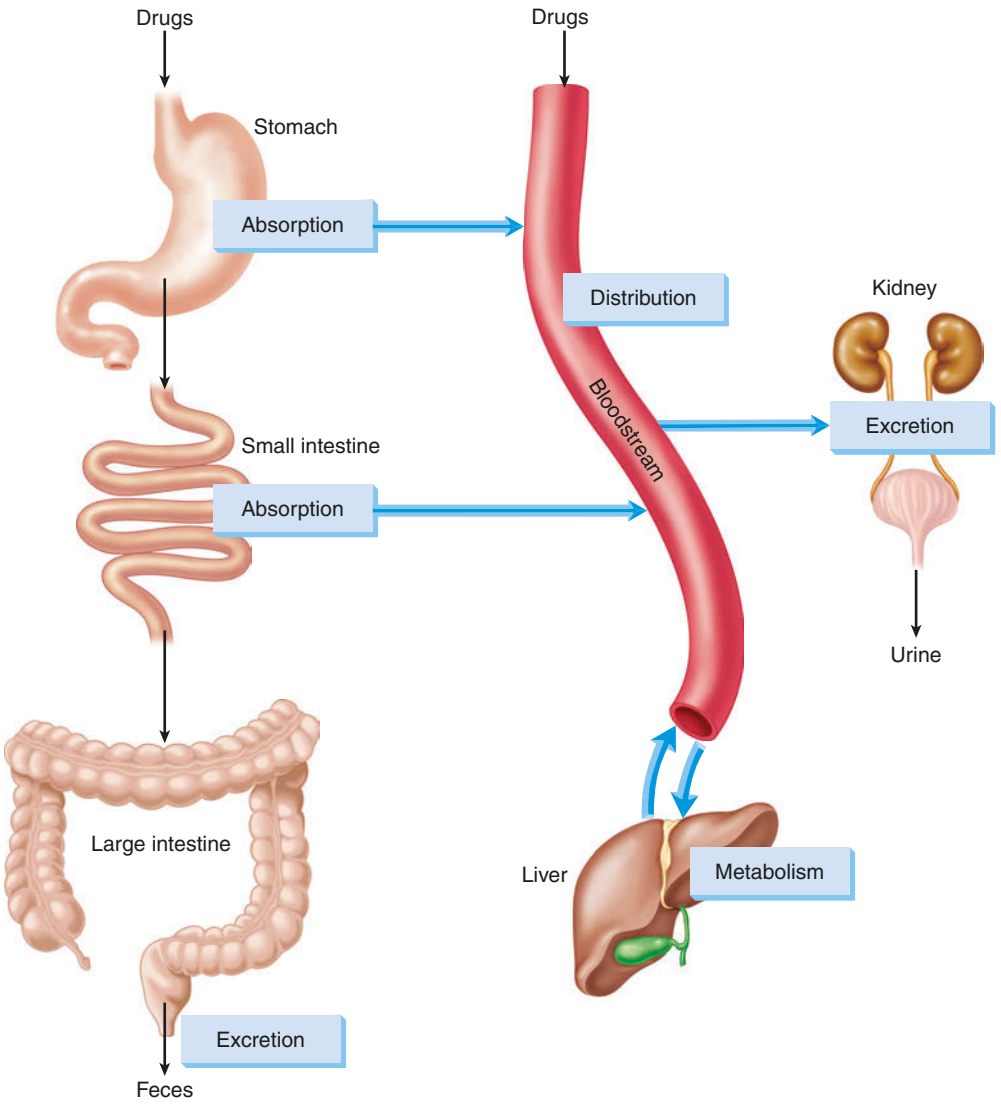

Figure 3.2 The four processes of pharmacokinetics: absorption, distribution, metabolism, and excretion.

Route of Administration

The route of administration is one of the most important variables affecting drug absorption. The three broad categories of routes of drug administration are enteral, topical, and parenteral. Each route has characteristics that offer both advantages and disadvantages. Whereas some drugs are formulated to be given by several routes, others are specific to only one route.

Enteral route: The **enteral route** includes drugs delivered to the GI tract, either orally (PO) or through nasogastric or gastrostomy tubes. Most medications administered by the enteral route are intended for absorption to the general circulation, taking advantage of the combined absorptive surfaces of the oral mucosa, stomach, and small intestine. A few enteral medications are administered for local effects, such as infections of the GI tract.

Tablets and Capsules: Tablets and capsules are the most common forms of oral medications. Most patients prefer tablets or capsules because of their ease of use. In some cases, tablets may be scored, allowing for one-half or one-quarter dosing. The oral route is considered one of the safest because the skin barrier is not compromised. In cases of overdose, drugs remaining in the stomach can be retrieved by inducing vomiting or by suctioning out the stomach contents.

Tablets and capsules must dissolve before the drug is available for absorption; thus their onset time is relatively slow. The dissolution rate of a tablet or capsule is often the slowest part of the absorption process of an oral medication. Because oral liquid formulations do not undergo dissolution, they are absorbed faster than tablets or capsules.

The strongly acidic stomach contents can destroy some enteral medications. To overcome this obstacle, tablets may have a hard, waxy coating that enables them to resist acidity. These **enteric-coated** tablets are designed to dissolve in the alkaline environment of the small intestine. Some drugs are enteric coated because the medications will irritate the stomach mucosa should they dissolve in the stomach.

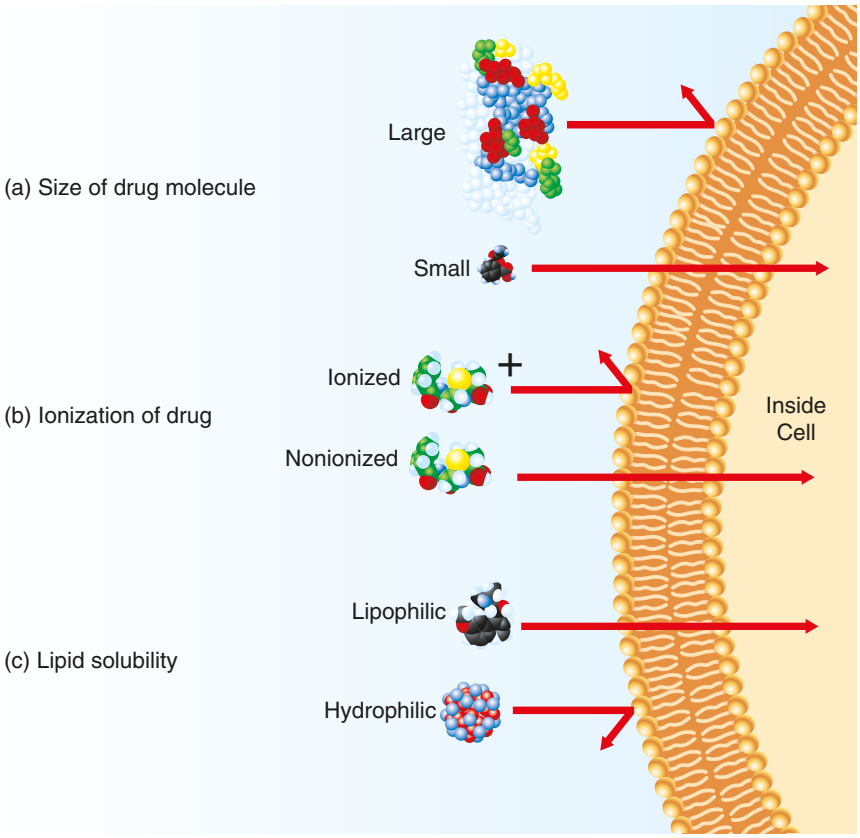

Figure 3.3 Passage of drugs across plasma membranes: (a) Small drugs, (b) nonionized drugs, and (c) lipophilic drugs are more likely to cross membranes.

As the number of doses per day increases, patients sometimes forget to take their medication properly. **Extended release** (XR, XL) tablets or capsules are designed to dissolve slowly, resulting in a longer duration of action for the medication. Also called long-acting (LA) or sustained release (SR) medications, these forms allow for the convenience of once or twice a day dosing.

Some patients, particularly children, have difficulty swallowing tablets and capsules. Crushing tablets or opening capsules and sprinkling the medication over food or mixing it with juice may make the drug more palatable and easier to swallow. The nurse should not crush tablets or open capsules, however, unless the manufacturer specifically states that this is permissible. In general, the following types of drugs should not be chewed, crushed, or opened:

- **Extended release formulations.** These drugs contain a high dose of medication that is intended to be released over an extended period. Opening the capsule or crushing the tablet will release the entire drug immediately, possibly resulting in a toxic effect.
- **Enteric-coated drugs.** When crushed or opened, these drugs are exposed to stomach acid, which may destroy them. In addition, the drugs may irritate the stomach mucosa and cause nausea or vomiting.
- **Oral cavity effects.** Drugs that have a bitter taste are often coated with a thin layer of glucose or inert material to mask their taste. If crushed or opened, the bitter taste is experienced. Other drugs stain the teeth, irritate the oral mucosa, or cause an anesthetic-like effect on the tongue if crushed and exposed to the oral cavity.

As an alternative to crushing, some drugs are available in liquid form for patients who have difficulty swallowing tablets or capsules. Liquid forms include elixirs, syrups, and suspensions. Liquid drugs are usually heavily flavored and sweetened to mask their bitter taste.

Tablets, liquids, and capsules have certain disadvantages. The patient must be conscious and able to swallow properly. Certain types of drugs, including proteins such as insulin, are inactivated by the digestive enzymes in the stomach and small intestine. Furthermore, drugs absorbed from the stomach and small intestine first travel to the liver, where they may be inactivated before they ever reach their target organs—a process called **first-pass effect** (first-pass metabolism) (see Section 3.5). There is also significant variation among patients in the motility of the GI tract and in its ability to absorb medications. In addition, children and some adults have an aversion to swallowing large tablets and capsules or to taking oral medications that taste bad.

Oral Transmucosal Routes: The mucosa of the oral cavity contains extensive capillaries that provide an excellent absorptive surface for many drugs. Medications given by

this route are not subjected to destructive stomach acid, and they do not undergo the hepatic first-pass effect. Medications delivered by this method include sublingual and buccal tablets, orally disintegrating tablets, and soluble films.

For the sublingual method, the medication is placed under the tongue and allowed to slowly dissolve. Because of the rich blood supply to the region, the sublingual route results in a rapid onset of drug action. When multiple medications are ordered, the sublingual preparations should be administered after oral medications have been swallowed. After moistening the oral cavity, the patient should be instructed not to move the drug with the tongue or to eat or drink anything until the medication has completely dissolved. The sublingual mucosa is not suitable for extended release formulations because it is a relatively small area and is constantly being bathed by saliva that will remove these drugs from the region.

For the buccal route, the drug is placed in the oral cavity between the gum and cheek. The patient should be instructed not to manipulate the drug with the tongue; otherwise it could get displaced to the sublingual area, where it will be more rapidly absorbed, or to the back of the throat, where it could be swallowed. The buccal mucosa is thicker and less permeable to medications than the sublingual area, providing for slower absorption. The buccal route is preferred over the sublingual route for sustained release delivery because of its greater mucosal surface area. For example, testosterone, a drug normally given by injection, is available in a buccal form (Striant). Buccal administration of testosterone releases the drug over 12 hours and gives a more consistent, sustained drug level than does the transdermal patch delivery system for testosterone (see Chapter 71). Drugs formulated for buccal administration generally do not cause irritation and are small enough to not cause discomfort to the patient. Like the sublingual route, drugs administered by the buccal route avoid the first-pass effect by the liver as well as the destructive enzymes of the stomach and small intestine.

In recent years, two alternatives to tablets, capsules, and liquids have been developed. Orally disintegrating tablets (ODTs) and oral soluble films are designed to dissolve in the oral cavity in less than 30 seconds, without the need to drink water. These dosage forms are convenient and especially appropriate for patients who have difficulty chewing or swallowing and patients who are nauseated, uncooperative, or have a mental impairment. ODTs and soluble films are now available for dozens of medications.

PharmFACT

Medicated lollipops are an emerging technology. The patient sucks or rotates a stick coated with the flavored medication, which dissolves slowly in the mouth (Vangara & Samala, 2015).

Nasogastric and Gastrostomy Tubes: Patients with a nasogastric (NG) tube or an enteral feeding mechanism, such as a gastrostomy (G) tube, may have their medications administered through these devices. Drugs administered through these tubes are usually in liquid form. Although solid drugs can be crushed or dissolved, they tend to clog the tubes. Sustained release medications should not be crushed and administered through NG or G tubes. Drugs administered by these routes are exposed to the same physiologic processes as those given PO.

Topical route: The **topical route** of drug administration includes medications applied to the skin or mucous membranes. The skin is the topical route most commonly used. Topical medications applied to the skin are absorbed very slowly because the drug must penetrate the thick, keratin layer of the epidermis.

Topical drugs are also applied to mucous membranes of the eye, ear, nose, respiratory tract, urinary tract, vagina, or rectum. Some of these medications are absorbed very rapidly because these membranes are relatively thin and have a rich blood supply.

Many drugs are applied topically to produce a local effect. For example, antibiotics are applied topically to treat skin infections. Antineoplastic agents may be instilled into the urinary bladder via catheter to treat localized tumors of the bladder mucosa. Corticosteroids are sprayed into the nostrils to reduce inflammation of the nasal mucosa due to allergic rhinitis. Topical delivery produces fewer adverse effects compared to the same drug given PO or parenterally. This is because, when given topically, drugs are absorbed more slowly and the amount of the drug reaching the general circulation is minimal. The most common adverse events resulting from topical administration are transient burning, stinging, or redness of the area where the medications are applied.

Some drugs are given topically to provide for slow release and absorption of the drug to the general circulation. These medications are given for their systemic, rather than local, effects. For example, a nitroglycerin patch is not applied to the skin to treat a local skin condition but to treat coronary artery disease. Likewise, prochlorperazine (Compazine) suppositories are inserted rectally not to treat a disease of the rectum but to alleviate nausea.

The distinction between topical drugs given for local effects and those administered for systemic effects is an important one for the nurse. In the case of local drugs, absorption is undesirable and may result in adverse effects if the drug reaches the systemic circulation in significant amounts. For systemic drugs, absorption across the skin or mucous membrane is essential for the therapeutic action of the drug. Neither type of topical agent should be applied to abraded or denuded skin because it could affect drug absorption.

The use of **transdermal patches** provides an effective means of delivering certain medications. Examples include

nitroglycerin to treat angina pectoris, testosterone for hypogonadism, and scopolamine (Transderm Scop) for motion sickness. Transdermal patches contain a specified amount of medication, although the rate of delivery and the actual dose received can vary. Patches are changed on a regular dosing schedule, often daily or weekly, depending on the medication. Medications administered by this route avoid the first-pass effect in the liver and bypass digestive enzymes.

The ophthalmic route is used to treat local conditions of the eye and surrounding structures. Common indications include excessive dryness, eye infections, glaucoma, and dilation of the pupil during eye examinations. Ophthalmic drugs are absorbed into the systemic circulation via drainage of the drug into the nasolacrimal ducts and subsequently to the nasopharynx and the GI tract. Generally this is a slow process and only small amounts reach the general circulation; thus ophthalmic drugs cause few systemic adverse effects. Infants are an exception. The concentration of drugs reaching the systemic circulation is higher than in an adult, giving a greater chance for adverse drug events.

The otic route is used to treat local conditions of the ear, including infections and accumulations of earwax in the auditory canal. Otic medications should always be brought to room temperature before administration because cold medications may cause dizziness or nausea. Systemic adverse effects from otic preparations are not observed unless the drug is applied to areas of open abrasions or injury, such as a ruptured tympanic membrane.

Drugs are applied by the intranasal route for their local effects on the nasal mucosa or for systemic absorption. Advantages of this route include convenience and rapid onset of action. Local indications include the application of drops or sprays for shrinking swollen nasal mucous membranes or for loosening secretions and facilitating drainage. For example, decongestant nasal sprays bring immediate relief from the nasal congestion caused by the common cold (see Chapter 45). Intranasal formulations of corticosteroids have revolutionized the treatment of allergic rhinitis due to their effectiveness and high safety margin.

The nasal mucosa also provides an excellent absorptive surface for certain medications to produce systemic actions. Advantages of this route include avoidance of the first-pass effect and digestive enzymes. For example, an intranasal form of vitamin B_{12} is available that is used for patients lacking intrinsic factor, a substance required for the absorption of this vitamin in the GI tract. Intranasal calcitonin is available to treat osteoporosis. Being a protein, calcitonin would be destroyed by stomach enzymes if given PO (see Chapter 72).

Although the nasal mucosa provides an excellent surface for drug delivery, there is a potential for damage to the ciliated cells within the nasal cavity and mucosal irritation is common. In addition, large amounts of intranasal mucus may prevent a drug from reaching the nasal mucosa.

The vaginal route is used to treat local conditions such as vaginal infections, pain, and itching. The vagina has a rich blood supply, and drugs inserted into it may be absorbed across the mucosa and produce systemic effects. For example, vaginal creams containing estrogen not only produce local effects on the vagina but also result in significant levels of this hormone in the circulation. The contraceptive NuvaRing, inserted into the vagina, contains estrogen and progestin, which are absorbed and provide contraception protection for a month.

The rectal route may be used for either local or systemic drug delivery. It is a safe and effective means of delivering medications to comatose patients or to those who are experiencing nausea and vomiting. Rectal medications are normally in suppository form, although a few laxatives and diagnostic agents are given via enema. Although absorption is slower than by other routes, the rectal route is steady and reliable provided the medication can be retained by the patient. Venous blood from the lower rectum is not transported to the circulation by way of the liver; thus the first-pass effect is avoided as are the digestive enzymes of the upper GI tract.

Parenteral route: The parenteral route refers to the administration of drugs by routes other than enteral or topical. A needle is used to deliver drugs into the skin layers, subcutaneous tissue, muscles, or veins. Less common parenteral delivery methods include administration into arteries (intra-arterial), bone (intraosseous), body cavities (intrathecal), or organs (intracardiac). Parenteral drug administration is more invasive than topical or enteral because of the potential for introducing pathogenic microbes directly into the blood or body tissues. The nurse must know the correct anatomic locations for parenteral administration, proper administration technique, and safety procedures regarding disposal of hazardous equipment.

Intradermal and Subcutaneous Administration: Injection into the skin delivers drugs to the blood vessels that supply the various layers of the skin. Medications may be injected either intradermally or subcutaneously. The major difference between these methods is the depth of injection. An advantage of both methods is that they offer a means of administering drugs to patients who are unable to take medications PO. Drugs administered by these routes avoid digestive enzymes and the hepatic first-pass effect. However, only small volumes can be administered by these routes, and injections can result in pain and swelling at the injection site.

The intradermal (ID) route administers drugs into the dermis layer of the skin. Because the dermis contains more blood vessels than the deeper subcutaneous layer, drugs are more readily absorbed. This route is usually employed for allergy and disease screening or for local anesthetic delivery prior to venous cannulation. ID injections are limited to very small volumes of medication, usually only 0.1 to 0.2 mL.

The subcutaneous route delivers drugs to the deepest layers of the skin. Insulin, heparin, vitamins, some vaccines, and other medications are given in this area because the sites are easily accessible and provide for rapid absorption. Subcutaneous doses are small in volume, usually ranging from 0.5 to 1 mL. It is important to rotate injection sites in an orderly and documented manner to promote absorption, lessen tissue damage, and minimize discomfort.

Intramuscular Administration: The intramuscular (IM) route delivers drugs directly into large muscles. Because muscle tissue has a rich blood supply, drug molecules quickly move into blood vessels to produce a more rapid onset of action than with oral, ID, or subcutaneous administration. In a few cases, the drug is formulated in an oily, viscous base that promotes slow and continuous absorption from the muscle.

The anatomic structure of muscle permits this tissue to receive a larger volume of drug than the subcutaneous region. Adults with well-developed muscles can tolerate up to 3 mL in the gluteus maximus and gluteus medius muscles. In the deltoid muscle, volumes of 0.5 to 1 mL are recommended.

Intravenous Administration: The intravenous (IV) route delivers drugs and fluids directly into the bloodstream, which immediately distributes them throughout the body. The IV route is used when a very rapid onset of action is desired. Unlike other routes in which absorption may be unpredictable, an exact level of drug in the bloodstream can be attained by fine adjustments to the IV flow rate. Like other parenteral routes, IV drugs bypass the enzymatic processes of the alimentary canal and avoid the first-pass effect of the liver. The IV route is useful for patients who are comatose or otherwise unable to take oral medications. The three basic types of IV administration include large-volume infusion, intermittent infusion, and IV bolus (push) administration.

Although the IV route offers the fastest onset of drug action, it is also the most dangerous. Once injected, the medication cannot be retrieved. If the drug solution or the needle is contaminated, pathogens have a direct route to the bloodstream and body tissues. Patients receiving IV injections must be closely monitored for adverse reactions. Although some adverse reactions occur immediately after injection, others may take hours or days to appear. Antidotes for drugs that can cause potentially dangerous or fatal reactions must always be readily available.

CONNECTION Checkpoint 3.1

Pharmaceutical companies are always exploring novel methods of drug delivery, such as the new soluble films, so that the period of exclusivity of a medication can be extended. From what you learned in Chapter 1, why is exclusivity important to a pharmaceutical company? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Drug Concentration and Dose

For almost all drugs, higher doses produce a faster and greater response. This is because a higher dose produces a greater concentration gradient for diffusion. As an example, consider the antihypertensive drug diltiazem (Cardizem) given as a 100-mg tablet, which is about 50% absorbed. Half of the drug (50 mg) will reach the bloodstream for distribution to target cells. If the dose of diltiazem is doubled to 200 mg, greater amounts of the drug (100 mg) will be absorbed in the bloodstream. Although the percentage absorbed remains the same (50%), the higher dose results in a greater quantity of drug in the blood and, subsequently, more drug is available to produce an action at its target cells. This concept is further explained in Chapter 4.

GI Tract Environment

For medications given by the enteral route, physical and chemical conditions within the GI tract can affect drug absorption. Most absorption occurs in the small intestine, because this portion of the GI tract is longer, and the absorptive surfaces of the microvilli are much more extensive as compared to the stomach. Furthermore, the time spent by food and drugs in the stomach is brief, and the thick mucus layer in the organ discourages absorption.

Digestive motility is variable among patients; very rapid motility may speed the drug through the GI tract before complete absorption occurs. Abnormally slow motility may cause the drug to be retained in the stomach, where it is exposed for a longer time to destructive enzymes and high acidity. Fatty foods in the stomach nearly always slow drug absorption. With few exceptions, absorption is most complete when the drug is taken between meals; the presence of food in the stomach may lessen the incidence of nausea and vomiting, but it also slows absorption. All these factors contribute to wide patient variability with regard to absorption and onset of drug action when drugs are administered PO.

Blood Flow to the Absorption Site

For a drug to be absorbed, the site of administration must have adequate blood flow; thus drugs are absorbed faster from areas of the body where blood flow is high. IM injections are placed into large muscles because they have a high blood flow that maximizes absorption. During heart failure or shock, the amount of blood flow to certain tissues is reduced and absorption from the GI tract or IM sites may be diminished. Topical drugs placed on the skin have slow absorption due to the poor blood supply to the upper layers of the skin.

In some circumstances blood flow can be manipulated to purposely slow absorption. For example, local anesthetics can be toxic if absorbed too quickly. To purposely slow

absorption, a vasoconstrictor (epinephrine) is sometimes added to local anesthetics to reduce blood flow to the treated region. As another example, applying ice packs to the site can slow the absorption of a drug to the region; adding heat can cause the opposite effect.

Drug Ionization

Ionized molecules are those that carry a positive or a negative charge. Most drugs can exist in either a charged or an uncharged state, depending on the pH of the surrounding fluid. The ionization of a drug affects its ability to cross plasma membranes and to be excreted by the body (see Section 3.6). Aspirin, or acetylsalicylic acid, provides an example of the effects of ionization on absorption, as depicted in Figure 3.4. In the highly acidic environment of the stomach, aspirin is in its nonionized form and is thus readily absorbed and distributed in the bloodstream. As aspirin enters the alkaline environment of the small intestine, however, it becomes ionized. In its ionized form, the aspirin molecule is less likely to be absorbed and distributed to target cells. Unlike acidic drugs such as aspirin, medications that are weakly basic are in their nonionized form in an alkaline environment; therefore, basic drugs are much more likely to be absorbed in alkaline environments such as the small intestine. In simplest terms, it may help the student to remember the following:

- Acids are absorbed in acids because they are nonionized.
- Bases are absorbed in bases because they are nonionized.

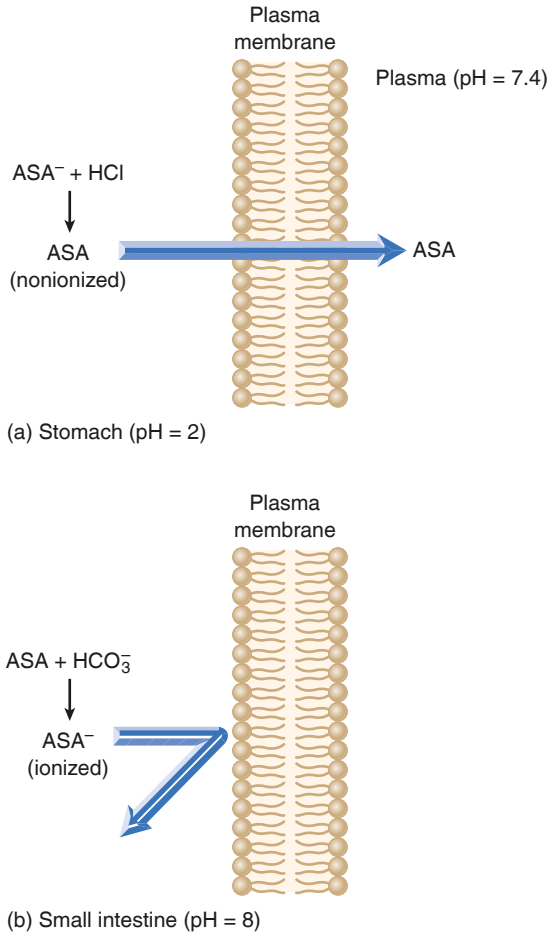

Figure 3.4 Effect of pH on drug absorption: (a) A weak acid such as aspirin (ASA) is in a nonionized form in an acidic environment and absorption occurs. (b) In a basic environment, aspirin is mostly in an ionized form and absorption is prevented.

Drug Interactions

Drug–drug and food–drug interactions have the potential to affect absorption. For example, administering oral tetracyclines with food or drugs containing calcium, iron, or magnesium can significantly delay absorption of the antibiotic. High-fat meals can slow stomach motility significantly and delay the absorption of oral medications taken with the meal. The mechanisms and types of drug interactions are presented in detail in Chapter 5.

Surface Area

Other factors being equal, drugs will be absorbed faster when applied to regions of the body having a larger surface area. This is one reason why the small intestine is such an important organ for drug absorption. Relative to the oral cavity and stomach, the microvilli of the small intestine provide a vast surface area that is richly supplied with blood vessels. Another region with an enormous surface area is the lung. Inhaled substances such as bronchodilators or crack cocaine act almost instantaneously due to the large absorptive surface provided by terminal bronchioles and alveoli.

3.4 Distribution describes how drugs are transported throughout the body.

Distribution is the phase of pharmacokinetics describing the *movement* of medications throughout the body after they are absorbed or injected parenterally. Drugs are not simply passive agents, being swept along an inert path to their target tissues. Rather, drugs may interact with blood components and may be chemically and physically changed before they reach their targets. Like absorption, several key factors influence drug distribution.

Blood flow to tissues: The simplest factor determining drug distribution is the amount of blood flow to body tissues. Because the heart, liver, and kidneys receive a great percentage of the blood supply, these organs receive the highest exposure to absorbed drugs. Skin, bone, and adipose tissue receive a meager blood flow; therefore, it is more difficult to deliver high concentrations of drugs to these areas.

Blood flow should also be considered at the local level. For example, after traumatic injury, the blood supply to a fractured bone may be reduced due to damaged blood vessels, or blocked by cellular debris from the inflammatory

process. Antibiotics may have difficulty reaching the injured area until blood flow can be restored. The delivery of high concentrations of drugs to injured, necrotic, or abscessed areas that have inadequate perfusion is always challenging.

Drug solubility: The physical properties of a drug greatly influence how it moves throughout the body after administration. Lipid solubility is an important characteristic because it determines how quickly a drug is absorbed, mixes within the bloodstream, crosses membranes, and becomes localized in body tissues. Lipid-soluble agents are not limited by the barriers that normally stop water-soluble drugs; thus they are more completely distributed to body tissues.

Tissue storage: Some tissues have the ability to accumulate and store drugs in high concentrations relative to other tissues. The bone marrow, teeth, eyes, and adipose tissue have an especially high **affinity**, or attraction, for certain medications. Examples of agents that are stored in adipose tissue are diazepam (Valium), lipid-soluble vitamins, and tetracycline, which binds to calcium salts and accumulates in bones and teeth. Once stored in tissues, drugs may remain in the body for many months and be released very slowly back to the circulation. For example, the therapeutic effects of alendronate (Fosamax), a drug for osteoporosis, will continue for 4 to 7 months after the drug is discontinued.

Drug-protein binding: Many drugs bind reversibly to plasma proteins, particularly albumin, to form **drug-protein complexes**. These complexes are too large to cross capillary membranes; the drugs continue circulating in the bloodstream and are unavailable for distribution to their site of action. Medications will remain trapped in the bloodstream bound to plasma proteins until they are released or displaced from the drug-protein complex. Only unbound, or free, drugs can reach their target cells or be excreted by the kidneys. This concept is illustrated in Figure 3.5. Some drugs, such as the anticoagulant warfarin (Coumadin), are highly bound; 99% of the drug in the plasma exists in drug-protein complexes, and only 1% exists as a free drug available to reach target cells.

The number of binding sites on a plasma protein such as albumin is limited. What happens when two or more drugs compete for the same binding sites? The drug that has the greater affinity for these binding sites binds first. This competition for binding sites may result in drug–drug and drug–food interactions when one medication displaces another from plasma proteins. The displaced medication can quickly reach high levels in the blood and produce adverse effects. This is especially important for drugs such as warfarin that have a narrow margin of safety. Most drug guides give the percentage of the drug bound to plasma proteins; when giving multiple medications that are highly bound, the nurse should monitor for potential adverse effects.This topic is further discussed in Chapter 5.

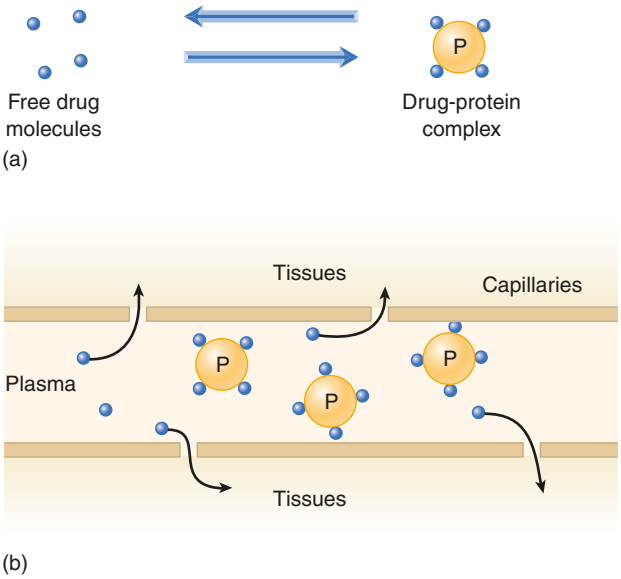

Figure 3.5 Plasma protein binding and drug availability: (a) The drug exists in a free state or is bound to plasma protein. (b) Drug-protein complexes are too large to cross membranes.

Special barriers to drug distribution: Most capillaries in the body are relatively porous due to spaces between the endothelial cells. Many drugs can exit the bloodstream by traveling through those spaces and enter the interstitial fluid with relative ease. The brain and placenta, however, possess special anatomic barriers that inhibit many chemicals and drugs from exiting the blood. These barriers are referred to as the **blood–brain barrier** and **fetal–placental barrier**.

Unlike other capillaries, those in the brain have endothelial cells that are sealed by tight junctions and a thick basement membrane. Brain cells known as astrocytes press firmly against the basement membrane, secreting chemicals that adjust the capillary permeability. The purpose of the blood–brain barrier is obvious: to protect the brain from pathogens and toxic substances. Some highly lipid-soluble agents such as general anesthetics, sedatives, antianxiety agents, and anticonvulsant drugs readily cross the blood–brain barrier to produce their actions on the central nervous system (CNS). In contrast, most antitumor medications and antibiotics do not easily cross this barrier, making brain cancers and infections difficult to treat. The blood–brain barrier becomes more permeable when it is inflamed due to infections such as meningitis. In neonates, the blood–brain barrier is not fully developed, allowing many drugs to readily cross the barrier.

The series of membranes that separate the maternal blood from the fetal blood serves as a fetal–placental barrier that prevents potentially harmful substances from passing from the mother's bloodstream to the fetus. In reality, the placenta is an inefficient barrier because substances such as alcohol, cocaine, caffeine, and certain prescription medications can easily cross the placental barrier and cause potential harm to the fetus. Consequently, no prescription medication, over-the-counter (OTC) drug, or herbal therapy

should be taken by a pregnant woman without first consulting a healthcare provider. The nurse should always question women of childbearing age regarding their pregnancy status before a drug is prescribed. Substances that cause birth defects, or teratogens, are presented in Chapter 5. Chapter 8 presents special concerns related to pharmacotherapy of pregnant and lactating patients.

3.5 Metabolism is a process that changes the activity of a drug and makes it more likely to be excreted.

Drug **metabolism**, also called biotransformation, is the process used by the body to chemically change a drug molecule. Metabolism involves hundreds of complex biochemical pathways and reactions that alter the structure and function of drugs, nutrients, vitamins, and minerals. The liver is the primary site of drug metabolism, although the kidneys and cells of the intestinal tract also have high metabolic rates. To survive, all cells must undergo metabolism to some extent. The types of metabolic reactions, however, are specific to each type of cell: Reactions occurring in liver cells are very different from those in skin cells or brain cells.

In most cases, metabolic reactions change the structure of a drug so that it can be more easily excreted by the body. This often changes the drug from lipid soluble (easily absorbed and distributed) to water soluble, which is more easily excreted by the kidneys. In addition, once the molecule has been changed to water soluble, it is less able to enter tissues. The products of drug metabolism, called *metabolites*, usually have less pharmacologic activity than the original molecule. In this way, metabolism provides an essential detoxifying effect for drugs and other substances entering the body.

On some occasions a metabolite may exhibit a *greater* therapeutic action than the original drug. This is the case for codeine. Although 90% of codeine is changed to inactive metabolites by the liver, 10% is converted to morphine, which has significantly greater ability to relieve severe pain. In a few cases, the metabolite has greater toxicity than the original drug. Probably the most common example of this is acetaminophen (Tylenol), which is converted to a metabolite that is highly toxic to the liver.

CONNECTION Checkpoint 3.2

Both codeine and morphine are scheduled drugs. From Chapter 2, which law was enacted to control the manufacturing, importation, possession, and distribution of these drugs? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

In a few cases, the drug administered to the patient has no pharmacologic activity at all until it undergoes metabolism. Medications that require metabolism to produce their therapeutic actions are called **prodrugs**. For example, the antihypertensive enalapril (Vasotec) is converted in the liver to a metabolite called enaliprat, which has considerably more ability to lower blood pressure than the original drug. Examples of other prodrugs include benazepril (Lotensin) and losartan (Cozaar).

Hepatic microsomal enzymes: Most metabolism in the liver is accomplished by the **hepatic microsomal enzyme system**. This enzyme complex is known as the CYP450 enzyme system, named after cytochrome P450 (CYP450), which is a key component of the system. Although this system is complex, a key point to remember is that CYP450 is simply an enzyme that metabolizes drugs as well as nutrients and other endogenous substances. Although the liver is the major site for CYP450 activity, nearly every tissue in the body has some CYP450 enzymes.

At one time researchers thought that a single CYP450 enzyme was responsible for all drug metabolism, but scientists have since identified more than 50 of them. These different forms are called **isozymes** of CYP450. Although very similar, each isozyme performs slightly different metabolic functions. CYP450 enzymes are named by assigning numbers to indicate their subfamily, such as CYP1, CYP2, CYP3, and so on. Additional letters and numbers are added to further identify the specific gene, such as CYP1A1, CYP3A4, and CYP26C1. Fortunately for nursing students, only a handful of the 50-plus isozymes are responsible for the majority of drug metabolism, as shown in Table 3.1. Indeed, a single isozyme, CYP3A4, is responsible for about 50% of all drug metabolism in the liver.

The CYP450 enzymes are important to pharmacotherapy because they determine the speed at which most drugs are metabolized and they contribute significantly to drug–drug interactions. Changes in hepatic microsomal enzyme activity have the potential to alter drug action. These effects may either increase or decrease drug action, depending on the specific interaction. There are three major consequences of the CYP450 system that have importance to pharmacotherapy:

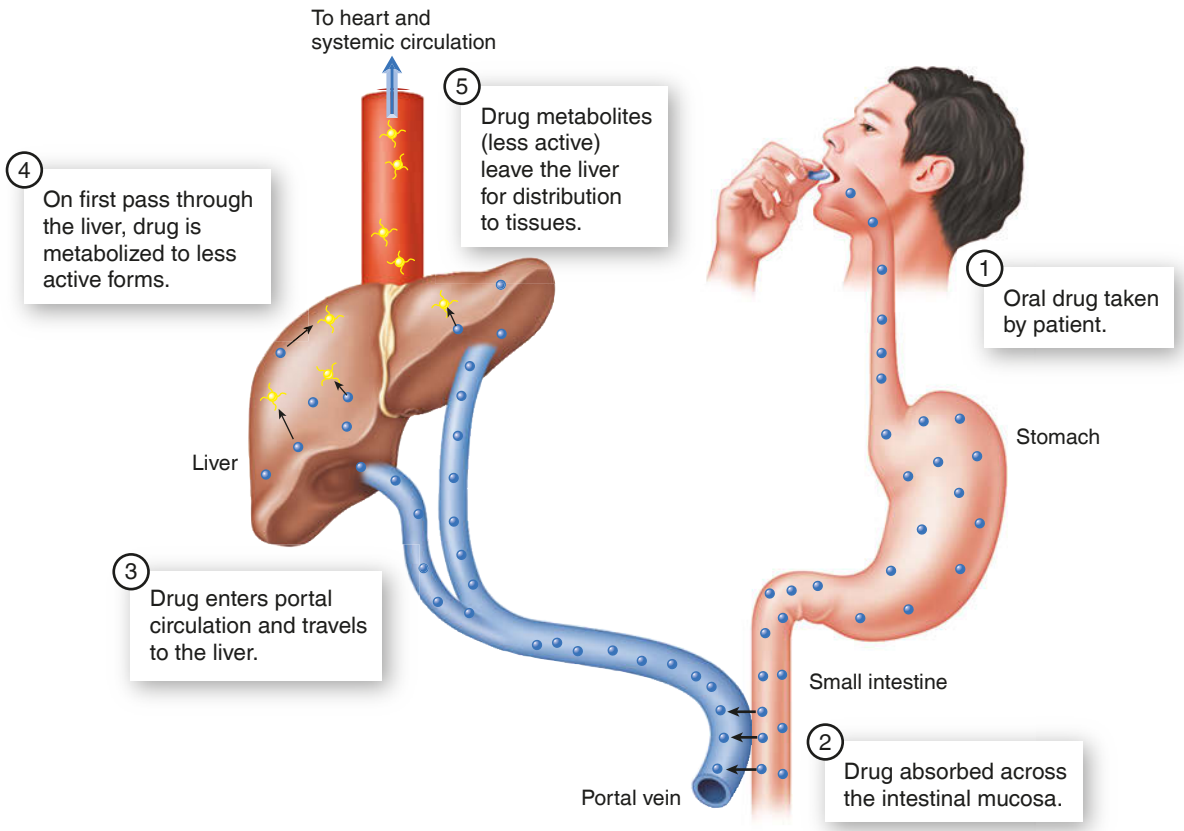
- **Drugs as substrates.** When a drug is metabolized by a CYP450 enzyme, it is said to be a **substrate** for the enzyme. For example, warfarin and NSAIDS such as naproxen are substrates for CYP2C9. Codeine and amphetamine are substrates for a different isozyme, CYP2D6. Each isozyme of CYP450 can metabolize many different drugs, and a drug may be metabolized by multiple CYP450 enzymes. Because of this overlap, two drugs that are administered concurrently may compete for binding sites on the same CYP450 isozyme, resulting in a drug–drug interaction.
- **Drugs as enzyme inhibitors.** Some drugs are able to *inhibit* the action of CYP450 isozymes. The inhibition may affect all hepatic microsomal enzymes or it may be specific to a single isozyme. Inhibiting a CYP450 enzyme could affect the amount of active drug available. For example, ciprofloxacin (Cipro) inhibits CYP1A2. Administering ciprofloxacin concurrently with naproxen

Table 3.1 Selected Isozymes of Cytochrome P450: Selected Substrates, Inducers, and Inhibitors

Isozyme	Substrates	Inducers	Inhibitors
CYP1A2	amitriptyline, caffeine, clozapine, duloxetine, estradiol, fluvoxamine, imipramine, naproxen, ondansetron, propranolol, ritonavir, tacrine, tamoxifen, verapamil, warfarin, zileuton, zolmitriptan	broccoli, Brussels sprouts, carbamazepine, insulin, omeprazole, rifampin, tobacco	amiodarone, cimetidine, ciprofloxacin, fluoroquinolones, fluvoxamine
CYP2C9	amitriptyline, celecoxib, fluoxetine, glipizide, glyburide, imipramine, nonsteroidal anti-inflammatory drugs (NSAIDs), losartan, phenytoin, rosiglitazone, sulfonylureas, tamoxifen, tricyclic antidepressants, valproic acid, warfarin	carbamazepine, phenobarbital, rifampin, St. John's wort	amiodarone, fluconazole, fluvoxamine, isoniazid, metronidazole, paroxetine, ritonavir, sertraline, statins, sulfamethoxazole, zafirlukast
CYP2C19	amitriptyline, citalopram, clopidogrel, diazepam, indomethacin, phenytoin, progesterone, propranolol, proton pump inhibitors, sertraline	carbamazepine, efavirenz, norethindrone, prednisone, ritonavir, St. John's wort	cimetidine, fluconazole, fluoxetine, fluvoxamine, isoniazid, ketoconazole, proton pump inhibitors, oral contraceptives
CYP2D6	amitriptyline, amphetamine, aripiprazole, carvedilol, clomipramine, codeine, duloxetine, fluoxetine, haloperidol, imipramine, lidocaine, metoprolol, mexiletine, ondansetron, oxycodone, paroxetine, propranolol, risperidone, ritonavir, tamoxifen, tramadol, venlafaxine	dexamethasone, rifampin	amiodarone, bupropion, celecoxib, cimetidine, citalopram, cocaine, diphenhydramine, duloxetine, escitalopram, fluoxetine, paroxetine, ranitidine, ritonavir, sertraline
CYP3A4	alprazolam, amiodarone, aprepitant, atorvastatin, buspirone, calcium channel blockers, carbamazepine, chlorpromazine, cocaine, cyclosporine, erythromycin, estradiol, hydrocortisone, lidocaine, lovastatin, methadone, prednisone, propranolol, quetiapine, risperidone, ritonavir, sildenafil, tamoxifen, testosterone, trazodone, venlafaxine, zolpidem	carbamazepine, corticosteroids, efavirenz, nevirapine, oxcarbazepine, phenobarbital, phenytoin, pioglitazone, rifampin, St. John's wort	amiodarone, aprepitant, azole antifungals, cimetidine, ciprofloxacin, diltiazem, erythromycin, fluvoxamine, grapefruit juice, norfloxacin, omeprazole, fluoxetine, ritonavir, verapamil

(a substrate for CYP1A2) could result in less metabolism of naproxen, higher amounts of naproxen in the blood, and a prolonged drug effect. Because naproxen is a relatively safe drug, this higher level may not produce noticeable toxicity. However, giving ciprofloxacin with a more toxic drug such as warfarin (also a substrate for CYP1A2) has the potential to increase levels of warfarin and cause a serious drug interaction. The dose of warfarin would need to be adjusted downward to avoid toxicity. It is important to note that CYP450 enzyme inhibition can occur after a single dose of an inhibitor.

- **Drugs as enzyme inducers.** A few drugs have the ability to *increase* metabolic activity in the liver, a process called **enzyme induction**. For example, carbamazepine (Tegretol) causes the liver to synthesize greater amounts of microsomal enzymes, including CYP1A2, CYP3A4, CYP2C19, and CYP2C9. By doing so, phenobarbital accelerates the metabolism (inactivation) of most drugs metabolized in the liver. In fact, with continued therapy phenobarbital increases the rate of its own destruction. In these patients, because drugs will be inactivated at a much faster rate, higher doses may be required to achieve an optimal therapeutic effect. Unlike CYP450 inhibition, which can occur after a single dose, enzyme induction generally takes from days to weeks of pharmacotherapy.



Metabolism has a number of additional therapeutic consequences. As shown in Pharmacotherapy Illustrated 3.1, drugs absorbed from the stomach or small intestine cross directly into the hepatic-portal circulation, which carries blood to the liver before it is distributed to other body tissues. Some drugs can be completely metabolized to an inactive form on their first trip through the liver *before they even reach the general circulation*. This first-pass effect is important to pharmacology, because a large number of oral drugs can be rendered inactive by hepatic metabolic reactions. Alternate routes of delivery, such as the sublingual, rectal, or parenteral routes that bypass the first-pass effect, may need to be considered for these drugs. Remember, however, that even drugs administered by parenteral routes may be rapidly inactivated when passing through the liver.

Patient variation in metabolism: The baseline level of hepatic microsomal enzyme function is genetically determined. Genetic differences in the function of CYP enzymes may cause people to metabolize drugs at widely different rates. Some patients metabolize at a faster rate, others at a slower rate. Certain genetic disorders have been recognized in which patients lack specific metabolic enzymes. In these "slow metabolizers" normal drug doses may cause toxicity. Genetic differences are not always predictable, although some occur at a higher rate in certain ethnic populations (see Chapter 4).

Certain age groups and patients with certain pathologic conditions exhibit diminished hepatic metabolic activity, which may result in altered drug action. Infants do not develop a mature microsomal enzyme system until at least 1 year of age. Hepatic enzyme activity is generally reduced in older adults; thus these patients may require lower doses. Patients with liver impairment will require reductions in drug dosage because of the decreased metabolic activity. The nurse should pay careful attention to laboratory values that may indicate liver disease so that drug doses may be adjusted accordingly.

Pharmacotherapy Illustrated 3.1

FIRST-PASS EFFECT: Oral Drug Is Metabolized to an Inactive Form Before It Has an Opportunity to Reach Target Cells

Chronic alcohol consumption and tobacco use induce certain CYP450 enzymes. St. John's wort, a popular herbal remedy for depression, is an enzyme inducer and can affect the therapeutic response to certain medications. On the other hand, grapefruit juice is an inhibitor of CYP3A4 activity. These examples underscore the importance of obtaining a thorough patient history prior to initiating drug therapy.

3.6 Excretion processes remove drugs from the body.

Drugs will continue to act on the body until they are either metabolized to an inactive form or removed from the body by **excretion**. The rate at which a drug is excreted determines its concentration in the blood and, ultimately, its duration of action. Pathologic states, especially liver or kidney disease, often increase the duration and intensity of drug action in the body because they interfere with natural excretion mechanisms.

Renal excretion: Although drugs are removed from the body by numerous organs and tissues, the primary site of excretion is the kidney. In an average size person, the kidneys filter approximately 180 L of blood each day. Unbound (free) drugs, water-soluble agents, electrolytes, and small molecules easily pass through the pores of the glomerulus and enter the filtrate in the renal tubule. Proteins, blood cells, and drug-protein complexes are not filtered because of their large size.

After filtration at the renal corpuscle, drugs may undergo reabsorption in the renal tubule. Mechanisms of reabsorption are the same as absorption elsewhere in the body. Nonionized and lipid-soluble drugs cross renal tubular membranes more easily and return to the circulation; ionized and water-soluble drugs generally remain in the filtrate.

Drug-protein complexes and other substances too large to be filtered at the glomerulus are sometimes secreted into the distal tubule of the nephron. For example, only 10% of a dose of penicillin G is filtered; 90% is secreted into the renal tubule. As with metabolic enzyme activity, secretion mechanisms are less active in infants and in older adults.

The renal excretion of drugs is greatly influenced by the pH of the filtrate in the renal tubule. Weak acids like aspirin are excreted more efficiently when the filtrate is slightly alkaline. This is because aspirin is ionized in an alkaline environment,

and the ionized drug will remain in the filtrate to be excreted in the urine. Weakly basic drugs such as diazepam (Valium) are excreted more quickly if the filtrate is slightly acidic because they are ionized in that environment. The pH of the filtrate may be intentionally manipulated to speed up renal excretion. For example, following an overdose of an acidic drug such as aspirin, nurses may administer sodium bicarbonate. Sodium bicarbonate makes the urine more basic, which ionizes the aspirin molecule, facilitating its urinary excretion. The excretion of diazepam, on the other hand, can be enhanced by giving a drug such as ammonium chloride, which acidifies the filtrate and ionizes the diazepam molecule.

Impairment of kidney function can dramatically affect pharmacokinetics. Patients with renal failure will have diminished ability to excrete medications and may retain drugs for extended periods. Doses for these patients must be reduced to prevent drug toxicity. Because small to moderate changes in renal function can cause rapid increases in serum drug levels, kidney function must be constantly monitored in patients receiving nephrotoxic drugs or medications that have a narrow margin of safety.

Pulmonary excretion: Drugs delivered by gas or volatile liquid (liquids that vaporize at room temperature) are especially suited for excretion by the respiratory system. The rate of respiratory excretion is dependent on factors that affect gas exchange, including diffusion, gas solubility, and blood flow to the lungs. The elimination of gaseous and volatile anesthetics following surgery is primarily dependent on respiratory activity: The faster the breathing rate, the more rapid the excretion. On the other hand, the respiratory removal of water-soluble agents such as alcohol is more dependent on blood flow to the lungs. The greater the blood flow through lung capillaries, the greater the pulmonary excretion. In contrast with other methods of excretion, the lungs excrete most drugs in their original unmetabolized form.

Glandular secretion: Glandular activity is another elimination mechanism. Water-soluble drugs may be secreted into the saliva, sweat, or breast milk. The "funny taste" that patients experience when given certain drugs is an example of the secretion of medications into saliva. Another example is the garlic smell that can be detected when standing next to a perspiring person who has recently eaten garlic. Excretion into breast milk is of considerable importance for basic drugs such as morphine or codeine, because these can achieve high concentrations and potentially affect the nursing infant. Lactating women should always check with their healthcare provider before taking any prescription medication, OTC drug, or herbal supplement. Drugs of special concern to the pregnant or breastfeeding patient are discussed in Chapter 8.

Fecal and biliary excretion: Certain oral drugs travel through the GI tract without being absorbed and are excreted in the feces. Examples include mebendazole (Vermox), a drug used to kill intestinal worms, and barium sulfate, a radiologic contrast agent.

Some drugs are secreted in bile, a process known as biliary excretion. Drugs secreted into bile will enter the duodenum and eventually leave the body in the feces. However, some substances in bile are reabsorbed and circulated back to the liver by **enterohepatic recirculation**, as illustrated in Figure 3.6. This is a normal physiologic mechanism for salvaging and reusing useful substances.

Drugs or their metabolites may participate in this process and recirculate numerous times with the bile. This has the result of extending their half-life in the body and possibly prolonging drug action. This is an important route of

CONNECTIONS: Treating the Diverse Patient

Pharmacogenomics: Beyond Designer Drugs

Pharmacogenomics, the study of how a patient's genome influences drug responses, has been developing at a rapid pace. Pharmacogenomics has the potential to allow the healthcare provider to select the most effective drug, with a better safety profile, and reduce the cost of treatment. An additional benefit to be realized as the field of pharmacogenomics matures is the possibility of answering the question about why a certain drug, or drug classification, may be experiencing an increase in the number of prescriptions. By answering this question through the use of pharmacogenetic testing (how variation in a single gene affects drug response), researchers may be able to determine whether a drug is just being used more frequently or whether the prevalence of the disease itself is increasing in the population.

Insel (2014) made note of the rise in the number of prescriptions for the treatment of psychobehavioral conditions in children, including toddlers. Conventional wisdom has suggested that the rise is due to demands from parents or schools to treat the behaviors, as a result of direct-to-consumer advertising that parents view or other factors that increase the likelihood of prescription. But similar to the rise in the incidence of type 1 diabetes and food allergies in children, Insel postulated that the increase in psychostimulant drugs may have been caused by an increased incidence in the diseases they are used to treat. By using pharmacogenomics to look deeper into the genetic codes that promote diseases or help make a drug more effective, proof of this may also be on the horizon. This has implications for future research into the etiology of diseases, and the ability to develop strategies to prevent the disease or to halt its progression, not just to provide treatment with the best drug that works with an individual patient's genetic makeup.

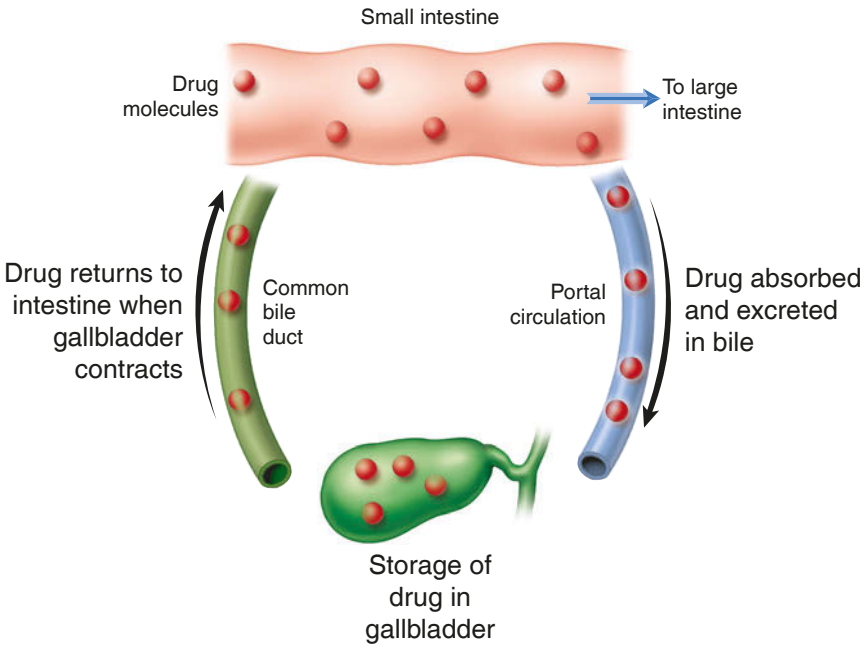


Figure 3.6 Enterohepatic recirculation of a drug can increase its half-life in the body and prolong its duration of action.

excretion for tamoxifen, barbiturates, carbamazepine, rifampicin, and oral contraceptives. Recirculated drugs are eventually metabolized by the liver and may be excreted by the kidneys. Recirculation and elimination of drugs through biliary excretion may continue for several weeks after therapy has been discontinued.

Time–Response Relationships

3.7 The therapeutic response of most drugs depends on their concentration in the plasma.

The therapeutic response from most drugs is directly related to their concentration in the plasma. Although the concentration of the drug at its target tissue is more predictive of drug action, this quantity is impossible to measure. For example, although it is possible to conduct a laboratory test that measures the serum level of lithium carbonate (Eskalith) by taking a blood sample, it is a far different matter to measure the quantity of this drug in neurons within the brain.

It is common practice to monitor the plasma levels of drugs that have a low safety margin and to use these data to predict drug action or toxicity. Results of **therapeutic drug monitoring** are used by the healthcare provider to keep the drug dose within a predetermined therapeutic range. For example, the therapeutic range for the antibiotic vancomycin (Vancocin) is 20 to 40 mcg/mL and the toxic level is considered to be greater than 80 mcg/mL. For patients with severe infections, the nurse would carefully monitor the laboratory results for vancomycin to be certain that serum levels fall within the therapeutic range. Dosages would be adjusted upward or downward based on therapeutic drug monitoring and the patient responses. The nurse should always remember, however, that individual responses to drugs are highly variable and patients may experience toxic effects (or no effects) even if the serum concentration of the drug lies in the normal range.

A number of important pharmacokinetic principles can be illustrated by measuring the drug plasma level following a single dose administered PO. These pharmacokinetic values for a hypothetical drug are shown graphically in Figure 3.7. In this example, the plasma drug level slowly increased and took about 2 hours before the **minimum effective concentration** was reached. The minimum effective drug plasma concentration, that amount of drug required to produce a therapeutic effect, is 6 mcg/mL. The level of drug then entered the **therapeutic range**, which for this drug lies between 6 and 12 mcg/mL. In this range, the drug produced its desired therapeutic action. After peaking, the drug plasma level slowly began to fall out of the therapeutic range due to excretion processes. A higher dose might have caused the drug plasma level to reach a **toxic concentration**, the level of drug that results in serious adverse effects. The goal of pharmacotherapy is to reach and maintain a plasma drug level in the therapeutic range while avoiding the toxic concentration.

These values have great clinical significance. For example, if the patient has a severe headache and is given half of an aspirin tablet, the plasma drug level will likely remain below the minimum effective concentration, and the patient will not experience pain relief. Two or three tablets will increase the plasma level of aspirin into the therapeutic range, and the pain will subside. Taking six or more tablets may result in adverse effects, such as GI bleeding or tinnitus. For each drug administered, the nurse's goal is to keep its plasma concentration in the therapeutic range. For some drugs, this therapeutic range is quite wide. For other medications, the difference between a minimum effective dose and a toxic dose can be extremely narrow.

3.8 The drug half-life estimates the duration of action for most medications.

In the example illustrated in Figure 3.7, the serum concentration of the drug reached a peak and then fell back below the therapeutic range. The length of time a drug concentration remains in the therapeutic range is its *duration of action*. In this example, the duration of action was 6 hours. The duration of action is an important pharmacokinetic variable that is determined by how rapidly the drug is metabolized and excreted.

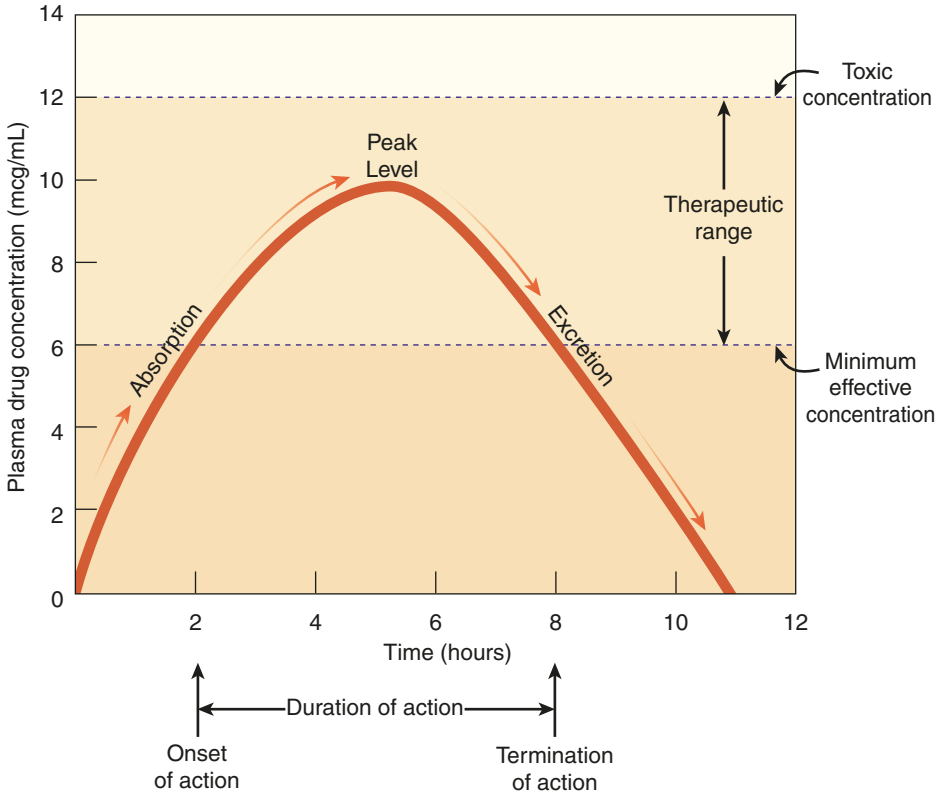

Figure 3.7 Single-dose drug administration. Pharmacokinetic values for this drug are as follows: onset of action = 2 hours; duration of action = 6 hours; termination of action = 8 hours after administration; peak plasma concentration = 10 mcg/mL; time to peak drug effect = 5 hours; $t_{1/2}$ = 4 hours.

The most common description of a drug's duration of action is its **plasma half-life ($t_{1/2}$)**: the length of time required for the plasma concentration of a drug to decrease by one half after administration. Some drugs have a half-life of only a few minutes, whereas others have a half-life of several hours or days. A few drugs have exceptionally long half-lives; for example, amiodarone (Cordarone) has a $t_{1/2}$ of 40 to 55 days.

Is it better to administer a drug with a short or long half-life? The answer depends on the patient's condition and the treatment goal. Drugs with short half-lives are ideal for conditions and procedures having a brief duration. For example, during a dental procedure, local anesthesia may only be needed for 15 to 20 minutes; thus procaine (Novocain), with a half-life of 8 minutes, may be sufficient. Giving a drug with a long duration of action could cause adverse effects after the patient leaves the office. As another example, a simple headache can be relieved with a short-acting drug such as aspirin ($t_{1/2}$ = 15 to 20 minutes), rather than a drug with a 10- or 12-hour duration. Because short-acting drugs are rapidly excreted, the risk of long-term adverse effects is reduced.

Long-duration drugs do have certain advantages. In the preceding example, procaine would not be suitable for a dental procedure that lasts 2 hours because multiple injections would be necessary. Long-duration drugs are beneficial in treating chronic conditions such as heart failure or hypertension and for the prevention of conditions such as migraine headaches, seizures, or pregnancy. Short-acting drugs such as aspirin must be given every 3 to 4 hours, whereas medications with longer half-lives, such as felodipine ($t_{1/2}$ = 10 hours), need to be given only once a day. As drugs stay in the body for prolonged periods, however, the risk for long-term adverse effects increases. This can become particularly serious for patients with significant renal or hepatic impairment; diminished metabolism and excretion will cause the plasma half-life of a drug to increase, and the concentration may reach toxic levels. In these patients, medications must be given less frequently, or the dosages must be reduced.

As a rule of thumb, when a drug is discontinued it takes approximately four half-lives before the agent is considered "functionally" eliminated. After four half-lives, 94% of the drug has been eliminated. In the case of procaine with a half-life of only 8 minutes, the drug is considered eliminated in 32 minutes. Although some drug remains, the amount is too small to produce any beneficial or toxic effect. In the example of felodipine ($t_{1/2}$ = 10 hours), the drug would take 40 hours to be eliminated. Note, however, that this "rule of thumb" does not apply to all drugs; it certainly does not apply to medications administered to patients with renal or hepatic impairment.

3.9 Repeated dosing allows a plateau drug plasma level to be reached.

Few drugs are administered as a single dose. When multiple doses are administered over an extended period, the goal is to keep the drug plasma level *continuously* within the therapeutic range. In other words, the next dose should be administered before the drug plasma level falls below the minimum effective concentration.

Multiple doses result in an accumulation of drug in the bloodstream, as shown in Figure 3.8. When doses are correctly timed, a plateau drug plasma level will be reached and maintained within the therapeutic range. From a pharmacokinetic perspective, at the plateau level the amount of drug absorbed equals the amount of drug being excreted, resulting in a steady therapeutic level of drug being distributed to body tissues. Theoretically, it takes approximately four half-lives to reach this equilibrium. If the medication is given as a continuous infusion, the plateau can be reached very quickly and maintained with little or no fluctuation in drug plasma levels.

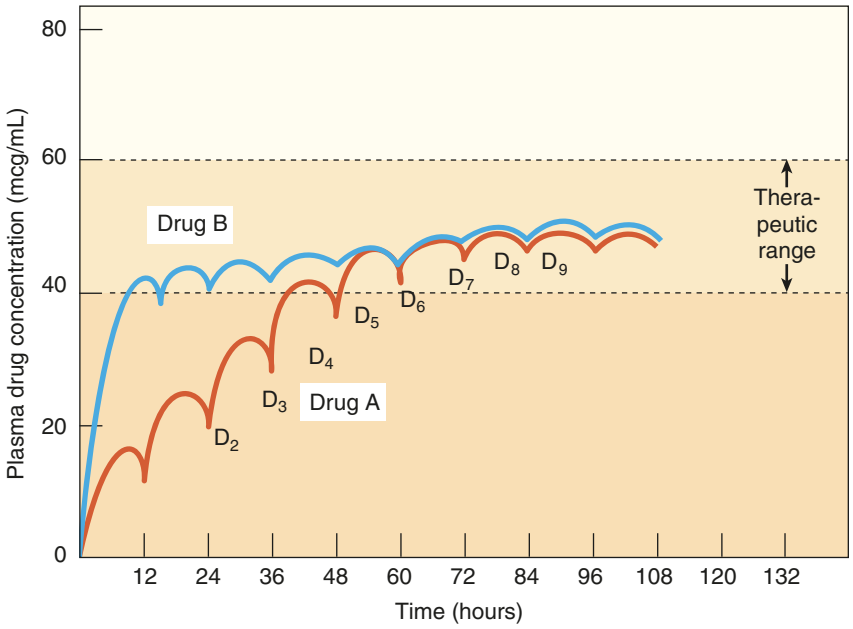

Figure 3.8 Multiple-dose drug administration. Drug A and drug B are administered every 12 hours. Drug B reaches the therapeutic range faster, because the first dose is a loading dose.

Note that in Figure 3.8, plasma drug levels are not necessarily smooth and continuous: There are peaks as well as troughs. When giving oral drugs, there is always some degree of fluctuation in peak concentration and trough concentration levels. A key point is that the peak should not rise into the toxic range, nor should the trough fall below the therapeutic range. Sustained or extended release formulations are designed to slowly release the drug so peak and trough fluctuations are minimized. Changing the dosing schedule can also reduce fluctuations. For example, rather than giving 60 mg of codeine once daily, it may be given 30 mg bid or 20 mg tid to reduce the possibility of breakthrough pain due to wide variation in the peak and trough levels.

The plateau may be reached faster by administration of loading doses followed by regular maintenance doses. A **loading dose** is a higher amount of drug, often given only once or twice, that is administered to "prime" the bloodstream with a level sufficient to quickly induce a therapeutic response. Before plasma levels drop back toward zero, intermittent **maintenance doses** are given to keep the plasma drug concentration in the therapeutic range. Although blood levels of the drug fluctuate with this approach, the equilibrium state can be reached almost as rapidly as with a continuous infusion. Loading doses are particularly important for drugs with prolonged half-lives and for situations in which it is critical to raise drug plasma levels quickly, as might be the case when administering an antibiotic for a severe infection. In Figure 3.8, it took almost five doses (48 hours) before a therapeutic level was reached using a routine dosing schedule. With a loading dose, a therapeutic level was reached within 12 hours.

Understanding Chapter 3

Key Concepts Summary

3.1 Pharmacokinetics focuses on what the body does to drugs after they are administered.

3.2 Drugs use diffusion and active transport to cross plasma membranes to reach their target cells.

3.3 Absorption is the process of moving a drug from the site of administration to the bloodstream.

3.4 Distribution describes how drugs are transported throughout the body.

3.5 Metabolism is a process that changes the activity of a drug and makes it more likely to be excreted.

3.6 Excretion processes remove drugs from the body.

3.7 The therapeutic response of most drugs depends on their concentration in the plasma.

3.8 The drug half-life estimates the duration of action for most medications.

3.9 Repeated dosing allows a plateau drug plasma level to be reached.

CASE STUDY: Making the Patient Connection

Remember the patient "John Kessler" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

John Kessler has been ill for a long time and his prognosis is poor. He is 84 years old with multiple debilitating and chronic conditions. He has had uncontrolled diabetes for more than 20 years and has experienced many complications due to this condition. Three years ago, he developed chronic kidney disease and requires dialysis 3 times a week. To further complicate his condition, John has continued to consume alcohol every day and smokes one pack of cigarettes per day. He has a long history of both alcohol and tobacco use.

Five days ago, his daughter noticed that he was becoming increasingly weak and lethargic. Last night when his temperature reached 38.8°C (102°F) and he became confused, his daughter took him to the emergency department, and he was admitted to the medical unit. A chest x-ray this morning revealed bilateral pneumonia. John is receiving multiple medications through both the IV and inhalation routes.

Critical Thinking Questions

1. What factors may influence drug metabolism or excretion in this patient?
2. Discuss why drug elimination for this patient may complicate the pharmacotherapy.
3. How will the IV or inhalation drug therapy affect the absorption of his medications?
4. John will receive a loading dose of IV antibiotic and then be placed on maintenance doses every 6 hours. What is the purpose of this regimen? Why would this patient be a candidate for a loading dose?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Janice Albertson is a student nurse caring for a patient on the unit in which you are the RN. She has researched every drug her patient will be receiving and is familiar with the dose, mechanism of action, and possible adverse effects. Now she comes to you and asks, "Why is the drug's plasma half-life listed in the drug reference book? What is the value of this information?"

1. How would you respond to Janice's questions?
2. When is the use of drugs with short half-lives indicated?
3. List the indications for the use of a drug with a long half-life.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is teaching the patient about a newly prescribed medication. Which statement made by the patient would indicate the need for further medication education?
    1. "The liquid form of the drug will be absorbed faster than the tablets."
    2. "If I take more, I'll have a better response."
    3. "Taking this drug with food will decrease how much drug gets into my system."
    4. "I can consult my healthcare provider if I experience unexpected adverse effects."
2. The nurse is caring for several patients. Which patient will the nurse anticipate is most likely to experience an alteration in drug metabolism?
    1. A 3-day-old premature infant
    2. A 22-year-old pregnant woman
    3. A 32-year-old man with kidney stones
    4. A 50-year-old executive with hypertension

3. The patient is receiving multiple medications, including one drug specifically used to stimulate gastric peristalsis. The nurse knows that this drug could have what influence on additional oral medications?
   1. Increased absorption
   2. Reduced excretion
   3. Decreased absorption
   4. Enhanced distribution

4. A patient is being discharged from the hospital with a nebulizer for self-administration of inhalation medication. Which statement made by the patient indicates to the nurse that patient education has been successful?
   1. "Inhaled medications should only be taken in the morning."
   2. "Doses for inhaled medication are larger than those taken orally."
   3. "Medicines taken by inhalation produce a very rapid response."
   4. "Inhaled drugs are often rendered inactive by hepatic metabolic reactions."

5. The nurse is caring for a patient with hepatitis and resulting hepatic impairment. The nurse would expect the duration of action for most medications to:
   1. Decrease.
   2. Improve.
   3. Be unaffected.
   4. Increase.

6. The nurse is monitoring the therapeutic drug level for a patient on vancomycin (Vancocin) and notes that the level is within the accepted range. What does this indicate to the nurse? (Select all that apply.)
   1. The drug should cause no toxicities or adverse effects.
   2. The drug level is appropriate to exert therapeutic effects.
   3. The dose will not need to be changed for the duration of treatment.
   4. The nurse will need to continue monitoring because each patient response to a drug is unique.
   5. This drug will effectively treat the patient's condition.

Chapter 4
Pharmacodynamics

Chapter Outline

- Interpatient Variability
- Therapeutic Index
- Dose–Response Relationship
- Potency and Efficacy
- Receptor Theory
- Agonists and Antagonists
- Pharmacogenetics

Learning Outcomes

After reading this chapter, the student should be able to:

1. Apply frequency distribution curves to explain interpatient variability in medication response.
2. Explain the importance of the median effective dose (ED_{50}) to clinical practice.
3. Compare and contrast median lethal dose (LD_{50}) and median toxicity dose (TD_{50}).
4. Relate a drug's therapeutic index to its margin of safety.
5. Identify the significance of the dose–response relationship to clinical practice.
6. Compare and contrast the terms *potency* and *efficacy*.
7. Describe the relationship between receptors and drug action.
8. Distinguish between an agonist, partial agonist, and antagonist.
9. Explain possible future developments in the field of pharmacogenetics.

Key Terms

agonist, 51
antagonist, 51
dose–response relationship, 48
efficacy, 49
frequency distribution curve, 46
intrinsic activity, 50
margin of safety (MOS), 47
median effective dose (ED_{50}), 46
median lethal dose (LD_{50}), 47
median toxicity dose (TD_{50}), 47
partial agonist, 51
pharmacodynamics, 46
pharmacogenetics, 52
potency, 49
receptor, 50
second messenger, 50
therapeutic index (TI), 47

The term *pharmacodynamics* comprises the root words *pharmaco*, which refers to medicines, and *dynamics*, which means "change." In simplest terms, pharmacodynamics refers to how a drug changes the body. A more complete definition explains **pharmacodynamics** as the branch of pharmacology concerned with the mechanisms of drug action and the relationships between drug concentration and responses in the body. This chapter examines the mechanisms by which drugs affect patients, and how the nurse can apply these principles to clinical practice.

Interpatient Variability

4.1 Patients have widely different responses to drugs, which can be depicted on a frequency distribution curve.

The principles of pharmacodynamics have important clinical applications. Healthcare providers must be able to predict whether a given dose of medication will produce a therapeutic change in their patients. Why does the "average" dose obtained from a drug guide sometimes produce a hyperresponse and at other times no response at all? Knowledge of dose–response relationships, therapeutic indexes, and drug–receptor interactions—all topics of pharmacodynamics—can help nurses provide safer and more effective treatment.

The interpatient variability observed during drug therapy can be illustrated by examining a frequency distribution curve. Shown in Figure 4.1, a **frequency distribution curve** is a graphic representation of the number of patients responding with a particular drug action at different doses. On the horizontal axis, notice the wide range in doses that produced the patient responses shown on the curve. A few patients responded to the drug at very low doses (10 to 20 mg). As the dose was increased, more and more patients responded. The peak of the curve (50 mg) indicates the largest number of patients responding to the drug. Some patients required very high doses (80 to 90 mg) to elicit the desired response. The curve does not show the magnitude of the response, only whether or not a measurable response occurred among the patients. As an example, think

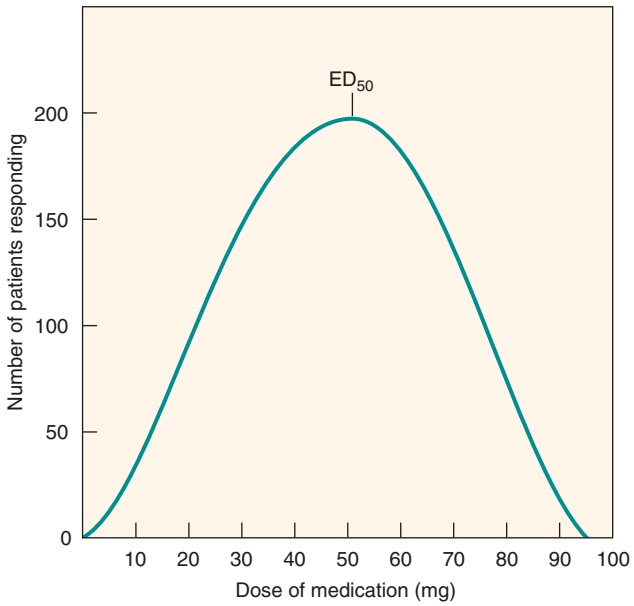

Figure 4.1 Frequency distribution curve: interpatient variability in drug response.

of possible patient responses to an antihypertensive drug as defined by a reduction of 20 mm in systolic blood pressure. A few patients experienced the desired 20-mm reduction at a drug dose of only 10 mg; a 50-mg dose gave the largest number of patients the 20-mm reduction in blood pressure. However, a few patients needed as much as 90 mg of the drug to produce the same 20-mm reduction.

The dose in the middle of the frequency distribution curve represents the drug's **median effective dose (ED_{50})**. The ED_{50} is the dose required to produce a specific therapeutic response in 50% of a group of patients. Drug guides usually use the ED_{50} as the "average" or standard dose for a drug.

The interpatient variability shown in Figure 4.1 has important clinical implications. First, the nurse should realize that the standard or average dose predicts a satisfactory therapeutic response for only half the population. But what about responses in the rest of the patients? Many patients will require more or less than the average dose for optimal pharmacotherapy. Using the systolic blood pressure example, assume that a large group of patients is given the average dose of 50 mg. Some of these patients will experience

toxicity at this level because they need only 10 mg to achieve blood pressure reduction. A few patients in this group will probably have no reduction in blood pressure at all. By monitoring the patient, taking vital signs, and interpreting any associated laboratory data, the nurse is key in determining whether the average dose is effective for the patient. *It is not enough to simply memorize an average dose for a drug; the nurse must have the skills to know when and how this dose should be adjusted to obtain the optimal therapeutic response.*

Therapeutic Index

4.2 The therapeutic index describes a drug's margin of safety.

Selecting a dose that produces an optimal therapeutic response for each individual patient is certainly important, but the nurse must also be able to predict whether that dose is safe for that patient. Frequency distribution curves can also be used to illustrate the safety of a drug.

The **median lethal dose (LD_{50})** is a value determined in laboratory animals in preclinical experiments during the drug development process. The LD_{50} is the dose of drug that will kill 50% of a group of animals. Just as with ED_{50}, a population of animals will exhibit considerable variability in lethal dosage; what may be a nontoxic dose for one animal may kill another.

To examine the safety of a particular drug, the LD_{50} is compared to ED_{50}, as shown in Figure 4.2a. In this example, 10 mg of drug is the average effective dose, and 40 mg is the average lethal dose. The ED_{50} and LD_{50} are used to calculate one of the most important values in pharmacology, a drug's therapeutic index. The **therapeutic index (TI)** is defined as the ratio of a drug's LD_{50} to its ED_{50}.

The larger the difference between the two doses, the greater the TI. In Figure 4.2a, the TI is 4 (40 mg ÷ 10 mg). Essentially, this means that it would take an error in magnitude of approximately 4 times the average dose to be lethal to an average patient. In terms of dosage, this is a relatively safe drug, and small to moderate medication errors or changes in the drug's bioavailability would likely not be fatal. Thus, the TI is a measure of a drug's safety margin: the higher the value, the safer the medication. Drugs exhibit a wide range of TIs, from 1 to 2 to greater than 100.

As another example, the TI of a second drug is shown in Figure 4.2b. Drug Z has the same ED_{50} as drug X but shows a different LD_{50}. The TI for drug Z is only 2 (20 mg ÷ 10 mg). The difference between an effective dose and a lethal dose is very small for drug Z; thus the drug has a narrow safety margin. Small medication errors or changes in the drug's metabolism or excretion could have lethal consequences. The TI offers the nurse practical information on the safety of a drug and a means to compare one drug to another.

In Figure 4.2b, notice that the two curves overlap. Some patients required a dose of 15 to 20 mg to produce the desired effect, yet this same dose was lethal in other patients. This type of drug would require careful assessment of hepatic and renal function prior to the initiation of therapy. With drugs exhibiting a low TI, it is prudent to begin with the lowest dose possible and then increase the amount of drug with careful monitoring.

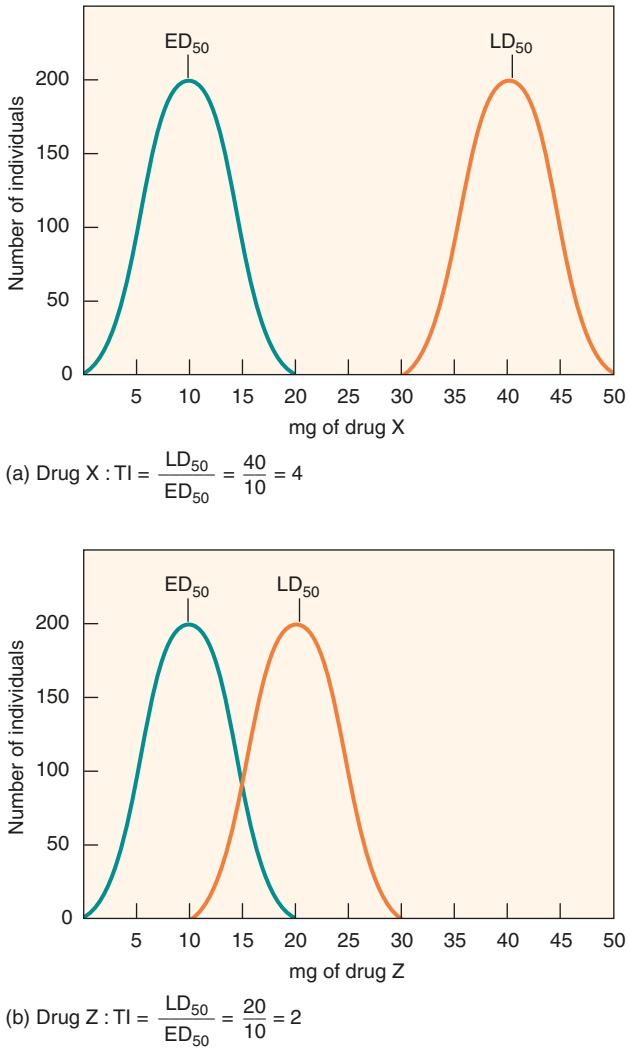

Figure 4.2 Therapeutic index: (a) Drug X has a therapeutic index of 4. (b) Drug Z has a therapeutic index of 2.

Because the LD_{50} cannot be experimentally determined in humans, other estimates of drug safety are available. The **median toxicity dose (TD_{50})** is the dose that will produce a given toxicity in 50% of a group of patients. The TD_{50} value may be extrapolated from animal data or based on adverse effects recorded in patient clinical trials.

The **margin of safety (MOS)** is another index of a drug's effectiveness and safety. The MOS is calculated as the amount of drug that is lethal to 1% of animals (LD_1) divided by the amount of drug that produces a therapeutic effect in 99% of the animals (ED_{99}). In general, the higher the MOS value, the safer the medication. Of course this considers only the lethality of the drug and does not account for nonlethal, though serious, adverse effects that may occur at lower doses.

CONNECTION Checkpoint 4.1

From what you learned in Chapter 2, before a pharmaceutical company tests a drug in patients after preclinical trials have been completed, what document must be submitted to the U.S. Food and Drug Administration (FDA)? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Dose–Response Relationship

4.3 The dose–response relationship describes how the actions of a drug change with increasing dose.

In the preceding section, frequency distribution curves were used to graphically visualize interpatient differences in responses to medications in a *population*. Pharmacodynamics is also used to study the variability in responses in a *single patient*.

How does a patient respond to varying doses of a drug? Common sense would suggest that a larger dose would produce more drug effect. For example, an antibiotic would kill more bacteria if the dose was increased from 10 to 20 mg. An antihypertensive drug would cause a greater reduction in blood pressure if the dose was increased from 50 to 100 mg. These simple examples describe the **dose–response relationship**, one of the most fundamental concepts in pharmacology. A graphic representation of this relationship, the dose–response curve, is illustrated in Figure 4.3. Examining and comparing dose–response curves can yield a large amount of information about a drug.

A dose–response curve plots the drug dose administered to the patient versus the intensity or degree of response obtained. A dose–response curve has three distinct phases that indicate essential pharmacodynamic principles. Phase 1 occurs at the lowest doses. The flatness of this portion of the curve indicates that few target cells have been affected by the drug; doses that are too small will not produce a therapeutic effect. Phase 2 is the rising, straight-line portion of the curve. In this portion, there is a linear relationship between the amount of drug administered and the degree of response obtained from the patient. For example, if the dose is doubled, twice as much response may be obtained. This is the most desirable range of doses for pharmacotherapeutics, because giving more drug results in proportionately more effect; a lower drug dose gives less effect. In phase 3 increasing the drug dose produces no additional therapeutic response—a plateau has been reached. This may occur for a number of reasons. One possible explanation is that all the target receptors for the drug are occupied. It could also mean that the drug has brought 100% relief, such as when a migraine has been terminated; giving higher doses produces no additional relief. Although increasing the dose during phase 3 does not result in additional therapeutic effects, the nurse should be mindful that increasing the dose may produce more adverse effects.

The dose–response curve in Figure 4.3 is smooth and continuous; thus it is sometimes called a graded dose–response curve. This is important to pharmacotherapeutics because, by adjusting the dose in small increments, the prescriber is able to attain virtually any degree of therapeutic response (0% to 100%) within the linear range of drug doses. This is especially true when using the intravenous (IV) route, during which the nurse can adjust the infusion rate in very small increments.

Many types of adverse effects also follow a graded dose–response relationship: the higher the dose, the more intense the adverse effect. By adjusting the dose lower, while still keeping it within the therapeutic range, adverse effects may be lessened. Some adverse effects, such as anaphylaxis, are independent of dose in that even the smallest amount of drug may trigger a serious adverse response (see Chapter 5).

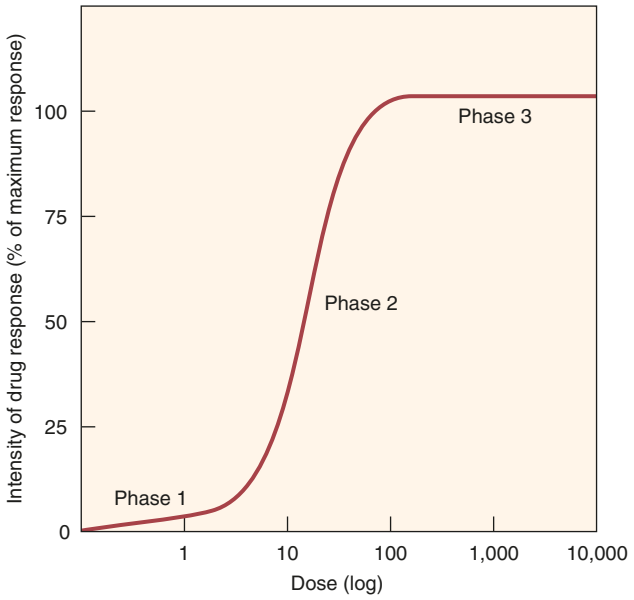

Figure 4.3 Dose–response relationship.

Potency and Efficacy

4.4 Potency and efficacy are fundamental concepts of pharmacodynamics that describe a drug's activity.

Within a pharmacologic class, not all drugs are equally effective at treating a disorder. For example, some antineoplastic drugs kill more cancer cells than others; some antihypertensive medications lower blood pressure to a greater extent than others; and some analgesics are more effective at relieving severe pain than others in the same class. Furthermore, drugs in the same class are effective at different doses: One antibiotic may be effective at a dose of 1 mg/kg, whereas another is most effective at 100 mg/kg. Nurses need a method to compare one drug to another so that they can administer treatment effectively.

There are two fundamental ways to compare medications within therapeutic and pharmacologic classes. First is

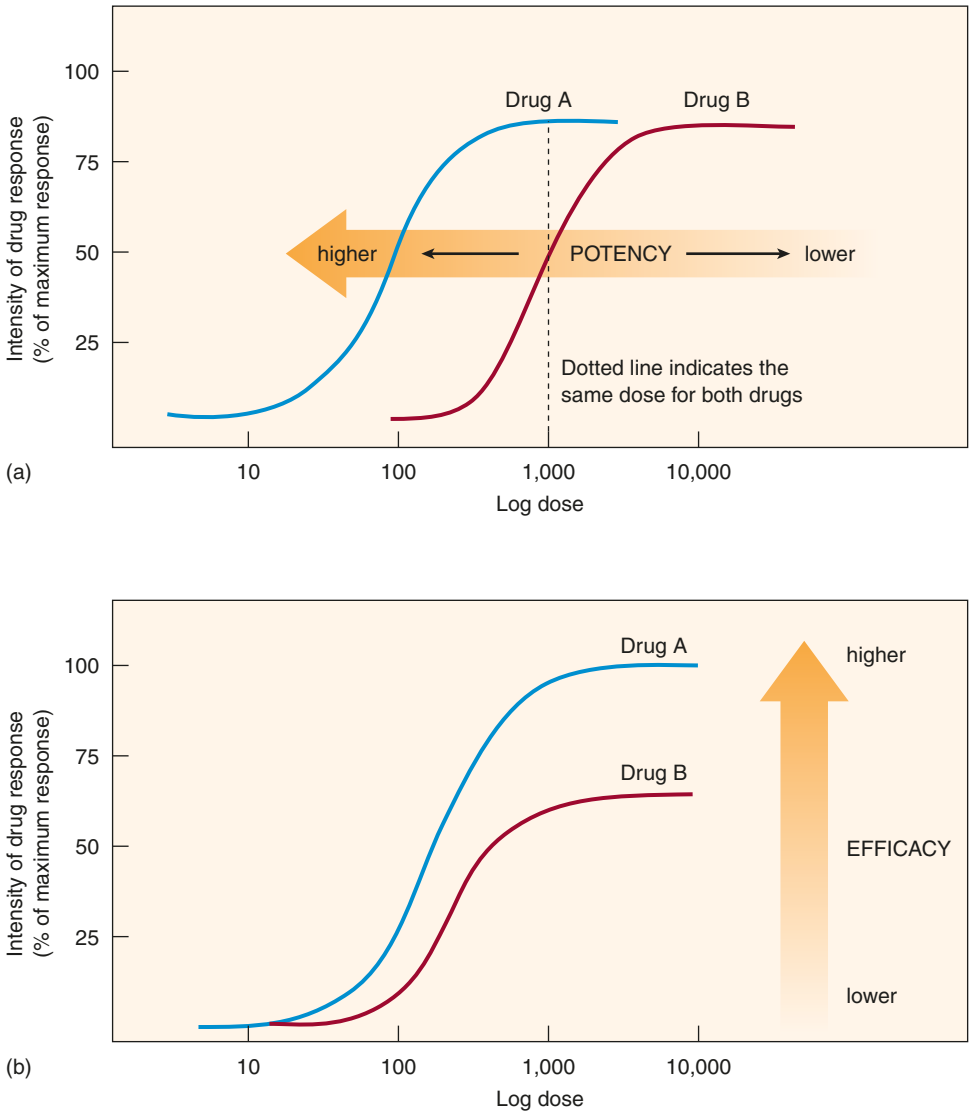

Figure 4.4 Potency and efficacy: (a) Drug A has a higher potency than drug B. (b) Drug A has a higher efficacy than drug B.

the concept of **potency**, which is the amount of drug needed to produce a specified effect. When compared to another drug in the same class, a drug that is more potent will produce its therapeutic effect at lower doses. As an example, consider two calcium channel blockers used for hypertension: amlodipine (Norvasc) and nifedipine (Procardia). Amlodipine produces its decrease in blood pressure at a dose of 10 mg/day and nifedipine at 60 mg/day. Amlodipine is clearly more potent than nifedipine because it takes a lower dose (6 times less) to produce its antihypertensive effect.

Thus, potency is a way to compare the doses of two independently administered drugs in terms of how much is needed to produce a particular response. A useful way to visualize the concept of potency is by examining dose–response curves. When comparing the two drugs shown in Figure 4.4a, drug A is more potent because it requires a lower dose to produce the same response.

A second method used to compare drugs is called **efficacy**, which is defined as the maximum response that can be produced from a particular drug. In the example in Figure 4.4b, drug A has greater efficacy because it produces a higher maximal response.

Which is more important to the outcomes of pharmacotherapy: potency or efficacy? Perhaps the best way to understand these important concepts is to use the specific example of headache pain. Two common over-the-counter (OTC) analgesic therapies are ibuprofen, 200 mg, and aspirin, 650 mg. The fact that ibuprofen relieves pain at a lower dose indicates that it is more potent than aspirin. At the given doses, however, both are equally effective at relieving headaches; thus they have the same efficacy. If the patient is experiencing severe pain, however, neither aspirin nor ibuprofen has sufficient efficacy to bring relief. Narcotic analgesics, such as morphine, have a greater efficacy than aspirin or ibuprofen and could effectively treat this type of pain. From a pharmacotherapeutic perspective, efficacy is almost always more important than potency. In the preceding example, the average dose is unimportant to the patient, but headache relief is essential. As another comparison, the patient with cancer is much more concerned with how many cancer cells have been killed (efficacy) than with the dose the nurse administered (potency). In the comparison of Norvasc to Procardia, although Norvasc is clearly more potent, both drugs reduce blood pressure to the same degree; thus they have the same efficacy. Although the nurse will often hear claims that one drug is more potent than another, a more compelling concern is which drug has greater efficacy.

A word of caution is necessary at this point. In Section 4.3, it is stated that many adverse effects are related to dose—that higher doses produce more intense adverse effects. This is true only when comparing doses of the *same* drug. For example, a therapeutic dose for amlodipine is 10 mg/day. Giving 20 or 30 mg of amlodipine will most certainly increase the risk of experiencing an adverse effect. Can the dose of amlodipine be compared to a dose of nifedipine, which is 60 mg/day? The answer is absolutely not. In fact, 10 mg of amlodipine gives the same risk of adverse

effects as 60 mg of nifedipine. *The point is that when two different drugs are compared, one cannot assume that the drug with the lower dose gives fewer adverse effects.*

An additional word of caution is necessary. In clinical practice the term *potency* is often misused to indicate a more effective drug. The nurse should remember the correct definitions of the words *potency* and *efficacy* and try to incorporate them into clinical practice.

Receptor Theory

4.5 Most drugs produce their actions by activating or inhibiting specific cellular receptors.

Drugs rarely create new actions in the body; instead, they enhance or inhibit *existing* physiologic and biochemical processes. To cause such changes, the drug must interact with specific chemicals that are normally found in the body. A cellular molecule to which a medication binds to produce its effects is called a **receptor**. A receptor may be thought of as the drug's specific target. The concept of a drug binding to a receptor and causing a change in physiology is a fundamental concept in pharmacology. Receptor theory predicts that the response of a drug is proportional to the concentration of receptors that are bound or occupied by the drug. Receptor theory explains the mechanisms by which most drugs produce their effects.

It is important to understand, however, that receptors do not exist in the body solely to bind drugs; their normal function is to bind endogenous molecules such as hormones, neurotransmitters, and growth factors. The drug simply uses existing targets to cause its effects. When drugs bind to the receptor they either enhance or inhibit a normal cellular function. The binding is usually reversible and the action of the drug is terminated once the drug leaves its receptor. In a few cases, binding of the drug is irreversible. Drugs that have the ability to bind to a receptor and produce a strong action are said to have high **intrinsic activity**. Intrinsic activity and efficacy are related. Drugs that have high intrinsic activity have high efficacy.

Although a drug receptor can be any type of molecule, the vast majority are proteins. As shown in Figure 4.5, a receptor may be depicted as a three-dimensional protein spanning across the plasma membrane. The extracellular component of a receptor often consists of subunits arranged in a specific shape that will bind the specific drug or endogenous chemical (sometimes called a ligand). The receptor may form a membrane channel that regulates substances entering and leaving the cell.

A drug binds to its receptor in a very selective manner, much like a lock and key. Once the receptor is occupied, a series of **second messenger** events is triggered within the cell such as the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cyclic AMP), the release of intracellular calcium, or the activation of specific G proteins and associated enzymes. These cascades of biochemical events initiate the drug's action by either stimulating or inhibiting the normal activity of the cell. Small changes to the structure of a drug, or its receptor, may weaken or even eliminate binding between the two molecules, rendering the drug ineffective.

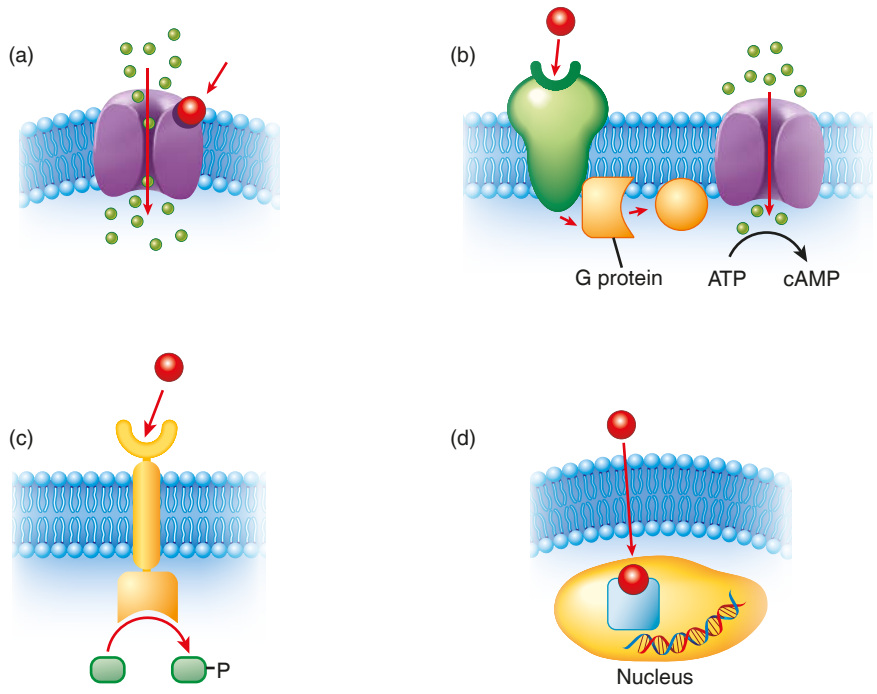

Figure 4.5 Types of cellular receptors: (a) Drug binds to the receptor opening channel. (b) Drug binds to the receptor, causing a G protein–mediated reaction in the cell. (c) Drug binds to the transmembrane receptor to signal a change inside the cell. (d) Drug enters the cell nucleus to increase synthesis of specific proteins.

Not all receptors are proteins bound to the plasma membrane. Some are intracellular molecules such as DNA or enzymes in the cytoplasm. By interacting with these types of receptors, medications are able to inhibit protein synthesis or regulate events such as cell division and metabolism. Examples of agents that bind intracellular components include steroid hormones and certain vitamins.

Receptor *subtypes* have been discovered that permit the "fine-tuning" of pharmacotherapy. For example, the first drugs affecting the autonomic nervous system affected all types of autonomic receptors. These agents were not very useful because they produced such a broad range of therapeutic and adverse effects. Later, it was discovered that two basic receptor types existed in the body, alpha and beta, and drugs were then developed that were selective for only

one type. This permitted more specific drug therapy (and fewer adverse effects). Still later, several subtypes of alpha and beta receptors, including alpha-1, alpha-2, beta-1, and beta-2, were discovered that allowed even more specificity in pharmacotherapy. In recent years, researchers have further divided and refined various drug receptor subtypes. It is likely that research will continue to result in the development of new medications that activate very specific receptors to cause therapeutic responses while avoiding some adverse effects.

Some drugs act independently of cellular receptors. These agents are associated with other mechanisms, such as changing the permeability of cellular membranes, depressing membrane excitability, or altering the activity of cellular pumps. Actions such as these are often described as nonspecific cellular responses. Ethyl alcohol, general anesthetics, and osmotic diuretics are examples of agents that act by nonspecific mechanisms.

Agonists and Antagonists

4.6 Agonists, partial agonists, and antagonists compete for cellular receptors and can modify drug action.

When a drug binds to a receptor, several possible consequences can result. In simplest terms, some specific action in the cell is either enhanced or inhibited. The actual biochemical mechanism underlying the therapeutic effect, however, may be extremely complex. In some cases, the mechanism of action is not known.

When a drug binds to its receptor, it may produce a response that mimics the effect of the endogenous regulatory molecule. For example, when the drug bethanechol is administered, it binds to acetylcholine receptors in the autonomic nervous system and produces the same actions as acetylcholine. A drug that activates a receptor and produces the same type of response as the endogenous substance is called an **agonist**. Agonists sometimes produce a greater maximal response than the endogenous chemical. The term **partial agonist** is used to describe a medication that produces a weaker, or less efficacious, response than an agonist.

A second possibility is that a drug will occupy a receptor and prevent the endogenous chemical from binding to produce its action. This type of drug, an **antagonist**, often competes with agonists for receptor binding sites. For example, the drug atropine competes with acetylcholine for certain receptors in the autonomic nervous system. If the dose is high enough, atropine may completely block the effects of acetylcholine because acetylcholine cannot reach its receptors. Antagonists may be used as medications when the body is producing too much of a response from an endogenous chemical or from a drug overdose, such as high blood pressure, fast heart rate, secretion of excess stomach acid, or sedation. Giving an antagonist in these situations may reverse the adverse effects. An antagonist has no intrinsic activity; the actions observed after administering an antagonist are caused by lack of agonist action.

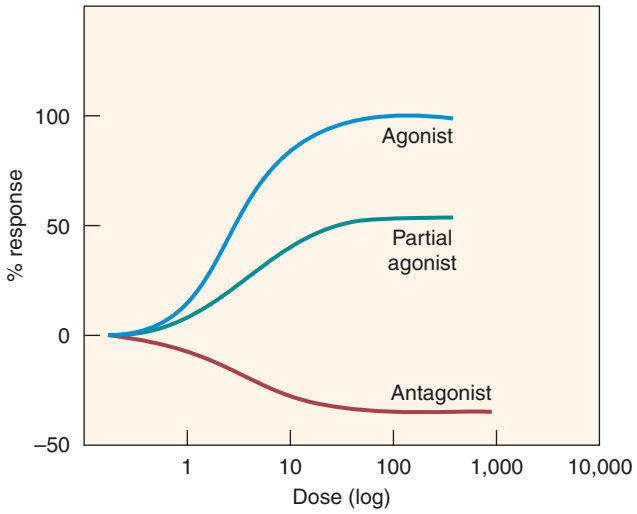

Figure 4.6 Effects of agonists, partial agonists, and antagonists on drug response: (a) An agonist results in maximum response. (b) A partial agonist results in less than maximum response. (c) An antagonist results in diminished response.

Not all antagonism is associated with receptors, as in the previous example. Functional antagonists inhibit the effects of an agonist, not by competing for a receptor but by changing pharmacokinetic factors. For example, antagonists may slow the absorption of an agonist, resulting in less pharmacologic effect. An antagonist may change the pH of the surrounding fluid and neutralize the agonist before it is even absorbed. By speeding up metabolism or excretion, an antagonist can enhance the removal of an agonist from the body. The relationships that occur between agonists and antagonists explain many of the drug–drug and drug–food interactions that occur in the body and which are described in Chapter 5. Figure 4.6 illustrates the concept of agonist and antagonist drug action.

CONNECTION Checkpoint 4.2

From what you learned in Chapter 3, phenytoin is an inducer of CYP1A2, the enzyme that metabolizes acetaminophen. Would phenytoin be considered a functional agonist or an antagonist to acetaminophen? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacogenetics

4.7 In the future, pharmacogenetics may allow customization of drug therapy.

As discussed earlier in this chapter, patients can have widely differing responses to medications. A significant portion of the population either develops unacceptable adverse effects to certain drugs or is unresponsive to them. Is it possible to predict, in advance, which patients will experience these types of responses? For example, is it

possible to predict which of 100 antineoplastic drugs will be most effective at killing a tumor, or which of 50 antidiabetic drugs will be most effective at maintaining a particular patient's blood glucose levels?

With data from the Human Genome Project and other advances in medicine, pharmacologists are hopeful that future drugs can be customized for patients with specific genetic similarities. In the past, any unpredictable and unexplained drug reaction has been labeled an idiosyncratic response. It is hoped that, by analyzing a DNA test before prescribing a drug, these idiosyncratic adverse effects can someday be avoided.

Pharmacogenetics is the branch of pharmacology that studies the role of genetic variation in drug responses. The most important advances in pharmacogenetics so far have been the identification of subtle genetic differences in drug-metabolizing enzymes. Genetic differences in these enzymes are responsible for a significant portion of drug-induced toxicity. The FDA has identified pharmacogenetic biomarkers for over 150 medications. These biomarkers are included in their drug labeling information (FDA, 2016). Therapies based on a patient's genetically based response are becoming more commonplace and will likely exert an even greater influence on the practice of pharmacotherapy in the future.

CONNECTIONS: Treating the Diverse Patient

Enzyme Deficiencies in Ethnic Populations

Pharmacogenetics has identified ethnic populations of people, such as males of Mediterranean and African descent, who are deficient in glucose-6-phosphate dehydrogenase (G6PD), an enzyme that is essential in carbohydrate metabolism. G6PD deficiency is among the most common enzyme deficiency, with about 400 million people affected worldwide. Over 60 different mutations that encode for G6PD have been identified. Researchers have noted that hematologic disorders such as G6PD deficiency are more common in areas of the world where high frequencies of malaria occur, and the existence of the deficiency appears to convey some benefit in lowering the risk of death from malaria (Malaria Genomic Epidemiology Network, 2014).

When certain oxidative drugs are given, such as primaquine, sulfonamides, or nitrofurantoin (Macrobid), an acute hemolysis of red blood cells (RBCs) occurs due to the breaking of chemical bonds in the hemoglobin molecule, with large numbers of circulating RBCs being destroyed. Genetic typing does not always predict toxicity. Patients may not realize they carry a genetically linked trait, although they may report a history of "severe allergy" to fava beans, for example, which induced the hemolytic symptoms in the past. The role of the nurse is critical in carefully observing patients for unusual reactions for 24 to 72 hours following administration of these medications.

Understanding Chapter 4

Key Concepts Summary

4.1 Patients have widely different responses to drugs, which can be depicted on a frequency distribution curve.

4.2 The therapeutic index describes a drug's margin of safety.

4.3 The dose–response relationship describes how the actions of a drug change with increasing dose.

4.4 Potency and efficacy are fundamental concepts of pharmacodynamics that describe a drug's activity.

4.5 Most drugs produce their actions by activating or inhibiting specific cellular receptors.

4.6 Agonists, partial agonists, and antagonists compete for cellular receptors and can modify drug action.

4.7 In the future, pharmacogenetics may allow customization of drug therapy.

CASE STUDY: Making the Patient Connection

Remember the patient "Katherine Hunter" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Katherine Hunter prides herself on being a wise consumer and cautiously examines the claims by manufacturers for all her purchases. She researches everything she buys, such as automobiles, household appliances, and medications. Recently, she has begun to seriously consider assertions made by the advertisements for various types of antacids. Most brands claim to be the most effective in relieving the symptoms of indigestion. Others say that their brand is the

most potent antacid available without a prescription. Some products claim that they not only relieve heartburn, but also supply the body with needed vitamins and minerals. When purchasing an OTC medication, all Katherine wants is something that will work quickly with few adverse effects.

Critical Thinking Questions

1. How would you teach Katherine the difference between potency and efficacy?
2. Which of the two concepts (potency and efficacy) would be most important for selecting a drug? Why?
3. What are the drawbacks of comparing two different medications?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

As the nurse practicing in a middle school, you have been asked to speak to the eighth-grade pre-health professionals' class. The topic for today's discussion is "how drugs work in the body." The teacher has provided you with an outline of concepts that you will need to address.

1. Describe the link between a drug's action and drug receptors.
2. Why do people respond differently to medication?
3. What are drug agonists and drug antagonists?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. What parameters would the nurse use to determine whether the average dose of a medication is effective for a patient? (Select all that apply.)
    1. Physical examination
    2. Vital signs
    3. Laboratory values
    4. Dosage time
    5. Efficacy

2. The nurse knows that a drug with a high therapeutic index is:
    1. Probably safe.
    2. Often dangerous.
    3. Frequently risky.
    4. Most likely effective.

3. While reviewing a drug manufacturer's package insert, the nurse reads about the dose–response curve. The purpose of the dose–response curve is to illustrate the relationship between:
    1. The amount of a drug administered and the degree of response it produces.
    2. The prevalence of toxic effects in a given population.
    3. The degree of response and the total duration of action of the drug.
    4. The peak serum drug level when half the dose is administered.

4. A research nurse is discussing the TD_{50} of a drug with the other members of the investigation team. On which of the following would the discussion focus?
    1. Effectiveness
    2. Dose response
    3. Receptor subtypes
    4. Toxicity

5. A patient with myasthenia gravis has been receiving neostigmine, a cholinergic agonist, for the past 2 years. The nurse is ready to administer benztropine, a cholinergic antagonist. Which result will likely occur when these drugs are combined?
    1. Neostigmine will exhibit a greater effect.
    2. Neostigmine will exhibit a lesser effect.
    3. Neostigmine will not be affected by the administration of benztropine.
    4. Neostigmine will first exhibit a greater effect, followed by a lesser effect.

6. When considering pharmacodynamic principles for a patient's drug therapy, the nurse is aware that affinity for a receptor is most closely associated with a drug's:
    1. Potency.
    2. Efficacy.
    3. Metabolism.
    4. First-pass effect.

"I was told to watch for drug reactions. But with all the drugs I take, how would I ever know if I'm having a reaction or not?"
Patient "Elizabeth Washington"

Chapter 5
Adverse Drug Effects and Drug Interactions

Chapter Outline

- Adverse Drug Effects
  - The Role of the Nurse in Managing Adverse Effects
  - Allergic Reactions
  - Idiosyncratic Responses
  - Carcinogenicity and Teratogenicity
  - Organ-Specific Drug Toxicity
- Drug Interactions
  - Pharmacokinetic Drug Interactions
  - Pharmacodynamic Drug Interactions
  - Drug Interactions with Food and Dietary Supplements

Learning Outcomes

After reading this chapter, the student should be able to:

1. Differentiate between adverse effects and side effects.
2. Create a plan to minimize or prevent adverse drug events in patients.
3. Explain the advantages and disadvantages of the FDA Adverse Event Reporting System.
4. Describe the incidence and characteristics of drug allergies.
5. Explain how idiosyncratic reactions differ from other types of adverse effects.
6. Explain why certain drugs with carcinogenic or teratogenic potential are used in pharmacotherapy.
7. Report the characteristic signs, symptoms, and treatment for each of the following organ-specific adverse events: nephrotoxicity, neurotoxicity, hepatotoxicity, dermatologic toxicity, bone marrow toxicity, cardiotoxicity, and skeletal muscle and tendon toxicity.
8. Use examples to explain the importance of drug interactions to pharmacotherapy.
9. Describe the mechanisms of drug interactions that alter absorption, distribution, metabolism, or excretion.
10. Differentiate between additive, synergistic, and antagonistic drug interactions.
11. Identify examples of drug–food interactions that may impact pharmacotherapeutic outcomes.

Key Terms

additive effect, 65
adverse drug effect, 56
antagonistic effect, 65
black box warning, 57
drug allergies, 58
drug interaction, 62
FDA Adverse Event Reporting System (FAERS), 57
idiosyncratic response, 58
ototoxicity, 61
risk–benefit ratio, 59
side effects, 56
synergistic effect, 65
teratogens, 60

Drugs are administered with the goal of producing a therapeutic effect. All drugs, however, have the potential to produce unintended effects as well as therapeutic effects. An **adverse drug effect** is an undesirable and potentially harmful action caused by the administration of medication. Adverse effects, also called adverse events, are a significant component of pharmacotherapy and, when severe, may cause treatment to be discontinued or result in permanent harm to the patient. The purpose of this chapter is to examine the different types of adverse effects and drug interactions, so that the nurse can minimize their impact on treatment outcomes.

Adverse Drug Effects

5.1 The nurse plays a key role in preventing and managing adverse drug effects.

Although every drug has the *potential* to produce adverse events, most pharmacotherapy can be conducted without significant undesirable effects. Indeed, drugs that produce serious adverse effects are screened and removed from consideration during the drug development and approval process or are restricted for treating serious health conditions such as cancer. Patients expect that their drugs, including over-the-counter (OTC) medications, herbal products, and dietary supplements, will be free from serious adverse effects when taken as directed. Although the majority of drugs are very safe, adverse effects cannot be entirely avoided.

Side effects are types of drug effects that are predictable and which may occur even at therapeutic doses. Side effects are less serious than adverse effects. Patients are often willing to tolerate annoying side effects if they believe the drug will improve their condition or prevent a disease. The distinction between an adverse effect and a side effect, however, is often unclear. For example, is headache a side effect or an adverse effect? What about nausea? The answer lies in the severity of the symptoms. Headache or nausea may be minor (side effects), or they may become intense and disabling (adverse effects).

Adverse drug events may be specific to a single type of tissue or affect multiple organ systems. The most common adverse events are serious nausea and vomiting, which may occur when drugs are administered by any route. Severe headache and significant changes in blood pressure are also very common adverse drug events. Some adverse effects, though rare, are serious enough to warrant regular or continuous monitoring. Examples of serious events include impairment or failure of entire organs, such as cardiac, hepatic, or renal failure or loss of vision or hearing. Anaphylaxis, Stevens–Johnson syndrome (SJS), cancer, and birth defects are additional rare, adverse drug events that occur with certain drugs. The U.S. Food and Drug Administration (FDA) defines serious drug effects as those that:

- Result in a patient's death, hospitalization, or disability.
- Cause a congenital abnormality.
- Cause a life-threatening event.
- Require an intervention to prevent permanent damage.

Many adverse effects are extensions of a drug's pharmacologic actions. These types of events are considered dose dependent: As the drug dose increases, the risk for adverse effects also increases. For example, antihypertensive drugs are given to lower blood pressure, but high doses cause hypotension, which may manifest as dizziness or fainting. Drugs for treating insomnia or anxiety may depress brain activity too much at higher doses, resulting in drowsiness or daytime sedation. Knowing the therapeutic actions of the drug enables the nurse to predict the signs and symptoms of many of the adverse effects that occur during treatment. It is important for nurses and their patients to understand that the difference between a drug being a beneficial medication or a toxic substance is often simply a matter of dose.

Can adverse effects be prevented? Although nurses play a key role in minimizing the number and severity of adverse events in their patients, some adverse effects simply cannot be predicted or prevented. Skilled healthcare providers, however, have multiple ways to minimize or prevent adverse effects, from having expert knowledge of how a drug acts to obtaining a comprehensive medical history from their patients. The following are means that nurses use to minimize or prevent adverse drug events in their patients:

- **Obtain a thorough medical history.** The medical history of the patient may reveal drug allergies or conditions that contraindicate the use of certain drugs. The history may also identify prescription drugs, OTC drugs, dietary supplements, and herbal products taken by the patient that could negatively interact with the prescribed medication. At each healthcare visit, a medication reconciliation should be conducted, comparing medications that the patient is taking currently to those that were recorded at the last visit.
- **Conduct a thorough assessment of the patient and all diagnostic data.** Assessment may reveal underlying hepatic or renal impairment that will affect the way a drug is handled by the body. The very young and older adults are most susceptible to drug reactions because metabolism and excretion of drugs in these populations are less predictable. To prevent adverse effects, average drug doses should be adjusted based on careful patient assessment.
- **Prevent medication errors.** Administering the incorrect dose or giving the drug to the wrong patient may cause unnecessary adverse effects. Methods of preventing medication errors are described in detail in Chapter 6.
- **Monitor pharmacotherapy carefully.** Monitor patient signs and symptoms regularly after initial drug doses or when doses are increased. This is especially critical when caring for patients who are very ill or when giving parenteral agents. Patients receiving drugs that have frequent or potentially severe adverse effects should be monitored continuously until the baseline effects of the drug have been established.
- **Know the drugs.** It is essential for nurses to know the most frequent and most serious adverse effects for every drug administered. A comprehensive knowledge of the drugs, herbal products, and supplements taken by their patients helps nurses to monitor for and identify adverse effects and provide the necessary interventions before they become serious.
- **Be prepared for the unusual.** Anaphylaxis may occur immediately and unpredictably (see Section 5.3). Other adverse effects may be delayed, occurring days, weeks, or months after therapy is initiated. Some drugs produce actions opposite to those expected (see Section 5.4). Patients may be reluctant to report certain adverse effects (such as impotence) without prompting by the nurse.
- **Question unusual orders.** If the nurse suspects that the wrong dose has been ordered or the pharmacy has filled the order incorrectly, the drug should not be administered until the prescriber or the pharmacy has been contacted.
- **Teach patients about adverse effects.** The patient is the nurse's ally in identifying and preventing adverse effects. Teaching patients what therapeutic and adverse effects to expect from the drug and which types of symptoms to report to their healthcare provider are important in self-management and preventing serious adverse events. Furthermore, inadequate teaching may result in poor patient adherence to the drug regimen and suboptimal treatment outcomes.

5.2 The FDA continues to monitor for new adverse events after a drug is approved and marketed.

Before approving a drug, the FDA carefully examines all clinical information supplied by the manufacturer regarding drug effectiveness and safety. Although extensive testing may have been conducted, clinical research has certain limitations and the FDA's decision is based on a relatively small number of clinical trials. Once marketed, the drug is disseminated to a larger and more diverse patient population, at which point adverse effects that were not discovered during clinical trials may begin to surface. For this reason, the FDA continues to monitor the safety of drugs after they are approved.

Established in 1993, the FDA's MedWatch Safety Information and **Adverse Event Reporting System (FAERS)** is a voluntary program that encourages healthcare providers and consumers to report suspected adverse effects directly to the FDA or the product manufacturer. By law, reports received by the manufacturers are forwarded to the FDA to be added to the computerized information database.

PharmFACT

The number of adverse events reported to the FDA has increased each year. From 2006 to 2014, the number of serious adverse events increased from 264,227 to 807,270 and the number of deaths from 37,309 to 123,927 (FDA, 2015).

Data from the FAERS are analyzed by clinical reviewers, usually a physician, pharmacist, or nurse, at the Center for Drug Evaluation and Research of the FDA. If a potential safety concern is identified, the FDA may take one of the following actions:

- Conduct additional epidemiologic studies to determine the validity or extent of the safety concern.
- Require changes to a product's labeling information.
- Require a **black box warning** in the drug insert that warns prescribers that the drug carries a risk for a serious adverse effect or death.
- Restrict the use of the drug in specific populations.
- Communicate safety information to healthcare providers and consumers.
- Recall a product that may have quality or performance concerns.
- Remove the product from the market.

The FDA disseminates changes in safety information through its MedWatch website. Interested parties may subscribe to podcasts, electronic newsletters, and even cell phone text message alerts giving them the latest drug safety information.

The FAERS provides a national database for making safety decisions about drugs, but it does have limitations. Because the system relies on voluntary reports, not all adverse events are reported. The FDA does not attempt to prove causation, which is whether the adverse event was caused by the drug or by some other factor involved in treatment. Reports sometimes contain insufficient or vague details regarding the incident.

A word of caution is necessary regarding the reporting of adverse drug events. The placebo effect predicts that a certain percentage of patients will respond with positive therapeutic outcomes to a treatment, even if the substance is inert and has no pharmacologic properties (essentially a "sugar pill"). The same holds true for side and adverse effects. A certain percentage of patients will experience headache, nausea and vomiting, rash, changes in blood pressure, or pain following the administration of a placebo. Thus when examining drug information, the nurse should always examine the incidence of adverse effects that occur over and above that caused by a placebo. It is important to understand that patients are not faking symptoms caused by a placebo; they truly believe they are experiencing the side effects and may even be visibly exhibiting them. However, the drug itself may not be responsible for the self-reported effects.

5.3 Allergic reactions are caused by a hyperresponse of the immune system.

Drug allergies are common events, comprising 6% to 10% of all adverse drug effects. Although drug allergies may elicit a diverse range of patient symptoms, all are caused by a hyperresponse of body defenses. Depending on the type of allergic response, basophils, mast cells, eosinophils, or lymphocytes secrete chemical mediators that trigger the allergic response. Specific chemical mediators of allergy include histamine, serotonin, leukotrienes, prostaglandins, and complement.

Several characteristics define a drug allergy. Allergies typically occur with very small amounts of drug; the severity of allergy symptoms is usually not proportional to the dose. The symptoms of allergy are unrelated to the pharmacologic actions of the drug; anaphylaxis has the same symptoms regardless of the drug that induces it. Patients often exhibit cross-allergy, an allergic reaction to drugs with a similar structure, such as those from the same pharmacologic class. Drug allergies require a previous exposure to the drug (or a very similar drug). This sensitizes the patient to subsequent exposures, during which a hyperresponse of body defenses is rapidly mounted upon reexposure to the drug.

The signs and symptoms of drug allergy are variable and range from minor to life threatening. Symptoms may appear within minutes after the drug is administered or they may develop after prolonged pharmacotherapy. Because the signs and symptoms of drug allergy are nonspecific, it is sometimes difficult to attribute an allergy symptom to a specific drug in patients receiving multiple medications. Complicating an accurate diagnosis is that symptoms of drug allergy are the same as those of allergy to environmental triggers, such as peanuts, seafood, insect stings, animal dander, or dust mites. It is important to determine the source of allergy, especially in patients with severe reactions, so that the offending drug or environmental substance can be avoided in the future. The pharmacologic treatment of allergy is presented in Chapter 45.

Although allergic reactions are possible with most drugs, some drugs exhibit a higher incidence. The medications most likely to cause allergic reactions include penicillins and related antibiotics (monobactams and cephalosporins); radiologic contrast media containing iodine; insulin; nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin; sulfonamides; cancer chemotherapy agents; preservatives (sulfites and paraben); and certain antiseizure drugs. The use of biologics such as monoclonal antibodies has greatly increased in recent years and the nurse should carefully monitor patients receiving these agents because they have been shown to produce a high incidence of allergic reactions.

Patients are usually unaware of the true definition of allergy and often report any adverse effect they experience as a drug allergy. For example, many patients experience acute nausea and vomiting with narcotic analgesics such as codeine and will report that they have an allergy to codeine during a drug history. In fact, these symptoms are not caused by an overactive immune response and are thus not a true allergy. Inaccurate reporting of allergies may lead to the healthcare provider avoiding the use of entire drug classes and prescribing more expensive second-line medications that could be less effective or produce more adverse effects.

5.4 Idiosyncratic reactions are unusual drug responses often caused by genetic differences among patients.

An **idiosyncratic response** is an adverse drug effect that produces unusual and unexpected symptoms that are not related to the pharmacologic action of the drug. Idiosyncratic reactions are not classified as allergies because they are not immune related. They are rare, unpredictable, and vary from patient to patient.

Many, though not all, idiosyncratic reactions are due to unique, individual genetic differences among patients. For example, mutations involving specific metabolic enzymes

may cause certain patients to be extremely sensitive to the effects of a drug or to be resistant. The drug may be handled by a different metabolic pathway, resulting in the accumulation of a metabolite that gives a different and unexpected response from the original drug.

Historically, the term *idiosyncratic* has been used to denote any drug effect that could not be explained. With advances in the understanding of drug mechanisms, more and more drug responses are now understood. With improved reporting of adverse drug events, rare "unexpected" events are now documented and may be "expected." Thus use of the term *idiosyncratic*, although still common in clinical practice, will likely continue to diminish with time.

PharmFACT

Death rates from adverse drug reactions are associated with age, race, gender, and urbanization. Highest death rates are experienced by individuals older than age 55, Blacks, men, and those residing in rural areas (Shepherd, Mohorn, Yacoub, & May, 2012).

5.5 Some drugs have the ability to induce cancer or cause birth defects.

Most adverse effects occur within minutes or hours after a drug is administered; some develop after several days or weeks of pharmacotherapy. In a few instances, the adverse effect may occur years or even decades after the drug was administered. Such is the case with drug-induced cancer.

Why would a drug be approved by the FDA if it was known to cause cancer in humans? In most cases, drugs that produce cancer in laboratory animals during preclinical trials are not submitted for approval to the FDA. However, there are a few conditions that may warrant the approval of a drug with carcinogenic potential. The answer lies in the **risk–benefit ratio**. If a patient has a condition that is likely to cause premature death if left untreated, the benefits of taking a drug with carcinogenic potential may outweigh the long-term risks. This assumes, of course, that effective, safer alternatives are not available.

Of the thousands of drugs and drug combinations approved for pharmacotherapy, only a few increase the risk of acquiring cancer. Most of these drugs, shown in Table 5.1, fall into three primary classes: antineoplastics, immunosuppressants, and hormonal agents.

Some of the antineoplastics are known chemical carcinogens. With the goal of eliminating cancer cells, some of these drugs cause molecular damage or mutations in deoxyribonucleic acid (DNA). Although much of the DNA damage in normal cells is repaired by enzymes, some mutations persist and accumulate in cells as an individual ages, increasing cancer risk. The initial damage done by the drug may take decades to manifest as cancer. Leukemia is the type of cancer with the greatest cancer risk from antineoplastic therapy. However, the patient may never develop cancer as a result of these medications; indeed, the majority of patients receiving antineoplastic drugs do not develop the disease. Furthermore, if the cancer treatment was successful, the patient may have benefited from additional years of life due to pharmacotherapy with these drugs. Because pharmacotherapy combined with surgery and radiation therapy can result in a total cure for some patients, the benefit of drug therapy often outweighs the small risk of developing cancer later in life.

Table 5.1 Selected Drugs Suspected of Causing Cancer in Humans

Class	Drug	Type of Cancer
Antineoplastic	chlorambucil cisplatin cyclophosphamide dacarbazine doxorubicin etoposide metronidazole nitrosoureas phenytoin propylthiouracil teniposide	Leukemia, urinary bladder
Hormones and hormone antagonists	anabolic steroids estrogen replacement therapy and oral contraceptives progesterone tamoxifen	Uterus, breast, hepatic
Immunosuppressants	azathioprine cyclosporine	Lymphoma, skin

The second class of drugs that can induce cancer is the immunosuppressants. These medications are administered to dampen the immune system of patients receiving transplanted tissues or who have serious inflammatory disorders. Because a natural function of the immune system is to remove cancer cells that form in the body, any drug that inhibits this system would be expected to have some degree of cancer risk. Lymphoma is the most frequent type of cancer resulting from immunosuppressant use. Again, the risk is small, compared to the benefits provided by these drugs.

The third group that may cause cancer consists of hormones or hormone antagonists. Little is known about the mechanisms by which hormone imbalances lead to cancer, and the topic is a subject of ongoing research. In some cases, hormones protect the patient from cancer, or they may reduce the incidence of one type of cancer but increase the risk of another type. Probably the best studied of the hormone mechanisms is how estrogen binds to its intracellular receptors. About 70% of patients with breast cancer are estrogen receptor (ER) positive: The hormone promotes tumor formation in the mammary gland. Cancers caused by hormones or hormone antagonists tend to affect reproductive organs, such as the vagina, uterus, or breast.

A similar question might be asked regarding drugs that cause birth defects, or **teratogens**. Why would a drug be approved by the FDA if it was shown to produce birth defects in laboratory animals during the preclinical stage of drug testing? The answer to this question is very different from that for cancer-inducing drugs.

Teratogens affect a small percentage of the overall population: those who are pregnant, or who become pregnant during pharmacotherapy. In most cases these drugs are safe for use by men and postmenopausal women. Thus, known teratogens may be approved for indications in patients who do not have the potential to become pregnant. For example, finasteride (Proscar) is a known teratogen and it is only approved to treat men with benign prostatic hyperplasia.

When approved for women with reproductive potential, however, drugs with teratogenic effects have increased risks. In some cases a negative pregnancy test may be required prior to pharmacotherapy and the nurse should warn the patient to discontinue the drug if pregnancy is suspected. In women with reproductive potential, teratogenic drugs are not prescribed unless they have clear benefits that outweigh the possible risk of birth defects. All healthcare providers must carefully assess patient compliance with instructions against this potential risk. In extreme cases, such as with the drug isotretinoin (Amnesteem, others), women of reproductive potential must provide two negative pregnancy tests prior to receiving the drug and one each month the prescription is refilled.

The nurse should remember that drugs are not tested in pregnant humans before FDA approval, and that animal testing cannot predict with great accuracy the effects on the human fetus. In some cases, the risks to a human embryo or fetus have been determined after a drug has been approved. The FDA has established pregnancy categories that are used to gauge the risk of a drug causing birth defects (see Chapter 8). All drug use should be assumed dangerous during pregnancy, unless data have otherwise demonstrated the drug to be safe. No woman should take a drug, herbal product, or dietary supplement during pregnancy unless approved by her healthcare provider.

5.6 Drug toxicity may be specific to particular organs.

Very few drugs produce adverse effects in every organ system; these agents would be too toxic for safe pharmacotherapy. Instead, adverse effects are often organ specific, targeting one or a few organs. It is important for the nurse to learn these specific toxicities so that appropriate signs, symptoms, and diagnostic tests can be carefully monitored. Selected organ-specific toxicities are summarized in Table 5.2.

Table 5.2 Organ-Specific Toxicity

Toxicity	Example Drugs and Classes
Bone marrow	ACE inhibitors, antimalarials, antineoplastics, antiseizure drugs (carbamazepine, phenytoin), antithyroid drugs, cephalosporins, chloramphenicol, chlorpromazine, chlorpropamide, cimetidine, furosemide, methyldopa, NSAIDs, phenylbutazone, sulfonamides
Cardiotoxicity	anthracycline antineoplastics (daunorubicin, doxorubicin, epirubicin, idarubicin, mitoxantrone)
Dermatologic	antiseizure drugs (carbamazepine, phenobarbital, phenytoin), cephalosporins, erythromycin, NSAIDs, penicillin, radiologic contrast media, sulfonamides, tetracyclines
Hepatotoxicity	carbamazepine, chlorpromazine, statins (HMG CoA reductase inhibitors)
Nephrotoxicity	ACE inhibitors, acyclovir, aminoglycosides, amphotericin B, cisplatin and other platinum-based antineoplastics, cocaine, cyclosporine, NSAIDs, radiologic contrast media, sulfonamides, tacrolimus
Neurotoxicity	aminoglycosides, cisplatin, ethanol, loop diuretics, methyldopa, salicylates, vincristine
Skeletal muscle and tendon toxicity	fluoroquinolone antibiotics, statins

Bone marrow toxicity: Drugs affecting the bone marrow are of great concern due to the possibility of serious and perhaps fatal outcomes. The bone marrow serves as a nursery for the production of red blood cells, white blood cells, and platelets. Drugs may affect only one of these types of cells or all three. When all three groups are affected, drug-induced pancytopenia or aplastic anemia occurs, and the patient is at great risk for serious illness. Loss of white blood cells may cause agranulocytosis or neutropenia, which places the patient at risk for serious infections. The drug class most likely to cause bone marrow toxicity is the antineoplastics. Bone marrow toxicity is the dose-limiting factor with these drugs (see Chapter 57).

The role of the nurse in preventing bone marrow toxicity is to carefully monitor laboratory data and recognize impending toxicity by reporting decreases in red blood cells, white blood cells, or platelets. In many cases, bone marrow toxicity can be quickly reversed if the condition is recognized early and the drug is discontinued. Furthermore, the nurse should carefully monitor the therapeutic regimen of patients who have preexisting blood cell disorders because adding a drug with bone marrow toxicity may worsen these conditions.

Cardiotoxicity: A few medications damage cardiac muscle cells, affecting the ability of the heart to effectively pump blood to the tissues. The most common cardiotoxic drugs belong to a chemical class called the anthracyclines, which include daunorubicin (Cerubidine, DaunoXome), doxorubicin (Adriamycin), epirubicin (Ellence), idarubicin (Idamycin), and mitoxantrone (Novantrone). These are all antineoplastic medications. The cardiotoxicity of these drugs can be severe and lead to bradycardia, tachycardia, heart failure, and acute left ventricular failure. The nurse

administering cardiotoxic drugs must be vigilant in observing for signs of cardiotoxicity such as excessive fatigue, cough, shortness of breath (especially when recumbent), weight gain, or peripheral edema.

A second type of cardiotoxicity is manifested as prolongation of the QT interval on an electrocardiogram (ECG). The QT interval represents the time needed to depolarize and repolarize the ventricles. Lengthening of the QT interval is associated with a rare type of ventricular tachycardia called torsade de pointes, which can cause sudden cardiac death. More than 100 drugs have been shown to cause QT prolongation and several have been removed from the market because of this adverse effect. Because the QT interval represents the dysrhythmia potential of a drug, the FDA now requires all new medications to be tested for QT prolongation prior to approval. When administering drugs that prolong the QT interval, nurses should carefully monitor cardiac function, especially in patients with preexisting heart disease.

Dermatologic toxicity: Drug reactions affecting the skin are some of the most common types of adverse effects. These reactions may be caused by a hypersensitivity reaction or by nonimmune-type responses. Rash, the most common cutaneous drug reaction, usually occurs within 1 to 2 weeks of initiation of drug therapy and resolves without serious complications. Drug-induced rash is sometimes accompanied by itching (pruritus). Although almost any drug can cause rash, antibiotics are the most frequent drug class causing this condition. Urticaria (hives) are raised welts that are often accompanied by intense pruritus and, although less common than rash, are a symptom of a potential allergic reaction that could lead to anaphylaxis.

Serious and even fatal dermatologic toxicity can occur. In angioedema, swelling occurs in the dermis, periorbital region, and around the mouth and throat. Angioedema is a severe drug reaction because the swelling may impair breathing and may be fatal. SJS is another drug-induced condition that can be fatal. This syndrome causes severe blistering of the skin, usually accompanied by mucous membrane involvement and fever.

Phototoxicity is a type of drug-induced dermatologic toxicity in which certain drugs cause the skin to absorb excess ultraviolet radiation from the sun or heat lamps. Symptoms resemble sunburn and are best prevented by advising patients to avoid direct sunlight. Phototoxicity resolves when the drug is discontinued.

Most types of drug-induced dermatologic toxicity do not require pharmacologic treatment. If pruritus is prominent, an antihistamine or a corticosteroid may be administered. In all cases of serious drug-induced hypersensitivity, the nurse should discontinue the drug until the cause of the skin condition can be diagnosed.

Hepatotoxicity: The liver receives all drugs absorbed across the stomach and intestinal mucosa via the hepatic-portal vein. A major function of the liver is to metabolize and detoxify drugs and other chemicals that enter the body; thus it should not be surprising that hepatotoxicity is one of the most common adverse drug effects. Effects of hepatotoxic drugs range from minor, transient increases in liver enzyme values to fatal hepatitis.

The nurse should regularly monitor liver enzyme tests when administering hepatotoxic drugs, because changes in these laboratory values are early signs of liver toxicity. Symptoms of liver impairment are vague and nonspecific and include right upper quadrant pain, anorexia, bloating, fatigue, and nausea or vomiting. During chronic hepatotoxicity, jaundice, itching, and easy bruising are evident. In serious cases, the liver will be unable to metabolize other drugs, resulting in high serum drug levels. Extreme care must be taken when administering potentially hepatotoxic drugs to patients with preexisting liver disease.

Nephrotoxicity: The kidneys are one of the most common organs affected by drugs. This is because these organs filter large volumes of blood, and most drugs are excreted by the renal route. Some drugs are reabsorbed or secreted by the kidney, exposing renal tubule cells to high concentrations of these agents. A few obstruct the urinary system by causing crystalluria in the urinary tract. Drug nephrotoxicity may manifest as acute symptoms that appear after one or several doses, or as chronic symptoms that appear after several months of pharmacotherapy.

It is critical for the healthcare provider to identify at-risk patients and attempt to prevent drug-induced nephrotoxicity. Means for prevention include providing proper hydration, monitoring urinary lab values, and adjusting doses appropriately for patients with renal impairment. Patients with serious renal impairment should not receive nephrotoxic drugs unless other therapeutic options have been exhausted.

Neurotoxicity: Although the blood–brain barrier prevents many drugs from reaching the brain, neurotoxicity is a relatively common adverse effect of certain drug classes. This is because the brain receives a large percentage of the blood supply and is especially sensitive to small amounts of toxic substances. For sedatives, antidepressants, antianxiety drugs, antiseizure drugs, and antipsychotics, the difference between a therapeutic dose and one that produces adverse effects may be very small. Indeed, drowsiness is seen in a majority of patients receiving these drugs when therapy is initiated. Signs and symptoms of toxicity in the central nervous system (CNS) include depression, mania, sedation, behavioral changes, suicidal feelings, hallucinations, and seizures. The special senses may be affected, including visual changes, loss of balance, and hearing impairment. Hearing impairment, or **ototoxicity**, can result from drug-induced damage to the eighth cranial nerve.

Effective teaching is essential when patients are beginning therapy with potentially neurotoxic drugs. The nurse should warn patients not to drive vehicles or perform other hazardous tasks until they are familiar with the effects of these drugs. Caregivers should be taught to report changes in patient behavior, because the individual receiving the medication may have difficulty recognizing these signs. The nurse should be aware that neurotoxic drugs can significantly worsen preexisting mental health disorders. Serious symptoms such as seizures, delirium, suicidal ideation, or significant visual or hearing impairment should be immediately reported to the prescriber.

Skeletal muscle and tendon toxicity: Skeletal muscle is relatively resistant to the effects of drugs, despite its extensive blood supply. In skeletal muscle the incidence of drug-induced myopathy is low but may be serious when it does occur. The most severe myopathy is rhabdomyolysis, a syndrome characterized by extensive muscle necrosis with the release of muscle enzymes and other constituents into the circulation. Rhabdomyolysis is a rare, though serious adverse effect of statins, common medications used to treat excessive lipid levels in the blood.

Some of the fluoroquinolone antibiotics exhibit toxicity to cartilage and tendons. This is most often manifested as rupture of the Achilles tendon and is most apparent in adults over age 65. Patients under age 18 should not take these medications because they may interfere with cartilage growth.

To prevent skeletal muscle or tendon toxicity, the nurse should assess for unexplained muscle or joint soreness or pain during therapy. Laboratory tests such as creatine kinase (CK) should be evaluated regularly during therapy with drugs that have muscle toxicity.

Drug Interactions

5.7 Drug interactions may significantly affect pharmacotherapeutic outcomes.

A **drug interaction** occurs when a substance increases or decreases a drug's actions. The substance causing the interaction may be another drug, a dietary supplement, an herbal product, or a food. The substance participating in the drug interaction must be external to the body and is usually taken concurrently with the medication. Although substances that are naturally found in the body (endogenous substances) routinely interact with drugs, these are not considered drug interactions because they are part of the body's normal response to the drug.

Because patients often take multiple drugs concurrently, drug interactions occur continually. Even if only one drug is taken, the potential for a drug–food interaction still exists. Drug interactions are impossible to totally eliminate; most go unnoticed and treatment outcomes are rarely affected. Indeed, it is likely that most drug interactions have yet to be documented or researched because they do not cause clinically noticeable effects or harm to the patient.

Some drug interactions are important to pharmacology because they are known to cause adverse effects or otherwise affect treatment outcomes. By understanding the mechanisms of potential drug interactions, the nurse can prevent certain adverse effects and optimize treatment outcomes. For example, if the patient is receiving gentamicin, the nurse should use caution when administering acyclovir, because the drug combination can cause higher than normal levels of acyclovir in the blood. The prescriber should reduce the dose of acyclovir or substitute a different drug. Understanding drug interactions can directly affect the success of pharmacotherapy.

Drug interactions occur by dozens of different mechanisms. To simplify their study, it may be helpful to remember that drug interactions can have three basic effects on the action of a medication:

- The actions of the medication can be *inhibited*, resulting in less therapeutic action. For example, milk interferes with the absorption of tetracycline, causing a lower serum level of antibiotic, thus diminishing its therapeutic effects.
- The actions of the medication may be *enhanced*, causing a greater therapeutic response. For example, coadministration of the two antiviral drugs lopinavir and ritonavir causes a greater reduction in levels of human immunodeficiency virus (HIV) than occurs when either drug is used alone.
- The interaction may produce a totally *new and different response*. For example, when used alone disulfiram (Antabuse) has no pharmacologic effects. When taken with alcohol, however, the combination produces dramatic, new actions such as severe headache, flushing, dyspnea, palpitations, and blurred vision (see Chapter 27).

5.8 Pharmacokinetic drug interactions include changes in the absorption, distribution, metabolism, or excretion of medications.

Recall from Chapter 3 that pharmacokinetics is the branch of pharmacology dealing with how the body acts on a drug after it is administered. Many drug interactions involve some aspect of pharmacokinetics. When studying drug interactions, it is convenient to use the same categories for pharmacokinetics that are presented in Chapter 3. The general types of pharmacokinetic interactions are illustrated in Figure 5.1.

Absorption: Most drugs need to be absorbed to produce their actions. Any substance that affects absorption has the potential to influence drug response. In fact, this is one of the most common mechanisms of drug interactions. By interfering with normal absorption, drug action may be

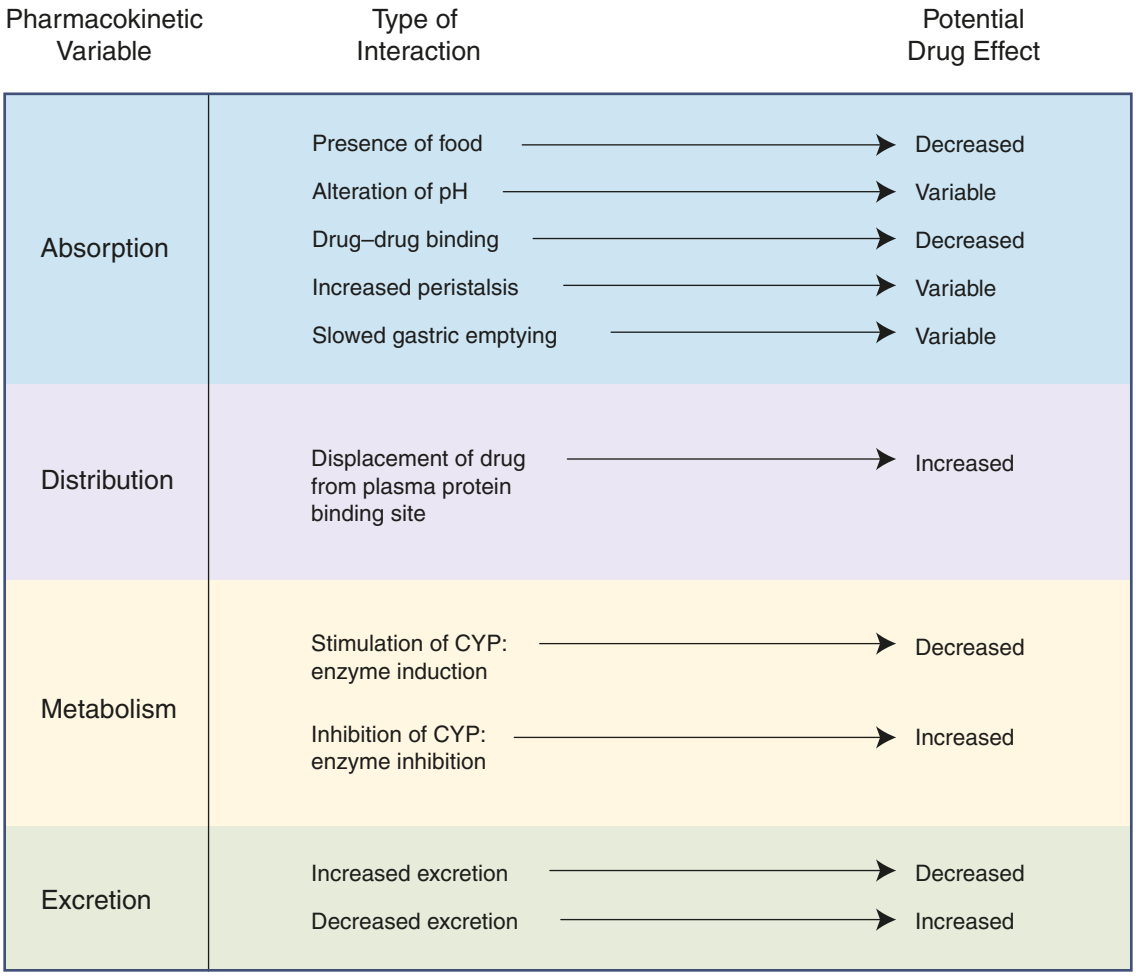

Figure 5.1 Types of pharmacokinetic drug–drug interactions.

inhibited or enhanced. Increasing absorption will raise drug serum levels and produce an enhanced effect; substances inhibiting absorption have the opposite effect.

The simplest way to affect absorption is to change the speed of substances moving through the gastrointestinal (GI) tract. Opioids such as morphine or heroin will slow peristalsis, giving drugs additional time for absorption. Laxatives and drugs that stimulate the parasympathetic nervous system will speed substances through the GI tract, diminishing the absorption time of other drugs. The bile acid resins such as cholestyramine (Questran) bind other drugs and prevent their absorption.

Many drug–drug interactions caused by changes in absorption may be prevented by taking the two medications at least 2 to 3 hours apart. In the case of drug–food interactions, the interacting food should be avoided, or the drug may be taken on an empty stomach. Taking drugs on an empty stomach, however, may increase the incidence of nausea or vomiting, which could result in loss of the drug before complete absorption occurs. The nurse must teach patients with drug-induced nausea not to take drugs with antacids or milk unless approved by the prescriber. Antacids are alkaline (basic) substances that raise the pH of the GI contents and have the potential to change the percentage of ionized drug. Ionized forms of drugs are less able to cross the intestinal mucosa than nonionized forms.

Distribution: Distribution is the movement of a drug from its site of absorption to its site of action. Many drugs travel through the blood bound to plasma proteins and, when bound, the drug is unable to leave the blood to reach its target. Drugs may compete for available binding sites on plasma proteins; one drug may prevent another from binding to plasma proteins or may displace a drug from its binding sites. If this occurs, the amount of unbound or free drug increases, potentially raising the drug serum concentration to toxic levels. For example, diazepam displaces phenytoin from plasma proteins, causing a rapid increase in the plasma concentration of free phenytoin and an increased risk of adverse effects. Drugs that have a high potential for displacing other drugs from protein binding sites include aspirin and other NSAIDs, phenylbutazone, and sulfonamides.

A second potential drug–drug interaction involving distribution can occur if the pH of the plasma is altered by a drug. For example, when an alkaline substance such as sodium bicarbonate is infused, the pH of plasma increases,

causing acidic drugs to become ionized. The ionized acidic drugs are less able to cross membranes and they accumulate in the extracellular spaces, creating an ionization (pH) gradient. The pH gradient moves acidic drugs from inside cells to the extracellular spaces, thus altering distribution.

Metabolism: A large number of drugs are metabolized by hepatic enzymes. Drug metabolites generally have less activity than the original drug and are more readily excreted by the kidneys. Any drug-induced change in the activity of hepatic enzymes has the potential to cause drug–drug interactions.

As discussed in Chapter 4, certain drugs have the ability to increase (induce) or decrease (inhibit) hepatic enzyme activity. Inducers such as phenobarbital will increase drug metabolism, thus promoting the inactivation and excretion of many drugs. Clinically, this will be observed as diminished drug effectiveness. For example, if phenobarbital is administered concurrently with the antihypertensive drug nifedipine, less blood pressure reduction will result. The dose of nifedipine will need to be increased to produce an optimal therapeutic effect. However, care must be taken if the inducer is discontinued because hepatic enzyme activity will return to baseline levels in a few days or weeks. Once hepatic enzymes return to normal, the dose of nifedipine will have to be adjusted downward to avoid toxicity. Also, remember that a few drugs (prodrugs) are *activated* by metabolism. Increasing the metabolism of prodrugs will cause an increase, rather than a decrease, in therapeutic response.

Inhibitors of hepatic metabolism will cause drug interactions that are opposite to those of inducers. For example, ritonavir inhibits the hepatic enzyme CYP3A4 and will decrease the metabolism of other drugs that are substrates for this enzyme. Giving ritonavir concurrently with nifedipine causes an increased blood pressure reduction due to the diminished metabolism of the antihypertensive. The nifedipine dose must be lowered to avoid toxicity. After ritonavir is discontinued, hepatic enzyme levels return to baseline and the nifedipine dose must be adjusted once again to maintain blood pressure control.

Drug interactions involving hepatic metabolism are some of the most complex in pharmacology. Although many of these interactions are not clinically significant, others clearly have the potential to cause adverse effects and affect therapeutic outcomes. The nurse will need to remember which drugs are inducers, inhibitors, and substrates of CYP enzymes to optimize pharmacotherapeutic outcomes and minimize adverse effects (see Chapter 3).

CONNECTION Checkpoint 5.1

From what you learned in Chapter 3, explain the significance of the first-pass effect on pharmacotherapy. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Excretion: Most drugs are eliminated from the body through renal excretion. A drug interaction may occur if a substance changes the glomerular filtration rate (GFR), the amount of blood filtered (in milliliters) by the kidney per minute. The higher the GFR, the more rapid the excretion of other drugs.

A second type of excretion-related interaction may occur if one drug changes the secretion or reabsorption of another drug in the renal tubule. For example, methotrexate competes with NSAIDs for the same secretion mechanism. If taken concurrently, NSAIDs will block the renal secretion of methotrexate, thus raising drug serum levels and increasing the potential for methotrexate toxicity.

Renal elimination may also be affected by drugs that change the pH of the filtrate in the renal tubules. Changing the pH causes drugs to become more (or less) ionized. The excretion of weak acids can be significantly increased by alkalinizing the urine through the administration of sodium bicarbonate. This drug interaction may be used therapeutically to promote more rapid excretion of acidic drugs such as aspirin during overdose situations. Similarly, excretion of weak bases can be increased by acidifying the urine through the administration of ammonium chloride.

Not all excretion-related drug interactions involve the kidneys. Some drugs are extensively excreted by the biliary system and two drugs excreted in this way may interact through this mechanism. For example, pravastatin and cyclosporine use the same carrier protein to move drug molecules from the liver to bile. Giving the two drugs concurrently will slow the biliary excretion of pravastatin and raise its serum concentration to potentially toxic levels. Because biliary excretion is not the dominant form of elimination for most drugs, this type of drug–drug excretion interaction is far less common than those involving the kidneys.

PharmFACT

Polycyclic aromatic hydrocarbons (PAHs) found in tobacco smoke are potent inducers of several hepatic microsomal enzymes. Smoking has been shown to interact with antipsychotics, antidepressants, benzodiazepines, oral contraceptives, inhaled corticosteroids, and beta blockers (Lucas & Martin, 2013).

5.9 Pharmacodynamic drug interactions include additive, synergistic, or antagonistic effects.

Recall from Chapter 4 that pharmacodynamics is the branch of pharmacology examining the mechanisms of drug action, meaning how a drug changes the body. Many drugs produce their actions by binding to specific receptors. When two drugs compete for the same receptor, or activate receptors that produce opposite effects, drug interactions are possible. Many common interactions encountered in clinical practice are pharmacodynamic in nature.

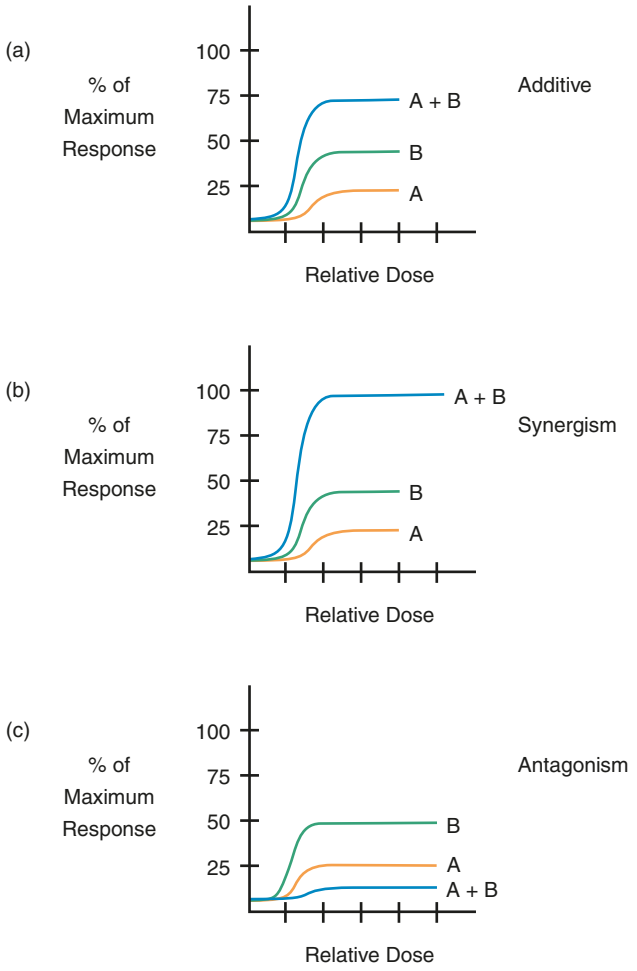

Figure 5.2 Additive, synergistic, and antagonistic drug interactions: (a) additive response; (b) synergistic response; (c) antagonistic response.

During a pharmacodynamic drug interaction, drug action may be either enhanced or inhibited. The result of the interaction may be desirable (increased therapeutic response or decreased adverse effect) or undesirable (decreased therapeutic response or increased adverse effect). The basic pharmacodynamic drug–drug interactions are illustrated in Figure 5.2.

The pharmacodynamic drug interaction that is easiest to visualize is the **additive effect**. In this interaction, two drugs from a similar therapeutic class produce a combined summation response. This is used extensively in treating hypertension. For example, a diuretic may be used to lower systolic blood pressure by 10 mmHg, and a beta blocker may be added to the regimen to produce another 15-mmHg reduction. Combined, the two drugs produce a 25-mmHg reduction. Why would two drugs be prescribed, rather than a single drug? There are two rationales. First, to produce a 25-mmHg reduction using only the diuretic, the dose would have to be increased. Keeping the doses of both the diuretic and beta blocker low and taking advantage of their additive effect reduces the potential for adverse drug events caused by higher medication doses. Second, some drugs have low efficacy and it may not be possible to achieve a 25-mmHg reduction with a single drug. The maximum effect from the diuretic may have been a 10-mmHg reduction, and another drug would need to be added to the regimen to achieve a greater response. In this example, the two drugs act at very different types of receptors to produce the additive therapeutic response: beta blockers in cardiac muscle and diuretics in the renal tubules.

Remember that additive effects also apply to adverse effects. This is seen frequently in drugs that affect the CNS. For example, narcotic analgesics, antidepressants, antiseizure drugs, and antianxiety drugs all may cause sedation as a side effect. When taken concurrently, drugs from these classes can cause additive sedation that could profoundly affect the ability to safely operate a vehicle. Caution must always be used when administering multiple medications that have similar adverse effects such as nephrotoxicity, hepatotoxicity, or bone marrow toxicity.

Another pharmacodynamic drug interaction that produces an enhanced response is a **synergistic effect**. In this interaction, the effect of the two drugs is greater than would be expected from simply adding the two individual drugs' responses. This type of interaction is used extensively in treating infections. For example, Synercid is a combination drug that contains quinupristin and dalfopristin, two antibiotics that are effective against resistant *Staphylococcus* infections. Both drugs bind to the bacterial ribosome and produce greater killing than would be predicted from adding the two individual drugs' effects. Another example is the combination antibiotic Bactrim, which combines trimethoprim and sulfamethoxazole to produce a synergistic effect on bacterial cell killing.

A third type of pharmacodynamic interaction occurs when adding a second drug results in a diminished pharmacologic response. This **antagonistic effect** can result in drug actions being "cancelled." For example, drugs activating the sympathetic nervous system, such as epinephrine, will increase the heart rate and dilate the bronchi. A drug such as carvedilol (Coreg) will have the opposite effects: slowed heart rate and bronchoconstriction. Thus, carvedilol is considered an antagonist to epinephrine and may cancel its actions, depending on the doses of the two drugs. Why would a nurse administer drugs with opposite actions? This is generally done to reduce the adverse effects of a drug. For example, if a drug given to treat hypertension has a potential adverse effect of increasing heart rate, an antagonist may be given to slow the heart rate, keeping it within normal limits. When given intentionally, an antagonist does not necessarily reverse *all* actions of the first drug; it may selectively inhibit an undesirable action.

In some cases, antagonists are used to treat symptoms of drug overdose. For example, patients taking an overdose of narcotics, such as morphine or heroin, experience coma and life-threatening CNS depression. The administration of

naloxone (Narcan), a specific narcotic antagonist, can quickly reverse some of the serious adverse effects of morphine.

Pharmacodynamic interactions can be indirect and complex. The well-documented drug interaction between digoxin (Lanoxin) and diuretics, such as furosemide (Lasix), is an excellent example of an indirect effect. Furosemide enhances the excretion of potassium ion (hypokalemia), which increases the cardiotoxicity of digoxin. This can be a life-threatening interaction. Another example is the inhibition of vitamin K production in the intestine caused by antibiotics. If the patient is also taking warfarin (Coumadin), bleeding may occur because the liver is prevented from producing certain clotting factors. Again, the antibiotic did not directly interact with warfarin, yet the combination produced a serious adverse effect.

CONNECTION Checkpoint 5.2

The types of curves shown in Figure 5.2 are called dose–response curves. From what you learned in Chapter 4, explain the three phases of these curves. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

5.10 Food, nutrients, and dietary supplements may interact with medications and affect their actions.

Historically, interactions between drugs and food, dietary supplements, and herbal products have been largely dismissed as clinically unimportant. Although a few interactions, such as tetracyclines with calcium products, have been documented for decades, only since the late 1980s have drug–food interactions been recognized as important to maximizing pharmacotherapeutic outcomes. The interaction that prompted the increased interest in this topic was that of a benign and healthy substance: grapefruit juice. The interaction was discovered by chance in a research study designed to examine the effects of alcohol on felodipine, a calcium channel blocker. The researchers used grapefruit juice incidentally to disguise the taste of the alcohol.

Patients often take medications with juice because it covers up the bitter taste of a drug and provides a plentiful source of vitamins and minerals. Unfortunately, grapefruit juice also contains substances that increase the absorption of certain oral drugs. This occurs because grapefruit juice inhibits the enzyme CYP3A4 in the wall of the intestinal tract. As drugs are absorbed, they are not inactivated by CYP3A4, and higher amounts reach the circulation. Surprisingly, the inhibition from grapefruit juice may last up to 3 days after drinking the juice. The substances in the juice inhibiting CYP3A4 enzymes are called furanocoumarins. Fortunately, only a few drug classes interact with grapefruit juice. Examples include benzodiazepines, certain calcium channel blockers, and statins (HMG CoA reductase inhibitors).

Most of the drug–food interactions act by either increasing or decreasing the absorption or bioavailability of the drug. Some of these interactions are shown in Table 5.3. Drug–food interactions are easily avoided by timing the drug dose appropriately with the food or supplement. In most cases, there should be a minimum 2-hour time gap between ingestion of the food and drug. In a few cases, the drug should be administered with food to increase its absorption.

Table 5.3 Selected Drug–Food and Drug–Herbal Interactions

Drug	Interaction
antiplatelet and anticoagulant drugs	Garlic can increase the risk of bleeding.
atovaquone (Malarone)	Fatty food enhances absorption.
azithromycin (Zithromax)	Food reduces absorption.
calcium channel blockers and cyclosporine	Grapefruit juice enhances absorption.
cholestyramine (Questran)	Drug binds iron, folic acid, and vitamin A to decrease their absorption.
CNS depressants	Valerian can increase drowsiness and sedation.
etidronate (Didronel)	Milk, calcium, and iron bind the drug and decrease absorption.
fluoroquinolones	Calcium, iron, and other metal ions bind the drug and decrease absorption.
lovastatin (Mevacor)	Food increases absorption.
MAO inhibitors	Foods containing tyramine can cause hypertensive crisis.
NSAIDs	Food reduces the incidence of side effects.
penicillin G	Food (milk) and metal ions reduce absorption.
selective serotonin reuptake inhibitors (SSRIs)	St. John's wort and grapefruit juice increase risk of adverse effects (serotonin syndrome).
sucralfate (Carafate)	Food protein binds the drug to decrease absorption.
tetracyclines	Dairy products and iron reduce absorption.
warfarin (Coumadin)	Vitamin K antagonizes the action of warfarin; ginkgo, garlic, and St. John's wort may increase risk of bleeding.
zidovudine (AZT)	Food reduces bioavailability.

Very few clinically significant interactions of drugs with herbal products have been documented. As more patients take these products, however, research is demonstrating that certain drug–herb combinations may significantly impact pharmacotherapy. Because patients view herbal products as natural, they do not usually mention them when recording their medication history; thus the healthcare provider must ask specific questions about their use.

One of the most widely studied herbs is St. John's wort, which is taken by patients as a complementary or alternative therapy for depression. The herb induces hepatic metabolic enzymes, which can reduce the effectiveness of certain prescription medications, including antidepressants, warfarin, and benzodiazepines. A second herb that has been extensively studied is ginkgo biloba, which is taken to improve

CONNECTIONS: Community-Oriented Practice

Food–Drug Interactions

The nurse has a critical role in patient education related to food–drug interactions. One of the common questions a patient will ask is "Do I take this drug with food?" Most medications can be administered with food, so of greater importance is what foods the patient should avoid when taking the drug.

Foods may contain naturally occurring substances or be fortified with vitamins that do not mix well with medications. The drug ingredients may not work as well as they should when certain foods are taken concurrently. Food nutrients can affect absorption, metabolism, or elimination of the drug by binding with ingredients in the medication. And as more is learned about the active compounds in foods such as phytochemicals, more study is needed to predict when significant food–drug interactions may occur.

As mentioned in this chapter, a common food–drug interaction may occur when a patient eats grapefruit or drinks grapefruit juice with select medications. However, other compounds in food or beverages may also significantly alter pharmacokinetic processes and, thus, drug effects. Other juices such as apple, orange, pomegranate, and tomato and other foods including tea, licorice, chocolate, and cruciferous vegetables have compounds that may also impact pharmacokinetic processes or the way in which the drugs work in the body, and not as much is known yet about these interactions or how to predict them. A detailed dietary recall is needed in addition to a medication history, especially when reactions to medications seem to relate to certain foods (Nicoteri, 2016). Because research into the influence of foods and juices other than grapefruit is limited, unless ordered otherwise, the safest way to take a medication is with a glass of water.

circulation and memory. Ginkgo may produce additive anticoagulant effects when taken with warfarin or antiplatelet drugs. It can also antagonize the effects of antiseizure drugs, thus increasing the risk for seizures. Because both St. John's wort and ginkgo can significantly affect drug action, the nurse should assess for the use of these substances when obtaining the patient's health history. Other effects of herbal products are presented in Chapter 7.

Understanding Chapter 5

Key Concepts Summary

5.1 The nurse plays a key role in preventing and managing adverse drug effects.

5.2 The FDA continues to monitor for new adverse events after a drug is approved and marketed.

5.3 Allergic reactions are caused by a hyperresponse of the immune system.

5.4 Idiosyncratic reactions are unusual drug responses often caused by genetic differences among patients.

5.5 Some drugs have the ability to induce cancer or cause birth defects.

5.6 Drug toxicity may be specific to particular organs.

5.7 Drug interactions may significantly affect pharmacotherapeutic outcomes.

5.8 Pharmacokinetic drug interactions include changes in the absorption, distribution, metabolism, or excretion of medications.

5.9 Pharmacodynamic drug interactions include additive, synergistic, or antagonistic effects.

5.10 Food, nutrients, and dietary supplements may interact with medications and affect their actions.

CASE STUDY: Making the Patient Connection

Remember the patient "Elizabeth Washington" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

The more medication an individual takes, the more likely it is that an adverse reaction may occur. For Elizabeth Washington this is a real possibility because she takes multiple medications for various physical problems. Elizabeth is a 77-year-old African American woman with several chronic conditions that require pharmacotherapy, including diabetes, heart failure, arthritis, and depression. She has been wheelchair bound since her stroke 2 years ago and has lost functional ability of her left side.

Unfortunately, she does not have a regular healthcare provider. Elizabeth obtains all her healthcare from a clinic operated for lower income individuals. The primary healthcare providers in the clinic are medical residents and interns who rotate every month as part of their medical training. Therefore, it is unlikely that she will see the same prescriber more than a couple of times. Her medical record is quite extensive and spans her health history for the past 15 years. Because her medical history record is so lengthy, Elizabeth fears that the new doctors will not take the time to read the entire chart before prescribing the newest treatment or therapy.

Critical Thinking Questions

1. Identify ways that you can minimize or prevent adverse drug events in this patient.
2. What existing conditions make Elizabeth more susceptible to a drug reaction?
3. Discuss how drug reactions can affect pharmacokinetics.
4. Differentiate among additive, synergistic, and antagonist drug effects.

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

As the triage nurse in the emergency department, you determine the patient's chief complaint, obtain vital signs, collect past medical history information, and ask about drug and food allergies. While assessing a patient with a suspected ankle fracture, she tells you that she is allergic to codeine because it makes her nauseated and sleepy.

1. What further questions would you ask the patient about drug allergies?
2. Differentiate between an adverse effect, a side effect, and drug allergy.
3. Is this patient experiencing an idiosyncratic reaction? Explain.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Prior to the administration of an antibiotic, the patient informs the nurse that 4 years ago the patient experienced an allergic reaction. Based on this information what should the nurse do first?
   1. Ask the patient to describe the reaction further.
   2. Notify the healthcare provider on call about the patient's statements.
   3. Administer the dose and observe the patient for a reaction.
   4. Check the medical administration record for documented allergies.
2. The nurse is researching a new drug prior to administration. The drug handbook states that the adverse effects are "dose related," which means that:
   1. As the dose increases, the risk of adverse effects also increases.
   2. The adverse effects should be expected after the first dose.
   3. Oral preparations will produce the most adverse effects.
   4. The timing of each dose should be correlated with the presence of adverse effects.
3. The patient is receiving a medication that may cause nephrotoxicity. To decrease the risk of this adverse reaction, the nurse should encourage the patient to:
   1. Avoid sunbathing and exposure to direct sunlight.
   2. Increase the intake of potassium-enriched foods.
   3. Abstain from alcoholic beverages.
   4. Increase fluid intake to promote adequate hydration.
4. On physical examination, the nurse observes raised hive-like welts covering the patient's trunk and arms. The patient also reports intense itching after receiving a new medication. The nurse will document which dermatologic adverse effect?
   1. Angioedema
   2. Stevens–Johnson syndrome
   3. Urticaria
   4. Photosensitivity

5. When observing a patient for bone marrow toxicity, the nurse would monitor for:
   1. Increased reports of muscle and bone pain in the lower extremities.
   2. Decrease in red blood cells, white blood cells, and platelets.
   3. Decrease in the range of motion of the upper and lower extremities.
   4. Increase in hepatic enzymes.
6. The patient is receiving a medication that causes hepatotoxicity. What symptoms would alert the nurse that this drug-related toxicity has occurred?
   1. Black furry tongue and vaginal yeast infection
   2. A sudden reduction in blood pressure on rising
   3. Right upper quadrant pain and anorexia
   4. Uncontrollable movements in the face, arms, and legs

Chapter 6
Medication Errors and Risk Reduction

Chapter Outline

- Medication Errors and Their Impact on Healthcare
- Factors Contributing to Medication Errors
- Drug Names and Medication Errors
- Reporting Medication Errors
- Strategies for Reducing Medication Errors

Learning Outcomes

After reading this chapter, the student should be able to:

1. Critique the following statement: "All medication errors can be prevented."
2. Describe the potential impact of a medication error on all aspects of healthcare delivery, including patients, nurses, and healthcare agencies.
3. Using specific examples, analyze major types of medication errors and how they can be prevented.
4. Describe procedures for reporting and documenting medication errors and incidents.
5. Explain how rules, policies, and procedures can help prevent medication errors.
6. Develop a list of strategies that the nurse can implement in practice to reduce medication errors.
7. Explain how medication reconciliation can lead to a reduction in medication errors.
8. Design patient teaching information that can be used to reduce medication errors.
9. Identify strategies that healthcare agencies use to prevent medication errors.

Key Terms

adherence, 78
healthcare failure mode and effect analysis (HFMEA), 79
high-alert medications, 75
medication administration record (MAR), 76
medication error, 71
medication error index, 71
medication reconciliation, 77
patient safety event, 71
polypharmacy, 77
risk management, 79
root-cause analysis (RCA), 79
sentinel event, 71

In their clinical practice, nurses must maximize patient safety by striving to be 100% accurate when administering medications. Drug administration, however, requires multiple complex steps to be accomplished by prescribers, pharmacists, nurses, and patients and can never be 100% error free. Occasionally, medication errors are made that can significantly impact treatment outcomes. The purpose of this chapter is to examine the reasons for medication errors and explore strategies that nurses may use to prevent them.

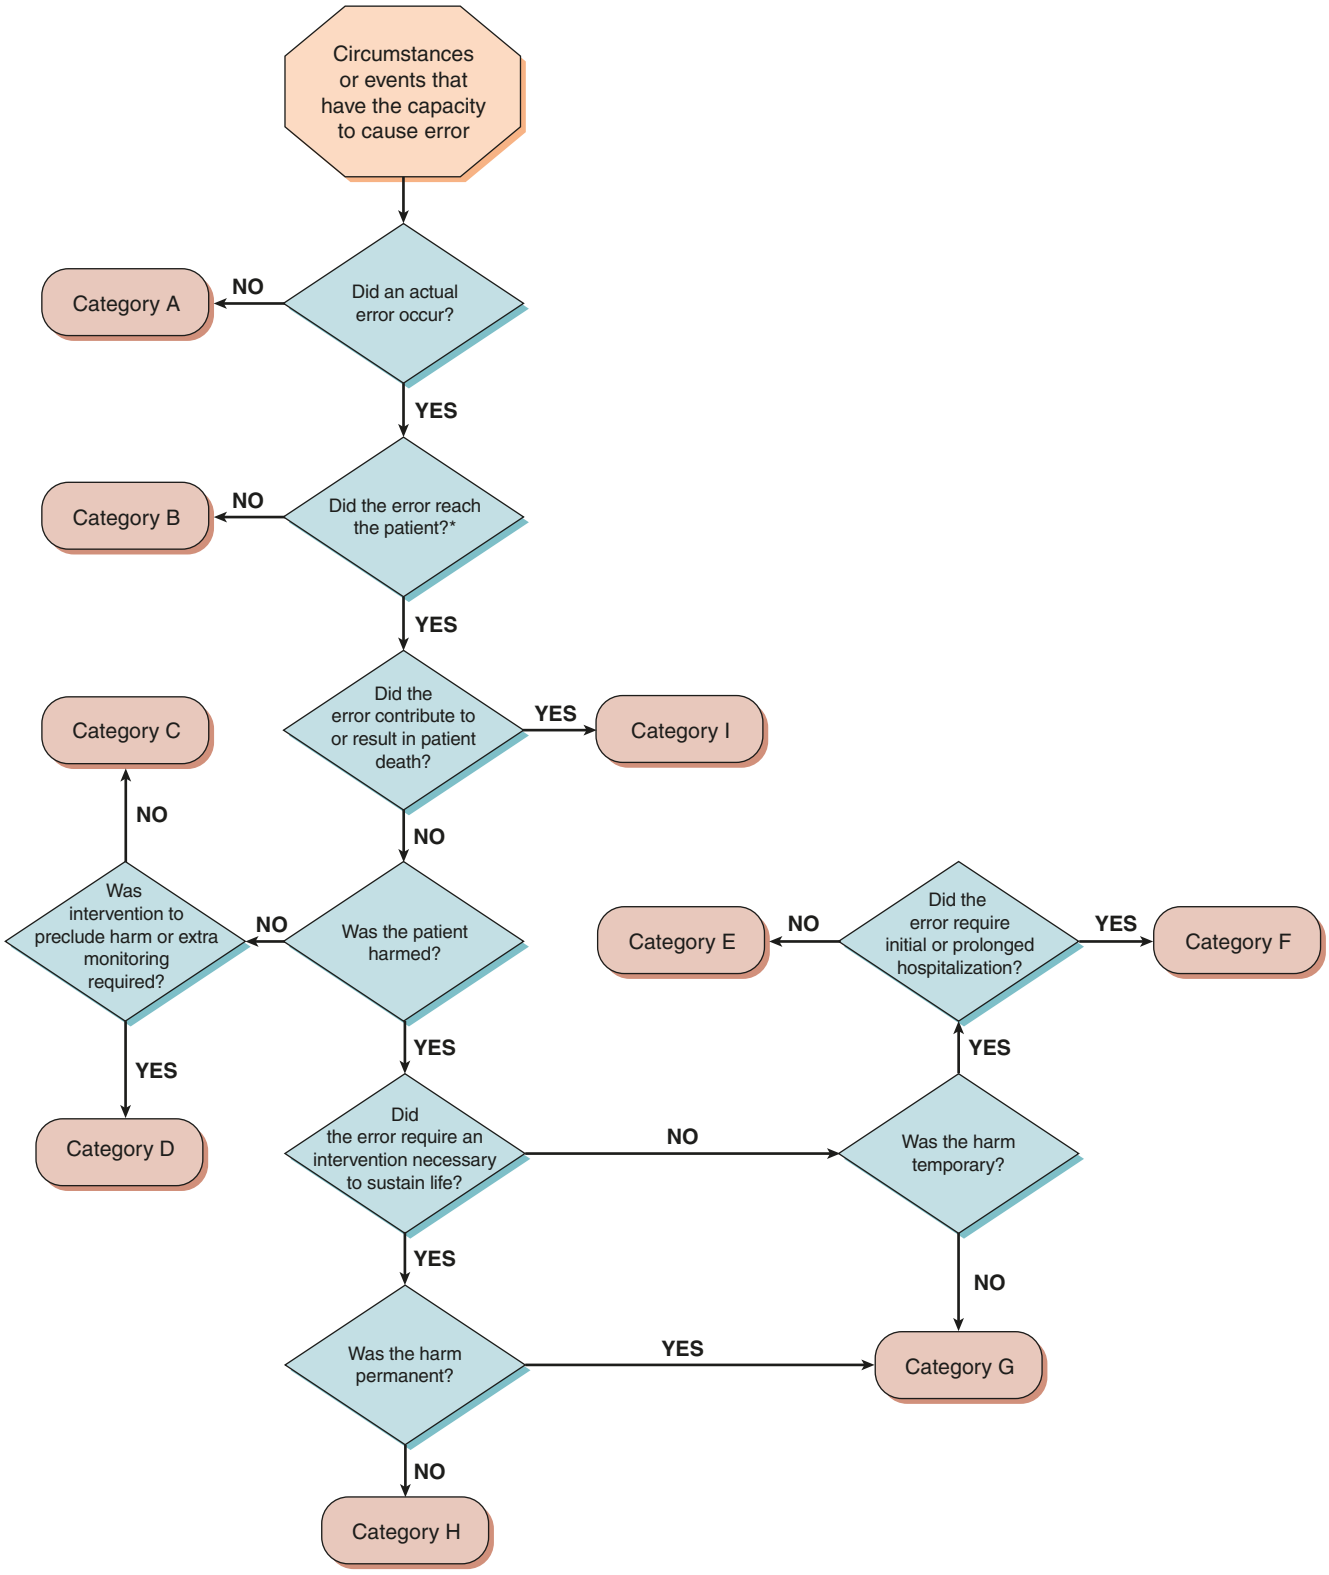
PharmFACT

It is estimated that 10% of all deaths in the United States are associated with medical errors. With medical errors accounting for 250,000 deaths annually, this becomes the third most common cause of death (Johns Hopkins Medicine, 2016).

Medication Errors and Their Impact on Healthcare

6.1 Medication errors are preventable events that may significantly impact treatment outcomes.

According to the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP, 2016), a **medication error** is:



> "any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the healthcare professional, patient, or consumer. Such events may be related to professional practice, healthcare products, procedures, and systems, including prescribing, order communication, product labeling, packaging, and nomenclature, compounding, dispensing, distribution, administration, education, monitoring, and use."

Whereas most medication errors do not result in patient harm, when they do, it may be devastating to the patient and to those healthcare providers involved in the error. The NCC MERP has developed a **medication error index** that categorizes medication errors by evaluating the extent of harm an error can cause, as shown in Figures 6.1 and 6.2.

The Joint Commission, an accrediting body for many healthcare agencies, considers certain categories of risk to patients to be "sentinel events." A **sentinel event** is a risk to patient safety that is so significant that it may result in death, permanent harm, or severe temporary harm (The Joint Commission, 2017b). These events pose such a risk to patient safety that The Joint Commission requires healthcare agencies to immediately conduct a review of any sentinel event and to take appropriate action to ensure it does not occur again. The definition of sentinel events was recently revised by The Joint Commission to highlight the need for healthcare partners to work with the commission to protect the patient and prevent further harm by improving the systems in place. The term *near miss*, also known as *close call* or *no harm*, is used to represent unexpected occurrences that posed a *risk* of harm, or occurrences that resulted in injury that did not rise to the same level of significance as a sentinel event. Both sentinel events and near misses are categorized as "patient safety events." A **patient safety event** is an event, incident, or condition that could have resulted or did result in harm to a patient (The Joint Commission, 2017a). Healthcare agencies are expected to conduct reviews of patient safety events and are strongly encouraged to report such events to the commission, although reporting is not mandatory.

Medication errors may have significant impact beyond just the patient's involvement. Errors may extend the length of hospitalization, which increases medical costs for the patient and agency. Undue harm to the patient due to medication errors is a cause of expensive legal challenges for the healthcare industry, physicians, and nurses. If frequent medication errors occur, the accreditation of the facility may be scrutinized and revoked. The agency also suffers loss of reimbursement as well as being perceived by the public as unsafe or delivering substandard care.

There is no acceptable occurrence rate for medication errors. The goal of every healthcare organization should be to improve medication administration systems to prevent harm to patients due to medication errors. All errors, whether or not they affect the patient, should be investigated with the goal of identifying policies and procedures that can improve the medication administration process to prevent future errors. The investigation of errors should be conducted in a nonpunitive manner that encourages staff to report errors, thereby building a culture of safety within an organization. Medication errors, especially those types that occur repeatedly, can alert nurses and healthcare administrators that a new policy, procedure, or process needs to be implemented to maximize patient safety.

*An error of omission does reach the patient.

Factors Contributing to Medication Errors

6.2 Medication errors may be caused by human factors, inadequate communication, or confusing labels, packaging, or drug names.

Many different factors contribute to medication errors. When considering the number of healthcare personnel involved, from medication order to administration, patient-related factors, packaging, and other non–human-related elements, there are many opportunities for a medication error to occur. It is not surprising that research into the causes of medication errors has found that the majority stem from human factors, such as deficient knowledge, prescribing or administration errors, and errors of omission, regardless of the type of healthcare setting (Chu, 2016; Franklin, 2014). The most frequent categories of errors include the following.

- Errors in patient assessment (e.g., inadequate medication history, incomplete physical assessment)
- Inaccurate prescribing (e.g., wrong drug, incorrect dose)
- Errors in administration (e.g., route or time of administration, omissions).

Most medication errors involve a breach of one of the cardinal "five rights" of medication administration: the right patient, drug, dosage, route, and time. Labeling designs, changes in packaging, and problems with dispensing devices are other factors contributing to errors. In many settings, the nurse remains the last line of defense to prevent an error from occurring.

Studying the types and causes of medication errors allows agencies and facilities to design ways to prevent them. Once a common source of error is identified, the U.S. Food and Drug Administration (FDA) works with healthcare agencies to determine changes that may be made to prevent that error in the future. For example, if two drug names sound too similar and are causing medication errors, the FDA may mandate a change in name. The FDA may also request pharmaceutical companies to more clearly label or package a drug to avoid confusion. Other forms of intervention include educating healthcare professionals and consumers about common errors and how to prevent them.

The Institute for Safe Medication Practices (ISMP) is a nonprofit agency comprising 23 national healthcare

organizations. It was founded in 1994 to help standardize medication error reporting systems, examine interdisciplinary causes of medication errors, and promote medication safety. ISMP offers many informational brochures and tools that assist in error avoidance. An example of a tool that has decreased error rates related to unclear medication orders is the ISMP's list of error-prone abbreviations, symbols, and dose designations (ISMP, 2015b). With the rise of the electronic health record (EHR), more abbreviations have been standardized or are now issued in fully written form.

The Affordable Care Act created an historical shift in the U.S. healthcare system. One early positive outcome appears to be a declining rate of hospital-acquired conditions (HACs). HACs include medical conditions or complications that a patient develops during a hospital stay that were not present on admission (American Hospital Directory, 2017). Although the precise causes of the decline in patient harm are not fully understood, the increase in safety has occurred during a period of concerted attention by hospitals throughout the country to reduce adverse events (Agency for Healthcare Research and Quality [AHRQ], 2014).

CONNECTION Checkpoint 6.1

From what you learned in Chapter 5, describe the similarities and differences between a synergistic effect and an additive effect and how they might contribute to a medication error. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Drug Names and Medication Errors

6.3 Certain drugs have higher rates of medication errors.

Some types of medication errors are independent of the drug being administered. For example, failure to perform adequate medication order checks, forgetting to give a dose, or administering the medication to the wrong patient can occur with any medication. Some drugs, however, have higher error rates than others. Furthermore, when an error does occur, certain medications have greater potential to cause harm. Learning which drugs have the highest error rates and produce the most serious consequences can help the nurse to be more vigilant when administering these agents.

With thousands of generic and trade names for drugs, it is inevitable that some will look or sound similar; for example, *hydroxyzine* and *hydralazine* or *Novalin* and *NovoLog*. It is easy to understand how a verbal order given in a hurry over a cell phone could result in the wrong drug. It is likely that hundreds of medication errors occur each year because of look-alike or sound-alike drugs. This is a primary reason why verbal drug orders should always be confirmed in writing before being administered. The ISMP publishes a list of confused drug names and recommends the use of "Tall Man Letters" as a method to reduce the chance that one drug will be mistaken for another (ISMP, 2015a). For example, "hydroxyzine" would be written as hydrOXYzine to avoid confusion with hydralazine (which is recommended as "hydrALAZINE"). A selection of look-alike or sound-alike drug names is included in Table 6.1.

Drugs that have a narrow therapeutic index are more likely to cause serious consequences should a medication error occur. These drugs are not necessarily more error prone than others, but the nurse should give extra care when administering them due to their toxicity. The ISMP

Table 6.1 Look-Alike and Sound-Alike Drug Names

acetazolamide	acetohexamide
AcipHex	Aricept
Adderall	Inderal
bupropion	Buspirone
carboplatin	cisplatin
Celebrex	Cerebyx
chlorpromazine	chlorpropamide
cycloserine	cyclosporine
daunorubicin	doxorubicin
dimenhydramine	diphenhydramine
Diprivan	Ditropan
dobutamine	dopamine
ephedrine	epinephrine
Humalog	Humulin
hydromorphone	morphine
infliximab	rituximab
isotretinoin	tretinoin
Kaletra	Keppra
Lamisil	Lamictal
lamivudine	lamotrigine
leucovorin	Leukeran
Lexapro	Loxitane
MS Contin	OxyContin
Neulasta	Neumega
oxycodone	OxyContin
paroxetine	fluoxetine
Retrovir	ritonavir
Seroquel	Sinequan
sumatriptan	zolmitriptan
Tiagabine	tizanidine
TobraDex	Tobrex
Tramadol	trazodone
Trental	tegretol
valacyclovir	valganciclovir
vinblastine	vincristine
Viracept	Viramune
Zantac	Zyrtec
Zestril	Zetia
Zyprexa	Celexa

maintains lists of **high-alert medications** and defines these as "drugs that bear a heightened risk of causing significant patient harm when used in error" (ISMP, 2014). Lists are available for both institutional and inpatient settings as well as community and ambulatory agencies. Healthcare agencies may build in additional safeguards with these medications such as independent double-checks or automated alerts. Each patient care unit may include its own, additional list of high-alert medications. For example, high-alert drugs on cancer units or a pediatric unit may differ from those on a medical–surgical unit. A selected list of high-alert medications is included in Appendix B of this text.

PharmFACT

In a 10-year study of medication errors in pediatric outpatient settings, medication errors occurred at a rate of over 63,000 per year, or approximately one error every 8 minutes. Analgesics and cough and cold remedies accounted for most of the errors (Smith et al., 2014).

Reporting Medication Errors

6.4 Medication errors must be properly documented and reported.

Although some medication errors go unreported, it is always the nurse's legal and ethical responsibility to document all occurrences. In severe cases, adverse reactions caused by medication errors may require the initiation of lifesaving interventions for the patient, including available antidotes. After such an incident, the patient may require close supervision, and additional medical treatments may be warranted.

The FDA has coordinated the reporting of medication errors at the federal level. The FDA Safety Information and Adverse Event Reporting Program, known as MedWatch, provides important and timely clinical information about safety issues involving medical products, including prescription and over-the-counter (OTC) drugs, biologics, medical- and radiation-emitting devices, and special nutritional products. The FDA encourages nurses and other healthcare providers to report medication errors to its database, which is used to assist other professionals in avoiding similar mistakes. Medication errors, or situations that can lead to errors, may be reported anonymously directly to the FDA by telephone or online. Since 2000, the FDA has received more than 95,000 reports of medication errors. The number of actual errors is likely much higher than what is reported.

In conjunction with the U.S. Pharmacopeial Convention (USPC), the ISMP operates the voluntary NCC MERP, which accepts reports from consumers and healthcare professionals related to medication safety. Medication errors from the NCC MERP voluntary reporting system are shared with the FDA. Establishment of the NCC MERP has resulted in dozens of medication-related patient safety changes, including nationwide hazard alerts; packaging, labeling, and nomenclature changes; and healthcare system changes.

The USPC also offers MEDMARX, a national, internet-accessible database that hospitals and healthcare systems use to track adverse drug events and medication errors. Agencies participate in MEDMARX voluntarily and subscribe to it on an annual basis. MEDMARX is operated as a quality improvement tool, which facilitates productive and efficient documentation, reporting, analysis, tracking, trending, and prevention of adverse drug events.

All medical facilities have policies and procedures that provide guidance to the nurse on reporting medication errors. Documentation of the error should occur in a factual manner and must include specific nursing interventions that were implemented following the error to protect patient safety, such as monitoring vital signs and assessing the

CONNECTIONS: Preparing for Advanced Practice

Medication Errors

Case

Daryl, a 4-year-old boy, came to the community clinic with a 1-week history of congestion, cough, and red irritated eyes. He did not have a fever and was happily playing on his father's lap. The nurse examined the child, made a diagnosis of allergic rhinitis, and recommended diphenhydramine (Benadryl).

The father purchased OTC, generic diphenhydramine (Benadryl) liquid (12.5 mg/5 mL), which was sold with a dosage cup. The product label indicated the recommended dose for a child younger than 6 years old as 1 to 2 teaspoons (12.5 to 25 mg). However, the dosage cup that came with the medication was marked in teaspoons and milliliters (mL), not in milligrams (mg). The father mistakenly poured the medication, missing the mL versus mg distinction. Luckily, as he was about to give 12.5 mL (31.25 mg) of the medication to Daryl, he realized the mistake.

Discussion

Errors measuring medicine using dosing cups are not uncommon and have led to serious consequences. Recently, a death occurred when a nurse confused two dosing scales that appeared on a plastic oral liquid dosing cup. To prevent confusion between variable measurement systems, devices should be marked with calibrated units of liquid measurement (tablespoon, teaspoon, milliliter) that are the same as the units of liquid measure specified on the product label and there should not be any unnecessary markings on the dosing cup (American Academy of Pediatrics, 2015; Consumer Healthcare Products Association, 2014; ISMP, 2016; National Council for Prescription Drug Programs, 2014).

patient for possible complications. Documentation does not simply record that a medical error occurred. Failure to document nursing actions taken related to the error could be interpreted as either negligence or failure to acknowledge that the incident occurred. The nurse should record the names of all individuals who were notified of the error and any follow-up monitoring or treatment prescribed or needed. The patient's **medication administration record (MAR)**, whether in print form or part of an EHR, should also contain information about what medication was given or omitted. The nurse who made or observed the medication error should complete a written occurrence report. The occurrence report allows the nurse an opportunity to identify factors that contributed to the medication error. The occurrence report is not usually included in the patient's health record and the nurse should learn the specific policies applicable to the agency of employment about the methods used to report errors.

Accurate documentation in the health record and on the occurrence report is essential for legal reasons. These documents verify that the patient's safety was protected and serve as a tool to improve medication administration processes. Legal issues may arise or worsen if an attempt is made to hide a mistake or delay corrective action, or if the nurse forgets to document interventions in the patient's chart.

CONNECTION Checkpoint 6.2

Additional important functions of the U.S. Pharmacopeial Convention are presented in Chapter 2. What is the role of the USPC in drug regulation? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Strategies for Reducing Medication Errors

6.5 Nurses use multiple strategies for reducing medication errors.

What can the nurse do in the clinical setting to avoid medication errors and promote safe drug administration? The nurse can begin by adhering to the four steps of the nursing process:

1. **Assessment.** Obtain a thorough medication history every time the patient enters the healthcare setting or transfers to another unit or agency. Ask the patient about food or medication allergies, current health concerns, and use of OTC medications and herbal supplements. Assess renal and hepatic functions, and determine if other body systems are impaired and could affect pharmacotherapy. Identify areas of needed patient education with regard to medications.
2. **Planning.** Minimize factors that contribute to medication errors: Avoid using abbreviations that could be misunderstood, question unclear orders, do not accept verbal orders, and follow specific facility policies and procedures related to medication administration. Be aware of situations or settings that may increase the risk of errors, such as a busy environment.
3. **Implementation.** When engaged in a medication-related task, focus entirely on the task. Noise, other events, and talking coworkers can distract the nurse's attention and result in a medication error. Keep the following points in mind as well:
   - Positively verify the identity of each patient before administering the medication, according to facility policy and procedures. Never bypass safeguards when checking for identification such as barcoded patient ID bands, which require scanning at the bedside.
   - Use the correct procedures and techniques for all routes of administration. Use sterile materials and techniques when administering parenteral medications.
   - Calculate medication doses correctly and measure liquid drugs carefully. Some medications, such as heparin, have a narrow safety margin for producing serious adverse effects. When giving these medications, ask a colleague or a pharmacist to check the calculations to make certain the dosage is correct and follow any agency-required nomograms as appropriate. Always double-check pediatric calculations prior to administration.
   - Open medication packages or bottles immediately prior to administering the drug and in the presence of the patient.
   - Record the medication and all dosing information on the MAR immediately after administration.
   - Always confirm that the patient has swallowed an oral medication. Do not leave the medication at the bedside unless there is a specific order that it may be left there.
   - Be alert for long-acting oral dosage forms with indicators such as SR, LA, XL, and XR. These tablets or capsules usually must remain intact for the extended release feature to remain effective. Instruct the patient not to crush, chew, or break the medication in half, because doing so could cause an overdose.
4. **Evaluation.** Assess the patient for expected therapeutic outcomes and determine if any adverse effects have occurred. The nurse should be especially vigilant in observing for adverse effects if this is the first time the patient has ever taken the drug, or if the dosage is being increased. Because antibiotics have the highest rate of drug allergy, the nurse must be especially observant for signs and symptoms of allergy following administration of these agents. All adverse effects noted should be reported to the healthcare provider, documented in the healthcare record, and reported to the next shift's nurse along with any additional orders from the provider. Have the patient restate information about the drug and dosing directions, including the correct dose of

medication and the right time to take it. Asking the patient to demonstrate an understanding of the goals of pharmacotherapy assists the nurse in determining whether additional patient education is necessary.

Nurses must stay current on pharmacotherapeutics and should never administer a medication unless they are familiar with its uses and adverse effects. There are many venues by which nurses can obtain updated medication knowledge. Each nursing unit should have current electronic or printed drug references available. Nurses can also call the pharmacy to obtain information about the drug. Interprofessional patient rounds, which include a clinical pharmacist assigned to a patient unit, and community primary care practice teams have become a trend around the country in an effort to decrease medication errors. When included as part of a patient team, pharmacists have been shown to reduce length of stay, reduce falls, improve patient and team communication, and improve outcome surveys as they relate to perception of teamwork, communication, and mutual respect (Reeves, Boet, Zierler, & Kitto, 2015).

A word of caution is necessary: Drug references may sometimes give incorrect information. Nurses must rely on common sense and good judgment. If a dose appears to be inaccurate in a reference source, nurses should always check with the prescriber or pharmacist before administering. In addition, some EHRs may have an automated drug reference available that may be accessed directly from the administration record. Whenever errors in drug references are encountered, nurses have a duty to contact the publisher of the inaccurate data, so that future medication errors may be prevented.

6.6 Thorough medication reconciliation is an important means of reducing medication errors.

Research suggests that inadequate medication reconciliation is a primary cause of many medication errors (Vecchione, 2016). **Medication reconciliation** is the "process of comparing the medications a patient is taking (and should be taking) with newly ordered medications. The comparison addresses duplications, omissions, and interactions, and the need to continue current medications. The types of information that clinicians use to reconcile medications include (among others) medication name, dose, frequency, route, and purpose. Organizations should identify the information that needs to be collected to reconcile current and newly ordered medications and to safely prescribe medications in the future" (The Joint Commission, 2015). Medication reconciliation should occur anytime there is a change in the site of the patient's care: admission to, transfer, or discharge from a healthcare facility, and with more care being given in community settings, anytime the patient seeks care from a provider.

The Joint Commission is responsible for monitoring healthcare safety for the public and evaluating healthcare organizations for safety standards. They are responsible for reviewing every patient safety event report to determine whether it relates to one or more Joint Commission standards. Medication reconciliation has been incorporated into The Joint Commission's National Patient Safety Goal 3, "Improve the safety of using medications." This national patient safety goal (NPSG) focuses on the risk points of medication reconciliation and is designed to help organizations reduce negative patient outcomes associated with medication discrepancies.

In 2015 The Joint Commission updated its recommendations on medication reconciliation under NPSG 3 to include the following:

- Obtain information on the medications the patient is currently taking when he or she is admitted to the hospital or in an outpatient setting with each interaction and appointment. Include a list of current medications taken at scheduled times and those taken on an as-needed basis. Examples of medication information that may be collected include name, dose, route, frequency, and purpose.
- Compare the medication information the patient brought to the hospital or clinic with the medications ordered for the patient by the hospital or clinic and resolve any discrepancies. Discrepancies include omissions, duplications, contraindications, unclear information, and changes.
- Provide written information about all medications the patient should be taking when he or she is discharged from the hospital or at the end of an outpatient clinic encounter.
- Take the time to explain the importance of managing medication information when the patient is discharged from the hospital or at the end of an outpatient encounter. Examples include instructing the patient to give a list to their primary care physician; to update the information when medications are discontinued, doses are changed, or new medications are added; and to carry medication information at all times in the event of emergency situations.

Many older adults have several chronic medical disorders concurrently, each of which may be treated by individual specialists. It is common for patients to receive multiple prescriptions, sometimes for the same condition, that have conflicting pharmacologic actions, a condition termed **polypharmacy**. Although not unique to older patients, polypharmacy is most often seen in the older age group. Keeping track of multiple medications, their doses, indications, routes, and frequency of administration is a major challenge for both patients and healthcare providers. Failure to properly record medication information and to communicate that information to healthcare providers is a potential cause of medication errors.

Information technology solutions are being widely studied and have the ability to help prevent medication duplications and discrepancies. Several studies have shown value and a decrease in medication errors with enhanced patient engagement in medication reconciliation in the outpatient setting and after hospital discharge (Heyworth et al., 2014; Mûnene & Ekman, 2015).

6.7 Adequate patient education and adherence are essential strategies for safe medication usage.

In the hospital setting, the physician, advanced practice nurse, nurse, and pharmacist are largely responsible for preventing medication errors, and they collaborate to ensure that the patient is receiving the correct drug in the manner designated by the prescriber. In the home setting, this responsibility relies on proper patient adherence to drug therapy. For prescription drugs, healthcare providers provide patients with verbal and written instructions on how and when to take the medication. Labels for OTC medications, herbal products, and dietary supplements indicate the correct method of taking the agent; however, patients do not always read or understand the information given.

Adherence is a major factor affecting pharmacotherapeutic outcomes and for increasing the risk of medication errors. As it relates to pharmacotherapy, **adherence** is defined as taking medications in the manner prescribed by the healthcare provider. In the case of OTC products, adherence means correctly following the instructions on the label. Patient nonadherence ranges from not taking the medication at all to taking it at the wrong time or at the wrong dose. It is estimated that out of the 3.8 billion prescriptions written each year in the United States, over half of them are taken incorrectly or not at all (Chesanow, 2014).

Many factors can influence patient adherence with pharmacotherapy. One of the most common sources of nonadherence is simply forgetting a dose of medication. This occurs frequently when the drug must be taken more than twice daily. Another source of nonadherence is that the drug may be too expensive or not approved by the patient's health insurance plan. Patients often discontinue the use of drugs that have annoying adverse effects or those that impair major lifestyle choices. Adverse effects that often prompt nonadherence are headache, dizziness, nausea, diarrhea, and impotence.

Patients often take medications in an unexpected manner, sometimes self-adjusting their doses. Some feel that if one tablet is good, two must be better. Others believe that they will become dependent on the medication if it is taken as prescribed, so they only take half the necessary dose. Still others simply stop taking the medication when they start feeling better. Patients are usually reluctant to admit or report nonadherence for fear of being reprimanded or feeling embarrassed.

The concept of adherence, or compliance, should be expanded to include patient-provider *concordance*. Compliance has been defined as "the extent to which the patient follows the health professionals' advice and takes the treatment"; adherence is "the extent to which a person's behavior—taking medication, following a diet, and executing lifestyle changes—corresponds with agreed recommendations from a healthcare provider"; and concordance as "agreement between the patient and healthcare professional, reached after negotiation that respects the beliefs and wishes of the patient in determining whether, when and how their medicine is taken, and (in which) the privacy of the person is recognized" (Poupoulas, n.d.). Concordance is integrated into a shared decision-making model of care, but may take time to develop between patient and provider. Early interactions may retain a paternalistic approach as the patient seeks information about treatment, with the healthcare professional providing treatment and the patient complying and adhering. As the patient learns more about his or her condition, disease, and treatment, a transition to more shared decision making occurs (Mathews, Coleska, Burns, & Chung, 2016). Transitioning to consensual prescribing using mutual patient and provider goal setting has been shown to improve medication compliance and patient outcomes (Bauer et al., 2014).

Because reasons for nonadherence are many and varied, the nurse must be vigilant in questioning patients about taking their medications. When pharmacotherapy fails to produce the expected treatment outcomes, nonadherence should always be considered as a possible explanation. There are steps the nurse can take to increase the potential for patient adherence to the therapeutic regimen. All of these steps focus on effective teaching. Knowing that patients often feel overwhelmed with the amount of information provided the nurse can discuss the prescription routine with the patient and ask questions: Will the patient be able to fill the prescription? How will it fit into the patient's usual routine or with other medications? Listening for clues that suggest the patient is overwhelmed by the routines, the nurse can ask further questions about what suggestions the patient might have to make the routine workable. Patients may be reluctant to discuss these suggestions with their provider but may feel comfortable doing so with the nurse because of the nurse–patient relationship.

In the plan of care, it is important to address essential information that the patient must know regarding the prescribed medications. This includes factors such as the name of the medication, why it has been ordered, expected drug actions, associated adverse effects, and information regarding interactions with other medications, foods, herbal supplements, or alcohol. Patients should be encouraged to take an active role in ensuring the effectiveness of their medication and their own safety. It is important to remember that, unless diagnosed as mentally incompetent, a well-informed adult always has the legal option of refusal to take any medication. It is the nurse's responsibility, however, to ensure that the patient has all the necessary information to make an informed decision.

For patients receiving outpatient therapy or those being released from a hospital, the nurse must carefully assess their ability to take their medications in a safe and effective manner. If the nurse believes that a patient may have difficulty in properly administering the medications, caregivers should be consulted and other arrangements made to ensure that the patient receives the correct drugs using the proper dosing schedule. With each successive healthcare visit, the nurse can review the medication history, asking questions about the prescribed medications. Being alert to reports that the patient is not taking, or is not taking correctly, the prescribed drugs may suggest an overwhelming, complex medication routine that needs to be reassessed if it is to be successful. Economic conditions sometimes result in difficult choices for patients between obtaining medications and other required necessities. Nurses provide medication education and follow-up that will result in positive health outcomes and the prevention of negative health effects and even larger expenditures as a result of poor medication adherence. Special considerations related to drug administration to pediatric and geriatric patients are presented in greater detail in Chapters 9 and 10, respectively.

PharmFACT

In the United States, almost half of adults, or approximately 117 million, have a diagnosis of at least one chronic condition and almost one third have a diagnosis of two or more chronic conditions. Of these 117 million people, 50% do not take their medications as prescribed and more than one quarter of the new prescriptions written for high blood pressure, diabetes, and high cholesterol, are never brought to the pharmacy to be filled (Gerteis et al., 2014).

6.8 Healthcare agencies are actively involved in reducing medication errors.

Most healthcare agencies use automated, computerized, locked cabinets for medication storage on patient care units. Each nurse on the unit has a code for accessing the cabinet and removing a medication dose. These automated systems also maintain an inventory of drug supplies. These systems are not foolproof, however, and the nurse must always perform system checks to ensure that the proper medication is in the correct patient drawer.

Large healthcare agencies often have **risk management** departments to examine risks and minimize the number of medication errors. Risk management personnel investigate incidents, track data, identify problems, and provide recommendations for improvement. Nurses collaborate with risk management committees to seek means of reducing medication errors by modifying policies and procedures within the institution. Examples of institutional policies and procedures include the following:

- Store medications under proper conditions (light and temperature control) and separate medications that have look-alike names or packaging.
- Read the drug label to avoid the administration of time-expired medications.
- Avoid the transfer of doses from one container to another.
- Avoid overstocking of medications.
- Monitor adherence to avoiding the use of prohibited prescription abbreviations.
- Remove outdated reference books.

6.9 Analytical tools may be used to identify risk and analyze errors.

Healthcare agencies use analytical tools to assess for the likelihood of errors and to analyze errors once they have occurred. Two such tools are the healthcare failure mode and effect analysis and root-cause analysis. These tools help agencies identify how errors occur and how to take steps to prevent them from occurring again.

In the case of medication administration, **healthcare failure mode and effect analysis (HFMEA)** identifies processes where errors may occur related to prescription, dispensing, and administration. Each process at risk for failure is analyzed and the severity and probability of each is determined. For example, when prescribing, an inaccurate assessment of the patient may occur. The level of the patient's pain may not be adequately assessed or the wrong analgesic may be chosen because of an inadequate consideration of all factors that may affect the use of that medication. The effects of these failures, if they occurred, might include poor pain control or the wrong drug or dose being prescribed. The severity of the failure may be estimated—catastrophic, major, moderate, or minor—and a severity score established. Catastrophic failures would rank as "4," whereas minor failures would rank as "1." The probability of a failure may also be ranked with possibilities ranging from frequent to remote. A "hazard score" is assigned, which is the severity score multiplied by the probability score (Cheng et al., 2012). In the above example of patient pain and the process of choosing (prescribing) an analgesic, the severity score for selecting an inappropriate analgesic for a patient with undiagnosed hepatic insufficiency may be catastrophic (ranked 4) and the probability of that occurring may be occasional (ranked 3). This would result in a hazard score of 12. The higher the hazard score, the more critical it is to identify strategies to prevent such a failure from occurring. Healthcare organizations use HFMEA as a risk management strategy to prevent health system errors of any kind from occurring.

Once an error has occurred, it is essential to analyze why it happened so that steps can be taken to prevent its recurrence. **Root-cause analysis (RCA)** attempts to focus

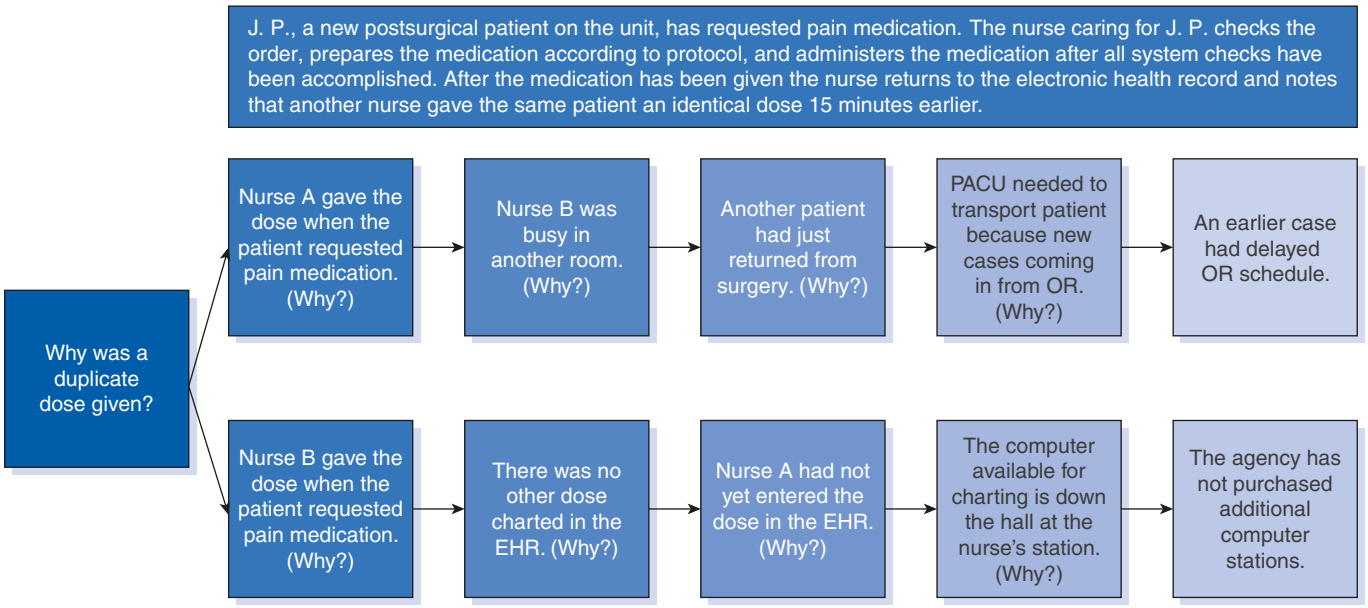

Figure 6.3 Sample root-cause analysis: duplicate dose of a narcotic analgesic.

attention on the causes of the error, rather than on the individual responsible for the error, so that patient harm can be reduced or eliminated through investigating system vulnerabilities (Latino, 2015). An analysis of what happened, why it occurred, and how to prevent it from happening again is conducted. RCA of medication errors is often interdisciplinary because of the many opportunities for errors to occur in various departments. An analysis of people, equipment or supplies, policies and procedures, and environmental factors involved in the error is included. For each category, "Why did the error occur?" is asked, with each question's answer prompting a further "Why?" question. This technique is sometimes called the "Five Whys" for this reason (iSixSigma, n.d.). There are many ways to diagram the analysis, and the nurse should utilize the tool(s) used in the specific healthcare agency. Figure 6.3 illustrates the beginning of a diagram for an error in which a duplicate dose of a narcotic analgesic was given after the patient returned from the recovery unit (PACU) from surgery (OR). Note that after asking "why" questions, causes are identified that involve equipment, procedures, and other departments. Each of those causes would also be examined to determine all possible remedies to prevent a recurrence.

Nurses aim to maximize patient safety by striving to be 100% accurate when administering medications. Drug administration, however, requires multiple complex steps accomplished by the entire healthcare team and can never be 100% error free. Being aware of potential areas that may increase medication errors and employing strategies to mitigate risk are integral components of the nursing role to ensure that pharmacotherapy provides maximum therapeutic effects with minimal harm.

Understanding Chapter 6

Key Concepts Summary

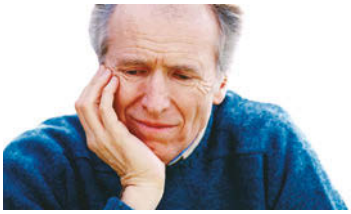
6.1 Medication errors are preventable events that may significantly impact treatment outcomes.

6.2 Medication errors may be caused by human factors, inadequate communication, or confusing labels, packaging, or drug names.

6.3 Certain drugs have higher rates of medication errors.

6.4 Medication errors must be properly documented and reported.

6.5 Nurses use multiple strategies for reducing medication errors.



6.6 Thorough medication reconciliation is an important means of reducing medication errors.

6.7 Adequate patient education and adherence are essential strategies for safe medication usage.

6.8 Healthcare agencies are actively involved in reducing medication errors.

6.9 Analytical tools may be used to identify risk and analyze errors.

CASE STUDY: Making the Patient Connection

Remember the patient "Ross Holland" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

What happened to Ross Holland was truly a tragedy. He entered the hospital for simple sinus surgery and never recovered. Ironically, Ross was a super-vigilant man. As a Vietnam veteran, he had seen the worst of combat for 4 years. During the last 6 months of the conflict, he survived in a prisoner of war camp. When he returned home, he took a job as a safety inspector in the automobile industry.

From a previous physical examination, Ross knew that he had a slightly irregular heartbeat, but he never really took it seriously. In fact, he never mentioned it to the nurse when she took his preoperative history. This condition became apparent soon after surgery though. The nurse caring for him noticed a series of cardiac dysrhythmias on the monitor and contacted the healthcare provider. The healthcare provider ordered Ross to receive a cardiac antidysrhythmic medication stat to correct the problem. In haste, the nurse never clarified the route that the medication was to be given. Additionally, the nurse was not familiar with the medication's usual dose or any precautions that needed to be taken. As a result, the medication was given by direct intravenous administration without being diluted as directed on the medication bottle. Ross was given 100 times the normal dose. Consequently, he experienced seizure activity that lasted 5 minutes followed by respiratory arrest. All efforts to resuscitate him were unsuccessful.

Critical Thinking Questions

1. Ultimately, who was responsible for this medication error? Ross? The healthcare provider? The nurse? Explain.
2. Identify the contributing factors that resulted in the error.
3. What strategies should the nurse have used to prevent the medication error?
4. What common policies should healthcare facilities implement to avoid medication errors?
5. What are the required reporting requirements for a medication error?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

A young mother brings her 6-month-old infant to the emergency department with a 3-day history of fevers, congestion, and increased irritability at night. The nurse practitioner diagnoses an acute otitis media (ear infection) and prescribes an oral antibiotic and acetaminophen (Tylenol) every 4 hours for pain and fever. The young mother appears weepy and concerned. When the nurse asks her why, she says, "Medications frighten me. When I give any of my children medications, I worry that I will make an error. There is so much that can go wrong."

1. How would you respond to this mother's concern?
2. Create a list of strategies that parents can use to prevent medication errors.
3. What referral resources could help reduce her anxiety?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. It is 2:45 a.m. and the nurse has telephoned the prescriber to report that the patient is experiencing an acute episode of postoperative pain. How can the nurse avoid medication errors when receiving a telephone order from a prescriber?
    1. Decline to accept the telephone order.
    2. Refuse to call the prescriber but attempt to comfort the patient.
    3. Instruct the patient's family to call the prescriber.
    4. Repeat the order verbally to ensure accuracy.
2. The nurse cannot read the number of milligrams (mg) to be administered in a drug order written by the healthcare provider. The nurse cannot determine whether 125 mg, 1.25 mg, or 12.5 mg should be administered. What action would be most appropriate to prevent a medication error?
    1. Telephone the healthcare provider about the illegible medication order.
    2. Ask another nurse to read the questionable medication order.

3. Contact the pharmacist about the medication order.
4. Consult a drug handbook and administer the normal dose.

3. The nurse is counseling the patient on a medication taken daily. Which strategy should the nurse include in this teaching session that might prevent a medication error?

1. Insist on trade-name drugs rather than generic drugs.
2. Have all prescriptions filled at one pharmacy.
3. Request all prescriptions be placed in easily opened containers.
4. Consult the internet about possible adverse effects.

4. When given a medication, the patient tells the nurse, "I've never seen this pill before. It's not like the others I take." Which would be the most appropriate action for the nurse to take?

1. Instruct the patient that different brands are frequently used.
2. Administer the medication in the existing form.
3. Verify the order and double-check the drug label.
4. Advise the patient to talk with the healthcare provider and give the drug.

5. While administering medication to several patients, the nurse suddenly realizes that the wrong medication has been given to a patient. Which would be the *first* priority action taken by the nurse?

1. Assess the patient in order to monitor for adverse effects.
2. Call the healthcare provider and report the error.
3. Complete the hospital's drug error form.
4. Report the medication error to the FDA.

6. As the nurse enters the room to administer medication, the patient states, "I'm in the bathroom. Please leave the medication on my bedside table, and I will take it when I come out." Which would be the appropriate response by the nurse?

1. "I will leave the medication and follow up with you in 30 minutes."
2. "You must take the medication now or refuse the dose."
3. "Let me know when you are ready, and I will then return with your medicine."
4. "I've given the drug to your visitors. Take it when you come out of the bathroom."

Chapter 7
The Role of Complementary and Alternative Therapies in Pharmacotherapy

Chapter Outline

- Types of Complementary and Alternative Therapies
- History of Herbal Therapies
- Standardization of Herbal Products
- Dietary Supplement Regulation
- Herb–Drug Interactions
- Specialty Supplements

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify specific types of complementary and alternative therapies that are used by patients to promote wellness.
2. Analyze why dietary supplements have steadily increased in popularity.
3. Explain why it is important to standardize herbal products based on specific active ingredients.
4. Describe legislation that governs the use of dietary supplements.
5. Describe drug interactions and adverse effects that may be caused by dietary supplements.
6. Distinguish between an herbal product and a specialty supplement.
7. Discuss the role of the nurse in teaching patients about complementary and alternative therapies.

Key Terms

botanical, 86

complementary and alternative medicine (CAM), 85

Dietary Supplement and Nonprescription Drug Consumer Protection Act, 89

Dietary Supplement Health and Education Act (DSHEA), 89

dietary supplements, 86

herb, 86

polyherbacy, 92

specialty supplements, 92

USP Verification Program, 90

Complementary and alternative medicine represents a multibillion dollar industry: Sales of dietary supplements exceed $32 billion annually (Garcia-Cazarin, Wambogo, Regan, & Davis, 2014). About one out of every three Americans uses complementary therapies (Clarke, Black, Stussman, Barnes, & Nahin, 2015). Despite the fact that these therapies have not been subjected to the same scientific scrutiny as prescription medications, consumers have turned to them for a variety of reasons. The availability of herbal and dietary supplements at a reasonable cost has convinced many consumers to try them, sometimes in lieu of prescription medications. This chapter focuses on the role of complementary and alternative therapies in the prevention and treatment of disease.

Types of Complementary and Alternative Therapies

7.1 Complementary and alternative therapies are used by a large number of people to prevent and treat disease.

Complementary and alternative medicine (CAM) comprises an extremely diverse set of therapies and healing systems that are considered to be outside of mainstream healthcare. Although diverse, the major CAM systems have certain common characteristics:

- Focus on treating the individual
- Consideration of the health of the whole individual
- Emphasis on the integration of mind and body
- Emphasis on disease prevention, self-care, and self-healing
- Recognition of the role of spirituality in health and healing.

Because of the widespread use of CAM by the public, the scientific community focused on determining the effectiveness, or lack of effectiveness, of these therapies. Although research into these alternative systems has been conducted, few CAM therapies have been subjected to rigorous, controlled clinical studies. It is likely that some of these therapies will be found ineffective, whereas others will become mainstream treatments. The definition of a complementary therapy as being "outside the mainstream" is somewhat ambiguous because the line between an alternative therapy and a conventional therapy is constantly changing. Increasing numbers of healthcare providers are now recommending CAM therapies to their patients. Table 7.1 lists the most common CAM therapies.

Nurses have long respected the value of CAM in preventing and treating certain conditions. Prayer, meditation, massage, and yoga have been used to treat both body and spirit for centuries. From a pharmacologic perspective the value of CAM therapies lies in their ability to reduce the need for medications. For example, if a patient can find anxiety relief through massage or biofeedback therapy, the use of antianxiety drugs may be reduced or eliminated. Reduction of drug dose leads to fewer adverse effects and better adherence to drug therapy.

Table 7.1 Complementary and Alternative Therapies

Healing Method	Examples
Biologic-based therapies	Herbal therapies
	Nutritional supplements
	Special diets
Alternative healthcare systems	Naturopathy
	Homeopathy
	Chiropractic
	Native American medicine (e.g., sweat lodges, medicine wheel)
	Chinese traditional medicine (e.g., acupuncture, Chinese herbs)
Manual healing	Massage
	Pressure-point therapies
	Hand-mediated biofield therapies
Mind–body interventions	Yoga, Pilates
	Meditation
	Hypnotherapy
	Guided imagery
	Biofeedback
	Movement-oriented therapies (e.g., music, dance)
Spiritual	Shamans
	Faith and prayer
Others	Bioelectromagnetics
	Detoxifying therapies
	Animal-assisted therapy

This chapter focuses on products used as dietary supplements. **Dietary supplements** are products available over the counter (OTC) that are intended to add to or supplement the nutritional value of the diet. The two subcategories of dietary supplements presented in this chapter include herbal products and specialty supplements. Vitamins and minerals, also considered dietary supplements, are presented in Chapter 61.

History of Herbal Therapies

7.2 Herbal products have been used as medicines for thousands of years.

An **herb** is technically a **botanical** (plant-based substance) that does not contain woody tissue such as stems or bark. In common usage, however, consumers tend to use "herb" to refer to a wide variety of products including substances such as ginkgo biloba (which is a tree) and chondroitin (which is derived from animals). Over time, the term *herb* has come to refer to any plant product with some useful application either as a food enhancer, such as flavoring, or as a medicine.

The use of herbs has been recorded for thousands of years. One of the earliest recorded uses was a prescription for garlic written in 3000 BC. Eastern and Western medicine have recorded thousands of herbs and herb combinations reputed to have therapeutic value. Over time, the popularity of specific herbs and remedies has varied, depending on the availability of the botanical (i.e., geographical region) and perceived effectiveness. The most popular herbals and their primary uses are shown in Table 7.2.

With the birth of the pharmaceutical industry in the late 1800s, the interest in herbal medicine began to wane. Synthetic drugs could be standardized and produced more cheaply than natural herbal products. Regulatory agencies required that products be safe and effective. The focus of healthcare was on diagnosing and treating specific diseases, rather than promoting wellness and holistic care. Most alternative therapies were no longer taught in medical or nursing schools. These healing techniques were criticized as being unscientific relics of the past.

Beginning in the 1970s and continuing to current times, alternative therapies and herbal medicine have experienced a remarkable resurgence, such that the majority of adult Americans are either currently taking herbal therapies on a regular basis or have taken them in the past. Why would people turn to folk remedies and products with uncertain effectiveness when effective prescription medications are available? This increase in popularity is due to a number of factors:

- Dietary supplements were once available only in specialty health food stores but can now be purchased in virtually all supermarkets and pharmacies.
- Complementary therapies are aggressively marketed by the supplement industry as viable and natural alternatives to conventional medicine. The increased availability of the internet as a marketing tool has led to sites with misleading information about the effectiveness of herbal and dietary supplements.
- The baby-boom generation has demonstrated a renewed interest in natural alternatives and preventive medicine.
- The gradual aging of the population has led people to seek therapeutic alternatives for chronic conditions such as pain, arthritis, anxiety, depression, hormone replacement therapy, and prostate difficulties.
- People have the impression that natural substances are safer than synthetic pharmaceuticals.
- The high cost of prescription medicines has driven people to seek less expensive alternatives.
- Nurses and other healthcare providers have been more proactive in promoting self-care and recommending CAM for their patients.

This text emphasizes CAM by the use of Connection features that appear throughout the chapters. The inclusion of these therapies is not an endorsement, nor does it imply their effectiveness. They are included because the nurse will frequently need to teach specific natural therapies, and because some of them have the potential to impact pharmacotherapy (see Section 7.5). The student should refer to the current medical literature for complete dosing and safety information. Several excellent sources of reliable information are available. The National Center for Complementary and Integrative Health (NCCIH) is a branch of the National Institutes of Health (NIH). It offers current information on research involving these products.

PharmFACT

In a study of almost 2000 Australian women, 34% used some form of herbal product during pregnancy. The most common reasons included anxiety, sleeping problems, and fatigue (Frawley et al., 2015).

Standardization of Herbal Products

7.3 Herbal products are available in a variety of formulations, some containing standardized extracts and others containing whole herbs.

The pharmacologically active chemicals in an herbal product may be present in only one specific part or in all parts of the plant. For example, the active chemicals in chamomile are in the aboveground portion such as the leaves, stems, or flowers. For other herbs, such as ginger, the underground roots are used for their healing properties. It is, therefore, essential to know which portion of the plant contains the active chemicals if growing or collecting herbs for home use.

Most prescription drugs contain only one active chemical. This chemical can be standardized and measured, so

Table 7.2 Popular Herbal Supplements

Herb	Medicinal Part	Primary Use(s)	Herb Feature (Chapter)
Acai	Berries	Vitamin and mineral supplement, antioxidant, possible weight loss	—
Aloe vera	Leaves	Topical application for minor skin irritations and burns	73
Bilberry	Berries and leaves	Terminate diarrhea, improve and protect vision, antioxidant	—
Black cohosh	Roots	Relieve symptoms of premenstrual syndrome and menopause	—
Chlorophyll/chlorella	Leaves	Improve digestion, vitamin and mineral supplement	—
Cranberry	Berries/juice	Prevent urinary tract infection	50
Echinacea	Entire plant	Enhance immune system, treat the common cold	42
Elderberry	Berries and flowers	Relieve congestion in respiratory system due to colds and flu	—
Evening primrose	Oil extracted from seeds	Relieve symptoms of premenstrual syndrome and menopause; relieve symptoms of rheumatoid arthritis and other inflammatory symptoms; source of essential fatty acids	—
Flaxseed (ground or oil)	Seeds and oil	Reduce blood cholesterol, laxative	35
Garlic	Bulbs	Reduce blood cholesterol, reduce blood pressure, anticoagulation	38
Ginger	Root	Antiemetic, antithrombotic, diuretic, promote gastric secretions, anti-inflammatory, increase blood glucose, stimulate peripheral circulation	—
Ginkgo	Leaves and seeds	Improve memory, reduce dizziness	21
Ginseng	Root	Relieve stress, enhance immune system, decrease fatigue	—
Grape seed	Seeds/oil	Source of essential fatty acids, antioxidant, restore microcirculation to tissues	34
Green tea	Leaves	Antioxidant; lower LDL cholesterol; prevent cancer; relieve stomach problems, nausea, vomiting	63
Horny goat weed	Leaves and roots	Enhance sexual function	—
Milk thistle	Seeds	Antitoxin, protection against liver disease	—
Red rice yeast extract	Dried in capsules	Reduce blood cholesterol	—
Saw palmetto	Berries	Reduce symptoms of benign prostatic hyperplasia	71
Soy	Beans	Source of protein, vitamins, and minerals; relieve symptoms of menopause, prevent cardiovascular disease, anticancer	69
Stevia	Leaves	Natural sweetener	—
St. John's wort	Flowers, leaves, stems	Reduce symptoms of depression and anxiety; anti-inflammatory	19
Valerian	Roots	Relieve stress, promote sleep	—
Wheat or barley grass	Leaves	Improve digestion, vitamin and mineral supplement	—

that the amount of drug received by the patient is precisely known. Herbs, however, may contain dozens of active chemicals, many of which have not yet been isolated, studied, or even identified. It is possible that some of these substances work together synergistically and may not have the same activity if isolated. Furthermore, the strength of an herbal preparation can vary from batch to batch, depending on where it was grown and how it was collected, prepared, and stored. How is it possible, then, for consumers to know the strength of an herbal product, given so much potential variability in ingredients?

To achieve consistency in the strength or dose of an herbal product, scientists have attempted to standardize herbal products. This standardization is based on one of the following methods:

- **Active ingredient extracts.** These standardize the amount of biologically active substances in the herb. For example, the active ingredient in saw palmetto has been determined to be fatty acids; therefore, these are used to standardize extracts of this herb.
- **Marker extracts.** These standardize the potency of the herb based on a common substance in the whole herb that may not be the active ingredient. For example, ginseng is standardized on the percent of ginsenosides in the extract.

Regardless of which method is used, standardization allows the consumer to compare products and know the strength of the herb. Some of these standardizations are shown in Table 7.3. Note that the active ingredient in an

Table 7.3 Standardization of Selected Herbal Products

Herb	Standardization	Percent
Black cohosh rhizome	Triterpene glycosides	2.5
Cascara sagrada bark	Anthocyanosides	25
Echinacea purpurea, whole herb	Echinacosides	4
Ginger rhizome	Pungent compounds (gingerols)	>10
Ginkgo leaf	Flavone glycosides	24–25
	Lactones	6
Ginseng root	Ginsenosides	5–15
Milk thistle root	Silymarin	80
St. John's wort, whole herb	Hypericins	0.3–0.5
	Hyperforin	3–5
Saw palmetto berries	Fatty acids and sterols	80–90

herb is not always known and there may be more than one. Furthermore, the active ingredient may be different, depending on the indication for which the herb is being used. Until science can better characterize these substances, it is best to conceptualize the active ingredient of an herb as being the entire herb. An example of the ingredients and standardization of ginkgo biloba using a marker substance is shown in Figure 7.1. As explained in Section 7.4, it should not be assumed that an herb is safe or effective simply because it contains the standard amount of extract.

PharmFACT

Ruiz et al. (2016) tested eight common herbal products and found that the amount of marker substance varied substantially among manufacturers. More importantly, there was no correlation between the amount of marker substance and the biological activity of the herb.

Table 7.4 Liquid Formulations of Herbal Products

Product	Description
Decoction	Fresh or dried herbs are boiled in water for 30–60 min until much of the liquid has boiled off; very concentrated
Extract	Active ingredients are extracted using organic solvents to form a highly concentrated liquid or solid form; solvent may be removed or be part of the final product
Infusion	Fresh or dried herbs are soaked in hot water for long periods, at least 15 min; stronger than teas
Tea	Fresh or dried herbs are soaked in hot water for 5–10 min before ingestion; convenient
Tincture	Active ingredients are extracted using alcohol by soaking the herb; alcohol remains as part of the liquid

The two basic formulations of herbal products are solid and liquid. Solid products include pills, tablets, and capsules made from the dried herbs. Other solid products are salves and ointments that are administered topically. Liquid formulations are made by extracting the active chemicals from the plant using solvents such as water, alcohol, or glycerol. The liquids are then concentrated in various strengths and ingested. The types of liquid herbal formulations are described in Table 7.4. Figure 7.2 illustrates some of the formulations of ginkgo biloba, one of the most popular herbals.

Dietary Supplement Regulation

7.4 Dietary supplements are not regulated in the same manner as prescription medications.

Since the passage of the Food, Drug, and Cosmetic Act in 1936, Americans have come to expect that all approved prescription and OTC drugs have passed rigid standards of safety prior to being marketed. Furthermore, it is expected that these drugs have been tested for effectiveness and that they truly provide the medical benefits claimed by the

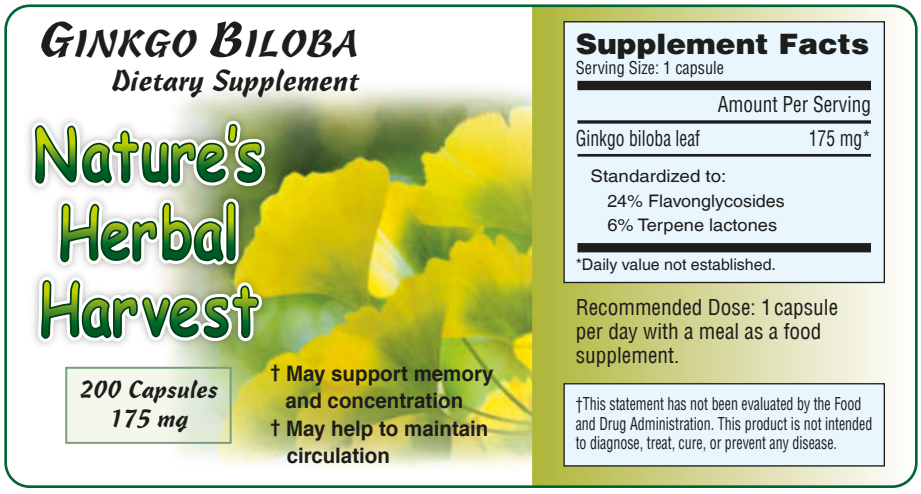

Figure 7.1 Ginkgo biloba label. This label indicates the product is standardized to percentages of the two active ingredients, flavonglycosides and terpenes, that are found in the ginkgo leaf. Also note the health claims on the label, which have not been evaluated by the FDA.

Figure 7.2 Three different ginkgo formulations: tablets, tea bags, and liquid extract.

manufacturer. Indeed, most people would be outraged if they found out that the drug they purchased for pain relief or to cure an infectious disease was totally ineffective. For dietary supplements, however, Americans cannot and should not expect the same quality standards. These products are regulated by a far less rigorous law, the **Dietary Supplement Health and Education Act (DSHEA)**.

The DSHEA exempts dietary supplements from the Food, Drug, and Cosmetic Act, the legislation that regulates prescription drugs. Because they are not classified as drugs or approved by the U.S. Food and Drug Administration (FDA), they are not subjected to the same degree of scrutiny as drugs.

A strength of the DSHEA is that it gives the FDA the authority to remove from the market any dietary supplement that poses a "significant or unreasonable" risk to the public. The FDA used this legislative authority when the dietary supplement ephedra was removed from the market because of reported serious side effects in some patients. However, it took 7 years from the time the FDA first warned consumers of the dangers of ephedra until it was removed.

The DSHEA requires these products to be clearly labeled as "dietary supplements." The product label must state that the dietary supplement is not intended to diagnose, treat, cure, or prevent any disease. However, the label may make claims about the product's effect on body structure and function, such as the following:

- Helps promote healthy immune systems.
- Reduces anxiety and stress.
- Helps to maintain cardiovascular function.
- May reduce pain and inflammation.

An example of a dietary supplement label for L-carnitine is shown in Figure 7.3.

Unfortunately, the DSHEA has significant flaws that lead to a lack of standardization in the dietary supplement industry and less protection for the consumer. These flaws include the following:

- The manufacturer does not have to test the safety of a dietary supplement prior to marketing. If it is to be removed from the market, the FDA has the burden of proving that the dietary supplement is harmful.
- Effectiveness does not have to be demonstrated by the manufacturer.
- The accuracy of the label is not regulated; the product may or may not contain the product listed in the amounts claimed.

Figure 7.3 L-carnitine is a popular dietary supplement. Notice the labels imply that their use may improve athletic performance and cause weight loss, neither of which has been supported by the scientific literature.

Lax government oversight has resulted in a lack of quality and sometimes blatant mislabeling of herbal and supplement products. For example, testing of more than 1200 dietary supplement products has determined that 25% did not contain the correct amount of labeled ingredients. In some cases, the products contained none of the ingredients claimed on the label, and others were contaminated with potentially dangerous heavy metals such as cadmium and lead.

Several steps have been taken to address the lack of purity and mislabeling of herbal and dietary supplements. In 2007, Congress passed the **Dietary Supplement and Nonprescription Drug Consumer Protection Act**. Companies that market dietary supplements are now required to include their contact information (address and phone number) on the product labels so consumers can report adverse events. Companies must notify the FDA of any serious adverse event reports within 15 days of receiving such reports. Under this act, a "serious adverse event" is defined as any adverse reaction resulting in death, a life-threatening

experience, inpatient hospitalization, a persistent or significant disability or incapacity, or a congenital anomaly or birth defect, as well as any event requiring a medical or surgical intervention to prevent one of these conditions based on reasonable medical judgment. Companies must keep records of such events for at least 6 years, and the records are subject to inspection by the FDA.

Also in 2007, the FDA announced a final rule that requires the manufacturers of dietary supplements to evaluate the identity, purity, potency, and composition of their products. The labels must accurately reflect the content of the products, which must be free of contaminants such as pesticides, toxins, glass, or heavy metals. The rule was phased in over a 3-year period.

The U.S. Pharmacopeial Convention (USPC) is a nonprofit public health organization that has attempted to raise the standards and quality of pharmaceuticals and dietary supplements (see Chapter 1). The organization publishes a large compendium of drug information annually, called the *United States Pharmacopoeia* (USP). The USPC has developed a voluntary process by which a manufacturer may submit a product for the **USP Verification Program**. Using a multistep approach, the USPC examines the manufacturing processes used to create a supplement and tests the product to see if it contains the ingredients specified on the label and whether the product will break down and release its ingredients in the body (bioavailability). If the product meets the stringent standards of the USP, it may then carry the USP verified dietary supplement mark on the label. The verification mark indicates to consumers that the product has been manufactured under acceptable standards of purity, has been tested for active ingredients stated on the label, and is free of harmful contaminants. However, it does not indicate that the product is safe or effective.

PharmFACT

A recent examination of the use of dietary supplements included the following statistics (Interlandi, 2016):

- Supplement sales have increased by 81% in the past 10 years.
- In a physician survey, 45% responded that they recommend herbal supplements.
- Each year 23,000 people end up at emergency departments after taking a supplement.
- There are 15,000 manufacturers of dietary supplements, but fewer than 400 have been inspected since 2010.
- In 2015, four out of five supplements tested by the State Attorney General Office in New York did not contain the herbs listed on the label.

CONNECTION Checkpoint 7.1

From what you learned in Chapter 2, what is a pharmacopeia? What function does it serve in the United States? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Herb–Drug Interactions

7.5 Herbal products may have pharmacologic actions and can interact with conventional drugs.

A key concept to remember when learning about alternative therapies is that "natural" is not synonymous with "better" or "safe." It is likely that some botanicals do indeed contain active chemicals that are as powerful as, and perhaps more effective than, some currently approved medications. Thousands of years of experience, combined with current scientific research, have shown that some of these herbal remedies have therapeutic actions. Just because a substance comes from a natural product, however, does not make it safe or effective. For example, poison ivy is natural but it certainly is not safe or therapeutic. The dried seed pods of the poppy plant yield opium, which has therapeutic effects but can also kill if taken inappropriately. Some natural products may not offer an improvement over conventional therapy in treating certain disorders and, indeed, may be of no value whatsoever. Furthermore, a patient who substitutes an unproven alternative therapy for an established, effective medical treatment may delay healing and cause irreparable harmful effects.

Some herbal products contain ingredients that may cause additive, synergistic, or antagonistic interactions with prescription or OTC drugs. For example, ginkgo biloba and ginger have the ability to increase bleeding time. If used concurrently with anticoagulants, these herbs may increase the potential for adverse bleeding events. St. John's wort, kava, and valerian cause relaxation and may result in excessive sedation if taken concurrently with central nervous system (CNS) depressants. A few herbals have organ-specific toxicity. The herb comfrey given concurrently with large doses of acetaminophen may increase the patient's risk of hepatotoxicity. Herbals such as psyllium, aloe, and flaxseed may bind to drugs in the gastrointestinal (GI) tract, thus slowing their absorption.

The true extent of herb–drug interactions is unknown. Most reports in the medical literature are anecdotal, often given as a case report on a single patient. It is often impossible to know the exact amount of herb taken because there is such a wide variation in the quality of products on the market or even to know what chemical within the herb (either active ingredients or contaminants) may have caused the reported interaction. Relatively few controlled scientific studies of herb–drug or dietary supplement–drug interactions have been conducted. The majority of the information regarding these interactions is theoretical, rather than clinically based.

Questions on the use of herbal supplements are important because these products are contraindicated for certain patients. Patients taking medications with potentially serious adverse effects such as insulin, warfarin (Coumadin), antiepileptic drugs, antineoplastic agents, or digoxin

(Lanoxin) should be warned to never take any dietary supplement without first discussing their needs with a healthcare provider. Pregnant or lactating women should not take these products without approval of their healthcare provider. The nurse should also remember that the potential for any drug interaction increases in older adults, especially those with hepatic or renal impairment. Potential drug interactions with selected herbs are shown in Table 7.5.

Another warning that must be heeded with natural products is to beware of allergic reactions. It is not unusual to find dozens of different chemicals in teas and infusions made from the flowers, leaves, or roots of a plant. Patients who have known allergies to food products or medicines should seek medical advice before taking a new herbal product. It is always wise to take the smallest amount possible when starting herbal therapy, even less than the recommended dose, to see if allergies or other adverse effects occur.

Nurses have an obligation to seek the latest medical information on herbal products, because there is a good possibility that their patients are using them to supplement traditional medicines. Each patient who takes an herbal product does so for a reason. The nurse needs to listen, assess, and understand the patient's goals for taking the supplement. Does the patient have an accurate understanding of the

Table 7.5 Documented Herb–Drug Interactions

Common Name (Scientific Name)	Interacts with	Effects of Interaction
Echinacea (*Echinacea purpurea*)	amiodarone, anabolic steroids, ketoconazole, methotrexate	May increase hepatotoxicity
Feverfew (*Tanacetum parthenium*)	aspirin and other NSAIDs, heparin, warfarin	Increases bleeding risk
Flaxseed (*Linum usitatissimum*)	most drugs	Binds to drugs; decreases absorption
Garlic (*Allium sativum*)	aspirin and other NSAIDs, warfarin	Increases bleeding risk
	insulin, oral antidiabetic drugs	Has additive hypoglycemic effects
	saquinavir	Induces CYP3A4 enzymes; decreases drug effectiveness
Ginger (*Zingiber officinale*)	aspirin and other NSAIDs, heparin, warfarin	Increases bleeding risk
Ginkgo (*Ginkgo biloba*)	anticonvulsants	Decreases drug effectiveness
	tricyclic antidepressants	May decrease seizure threshold
	omeprazole	Induces CYP2C19 enzymes; decreases drug effectiveness
	trazodone	Increases drug effects
Ginseng (*Panax quinquefolius/ Eleutherococcus senticosus*)	CNS depressants digoxin diuretics insulin, oral antidiabetic drugs	Potentiates sedation Increases toxicity May attenuate diuretic effects Increases hypoglycemic effects
	MAO inhibitors	May cause hypertension, manic symptoms, headaches, nervousness
	Warfarin	Decreases anticoagulant effects
Goldenseal (*Hydrastis canadensis/ Eleutherococcus senticosus*)	Diuretics	May attenuate diuretic effects
Green tea	Warfarin	Decreases anticoagulant effects
Kava kava (*Piper methysticum*)	barbiturates, benzodiazepines, alcohol and other CNS depressants	Potentiates sedation
	levodopa/carbidopa	Worsens Parkinson's symptoms
	phenothiazines	Increases risk and severity of dystonic reactions
Soy	Warfarin	Decreases anticoagulant effects
St. John's wort (*Hypericum perforatum*)	opioids, alcohol, and other CNS depressants	Potentiates sedation
	cyclosporine	May decrease cyclosporine levels
	efavirenz, indinavir	Decreases antiretroviral activity
	MAO inhibitors	May cause hypertensive crisis
	oral contraceptives	Decreases drug effectiveness
	selective serotonin reuptake inhibitors, tricyclic antidepressants	Increases risk of serotonin syndrome
	warfarin	Decreases anticoagulant effects
Valerian (*Valeriana officinalis*)	barbiturates, benzodiazepines and other CNS depressants	Potentiates sedation

CONNECTIONS: Preparing for Advanced Practice

Older Adults at Risk for Polyherbacy

Case

Mrs. Danville is an 84-year-old woman who came to the Geriatric Primary Care Clinic with new complaints of general fatigue and frequent falls. While taking her health history and conducting her medication reconciliation, you discover she has a history of hypertension, hyperlipidemia, glaucoma, and stroke. Her medications include lisinopril (Prinivil) and hydrochlorothiazide (Microzide), glaucoma eyedrops, low-dose aspirin, and OTC dietary supplements. She is cognitively and functionally intact, with vital signs showing a pulse rate of 76 beats/min lying down and 94 beats/min standing up. Blood pressure was 138/72 mmHg lying down and 130/70 mmHg standing up; respiratory rate, 16 breaths/min; and temperature, 37.2°C (99°F). Examination of her neurologic system, lungs, heart, abdomen, and extremities were all within normal limits for her age. Laboratory work showed a normal complete blood count without any signs of infection or anemia. Vitamin B_{12} level, electrolytes, renal and liver laboratory findings were normal. Her thyroid-stimulating hormone (TSH) was decreased.

On consultation with the community pharmacist you discover her specific dietary supplements include sea algae, alfalfa, bee pollen, barley malt, licorice, ginseng, ginkgo biloba, and many other herbs. You begin researching these herbs and wonder if they may be contributing to her complaints.

Discussion

Although healthcare providers assess for polypharmacy, older patients may not divulge the use of herbs and supplements. **Polyherbacy,** the use of multiple herbs or dietary supplements, may also be present. Healthcare providers should always inquire about herbal use as a routine part of history taking and medication reconciliation and should be aware of the side effects that may result from the use of such products (Gardenier, Woods, & Earp, 2016).

In older adults potential risk for adverse herb–disease interactions can be significant. The following potential adverse herb–disease interactions were identified in Mrs. Danville's case:

- Ginseng may exacerbate hypotension (Kutt et al., 2016).
- Ginkgo biloba may increase the risk of bleeding in a patient with falls and those using aspirin (Kutt et al., 2016).
- Licorice and ginseng have been linked to hypertension (Kutt et al., 2016).
- Sea algae may precipitate hyperthyroidism due to its high iodine content (Combet, Ma, Cousins, Thompson, & Lean, 2014).

actions of the herb? Are there more effective therapies, either pharmacologic or nonpharmacologic, for the patient's condition? Is there a potential for harmful effects from the product due to high doses or herb–drug interactions? Establishing a supportive attitude toward the use of CAM is important. Nurses often need to educate their patients on the role of alternative therapies in the treatment of their disorder and discuss which treatment or combination of treatments will best meet their patients' health goals. Patients should be advised to be skeptical of marketing claims for herbal products and to seek health information from reputable sources.

CONNECTION Checkpoint 7.2

St. John's wort induces hepatic CYP metabolic enzymes. From what you learned in Chapter 5, how could this herb affect therapy with antidepressants or benzodiazepines that are substrates for CYP enzymes? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Specialty Supplements

7.6 Specialty supplements are nonherbal dietary products that are widely used to promote wellness.

Specialty supplements are dietary products used to enhance or complement a specific function in the body, such as supporting joint health or immune function. These supplements form a diverse group of products obtained from plant and animal sources that include probiotics, fish oils, amino acids, and enzymes. Like herbal therapies, they are available OTC and are widely used by patients to enhance wellness. However, they are more specific in their action than herbal products and are generally targeted for one condition or a smaller group of related conditions. Popular specialty supplements are listed in Table 7.6.

In general, specialty supplements have a legitimate rationale for their use. For example, chondroitin and glucosamine are natural substances in the body necessary for cartilage growth and maintenance. Amino acids are natural building blocks of muscle protein. Flaxseed and fish oils contain omega fatty acids that have been shown to reduce the risk of heart disease in certain patients.

As with herbal products, the link between most specialty supplements and their intended benefits is unclear. In most cases, the body already has sufficient quantities of the substance; thus taking additional amounts may be of no benefit. In other cases, the supplement may be marketed for conditions for which the supplement has no proven effect. The good news is that these substances are generally not harmful unless taken in large amounts. The bad news, however, is that they can give patients false hopes of an easy cure for chronic conditions such as heart disease or the pain of arthritis. As with herbal products, the healthcare provider should advise patients to be cautious about the health claims regarding the use of specialty supplements.

Table 7.6 Selected Specialty Supplements

Name	Primary Uses	Supplement Feature (Chapter)
Amino acids	Build protein, muscle strength, and endurance	—
Carnitine	Enhance energy and sports performance, heart health, memory, immune function, and male fertility	—
Chromium	Treat diabetes	—
Coenzyme Q10	Prevent heart disease, provide antioxidant therapy	29
DHEA	Boost immune and memory functions	—
Fish oil	Reduce cholesterol levels, enhance brain function, and increase visual acuity	68
Glucosamine and chondroitin	Reduce the pain of arthritis and other joint conditions	72
Lactobacillus acidophilus	Maintain intestinal health	60
Melatonin	Reduce sleeplessness and jet-lag during travel	18
Methyl sulfonyl methane (MSM)	Reduce allergic reactions to pollen and foods, relieve pain and inflammation of arthritis	—
Selenium	Reduce the risk of certain types of cancer	—
Vitamin C	Prevent colds	45

Understanding Chapter 7

Key Concepts Summary

7.1 Complementary and alternative therapies are used by a large number of people to prevent and treat disease.

7.2 Herbal products have been used as medicines for thousands of years.

7.3 Herbal products are available in a variety of formulations, some containing standardized extracts and others containing whole herbs.

7.4 Dietary supplements are not regulated in the same manner as prescription medications.

7.5 Herbal products may have pharmacologic actions and can interact with conventional drugs.

7.6 Specialty supplements are nonherbal dietary products that are widely used to promote wellness.

CASE STUDY: Making the Patient Connection

Remember the patient "Larry Bunch" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Sixty-nine-year-old Larry Bunch was not only frustrating his daughter, but his forgetfulness was annoying him as well. Since the death of his wife 2 years ago, his forgetfulness seemed to be worsening. To remedy the situation, he purchased a bottle of ginkgo biloba at the health food store and began taking the supplement about 6 months ago.

Larry was hospitalized 3 years ago for atrial fibrillation. When he was discharged from the hospital, he was placed on an anticoagulant therapy to decrease his risk for a stroke. Today, Larry comes to his healthcare provider's office for a scheduled blood test to determine the effectiveness of his anticoagulant.

When the results from the blood test return, it is noted that Larry's coagulation time is abnormally high and he is at high risk of hemorrhaging. As the nurse, you note that his vital signs are within normal limits, and he states he feels well. However, you also observe some large bruises on Larry's arms, which he cannot explain.

Critical Thinking Questions

1. What is the relationship between this patient's use of ginkgo and the laboratory results?
2. What instructions should this patient receive about taking the supplement?
3. Discuss the hazards that patients face when using complementary and alternative therapies.
4. What should the healthcare provider do concerning Larry's forgetfulness?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

"It must be safe, after all, it is sold in the grocery store!" exclaimed Linda. As you, the nurse, talk with the patient, Linda Thomas, she explains to you that she takes multiple OTC dietary supplements. Because the bottle states that the ingredients are "all natural," she knows it must be good for her.

1. What are the hazards associated with believing that all medication-type substances sold in the supermarket are safe?
2. Discuss how the words "all natural ingredients" can be confusing.
3. Identify the nurse's role in working with patients who participate in complementary and alternative therapies.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient asks why all healthcare providers do not rely on complementary and alternative medicine. When talking to this patient, the nurse knows that many complementary and alternative therapies:
   1. Have not been subjected to rigorous clinical studies.
   2. Consist only of old wives' tales and fables.
   3. Only provide a placebo effect.
   4. Are costly and not worth the risk.
2. Which health teaching concept should be included in the instructions for a patient taking echinacea?
   1. Dosage can be doubled if symptoms fail to resolve in 48 hours.
   2. Limit fluid intake while taking this supplement.
   3. Take the smallest amount possible when starting herbal therapy.
   4. Allergic reactions are not possible with natural supplements.
3. Which patient is most likely to experience drug toxicity while taking dietary supplements?
   1. An 80-year-old woman with cirrhosis
   2. A 58-year-old man with cardiac irregularities
   3. A 30-year-old woman with pneumonia
   4. An 18-year-old man with chronic acne
4. The patient asks the nurse, "Why are dietary supplements so popular?" The nurse's answer is based on which factors? (Select all that apply.) Herbal supplements:
   1. Can now be purchased in virtually all supermarkets.
   2. Are aggressively marketed by the herbal and supplement industry.
   3. Cost less than prescription medicines.
   4. Are safer than synthetic pharmaceuticals.
   5. Appeal to the aging population.
5. The nurse is teaching at a community wellness seminar when one participant asks, "How can I be sure that my herbal supplement is pure?" Which of the following labeling marks indicates that the product meets acceptable standards of purity?
   1. USP verified dietary supplement mark
   2. DEA prescriber number
   3. FDA identification and regulation code
   4. U.S. Customs Service integers
6. Polyherbacy may be of concern in the older adult population. A pharmacokinetic factor for this concern is that the older adult:
   1. Is more likely to have difficulty using herbal products correctly.
   2. May spend too much on herbal products rather than prescriptions.
   3. May hold unrealistic expectations for the outcomes of herbal therapy.
   4. May have age-related changes in liver or kidney function.

See Answers to Chapter Review in Appendix A.

Pharmacology and the Nurse–Patient Relationship

CHAPTER 8 Pharmacotherapy During Pregnancy and Lactation / 98

CHAPTER 9 Pharmacotherapy of the Pediatric Patient / 110

CHAPTER 10 Pharmacotherapy of the Geriatric Patient / 123

CHAPTER 11 Individual Variations in Drug Responses / 133

"I've been so nauseated every morning during the past 3 weeks and I'm late with my period. Please tell me I'm not pregnant. I just can't deal with a baby right now."
Patient "May David"

Chapter 8
Pharmacotherapy During Pregnancy and Lactation

Chapter Outline

- Rationale for Drug Use During Pregnancy and Lactation
- Pharmacotherapy During Pregnancy
  - Changes in Pharmacokinetic Variables During Pregnancy
  - Placental Transfer of Drugs from Mother to Infant
  - FDA Fetal Risk Categories
  - Adverse Drug Effects During Pregnancy
- Pharmacotherapy During Lactation
  - Transfer of Drugs into Breast Milk
  - Adverse Drug Effects During Lactation

Learning Outcomes

After reading this chapter, the student should be able to:

1. Discuss the rationale for using drugs during pregnancy and lactation.
2. Describe physiologic changes during pregnancy that may affect the absorption, distribution, metabolism, and excretion of drugs.
3. Describe the placental transfer of drugs from mother to infant.
4. Differentiate among the U.S. Food and Drug Administration pregnancy risk categories.
5. Explain how drugs administered during the different stages of fetal development affect the potential for teratogenic effects.
6. Identify factors that influence the transfer of drugs into breast milk.
7. Describe signs of adverse drug reactions in the breastfeeding infant.
8. Outline important points in patient and family education regarding drug use during pregnancy and lactation.

Key Terms

placenta, 100 **pregnancy categories, 101** **teratogen, 103**

The prescribing and administration of medications to pregnant women require special precautions. The nurse must be aware of the physiologic changes occurring in the pregnant woman along with the developmental stage of the fetus. The nurse must also be able to identify potential adverse drug events occurring in both the mother and the fetus. This chapter describes the pharmacokinetic changes that occur during pregnancy and explains the importance of carefully monitoring the pharmacotherapy of pregnant and lactating women. Emphasis is placed on drugs to avoid or use cautiously, strategies to prevent adverse effects, and the importance of patient and family education.

Rationale for Drug Use During Pregnancy and Lactation

8.1 Women frequently use drugs during pregnancy and lactation.

The nurse caring for the pregnant or lactating woman faces the challenge of concurrently being responsible for the health and safety of two people, knowing that most medications cross the placenta and are secreted in breast milk. Despite potential risks to the fetus, it is estimated that 90% of women will take at least one medication during their pregnancy, and more than 80% of pregnant women report taking medication during their first trimester. The number of women taking drugs during pregnancy continues to increase as maternal age increases and with the increasing use of medications in developed countries (Mazer-Amirshahi, Samiee-Zafarghandy, Gray, & van den Anker, 2014).

With the availability of the internet, many women search online for drug information that, in many cases, is unclear. By identifying women who may have lower health literacy skills, community-based nurses, pharmacists, and other healthcare personnel can assist women to find and use appropriate information about drugs used in pregnancy and tailor education according to the needs of each individual patient (Hämeen-Anttila et al., 2015).

Healthcare providers always exercise great caution when initiating pharmacotherapy during pregnancy or lactation. Drug therapy is often postponed until after delivery and lactation; if that is not possible, safer nonpharmacologic alternatives may be implemented. Certain acute and chronic conditions, however, must be managed with medications during pregnancy. These include the following:

- **Treatment of certain preexisting illnesses.** If the patient has preexisting epilepsy, asthma, hypertension, or a psychiatric disorder, it would be unwise to discontinue pharmacotherapy during pregnancy or lactation.
- **Treatment of complications related to pregnancy.** Thromboembolic disorders, gestational diabetes, and gestational hypertension may occur during pregnancy and must be treated for the safety of both the mother and growing fetus.
- **Treatment of conditions unrelated to pregnancy.** Antibiotics may be necessary to treat infections acquired during pregnancy. Acute urinary tract infections and sexually transmitted infections have the potential to harm the mother or fetus if undetected or inadequately treated.

The goal of pharmacotherapy in pregnant patients is to treat the mother without causing ill effects for the fetus. Often, pharmacotherapy can be safely conducted with the same drugs and dosage levels as in nonpregnant patients. In other cases, a medication may need to be discontinued, changed to a lower dose, or replaced with a safer drug. In all pregnant patients, healthcare providers must carefully consider the therapeutic value of a given medication against its potential adverse effects.

Pharmacotherapy During Pregnancy

8.2 Physiologic changes during pregnancy can alter normal pharmacokinetic responses.

Most body systems in a woman undergo predictable changes during pregnancy. Some organs increase in size. Some physiologic activities speed up while others slow down, altering the pharmacokinetic responses to drugs. The healthcare provider must understand these changes in maternal physiology when prescribing drugs for the pregnant woman (Figure 8.1).

Absorption: During pregnancy, increased levels of progesterone cause a decrease in gastric tone and intestinal motility, resulting in delayed gastric emptying. Drugs remain longer in the gastrointestinal (GI) tract, leading to extended time for absorption of oral drugs. High estrogen levels in the pregnant woman cause increased hydrochloric acid production in the stomach, which may affect the absorption of certain acid labile drugs. Furthermore, as the enlarging uterus rises into the abdomen it presses up against the stomach, leading to slower gastric emptying. Medications may take a longer time to be absorbed and

Figure 8.1 Teaching women about the safety of drug use during pregnancy is an essential component of nursing care.
Courtesy of Flying Colors/Photodisc/Getty Images.

distributed, thus prolonging their onset and durations of action. Some women experience nausea and vomiting and are unable to take oral medications during early pregnancy.

Progesterone also increases pulmonary blood flow, respiratory tidal volume, and minute volume by 40%. As a result, respiratory drugs may be absorbed in larger quantities, leading to higher serum drug levels.

Distribution: Distribution of drugs during pregnancy is affected by changes in total body water, which may increase by over 50%. This increase leads to greater hemodilution of plasma proteins and drugs. Because the plasma proteins are diluted, fewer are available to bind with drugs, thus causing a higher concentration of "free" drug in the plasma. This results in more drug molecules being available for transfer across the placenta or to be secreted in breast milk. Highly lipophilic drugs are distributed into the lipid-rich breast milk and are ultimately passed to the breastfeeding infant. A woman's heart rate may increase up to 15 beats per minute during pregnancy, leading to greater drug distribution.

Metabolism: It was originally thought that metabolism was the pharmacokinetic process least affected by pregnancy. Evidence, however, suggests that metabolism is significantly altered throughout pregnancy.

Some of the cytochrome P450 enzymes increase, noticeably CYP2D6 and CYP3A4, whereas others such as CYP1A2 decrease. Researchers have also found that a single CYP enzyme system may have multiple alleles, different genetic forms of the same enzyme. Because of these unique differences among individuals, even knowing the pathway through which a drug is metabolized will not always accurately predict how that drug will be metabolized. The fetal liver is still developing throughout this time and lacks the ability to metabolize most drugs received from the mother's system. Lifestyle factors, such as smoking and eating broccoli or other cruciferous vegetables, may also alter how an enzyme system metabolizes a drug. Until more is learned about how drug metabolism is affected during pregnancy, providers should use caution when prescribing any drug during this time and limit prescriptions to those drugs known to have demonstrated a low-risk safety profile.

Excretion: Excretion of drugs during pregnancy is enhanced by renal plasma flow, which can increase 50% to 70% during the first two trimesters. This increased flow leads to a higher glomerular filtration rate and marked decreases in blood urea nitrogen (BUN) and creatinine levels. Because these changes result in the increased renal elimination of drugs, doses of many medications must be adjusted.

CONNECTION Checkpoint 8.1

From what you learned in Chapter 3, what effects on drug metabolism may occur if a woman required any of the following drugs during pregnancy: acetaminophen, sertraline, or propranolol? (See Table 3.1 for specific CYP450 enzymes listings.) *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

8.3 Many drugs pass from mother to infant via the placenta.

The **placenta** is a temporary organ that allows for nutrition and gas exchange between the mother and fetus. As much as 10% of the mother's cardiac output circulates through the placenta. Although the blood of the mother does not circulate through the fetus, capillary-like structures in the placenta allow an extensive exchange of substances. The placenta offers a degree of protective filtration of the maternal blood, preventing certain harmful substances from reaching the fetus. Nutritional substances such as vitamins, fatty acids, glucose, and electrolytes freely pass from mother to fetus.

Most drugs cross the placenta and pass from mother to fetus by simple diffusion. A few drugs cross by way of active transport. The role the placenta plays in drug metabolism is under study. It is known that metabolic enzymes are present in the placenta and likely contribute to drug metabolism. What is not known with certainty is how a particular drug is metabolized through the placenta. Some drugs may be metabolized extensively and presumably have little or no effect on the developing fetus, whereas other drugs may be altered to become toxic metabolites capable of harm. It should be understood that drugs may cause fetal harm without crossing the placenta or entering the fetal blood. For example, certain drugs may cause constriction of placental blood vessels, impairing nutrient exchange. Other drugs can alter maternal physiology to such an extent that the fetus is affected.

Multiple factors impact the transfer of drugs across the placenta. These variables are the same as those affecting the

movement of substances across other biological membranes (see Chapter 3):

- **Plasma drug level in the mother.** In general, the higher the dose taken by the mother, the greater the amount of drug available to cross the placenta and affect the fetus. This is the rationale for prescribing the lowest effective doses of drugs during pregnancy.
- **Solubility of the drug.** Highly lipid-soluble drugs will cross the placental barrier more easily than water-soluble drugs.
- **Molecular size.** Small molecules such as alcohol with molecular weights (MW) less than 300 easily cross the placental barrier; those with MW greater than 500 are slower to cross. Large drugs such as heparin, with MW greater than 1000, do not generally cross the placenta to the fetus.
- **Protein binding.** When a drug is bound to maternal plasma proteins, the drug-protein complex is too large to cross the placental membrane. Thus, drugs that are highly protein bound are more likely to cross the placenta more slowly and in lower doses compared to nonbound drugs.
- **Drug ionization.** Nonionized drugs cross the placenta more easily than ionized drugs. The maternal serum pH is slightly higher than that of the fetus. Upon reaching the relatively acidic environment of the fetus, drugs that are weak bases become ionized. This effectively traps them on the fetal side of the placenta, because ionized drugs cannot recross the placental membrane back to the mother (ion trapping). An example is nicotine (a weak base), which can appear in higher concentrations in the fetus than in the mother due to ion trapping.
- **Blood flow to the placenta.** Decreased uterine blood flow may cause drugs to remain trapped in the fetus for extended periods, resulting in fetal adverse effects. During labor the patient is usually instructed to remain in the lateral position during active uterine contractions to prevent pressure on the aorta and vena cava. Pressure on these vessels will obstruct uterine blood flow and may cause drug accumulation in the fetus.

PharmFACT

The most common antidepressants, the selective serotonin reuptake inhibitors (SSRIs), when taken by pregnant women, have been shown to increase the risk of preterm labor and may cause withdrawal symptoms in newborns that include agitation, irritability, trouble feeding, sleep disturbances, and convulsions (Saccone, Eke, & Berghella, 2016). Healthcare providers have been advised to taper dosages of SSRIs during the third trimester so that the fetus receives no drug through the placenta for at least 7 to 10 days prior to birth.

8.4 The U.S. Food and Drug Administration pregnancy risk categories are used as guides in prescribing medications during pregnancy.

In an effort to protect an unborn child from negative drug effects, the U.S. Food and Drug Administration (FDA) has developed drug **pregnancy categories** that rate medications as to their risks during pregnancy. Table 8.1 shows the five pregnancy categories, which guide the healthcare team and the patient in selecting drugs that are least hazardous for the fetus. Nurses who treat pregnant women must be knowledgeable of the drug pregnancy categories for all medications commonly prescribed for their patients.

Testing drugs in humans to determine their ability to cause birth anomalies is unethical and prohibited by law. Although drugs are tested in pregnant laboratory animals, the structure of the human placenta is unique among mammals. The FDA pregnancy drug categories are extrapolated from these animal data and may only be crude approximations of the actual risk to a human fetus. In a few cases, human data are available to show pregnancy risks. Regardless of the pregnancy category, no prescription drug, over-the-counter (OTC) medication, or herbal product should be taken during pregnancy unless the healthcare provider verifies that the therapeutic benefits to the mother clearly outweigh the potential risks for the unborn.

In a few cases, drugs are encouraged during pregnancy because they improve the health of the mother. For example, women are encouraged to take multivitamins and iron due to the increased metabolic demands placed on the mother during pregnancy. Vitamin B_9 (folic acid) has been found to prevent fetal spinal cord defects. These drugs are designated as pregnancy category A drugs and are safe for use during pregnancy. The category B drugs are also considered safe. For example, the penicillin and macrolide antibiotics are category B drugs that can be safely used to treat infections during pregnancy.

The category C drugs make up about two thirds of all prescription medications. The primary reason for a category C designation is that sufficient data are simply not available to decide whether the drug is safe or whether it may cause birth defects. Category C drugs should be avoided during pregnancy because there is a possibility they may cause fetal abnormalities.

All category D and X drugs should be avoided during pregnancy because they have the potential to cause birth defects (Table 8.2). For example, angiotensin-converting enzyme (ACE) inhibitors, a class of antihypertensive drugs, are known to impede intrauterine growth and increase the risk of fetal demise. Use of certain other antihypertensive drugs can result in renal atrophy. Certain antibiotics such as tetracyclines cause permanent staining of deciduous teeth. A category X drug such as isotretinoin (Accutane), which is used for serious acne, can cause fetal brain damage. Other category X drugs such as misoprostol (Cytotec),

Table 8.1 FDA Pregnancy Category Ratings with Examples

Risk Category	Interpretation	Drugs
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities to the fetus in any trimester of pregnancy.	Prenatal multivitamins, insulin, thyroxine, folic acid
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women. OR Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate risk to the fetus in any trimester.	Penicillins, cephalosporins, azithromycin, acetaminophen, ibuprofen in the first and second trimesters
C	Animal studies have shown an adverse effect and there are no adequate and well-controlled studies in pregnant women. OR No animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.	Most prescription medicines; antimicrobials such as clarithromycin, fluoroquinolones, and Bactrim; SSRIs; corticosteroids; and most antihypertensives
D	Adequate well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.	ACE inhibitors, alcohol, alprazolam, angiotensin receptor blockers (ARBs) in the second and third trimesters, carbamazepine, cyclophosphamide, gentamicin, lithium carbonate, methimazole, mitomycin, nicotine, nonsteroidal anti-inflammatory drugs (NSAIDs) in the third trimester, penicillamine, phenytoin, propylthiouracil, streptomycin, tetracyclines, and valproic acid
X	Adequate well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks. The use of the product is contraindicated in women who are or may become pregnant. There is no indication for use in pregnancy.	Clomiphene, fluorouracil, isotretinoin, leuprolide, menotropins, methotrexate, misoprostol, nafarelin, oral contraceptives, raloxifene, ribavirin, statins, temazepam, testosterone, thalidomide, and warfarin

a GI protective agent, may lead to abortion, and thalidomide (Thalomid), an immunosuppressant, has been known to cause fetal limb abnormalities. Additionally, alcohol, nicotine, and certain illicit drugs such as cocaine may negatively affect the unborn child. Selected abused substances and their effects on the fetus are listed in Table 8.3.

Table 8.2 Selected Prescription Medications with Pregnancy-Related Black Box Warnings

Medication	Primary Indication
ACE inhibitors and angiotensin receptor blockers	Hypertension, heart failure
Aliskiren (Tekturna)	Hypertension
Ambrisentan (Letairis)	Hypertension
Azilsartan (Edarbi)	Hypertension
Isotretinoin (Accutane)	Acne
Lenalidomide (Revlimid)	Antineoplastic
Misoprostol (Cytotec)	Peptic ulcers
Mycophenolate (CellCept)	Transplants
Ribavirin	Chronic hepatitis C
Telavancin (Vibativ)	Anti-infective
Terbutaline	Asthma
Teriflunomide (Aubagio)	Multiple sclerosis
Valproic acid/valproate (Depakote, Depacon)	Epilepsy
Vismodegib (Erivedge)	Antineoplastic

The A, B, C, D, and X pregnancy labeling system, in use since 1979, had several limitations. The system gave no current specific clinical information about the safety of a medication to help guide nurses or their patients. Furthermore, the system did not indicate how the dose should be adjusted during pregnancy or lactation. In 2014 the FDA announced a Pregnancy and Lactation Labeling Rule (PLLR) that replaced the pregnancy risk letter system with narrative sections and subsections . The new labeling began in 2015 for all newly approved drugs and biologics. Labeling on previously approved medications will be changed gradually (FDA, 2014).

The "Pregnancy" subsection provides information about dosing and potential risks to the developing fetus and maintains data on how pregnant women may be affected when they use the drug. The "Lactation" subsection replaces the "Nursing Mothers" subsection of the old label. Information includes drugs that should not be used during breastfeeding, known human or animal data regarding active metabolites in milk, and clinical effects on the infant. In the "Females and Males of Reproductive Potential" subsection, relevant information on pregnancy testing or use of contraception before, during, or after drug therapy, and a medication's effect on fertility or pregnancy loss is provided (when available).

The new labeling system is an improvement and allows for better patient-specific counseling and informed decision making for pregnant women seeking medication therapies.

Table 8.3 Street Drugs and Their Potential Effects During Pregnancy

Drug	Potential Effects
Amphetamines/methamphetamine	Increased risk of pregnancy complications, such as premature birth and placental problems Possible birth defects, including heart defects and cleft lip or palate After birth, the infant may have withdrawal-like symptoms such as jitteriness, drowsiness, and breathing problems
Cannabis/marijuana	Reduced fertility in both men and women Slowed fetal growth Slightly decreased length of pregnancy After birth, the infant may have withdrawal-like symptoms such as excessive crying and trembling
Club drugs such as PCP, ketamine, and LSD	After birth, the infant may have withdrawal symptoms Increased risk of learning and behavioral problems
Cocaine	Increased risk of miscarriage or premature birth Low birth weight with increased risk of health problems such as mental retardation and cerebral palsy, and even death Increased risk of birth defects involving the urinary tract and possibly other birth defects May cause an unborn baby to have a stroke, which can result in irreversible brain damage or a heart attack, and sometimes death Placental problems, including placental abruption, which can lead to heavy bleeding that can be life threatening for both mother and baby After birth, the infant may have mild behavioral disturbances, jitteriness, and irritability; may startle and cry at the gentlest touch or sound Increased risk of sudden infant death syndrome (SIDS)
Heroin	Increased risk of serious pregnancy complications, including poor fetal growth, premature rupture of the membranes, premature birth, and stillbirth Low birth weight often combined with breathing problems and possibility of lifelong disabilities Increased risk of birth defects After birth, the infant may have withdrawal symptoms such as fever, sneezing, trembling, irritability, diarrhea, vomiting, continual crying, and, occasionally, seizures Increased risk of SIDS
Inhalants, glues, and solvents	Miscarriage, slow fetal growth, preterm birth, and birth defects

Adapted from "Street Drugs and Pregnancy," March of Dimes, 2016.

8.5 The stage of development has an important influence on adverse drug effects in the embryo and fetus.

The effects of drugs on the fetus depend on the stage of fetal development and the dosage received by the fetus. For the vast majority of medications, very little scientific data are available on the effects of drugs on the human fetus. Lack of knowledge does not mean they are safe; these drugs have the potential to cause adverse drug reactions in the fetus and, in some cases, may cause fetal malformations.

A **teratogen** is any substance, organism, or physical agent that interferes with growth or development of the embryo or fetus and produces a permanent abnormality or death. The word derives from the Greek *gennan* ("to produce") and *terata* ("monster"). The baseline incidence of teratogenic events is approximately 3% of all pregnancies. Potential fetal consequences of drug use include intrauterine fetal death, physical malformations, growth impairment, behavioral abnormalities, and neonatal toxicity.

There are no "absolute" teratogens. Whether or not a drug produces a teratogenic effect depends on multiple, complex factors. Like other effects of drugs, there is a dose–response relationship, with risk increasing with higher doses. The timing of drug therapy and the stage of fetal development critically affect the risk for possible fetal consequences. Because of the constant changes that occur during fetal development, the specific risk is dependent on when during gestation the drug is administered. A well-known example is the drug thalidomide, which causes its fetal effects from day 35 to day 48 after the last menstrual period. The specific malformation is linked to the time of exposure: 35 to 37 days, no ears; 39 to 41 days, no arms; 41 to 43 days, no uterus; 45 to 47 days, no tibia; and 47 to 49 days, triphalangeal thumbs.

Preimplantation period: Weeks 1 to 2 of the first trimester are known as the preimplantation phase. Before implantation, the developing embryo has not yet established a blood supply with the mother. This is sometimes called the "all-or-none" period because exposure to a teratogen either causes death of the embryo or has no effect. Drugs are less likely to cause congenital malformations during this period because the baby's organ systems have not yet begun to form. Drugs such as nicotine, however, can create a negative environment for the embryo and potentially cause intrauterine growth retardation.

Embryonic period: During the embryonic period, from 3 to 8 weeks postconception, internal structures develop rapidly. This is the period of maximum sensitivity to teratogens. Teratogenic drugs taken during this phase can lead to structural malformation and spontaneous abortion. The specific abnormality depends on which organ is forming at the time of exposure.

Fetal period: The fetal phase is from 9 to 40 weeks postconception or until birth. During this time there is continued growth and maturation of the baby's organ systems. Blood flow to the placenta increases and placental vascular membranes become thinner. Such alterations maximize the transfer of substances from the maternal circulation to the fetal blood. As a result, the fetus may receive larger doses of medications and other substances taken by the mother. Because the fetus lacks mature metabolic enzymes and efficient excretion mechanisms, medications will have a prolonged duration of action within the unborn child. Exposure to teratogens during the fetal period is more likely to produce slowed growth or impaired organ function, rather than gross structural malformations.

The nurse caring for the pregnant woman must differentiate adverse drug effects from the normal symptoms of pregnancy. Nausea, vomiting, abdominal cramps, flushed skin, or diaphoresis may indeed be either normal symptoms of pregnancy or adverse drug effects. Fetal tachycardia may be due to drugs being taken by the mother or a fetal cardiac anomaly. During all stages of pregnancy, the nurse should help the mother assess medications and dietary supplements to determine if they are necessary and if adjustments are required. Impairments in the functioning of the mother's liver or kidneys may have a profound impact on maternal and fetal safety. Healthcare providers must consider these factors, so as to minimize the risk of toxicity to the mother and child. Through careful assessments, the nurse contributes greatly to this risk–benefit analysis, which is essential for protecting both the mother and her baby.

PharmFACT

Most medications commonly used in pregnancy have insufficient data available to allow a full understanding of their fetal risk. This limits the ability of providers to make informed clinical decisions on the management of acute and chronic disorders that require medication use during pregnancy. Additional research is needed to fully understand medications and fetal risk (Thorpe et al., 2013).

CONNECTION Checkpoint 8.2

From what you learned in Chapter 5, explain why the FDA might approve a drug even though it is a known teratogen and can cause fetal abnormalities. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy During Lactation

8.6 Transfer of drugs from mother to infant may occur through breast milk.

According to the *Breastfeeding Report Card 2013* by the Centers for Disease Control and Prevention (2013), 77% of mothers breastfeed their infants and about 49% continue to breastfeed for at least 6 months. Breastfeeding is highly recommended as a means of providing nutrition, emotional bonding, and immune protection to the neonate (Figure 8.2).

Figure 8.2 Nurses should teach lactating women to avoid all drugs, herbal products, or dietary supplements unless approved by their healthcare provider.
Courtesy of Africa Studio/Shutterstock.

The majority of drugs are secreted into breast milk to some extent. Fortunately, there are relatively few instances in which breastfeeding must be discontinued due to medication use. For the few drugs that are absolutely contraindicated during lactation, equally effective, safer alternatives are usually available. Some of these drugs are shown in Table 8.4. Although most medications probably cause no harm to the breastfeeding baby, their effects have not been fully studied.

Drugs enter breast milk primarily by passive diffusion. In the first week of life, the alveolar cells in the breast have large gaps between them, allowing drugs and other substances to penetrate the milk. By the second week of life the alveolar cells swell, closing the intracellular gaps and limiting the drug's access to the milk.

It is important for the nurse to understand factors that influence the amount of drug secreted into breast milk. This allows the nurse to aid the patient in making responsible choices regarding lactation and in reducing exposure of her newborn to potentially harmful substances. The amount of drug that passes to the infant during lactation depends on multiple factors:

- **Plasma drug level in the mother.** The higher the dose of drug taken by the mother, the more will be secreted into breast milk. It is therefore standard practice that if a drug must be prescribed for a lactating patient, the lowest effective dose should be ordered.
- **Solubility of the drug.** Highly lipid-soluble drugs enter the milk at higher concentrations. Milk at the end of a feed contains considerably more fat and may have a higher concentration of lipid-soluble drugs. Furthermore, the percentage of lipids in milk increases progressively from day 1 to day 84 of lactation. Drugs that act on the central nervous system (CNS) are usually lipophilic and have a tendency to penetrate milk at higher concentrations.

Table 8.4 Selected Drugs Compatible with Breastfeeding

Class	Compatible Drugs	Drugs to Be Avoided
Analgesics (nonopioid)	acetaminophen, aspirin, ibuprofen	—
Analgesics (opioids)	codeine and morphine in occasional doses	—
Anti-infectives	acyclovir, aminoglycosides, cephalosporins, fluconazole, isoniazid, macrolides, penicillins, trimethoprim, sulfisoxazole (over 1 month of age)	chloramphenicol, ciprofloxacin, metronidazole, tetracyclines
Antimigraine drugs	propranolol	ergotamine
Antiseizure drugs	carbamazepine, diazepam (single dose), phenytoin, valproic acid	ethosuximide
Cardiovascular drugs	digoxin, furosemide, heparin, iron salts, lidocaine, nifedipine, prazosin, spironolactone, verapamil, warfarin	ACE inhibitors, atenolol, hydrochlorothiazide, statins
Central nervous system drugs	paroxetine, sertraline, tricyclic antidepressants	lithium carbonate
Cytotoxic drugs and immunosuppressants	—	all drugs in this class should be avoided
Gastrointestinal drugs	aluminum hydroxide, magnesium hydroxide, promethazine (single dose)	cimetidine, metoclopramide
Hormones	hydrocortisone (single dose), insulin, oxytocin (short term), prednisone, thyroid hormone	estrogens, oral contraceptives, testosterone

Data From *LactMed: A TOXNET database*, n.d., National Institutes of Health, U.S. National Library of Medicine. Retrieved from http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm

- **Molecular size and protein binding.** Some drugs, such as heparin and insulin, are simply too large to pass through membranes by passive diffusion. In addition, when drugs are highly protein bound, they are less likely to enter the milk than those that are free. The healthcare provider may choose drugs with greater protein binding capacity for the lactating mother to limit the amount secreted in milk.
- **Drug ionization.** Milk is slightly more acidic than plasma; the pH of milk is 7.2 and plasma 7.4. This pH gradient allows weakly basic drugs to transfer more readily into breast milk and accumulate due to ion trapping (see Chapter 4).
- **Drug half-life.** Drugs with short half-lives will be metabolized and eliminated quickly by the mother. This results in smaller amounts being secreted into milk.

Once ingested by the infant, a drug is subjected to the usual pharmacokinetic influences. The infant's stomach content is quite acidic; therefore, some drugs may be destroyed and have reduced bioavailability. Additionally, some drugs are inactivated when ingested with calcium and protein-rich nutrients in the mother's milk. Some drugs by their nature are likely removed by the infant's liver during first-pass metabolism and never get to the plasma. It is important to remember that the baby's organs responsible for metabolizing and eliminating medications are immature and are not able to perform all the functions of adult organs.

Considering the many variables, it is not surprising that it is difficult to accurately predict the amount of maternal drug that will transfer to the infant plasma during lactation. Estimates of drug transference to breast milk range from less than 1% to 3%. Regardless of the amount, it is imperative for the nurse to teach the mother that many prescription medications, OTC drugs, and herbal products are secreted in breast milk and have the potential to affect her child. The same guidelines for drug use during pregnancy apply during lactation—drugs should be taken only if the benefits to the mother clearly outweigh the potential risks to the infant.

PharmFACT

Because the negative effects of tobacco smoking on the fetus are well documented, the American Congress of Obstetricians and Gynecologists (ACOG) recommends that healthcare providers counsel their pregnant patients on smoking cessation techniques and provide resources to support their efforts. The safety and efficacy of nicotine replacement therapy (NRT) during pregnancy have not been established. Therefore, ACOG (2014) recommends that NRT only be used under the close supervision of a healthcare provider.

8.7 Drugs present in breast milk may cause adverse effects in the breastfeeding infant.

Although the concentration of drugs in breast milk is often very low (less than 3%), their effects on the infant can be serious. Common drug effects seen in breastfeeding infants are nonspecific and include diarrhea, constipation, sedation, and irritability. The nurse has an important responsibility to monitor for adverse drug effects in breastfeeding infants and to teach new mothers to do the same. Selected drugs that enter the breast milk and are believed to produce adverse effects are shown in Table 8.5.

The nurse must inform the mother that all drugs of abuse are contraindicated during both pregnancy and breastfeeding. If she takes such drugs, her infant may experience withdrawal symptoms and test positive for the drug for several weeks to months following exposure.

In general, topical medications applied to the mother's skin are safe to use during lactation. The nurse must remind the mother, however, that the breastfeeding infant may ingest substances like vitamins E, A, or D in creams that are rubbed on her nipples to soften them.

Table 8.5 Classes of Medications that May Cause Serious Effects in a Baby Following Breastfeeding

Drug Class	Potential Adverse Effect
Antiepileptics (e.g., phenobarbital, ethosuximide)	Sedation
Antineoplastics	Neutropenia
Beta blockers	Lethargy and bradycardia
Benzodiazepines	Sedation and weight loss
Ergot alkaloids	Vomiting and diarrhea
NSAIDs	Increased bleeding
Opioids	Sedation and withdrawal symptoms
Phenothiazines	Sedation
Pseudoephedrine	Inhibition of milk production

The National Institutes of Health maintains a searchable database of drugs to which breastfeeding women may be exposed. The database, called LactMed, is updated monthly and contains clinical data on drug effects on the baby during lactation. Nurses should consult this source for current information when counseling their breastfeeding patients.

CONNECTION Checkpoint 8.3

From what you learned in Chapter 3, how long would it take a 600-mg dose of a drug with a $t_{1/2}$ of 8 hours to reach five half-lives and be safe for a lactating patient concerned about passing the drug through her breast milk? How much drug would be left at that time?

Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.

CONNECTIONS: Preparing for Advanced Practice

Zika Virus

Case

Maria is a healthy 22-year-old pregnant woman who came to the free clinic for care. She is new to the country from Brazil. During her first appointment a complete history was taken and blood was drawn to test for human immunodeficiency virus (HIV), cytomegalovirus, rubella, and hepatitis B and C. All laboratory tests came back negative. She appears healthy with no cause for concern. After her first appointment at 12 weeks, she was thrilled to hear her baby's heartbeat and left excited to tell her husband. She continued to come to the clinic for care and at her 16-week appointment she was given a referral for a routine ultrasound.

At 18 weeks, an ultrasound showed that the fetus's weight was significantly lower than expected. Subsequent ultrasounds performed between 18 and 28 weeks continued to show additional fetal abnormalities. At week 32, labor was induced and resulted in a stillbirth. Laboratory tests later showed that the Zika virus was present in the fetus's tissue. At her postpartum appointment Maria asks if there are any medications she could have taken to prevent the stillbirth. What do we know about medications and Zika?

Discussion

Zika virus is mainly spread via mosquito bites. Infection poses significant risks to pregnant women, because it can cause a birth defect called microcephaly, which results in babies born with undersized heads and underdeveloped brains. Zika has achieved epidemic status in the U.S. territory of Puerto Rico and is widespread throughout Central and South America.

Three already existing drugs may offer pregnant women and their developing fetuses protection against the damaging effects of Zika virus. In search of a quick option, some researchers are now studying the possibility of repurposing drugs that were originally developed for other indications. To date, researchers have identified three potential Zika treatments that include already approved drugs (Kincaid, 2016).

Niclosamide is used to treat tapeworm and appears to also have antiviral properties that inhibit Zika from replicating. PHA-690509 is an antiviral drug that potentially may have an effect against Zika by interfering with gene expression of the virus. Emricasan works by inhibiting a natural process that causes viral cell death (Kincaid, 2016). These medications still must undergo extensive animal testing to determine if they are effective and if they are safe to take during pregnancy.

Understanding Chapter 8

Key Concepts Summary

8.1 Women frequently use drugs during pregnancy and lactation.

8.2 Physiologic changes during pregnancy can alter normal pharmacokinetic responses.

8.3 Many drugs pass from mother to infant via the placenta.

8.4 The U.S. Food and Drug Administration pregnancy risk categories are used as guides in prescribing medications during pregnancy.

8.5 The stage of development has an important influence on adverse drug effects in the embryo and fetus.

8.6 Transfer of drugs from mother to infant may occur through breast milk.

8.7 Drugs present in breast milk may cause adverse effects in the breastfeeding infant.

CASE STUDY: Making the Patient Connection

Remember the patient "May David" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

May David, a 22-year-old woman, comes to the clinic to obtain a pregnancy test. She has not had her menstrual period for the past 6 weeks but claims that infrequent menses are not unusual for her. She feels nauseous in the mornings but the feeling is only temporary. You ask May, "Is it possible that you might be pregnant?" May's response is "I doubt it, since we have always used a condom during intercourse." She goes on to explain that she has been taking an antiseizure medication for several years to control her epilepsy and is taking some herbal medicines for a feeling of well-being.

May's vital signs are as follows: temperature, 36.7°C (98°F); pulse, 68 beats/min; respiration, 18 breaths/min; and blood pressure, 110/70 mmHg. She is 1.7 m (5 feet 6 inches) tall and is surprised that she has gained 2.3 kg (5 lb) in the past 4 weeks, bringing her weight to 65.8 kg (145 lb). A urine specimen is sent to the laboratory for human chorionic gonadotropin (HCG). A complete physical examination is performed, followed by a vaginal examination via speculum. All physical findings were within normal limits except for the urine qualitative HCG, which is positive and quantitative HCG = 550, indicating pregnancy. May smokes approximately a half pack of cigarettes per day.

Critical Thinking Questions

1. What are some key points the nurse will discuss with May regarding her condition and the medication she is taking?
2. What education should the nurse provide for May regarding the use of medication during pregnancy?
3. While caring for May, the nurse must consider FDA pregnancy risk categories. In your own words explain these categories.
4. What effect does May's tobacco use possibly have on her unborn baby? What are the recommendations from ACOG on the use of NRT?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

You are caring for Irina, an 18-year-old mother of a 6-month-old baby boy. She confides in you that she has experienced postpartum depression since her child was born. She tries to take care of herself but just does not feel very good most of the time. Her husband insists that she continue breastfeeding, but she is now having doubts. After a lengthy discussion Irina states, "The only time I feel good is when I smoke a joint (marijuana) before feeding my son."

1. How should the nurse respond to Irina?
2. What teaching should the nurse carry out at this time?
3. Should Irina ask her provider for an antidepressant medication?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient in her first trimester of pregnancy asks the nurse which medications should be avoided during pregnancy. The nurse's response is based on the knowledge that during pregnancy:
    1. Most over-the-counter medications are safe.
    2. When possible, drug therapy is postponed until after pregnancy and lactation.
    3. It is wise to discontinue all drugs used in treating medical conditions.
    4. The decision whether or not to take medication is the responsibility of the woman.

2. The nurse is preparing to discuss drug use during pregnancy with a group of nursing students. The main topic is the FDA drug classifications. Which of the following drugs should the nurse inform the students are the most detrimental to the fetus?
   1. Category A
   2. Category B
   3. Category C
   4. Category X

3. A pregnant patient asks the nurse what factors determine if a drug will cross the placenta. The nurse's response will be based on which of the following principles?
   1. Highly lipid-soluble drugs cross the placental membrane more easily than low lipids.
   2. The lower the lipid content of a drug, the easier it crosses the placental membrane.
   3. Drugs with large molecular weight pass rapidly through the placental membrane.
   4. Highly protein-bound drugs pass rapidly through the placental membrane.

4. The nurse is administering medication to a group of pregnant women. At which stage of fetal development are congenital malformations *least* likely to occur?
   1. 1 to 2 weeks
   2. 3 to 4 weeks
   3. 5 to 6 weeks
   4. 7 to 8 weeks

5. The community health nurse is visiting a postpartum mother who is breastfeeding her 3.2-kg (7-lb) infant daughter. Which of the following statements, if made by the mother, indicates that further teaching is necessary? (Select all that apply.)
   1. "When using over-the-counter medication, I should take only the lowest effective dose."
   2. "The higher the dose of medication, the more likely it will be secreted into breast milk."
   3. "I shouldn't take any drug during breastfeeding, even my prescriptions."
   4. "Medication in liquid form should be avoided since it more readily enters the breast milk."
   5. "Now that I'm no longer pregnant, I don't need to worry about the medicines affecting my baby."

6. The nurse is administering medications to a patient who is 32 weeks pregnant. Which of the following normal physiologic principles associated with pregnancy will affect drug absorption?
   1. Medications are absorbed and distributed more quickly in pregnant women.
   2. There is greater hemoconcentration of drugs in pregnant patients.
   3. Drugs remain longer in the gastrointestinal tract, leading to extended time for absorption.
   4. Drug metabolism is highly affected by pregnancy.

Chapter 9
Pharmacotherapy of the Pediatric Patient

Chapter Outline

- Testing and Labeling of Pediatric Drugs
- Pharmacokinetic Variables in Pediatric Patients
- Pharmacologic Implications Associated with Growth and Development
- Medication Safety for Pediatric Patients
- Determining Pediatric Drug Dosages
- Adverse Drug Reactions in Children and Promoting Adherence

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the purposes of the Food and Drug Administration Modernization Act of 1997, the Best Pharmaceuticals for Children Act of 2002, and the Pediatric Research Equity Act of 2003.
2. Explain how differences in pharmacokinetic variables can impact drug response in pediatric patients.
3. Discuss the nursing and pharmacologic implications associated with each of the pediatric developmental age groups.
4. Describe safe methods and techniques appropriate for administering medications to pediatric patients.
5. Explain several methods for accurately calculating drug doses in pediatric patients.
6. Describe nursing interventions for minimizing adverse effects during pediatric pharmacotherapy.
7. Propose appropriate teaching strategies to enhance medication adherence in pediatric patients.

Key Terms

Best Pharmaceuticals for Children Act (BPCA), 111
body surface area (BSA) method, 118
body weight method, 117
directly observed therapy (DOT), 120
Food and Drug Administration (FDA) Modernization Act, 111
Pediatric Research Equity Act of 2003 (PREA), 112

It is true that children are not just little adults. Beginning with conception, and continuing throughout the lifespan, the organs and systems within the body undergo predictable physiologic changes that influence the absorption, metabolism, distribution, and elimination of medications. A child's body systems are in a constant state of development; therefore, the effects of drugs can often be unpredictable. Healthcare providers must recognize such changes to ensure that drugs are delivered in a safe and effective manner to children and patients of all ages.

The purpose of this chapter is to examine how principles of developmental physiology and lifespan psychology apply to drug administration. Emphasis is placed on determining drug dosages, maximizing therapeutic effects, and minimizing adverse effects. There is strong focus on patient and family education as well as on the importance of promoting adherence with pharmacotherapy.

Testing and Labeling of Pediatric Drugs

9.1 Legislation has attempted to improve the testing and labeling of pediatric drugs.

Pediatric patients receive large numbers of drugs, nearly all of which are the same as those given to adult patients. The distribution of the drug classes, however, is different in children. Cardiovascular drugs are the most commonly prescribed class in adults, whereas children are more likely to receive respiratory drugs and anti-infectives due to the high incidence of infectious diseases in this population. Table 9.1 provides a summary of the top drug prescriptions by age given to patients by outpatient providers (National Center for Health Statistics, 2014; Ziesenitz, van den Anker, & Amirshahi, 2016).

Antibiotics are the most commonly prescribed drugs, followed by drugs for asthma. As the child's age increases, prescriptions for drugs used for attention-deficit/hyperactivity disorder (ADHD) also increase.

Until the 1990s very little drug information was specifically targeted for the pediatric patient. Drug trials with pediatric patients were virtually unheard of, and data regarding the pharmacokinetics and adverse effects of most drugs were not well documented in this population. Most pediatric drugs were not available in dosage and delivery forms compatible with neonates or infants. Few drugs contained labeling information specifically for pediatric patients. Drugs that were found to be effective in adults were assumed to also be effective in children.

In 1997, the **Food and Drug Administration (FDA) Modernization Act** was passed, which established the pediatric exclusivity (PE) program to provide financial incentives to drug sponsors in exchange for studying products used in pediatric populations. This gave pharmaceutical companies a financial incentive to conduct the much needed pediatric research in pharmacology requested by the FDA. In exchange for providing pediatric labeling, the legislation provided drug companies with an additional 6 months of exclusivity, giving them the ability to market the drug with no competition. Of the 189 products studied under the PE program from 1998 through 2012, 173 (92%) received new pediatric labeling information and 108 (57%) were given a new or expanded pediatric indication. This information better informs caretakers on the safety and efficacy of the product and provides additional dosing and safety information (Wharton et al., 2014).

Several flaws in the FDA Modernization Act were quickly noted. Many of the medications studied by the drug companies were chosen not for their potential value in children, but instead to extend their exclusivity and generate higher profits. The act gave no incentives for studying off-patent (generic) drugs or those that have smaller markets. In 2002, Congress passed the **Best Pharmaceuticals for Children Act (BPCA)**, which authorized the FDA to contract for the testing of already approved pediatric drugs or when the pharmaceutical company declines the option

Table 9.1 Top Prescriptions for Children

Drug	Use
albuterol (Proventil)	Asthma
amoxicillin (Amoxil)	Antibiotic
amoxicillin/clavulanate (Augmentin)	Antibiotic
azithromycin (Zithromax, Zmax)	Antibiotic
cefdinir (Omnicef)	Antibiotic
cephalexin (Keflex)	Antibiotic
fluticasone (Flonase)	Allergies
methylphenidate (Ritalin)	ADHD
montelukast (Singulair)	Asthma
prednisolone	Allergies, inflammation

of exclusivity. This act was reauthorized by Congress in 2007 with several new provisions. The **Pediatric Research Equity Act of 2003 (PREA)** authorized the FDA to require research of pediatric uses for new drugs when an approved use includes a condition or conditions applicable to pediatric patients (U.S. Government Accountability Office, 2003). In addition to studying drugs, this mandate was extended to biologics in 2010, recognizing the increased development and use of these therapeutic drugs in recent years.

The increased emphasis on pediatric drugs has led to more than 500 pediatric labeling changes as a result of studies directly associated with the BPCA and PREA (Field & Boat, 2012). Table 9.2 shows some of the changes that resulted from research studies conducted under these acts.

Despite the limitations of current research, more information is available to guide the pharmacotherapy of the pediatric patient than previously. Drugs such as vaccines and antibiotics have adequate pediatric labeling. Unfortunately, the amount of information about the use of steroids and drugs for treating human immunodeficiency virus (HIV), gastrointestinal (GI) disorders, pain, and hypertension in children is still minimal.

PharmFACT

Off-label prescribing is common practice in pediatrics. One study, looking at the characteristics of off-label prescribing and adverse drug reaction occurrence in a sample of pediatric outpatients treated by general practitioners, found that among the 2313 children studied, 84.7%, were exposed to one or more prescribed drugs, and 37.6% were exposed to more than one off-label prescription (Palmaro et al., 2015).

Table 9.2 Examples of Labeling Changes

Potential Risks or Hazards	Drug Name	Disease or Condition Treated	Summary of New Information Contained in Drug Labeling
Unnecessary exposure to ineffective therapies	sumatriptan (Imitrex)	Migraines	Five studies did not establish safety and effectiveness, and postmarketing experience showed that children were having serious adverse effects, such as stroke and vision loss. The product is not recommended for children under age 18 years.
	tolterodine (Detrol)	Overactive bladder and urge incontinence	The drug was not shown to be effective for children and appeared to show a possible increase in aggressive, hyperactive, and abnormal behavior.
	irinotecan (Camptosar)	Tumors	Children had more rapid disease progression and died more quickly. The labeling states that the drug should not be used to treat children with a particular kind of tumor.
	temozolomide (Temodar)	Astrocytoma	Effectiveness in children is not demonstrated.
Ineffective dosing	oxcarbazepine (Trileptal)	Partial seizures	Dose for children ages 2 to 4 and weighing less than 44 lb is twice the dose per body weight compared to adults.
	methylphenidate (Ritalin)	ADHD	Children ages 13 to 17 eliminated the drug from their bodies faster than the comparison age group. Therefore, the dosing regimen may be increased to prevent ineffective dosing.
Overdosing	leflunomide (Arava)	Juvenile rheumatoid arthritis	Children weighing less than 88 lb require a lower-than-expected dose. Overdosing on leflunomide, which has significant toxicity, could make the drug's risks to children outweigh its benefits.
Previously unlabeled adverse effects, including effects on growth and development	venlafaxine (Effexor)	Depression, generalized anxiety disorder	This drug is associated with an increased risk of suicidal thinking and behavior.
	ciprofloxacin (Cipro)	Complicated urinary tract infection or kidney infection	This drug is associated with increased adverse effects to joints or surrounding tissues for children.
	fentanyl (Duragesic)	Chronic pain	This drug should be used only by children age 2 or older who are opioid tolerant. Use by others can lead to life-threatening respiratory depression and death.
	budesonide (Pulmicort Respules)	Asthma	This drug is now labeled with safety information in patients as young as 6 months. Drug can cause growth suppression and pneumonia.
	fluoxetine (Prozac)	Depression, obsessive-compulsive disorder (OCD)	Effectiveness established in ages 7 to 17 with OCD and ages 8 to 17 with depression. Drug can cause height and weight suppression. It also has a possible link to suicide ideation.
	fluticasone	Flonase: allergic rhinitis (intranasal)	Effectiveness and safety have been established in ages 3 to 9 years with no effect on bone function.
		Cutivate: dermatoses (topical)	Subnormal adrenal function was noted. Drug is not recommended for children.

Pharmacokinetic Variables in Pediatric Patients

9.2 Pharmacokinetic responses in children differ from those in adults.

As discussed in Chapters 3 and 4, drugs must reach their target cells in sufficient quantities to produce therapeutic effects. This depends on what the body does to the medication after it is administered (pharmacokinetics) and the mechanisms by which a drug changes the body (pharmacodynamics). The normal physiologic changes of growth and development markedly affect pharmacokinetics and pharmacodynamics. The nurse must understand the unique actions of drugs in their pediatric patients to deliver safe and effective pharmacotherapy.

Absorption: Two primary factors have the potential to influence the oral absorption of drugs in pediatric patients: increased gastric pH and delayed gastric emptying. Low gastric acid production may enhance the absorption of acid-labile drugs such as ampicillin and penicillin and slow the absorption of weak acids like phenobarbital. This is especially true for premature infants and neonates. Gastric acid production may not reach adult levels until age 2 or 3.

Slowed gastric motility in very young children will keep the drug in the stomach longer. This will increase the absorption of drugs that are absorbed across the stomach mucosa, but slow the rate of drug absorption for drugs that rely on the intestine for absorption. The rate of bile salt secretion is diminished in premature infants and neonates, which will delay the absorption of lipid-soluble drugs and vitamins.

In the infant, relatively low blood flow to skeletal muscles leads to slow and erratic absorption of drugs administered by the intramuscular (IM) and subcutaneous routes. Weak muscle contractions may also contribute to the delayed absorption and distribution of IM drugs. IM injections are generally avoided due to their unpredictable absorption rates and their associated pain.

The skin of infants is thin and highly permeable, allowing lotions and topical drugs to be absorbed at a more rapid rate than in adults. For example, use of topical corticosteroids in infants may cause systemic effects such as adrenal insufficiency, hyperglycemia, and glaucoma. Care must be taken to prevent accidental overdose.

CONNECTION Checkpoint 9.1

From what you learned in Chapter 3, what effect does food in the stomach have on drug absorption? What effect might this have on neonates who are given frequent feedings? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Distribution: Three main factors affecting drug distribution in children are the proportion of water to fat, immature liver function, and the underdeveloped blood–brain barrier.

Approximately 80% of a newborn's body weight is due to water. This gradually decreases to 60%, that of an adult, during the first year. The higher proportion of water dilutes water-soluble drugs such as furosemide (Lasix). In addition, water-soluble drugs will move out of the serum to other areas of the infant's body where water concentration is high. The overall effect is lower serum drug levels; higher doses may be needed to maintain adequate serum levels of the drug.

What about lipid-soluble drugs? Infants have a low percentage of body fat compared to adults. Lipid-soluble drugs that would normally be distributed to fat tend to stay in the blood, raising serum drug levels.

Prior to age 6 months, the child's immature liver produces very small amounts of plasma proteins. Drugs that normally bind to plasma proteins will now be present as "free" drugs in the serum. Drugs and endogenous substances such as bilirubin compete for the few available protein-binding sites. In some cases, previously bound substances or drugs may be displaced into the serum, leading to potential toxicity. Drugs with high levels of protein binding include ampicillin, morphine, phenytoin (Dilantin), and propranolol (Inderal).

The blood–brain barrier is a network of capillaries in the central nervous system (CNS) that form tight junctions, which prevent the passage of certain medications into the brain. Because the child's blood–brain barrier is not fully developed at birth, drugs and other chemicals can easily penetrate the CNS, resulting in heightened responses. The nurse caring for neonates taking drugs such as barbiturates that affect CNS functions should assess for potential toxicity. It is also possible that some drugs not intended for CNS penetration may access the brain, causing adverse CNS effects such as seizures, drowsiness, or dizziness.

Metabolism: The rate at which drugs are metabolized in children is impacted by the immaturity of the hepatic cytochrome P450 (CYP450) enzyme system. Metabolism is significantly slower in children, leading to reduced clearance rates and extended half-lives for drugs extensively metabolized by the liver. To avoid toxicity, drug doses must be accurately determined and administered at adequately spaced intervals to allow sufficient time for metabolic handling of the drug. The metabolic rate reaches adult levels by ages 3 to 5 years. Until then, the nurse should remain vigilant for signs of toxicity in patients taking drugs such as salicylates that are metabolized primarily in the liver.

The enzyme alcohol dehydrogenase is markedly reduced at birth, gradually increasing until age 5. This enzyme is responsible for detoxifying benzyl alcohol, a preservative found in parenteral drug formulations. Newborns are especially sensitive to the effects of benzyl alcohol and can develop "gasping syndrome," which can lead to respiratory and cardiovascular failure. The nurse must ensure that neonates do not receive products containing benzyl alcohol.

Excretion: The child's ability to effectively excrete most drugs depends on the maturity and function of the kidneys. For drugs to be excreted efficiently, the kidneys must have an adequate glomerular filtration rate and active tubular secretion and reabsorption functions. Young children have immature renal systems with slower renal clearance, resulting in accumulation of drugs excreted by the kidneys. Signs of nephrotoxicity include oliguria, urinary frequency, hematuria, cloudy urine, rising blood urea nitrogen (BUN) and creatinine, and fever. Although standard pediatric doses can be administered at approximately 3 to 5 months of age when the infant is able to concentrate urine, serum levels of nephrotoxic drugs such as gentamicin must be monitored closely to prevent adverse reactions.

Pharmacologic Implications Associated with Growth and Development

9.3 The role of the nurse in administering medications changes with each developmental age group.

The nurse responsible for administering pediatric medications must take into consideration the age, weight, and developmental level of the child. For the purposes of medication administration, the pediatric patient is defined as being any age from birth to 16 years and weighing less than 50 kg (110 lb). Additionally, children are classified as neonates, infants, toddlers, preschoolers, school-age children, and adolescents.

Growth is a term that characterizes the progressive increase in physical (body) size. *Development* refers to the functional evolution of the physical, psychomotor, and cognitive capabilities of a living being. Stages of growth and physical development usually go hand in hand in a predictable sequence, whereas psychomotor and cognitive development have a tendency to be more variable in nature.

From birth through adolescence, the growth and development of the pediatric patient mandate adjustments in pharmacotherapeutics above and beyond the calculation of doses. The child's ability to become an active (and willing) partner in his or her own wellness has important implications to nursing care and pharmacotherapeutics.

Pharmacotherapy of the infant: Infancy is the period from birth to 12 months of age. The first 28 days of life are referred to as the neonatal period. During this time, nursing care and pharmacotherapy are directed toward safety of the infant, proper dosing of prescribed drugs, and teaching parents how to administer medications properly. A primary goal is to have the child ingest the entire dose of medication without spitting it out because it is difficult to estimate the amount lost. If the child vomits immediately after taking the drug, the dose may be reordered. The following nursing interventions and parental teaching points are important for this age group:

- The infant should be held and cuddled while administering medications and offered a pacifier if the infant is on fluid restrictions caused by vomiting or diarrhea.
- Medications are often administered to infants via droppers into the eyes, ears, nose, or mouth. Oral medications should be directed to the inner cheek and the child given time to swallow the drug to avoid aspiration. If rectal suppositories are administered, the buttocks should be held together for 5 to 10 minutes to prevent expulsion of the drug before absorption has occurred.
- Special considerations must be observed when administering IM or intravenous (IV) injections to infants. Unlike adults, infants lack well-developed muscle masses, so the smallest needle appropriate for the drug should be used. For volumes less than 1 mL a tuberculin syringe is appropriate. The vastus lateralis is a preferred site for IM injections, because it has few nerves and is relatively well developed in infants. The gluteal site is usually contraindicated because of potential damage to the sciatic nerve, injury to which may result in permanent disability.
- Because of the lack of choices for injection sites, the nurse must rotate injection sites from one leg to the next to avoid overuse and to prevent inflammation and excessive pain.
- For IV sites, the feet and scalp veins may provide good venous access.

Pharmacotherapy of the toddler: Toddlerhood ranges from 1 to 3 years of age. By age 1 most of the pharmacokinetic responses are similar to that of the adult. The 2-year-old is able to metabolize drugs at a very rapid rate; therefore, the healthcare provider must adjust drug doses accordingly to maintain therapeutic levels.

During this period, a toddler displays a tremendous sense of curiosity. The child begins to explore, wants to try new things, and tends to place everything in the mouth. This becomes a major concern for medication and household product safety. Toddlers can swallow liquids and may be able to chew solid medications. When prescription drugs are supplied as flavored elixirs, it is important to teach parents that the child not be given access to the medications. Poisoning is extremely common at this age. Some of the most common poisonous substances involved in the exposure of children less than 6 years are analgesics, cough and cold preparations, topical ointments, and vitamins.

Administering medications to toddlers can be challenging for the nurse. At this stage, the child is rapidly developing increased motor ability and learning to assert

independence but has extremely limited ability to reason or understand the relationship of medicines to health. Giving long, detailed explanations to the toddler will prolong the procedure and create additional anxiety. Short, concrete explanations followed by immediate drug administration are best for this age group. Physical comfort in the form of touching, hugging, or verbal praise following drug administration is important.

- Pharmaceutical companies often formulate pediatric medicines in sweet syrups to facilitate drug administration. Extra caution should be observed when medications are flavored. Toddlers may not differentiate between a food product and the medication and may ingest an overdose if the medication is not kept in a child-safe location.
- The nurse should mix unpleasant tasting oral medications with more appetizing food such as jam, syrup, or fruit puree, if possible. The medication may be followed with a carbonated beverage or mint-flavored candy. Nurses should teach parents to avoid placing medicine in milk, orange juice, or cereals because children may associate these healthy foods with unpleasant tasting medications in the future.
- IM injections for toddlers may be given into the vastus lateralis muscle. For IV medications, the nurse may choose to access the scalp or feet veins. Additional peripheral site options become available in late toddlerhood.
- Suppositories may be difficult to administer due to the child's resistance. For these invasive administration procedures, having a parent close by will usually reduce the toddler's anxiety and increase cooperation.

Pharmacotherapy of preschoolers: The preschool child ranges in age from 3 to 5 years. In general, principles of medication administration that pertain to the toddler also apply to this age group. Preschoolers tend to cooperate better in taking oral medications if they are crushed or mixed with food or flavored beverages.

- After a child has been walking for about a year, the ventrogluteal site may be used for IM injections because it causes less pain than the vastus lateralis site. Use of the dorsogluteal site has declined due to the risk of affecting the sciatic nerve. The scalp veins can no longer be used for IV access; peripheral veins are used for IV access.
- Like the toddler, the preschooler often physically resists medication administration. A brief explanation followed immediately by medication administration is usually the best method. Uncooperative children may need to be restrained, and patients over 4 years of age may require two adults to administer the medication.
- Before and after medication procedures, the child may benefit from opportunities to play-act troubling experiences with dolls. When the child plays the role of doctor or nurse by giving a "sick" doll a pill or injection, comforting the doll, and explaining that the doll will now feel better, the little actor feels safer and more in control of the situation.

Pharmacotherapy of the school-age child: The school-age child is between 6 and 12 years of age. Some refer to this period as the middle childhood years. Rapid physical, mental, and social development occur and early ethical–moral development begins to take shape. During this time, most children remain relatively healthy, with respiratory infections and GI upsets being the most common complaints. When serious illness occurs at this age, the child may become confused and depressed because it is important for the child to be like his peers during this developmental age. When caring for an ill child, the nurse must be aware of possible nonadherence to treatment regimens.

The nurse is usually able to gain considerable cooperation from school-age children. Detailed explanations of the effects and importance of medications in maintaining wellness may be of value, because the child has developed some reasoning ability and can understand the relationship between receiving the medicine and feeling better. When children are old enough to welcome choices, they can be offered limited dosing alternatives to provide a sense of control and encourage cooperation. The option of taking one medication before another or the chance to choose which drink will follow a chewable tablet helps to distract children from the issue of whether they will take the medication at all. It also makes an otherwise strange or unpleasant experience a little more tolerable.

- Allowing children to feel that they are willing participants, rather than victims, in medication administration is an important foundation for adherence.
- Praise for cooperation is appropriate for any pediatric patient and will set the stage for successful medication administration in the future.
- School-age children can take chewable tablets and may be able to swallow tablets or capsules. Many still resist injections; however, an experienced pediatric nurse can usually administer parenteral medications quickly and compassionately without the need for restraining the child.
- The ventrogluteal site is preferred for IM injections, although the muscles of older children are developed enough for the nurse to use other sites.

Pharmacotherapy of the adolescent: Adolescence occurs between ages 13 and 16 years. Rapid physical growth and psychologic maturation have a great impact on personality development. The adolescent strongly relates to peers, wanting and needing their support, approval, and presence. Physical appearance and conformity with peers

CONNECTIONS: Preparing for Advanced Practice

Ingestion of Suspected Poison

Case

Nancy, the mother of a 17-month-old toddler named Sammy, heard a cry and ran into the bathroom to find her son on the floor next to a spilled container of bleach. The toddler was drooling, his lips were blue, and there were blisters on his chin and chest. Desperate, Sammy's mother phoned the poison control center in Washington, D.C., where you work as a nurse specialist. You tell Nancy not to induce vomiting because bleach is a caustic substance that could severely damage the esophagus when it comes back up. You then instruct her to call for an ambulance immediately.

Shortly after Sammy arrived at the hospital, an endoscopy showed burns to the esophagus and trachea and he was admitted to the pediatric intensive care unit (PICU) with a breathing tube. Sammy was hospitalized for several weeks before he was finally well enough to go home. What important actions are needed when ingestion of a poison is suspected?

Discussion

When a child presents with suspected poisoning, start with an assessment of the emergency ABCs (airway, breathing, circulation), and administer oxygen if the child shows signs of respiratory distress. Chart the patient's age, weight, medications, and existing medical conditions. Find out what substance was ingested, the quantity, and when it was taken. Pay close attention to arterial blood gases (ABGs) and blood glucose levels in a child with depressed consciousness, and continue to monitor vital signs. When information about what was ingested is incomplete or inaccurate, the physical examination, laboratory tests, and a toxicologic screen should be used to determine treatment.

This case is far from unique and occurs daily in emergency departments (EDs) and poison control centers. The incident could have been avoided by having child-protective locks on the cabinets. Each year in the United States, well over 1 million children are poisoned. Annually, more than 500,000 children younger than 5 years accidentally ingest pharmaceuticals and more than 50,000 go to the ED (Targeted News Service, 2015).

Because most of these incidents occur in the home, teaching parents how to minimize the risks of poisoning is essential. It has been shown that poison-prevention counseling, which is recommended by the American Academy of Pediatrics as well as the Academy of Family Physicians, as part of routine pediatric care, results in greater prevention efforts at home. When preventive strategies are overlooked or efforts fail, rapid action is required. Knowing the causes, signs, and symptoms of pediatric poisoning is key for any nurse who cares for young children.

in terms of behavior, dress, and social interactions are important. The strong sense of independence leads teens to self-medicate, either with or without their parents' knowledge. Treatment objectives for the nurse should include teaching parents to keep their medications safely stowed out of sight of inquisitive, experiment-minded adolescents. Parents should also be taught the signs and symptoms of drugs commonly abused by teens such as marijuana, inhalants, and methamphetamine.

The most common needs for the pharmacotherapy of teens are for skin problems, headaches, menstrual symptoms, sex-related concerns, eating disorders, contraception, alcohol and tobacco use, and sports-related injuries.

- Of primary concern to the adolescent are the initiation of sexual intercourse and the avoidance of pregnancy and sexually transmitted infections. The nurse must be prepared to address a variety of topics related to sexuality, including the importance of responsible sexual practices and contraceptive methods.
- Eating disorders commonly occur in this population. The nurse should carefully question adolescents about their eating habits and their use of over-the-counter (OTC) appetite suppressants or laxatives that may be contributing to bulimia or anorexia.
- Alcohol, tobacco use, and other illicit drug experimentation are prevalent in this population. Teenage athletes may use amphetamines to delay the onset of fatigue as well as anabolic steroids to enhance performance. The nurse assumes a key role in educating adolescent patients about the hazards of tobacco use and illicit drugs.
- The adolescent has a need for privacy and control in drug administration. The nurse should communicate with the teen more in the manner of an adult rather than as a child. Teens usually appreciate thorough explanations of their treatment, and ample time should be allowed for them to ask questions.
- Despite their need to have independence and the desire to self-medicate, teens have a very poor understanding of medication information. Adolescents are reluctant to admit their lack of knowledge, so the nurse should carefully explain important information regarding their medications and expected adverse effects, even if these patients claim to understand.

CONNECTION Checkpoint 9.2

The nurse educator is teaching a group of new graduate nurses about the use of the anticoagulant heparin in pediatric patients admitted to the ICU. From what you learned in Chapter 6, what should the nurse include in her instructions about the necessary precautions for this type of drug? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Medication Safety for Pediatric Patients

9.4 The nurse is a key member of the healthcare team in ensuring medication safety in pediatric patients.

The nurse is often responsible for administering medications to children. The importance of accurate drug dosage calculations, proper administration techniques, proper efforts to minimize adverse effects, and the need for overall safety cannot be overemphasized.

Principles of safe medication practice for pediatric patients are identical to those of adult patients. Medication safety is a team approach. Every level of responsibility is involved, including hospital-wide (or corporation-wide) policies, prescriber actions, pharmacy guidelines, nursing interventions, and patient and family adherence. Responsibility for preventing medication errors in pediatric patients is shared by every member of the team.

The safety and effectiveness of a medication regimen depends on proper procurement, storage, and administration of the drug. In the hospital setting, nurses are responsible for adherence to the basic rules of drug administration: right patient, right drug, right route, right dose, at the right time. Younger pediatric patients may not be able to accurately identify themselves; thus it is imperative that the nurse use precautions to ensure that the right child receives the prescribed medication. The nurse must check the child's identification band against the medication record. Most hospitals' policies require that drugs such as digoxin, heparin, insulin, chemotherapeutic drugs, opioid analgesics, and barbiturates be double-checked with another nurse prior to administration. If the nurse suspects that a dose of medication ordered by the prescriber is outside the normal range, it is the nurse's responsibility to question the order because some drugs can be lethal to pediatric patients. The nurse should regularly check reputable online drug information sources for the most recent information on pediatric drugs and their adverse effects.

The American Academy of Pediatrics established guidelines in 2007 to prevent pediatric medication errors in the inpatient setting. Since that time, computerized physician order entry programs, electronic health records, programmable infusion pumps, and other technologies have been implemented. Because no system is fail-safe, the nurse should always follow these guidelines for safe medication practice:

Nursing Actions and Guidelines

- Check medication calculations with another professional member of the healthcare team.
- Confirm patient identity before administration of each dose.
- Be familiar with medication ordering and dispensing systems.
- Verify drug orders before medication administration.
- Verify unusually large or small volumes or dosage units for a single patient dose.
- When a patient, a parent, or a caregiver questions whether a drug should be administered, listen attentively, answer questions, and double-check the medication order.
- Remain familiar with the operation of medication administration devices and the potential for errors with such devices, particularly patient-controlled analgesia (PCA) or infusion pumps.

Nursing Education and Communication

- Develop and maintain continuous education programs for nursing competencies in devices used for pediatric medication administration, particularly PCA and infusion pumps.
- Develop and maintain a pediatric medications knowledge base.
- Discuss medication orders with the prescriber whenever possible.
- Integrate and provide education for the patient and caregiver regarding the medication regimen.
- Record and verify patient identity, weight, allergies, and previous medication use.
- Be aware of and be involved in ongoing error-tracking systems and pharmacy programs. Encourage blame-free error reporting. Ensure that all staff members understand the method of reporting and are knowledgeable about the healthcare agency's system for reporting errors.

Determining Pediatric Drug Dosages

9.5 The nurse must be accurate when calculating drug dosages of pediatric patients.

Nurses must consistently update their skills in calculating pediatric doses because errors in drug administration can have serious consequences. Drug dosage calculation for pediatric patients should be individualized and nurses should take into consideration the child's age, height, weight, maturational state, and body surface area. All drug calculations for pediatric patients in critical care settings should be double-checked by the pharmacist and another nurse prior to administration.

Two common procedures of calculating pediatric dosages are the body weight method and body surface area method. Utilization of the **body weight method** requires a calculation of the number of milligrams of drug, based on the child's weight in kilograms (mg/kg). A unit of time is usually included; for example, gentamicin 5 mg/kg/24 h. The body weight method is simple and a dose can be

calculated quickly. However, the serum concentrations of many drugs are not proportional to body weight, and body weight does not take into consideration pharmacokinetic variables such as changes in metabolism and elimination rates, as discussed in Section 9.2.

The **body surface area (BSA) method** uses an estimate of the child's BSA. This method is believed to be the most valid basis for dosage, because it is related to certain physiologic functions that account for the pharmacokinetic differences in pediatric patients. The BSA method better estimates blood volume, metabolism, and the effects of drugs. Measurements of the fluid volume compartment and the serum concentrations of drugs also correlate well with the BSA. Several different formulas have been used to calculate BSA, and each gives slightly different results. There is a lack of consensus as to which calculation method gives the most accurate results.

Calculators are readily available online to calculate BSA. The child's height (in centimeters) and weight (in kilograms) is entered and the body mass is calculated in square meters. The BSA can then be used to calculate a correct dose (Medscape, n.d.).

CONNECTIONS: Patient Safety

A Tenfold Error

The nurse is caring for a 6-year-old boy newly diagnosed with seizures, tonic-clonic type. In reviewing the written orders, valproic acid (Depakene) 150 mg/kg/day is ordered. The pharmacist calls the unit to verify the order and the nurse contacts the prescriber. The order is corrected to 15 mg/kg/day. What could be done to prevent this error from recurring?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Adverse Drug Reactions in Children and Promoting Adherence

9.6 Pediatric patients are more susceptible than adults to adverse drug effects.

Because of their smaller size and immature or developing organ systems, pediatric patients are more susceptible to adverse effects. The nurse may find it challenging to identify adverse effects because infants and young children often do not have the maturity or verbal skills to accurately describe their feelings following the medication administration. Identifying pediatric adverse effects will depend on the skill and ability of the nurse to assess subtle changes in patient response. For example, a child on diuretics should have strict intake and output measurements to help determine if the drug is working properly. Excessive weight gain could be caused by edema resulting from poor kidney excretion, or weight loss might be due to excessive diuresis. Signs of ototoxicity may go unnoticed for a long time unless someone checks that the child no longer responds to verbal commands. It may be necessary to consult a psychologist to identify signs of suicidal ideation from antidepressant use in adolescents.

Most types of adverse effects that occur in children age 1 or older are the same as those in adults. Like adults, the majority of adverse effects are dose related; thus the nurse must pay close attention to the proper dose and frequency of drug administration. Knowing specific drugs and their adverse effects in the adult population will help the nurse quickly identify signs and symptoms in pediatric patients. For example, antibiotics such as amoxicillin frequently result in diarrhea in both adults and children. Antianxiety drugs, antidepressants, and antipsychotic drugs that cause CNS depression will likely cause drowsiness in both adults and children.

A few types of adverse effects are specific to children due to their immature or developing organs and tissues. For example, tetracycline must be avoided in the neonate because of the potential for permanent staining of the teeth. Sulfonamides can cause jaundice in neonates, and aspirin is contraindicated in children with fever due to the potential for Reye's syndrome. Glucocorticoids can inhibit growth. Table 9.3 illustrates a list of commonly used drugs and their adverse effects on the pediatric patient.

CONNECTION Checkpoint 9.3

The nurse gives a preschooler a sedative but, rather than sleep, the child becomes excited and experiences insomnia. From what you learned in Chapter 5, this reaction is most likely classified as what type of effect? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Like adults, children may also experience drug interactions. Drugs that are most likely to contribute to drug interactions in pediatric patients are those with high potency, narrow therapeutic index, and extensive protein binding, and those that affect vital organ functions or hepatic metabolism.

Often parents' first response to their child's illness is to provide home remedies. OTC and herbal treatments are extremely common in some households, and research suggests that they are on the rise among a large segment of the population. The nurse must become aware of commonly used OTC and herbal remedies in order to advise the families about the pros and cons. Parents must understand that OTC and herbal therapies may have adverse effects of their own and may interact with prescription medications. Herbal remedies commonly used in homes include St. John's wort, echinacea, ginseng, licorice, and sassafras.

Table 9.3 Selected Pediatric Drugs for Which Specific Indications and Dosage Guidelines Exist

Drug	Dosage/Route (Maximum Dose Where Indicated)	Adverse Effects
acetaminophen (Tylenol)	PO: 10–15 mg/kg q4–6h for children under age 12, not to exceed 2.6 g/day	Methemoglobinemia, hepatotoxicity
acyclovir (Zovirax)	PO: 200 mg 5 times daily for genital herpes	*Diarrhea, nausea* Renal failure, seizures
amoxicillin (Amoxil, Trimox) or amoxicillin/clavulanate (Augmentin)	PO: 20–40 mg/kg/day	*Diarrhea* Anaphylaxis
amphetamine and dextroamphetamine (Adderall)	PO: 2.5–5 mg once or twice daily (regular release) or 10 mg once daily (extended release)	*Insomnia, anorexia, headache* Tachycardia, psychotic episodes, abuse potential
ampicillin (Principen)	PO: 50–100 mg/kg/day	*Diarrhea* Anaphylaxis
atomoxetine (Strattera)	PO: 40–80 mg once daily	*Dry mouth, anorexia, insomnia, headache* Depression, suicidal ideation
azithromycin (Zithromax)	PO: 5–10 mg/kg/day	*Diarrhea* Hepatotoxicity
budesonide (Rhinocort)	Intranasal: 2 sprays in each nostril bid for allergies	*Headache, fatigue* Paresthesia
ceftriaxone (Rocephin)	IV/IM: 50–100 mg/kg/day	*Diarrhea* Colitis
cephalexin (Keflex)	PO: 25–50 mg/kg/day q6h	*Diarrhea* Anaphylaxis, angioedema
clarithromycin (Biaxin)	PO: 15 mg/kg/day	*Vomiting, diarrhea* Colitis
diphenoxylate and atropine (Lomotil)	PO: 1/2–1 tsp, up to 4 doses/day	*Dizziness, sedation* Paralytic ileus
erythromycin (EryC, Erythrocin)	PO: 30–50 mg/kg/day	*Nausea, vomiting* Hepatotoxicity
ferrous sulfate (Feosol, Fergon, others)	PO: 0.5–1 mg/kg/day maintenance	*Nausea, black stools* Shock
fluconazole (Diflucan)	PO: 6 mg/kg/day first dose, then 3 mg/kg/day	*Headache, nausea* Hepatotoxicity
fluticasone (Flonase)	Intranasal: 1 spray in each nostril once a day; may increase to 2 sprays daily	*Nasal dryness* Epistaxis
gentamicin (Garamycin)	IV/IM: 6–7.5 mg/kg/day (2–2.5 mg/kg administered q8h)	*Pain at injection site* Neurotoxicity, nephrotoxicity
ibuprofen (Advil, Motrin)	PO: 5–10 mg/kg/dose given q6–8h	*Nausea, heartburn* GI bleeding
imipramine (Tofranil)	PO: 25–50 mg/day for nocturnal enuresis	*Urinary retention* Angioedema
methylphenidate (Ritalin)	PO: 5–10 mg/day (dose not to exceed 60 mg/day, depending on trade name)	*Nervousness, insomnia* Palpitations
minocycline (Minocin)	PO: 4 mg/kg/day bid	*Dizziness, nausea*
oxcarbazepine (Trileptal)	PO: 8–10 mg/kg/day not to exceed 600 mg/day	*Fatigue* Somnolence
penicillin G	PO: 25–50 mg/kg/day q3–4h	*Diarrhea* Anaphylaxis
trimethoprim-sulfamethoxazole (Bactrim, Septra)	PO: 8 mg/kg/day trimethoprim–40 mg/kg/day sulfamethoxazole q12h	*Nausea, rash, anemia* Exfoliative dermatitis
valproic acid (Depakene, Depakote)	PO: 10–15 mg/kg/day initially (dose not to exceed 60 mg/kg/day)	*Drowsiness, nausea* Bone marrow suppression

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

A drug will fail to achieve optimal therapeutic outcomes if it is not taken properly. Adherence, also called compliance, is taking the drug according to the instructions on the label or as provided by the prescriber. Maximizing adherence to the medication regimen is a major goal of the pediatric nurse. The nurse must assess the patient and family to determine factors that could affect the family's ability to assist the child with the medication regimen and develop strategies that will enhance medication adherence. The more complex, expensive, and inconvenient the medication

regimen, the less likely the child and family will adhere. Children are most likely to adhere to their medication regimen if the following conditions exist:

- High expectations of successful outcomes of the therapy
- Supportive family members who are able to communicate with the prescriber
- Positive interactions with the nurse and caregivers
- Minimal adverse effects from the medications
- Simple, short-term, inexpensive regimen with minimum disruption to daily routine.

The nurse works with the child and family to enhance adherence by applying direct measures. The patient and family should be asked directly whether or not they have doubts about their ability to adhere to the regimen. If there is doubt, the nurse should explore the areas of concerns with the family and start by teaching the importance of the drug, route of administration, expected outcomes, and possible adverse effects. In long-term drug therapy, the nurse may have to arrange for follow-up appointments to assess drug responses or to administer the oral drug(s) to the child and observe the drug being swallowed. This technique is known as **directly observed therapy (DOT)**. In extreme cases when the child does not appear to be responding appropriately to the prescribed regimen, periodic measurement of plasma drug levels can help determine the amount of drug ingested and whether it has been taken as prescribed.

Understanding Chapter 9

Key Concepts Summary

9.1 Legislation has attempted to improve the testing and labeling of pediatric drugs.

9.2 Pharmacokinetic responses in children differ from those in adults.

9.3 The role of the nurse in administering medications changes with each developmental age group.

9.4 The nurse is a key member of the healthcare team in ensuring medication safety in pediatric patients.

9.5 The nurse must be accurate when calculating drug dosages of pediatric patients.

9.6 Pediatric patients are more susceptible than adults to adverse drug effects.

CASE STUDY: Making the Patient Connection

Remember 7-month-old "Liam," the patient introduced at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Ms. Nguyen reports that Liam has not been eating well for the past 48 hours. Last night he vomited 3 times after drinking sips of water and also had several very loose, green foul-smelling bowel movements. He voided only once in the past 12 hours. For the past 5 days Liam has been taking amoxicillin for an ear infection. Liam lies still on the examination table but responds to his mother's commands. The nurse prepares Liam for examination.

Liam's preliminary diagnosis is gastroenteritis with mild dehydration. His vital signs are as follows: temperature, 39.1°C (102.4°F); heart rate, 160 beats/min; respiration, 38 breaths/min; blood pressure, 100/57 mmHg; and weight, 8.6 kg (19 lb). His skin is dry and warm to touch, and there is slight tenting. The following laboratory studies were performed: serum electrolytes, complete blood count, blood urea nitrogen, creatinine, urinalysis, and stool for culture and sensitivity. Electrolytes were as follows: sodium, 136 mEq/L; potassium, 4.2 mEq/L; chloride, 114 mEq/L; bicarbonate, 9 mEq/L.

An IV line was inserted immediately and a solution of D_5W in 1/3 NSS was started to infuse at 30 mL/h. Liam was placed on NPO.

Critical Thinking Questions

1. What primary factors are contributing to Liam's risk for deficient fluid balance?
2. What are some physical signs to assess when evaluating dehydration in this infant?
3. What would best explain the cause for diarrhea in this patient?
4. What are some key points to focus on when monitoring the infant's IV fluid intake?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Sinead, a 3-year-old girl, arrives at the ED in status asthmaticus. Her mother informs you that she was diagnosed with asthma 9 months ago and since then has been back to the ED for treatment twice. Two hours prior to admission, Sinead started coughing and wheezing and then an hour ago started having difficulty breathing. Her mother attempted to relieve the symptoms by giving steam and fluids but the condition only worsened. Sinead has audible expiratory wheeze, nasal flaring, and inter- and substernal retractions.

1. What nursing actions would take priority?
2. What nursing assessment should the nurse carry out immediately?
3. What immediate outcomes could be expected from treatment?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is preparing to administer medication to the pediatric patient. Which factor(s) is/are true regarding the pharmacokinetics in the pediatric population? (Select all that apply.)
    1. Slower gastric motility in young children will keep the drug in the stomach longer.
    2. Before 6 months of age, there is greater plasma protein binding of drugs, and drug distribution will be lower in this age group.
    3. Before age 5, the liver may not metabolize drugs as readily as an adult's liver and doses must be adjusted accordingly.
    4. Drug excretion by the kidneys will not equal an adult's until the child is at least 2 years of age.
    5. Drugs with CNS effects have little to no effect in infants and very young children.

2. A mother calls the urgent care center and frantically tells the nurse that her toddler drank a bottle of cleaning fluid. Which of the following is the priority instruction the nurse should give the parent?
    1. Contact the poison control center.
    2. Watch the child closely and call back if there are signs of respiratory distress.
    3. Take the child immediately to the emergency department.
    4. Give the child syrup of ipecac.

3. The experienced pediatric nurse is teaching a new nursing student about injections in the pediatric population. Which statement by the student would indicate that teaching was effective?
    1. "Intramuscular (IM) injections in infants are absorbed slowly."
    2. "Children experience rapid absorption of IM medications."
    3. "IM injections are encouraged due to their predictable absorption rate."
    4. "Strong muscle contractions result in delayed absorption of IM medication."

4. It is time to give a 3-year-old oral medication. Which comment by the nurse is most therapeutic?
    1. "This is the medicine that makes you better."
    2. "If you don't take your medicine you can't go home."
    3. "Would you like to take your medicine with water or juice?"
    4. "See how easily your roommate has taken his medicine?"

5. Drugs that are most likely to create drug interactions in pediatric patients are those with:
    1. Low potency.
    2. Wide therapeutic index.
    3. Extensive protein binding.
    4. Effects on the skin.

6. The healthcare provider knows that the pediatric patient and parents will most likely adhere to the medication regimen if the:
    1. Regimen is simple and inexpensive.
    2. Medications are costly but well known.
    3. Medications are prescribed for a long period.
    4. Medications are taken at different times each day.

Mary Smith, 80 years old, is being transported via ambulance to the emergency department. She looks pale and thin with sunken eyes and chapped, dry lips. "I'm so relieved my neighbor came by to check on me. I have not been able to get out of bed for 2 days."

Patient "Mary Smith"

Chapter 10
Pharmacotherapy of the Geriatric Patient

Chapter Outline

- Polypharmacy
- Physiologic Changes Related to Aging
- Pharmacokinetic and Pharmacodynamic Changes in Older Adults
- Adherence and Drug Misuse Among Older Adults
- Adverse Drug Reactions in Older Adults

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe factors that lead to polypharmacy in older adults.
2. Identify age-related physiologic changes in the older adult.
3. Explain how age-related physiologic changes alter pharmacokinetics and pharmacodynamics and affect drug response in older adults.
4. Explain strategies that the nurse may implement to improve adherence with drug therapy in geriatric patients.
5. Explain why older adults are more likely to experience adverse drug reactions and interactions.
6. Identify specific drugs that are particularly hazardous for use in older patients.
7. Differentiate medication responses that result from age-related alterations in specific body systems from those that occur in younger individuals.
8. Develop nursing interventions that maximize pharmacotherapeutic outcomes in older adults.
9. Generate key points for family and patient education regarding drug pharmacotherapy for older adults.

Key Terms

Beers criteria, 128
drug misuse, 127
polypharmacy, 124
potentially inappropriate medications (PIMs), 128

There is no universally accepted age that is considered old. The older adult, or an elderly individual, is typically defined as someone over age 65. Of this age group, those older than 84 years are the fastest growing segment of the population. The average age of the population has increased significantly during the past few decades because of improved access to healthcare, people choosing healthier lifestyles, and more effective treatment of chronic diseases. With the increase in lifespan, however, has come an increased reliance on medications to maintain health. This chapter focuses on aspects of pharmacology unique to geriatric patients and provides steps that the nurse can take to provide safe, effective pharmacotherapy for this population.

PharmFACT

Between 2012 and 2050, the United States will experience considerable growth in its older population. By the year 2050, the population ages 65 and over is projected to be 83.7 million, which is almost double its estimated population of 43.1 million in 2012. The baby boomers are largely responsible for this increase as they began turning 65 in 2011 (Ortman, Velkoff, & Hogan, 2014).

Polypharmacy

10.1 Older adults take more medications than any other segment of the population.

The pharmacotherapy of older adults is more challenging than that of their middle-age or younger counterparts. To deliver safe and effective treatment for patients in this age group, the nurse must consider many age-related variables that affect pharmacotherapy. In addition, older adults generally experience more chronic conditions than their younger counterparts. Most of these conditions require drug therapy to treat and prevent complications. Finally, many older adults self-medicate for minor conditions that do not require prescription drug therapy.

Longevity inevitably leads to increased illnesses, which, in turn, results in the use of increased numbers of medications. Comorbidity, the presence of several chronic medical disorders concurrently, is common among older adults. By about age 65, half the older population has two or more chronic disorders, the most prevalent being a combination of hypertension and arthritis. Other comorbidities that occur in a significant number of older adults are heart disease with arthritis, hypertension with diabetes, and depression with nearly any other chronic disorder.

Comorbidities often result in the need for multiple drugs, a condition termed **polypharmacy**. Although not unique to older patients, polypharmacy is prevalent in this age group because of these comorbidities. The higher the number of drugs taken by a patient, the greater the possibility of experiencing adverse effects and drug interactions. As presented in Chapter 5, drugs that may be safe when used as monotherapy can have additive adverse effects when combined with other drugs. For example, taking multiple drugs that cause central nervous system (CNS) depression can lead to excessive sedation, thus increasing the risk for injuries due to falls. Taking two or more drugs that cause renal or liver impairment can result in additive organ damage in older adults who may already have some degree of function loss due to normal aging processes.

Polypharmacy may also occur when the patient takes over-the-counter (OTC) drugs, herbal products, and dietary supplements in conjunction with prescribed medications. For example, older adults frequently seek OTC medications to treat constipation and minor aches and pains. Many also take vitamins, alternative therapies, and dietary supplements. Most patients are unaware that these agents can interact with prescription medications.

Patients who visit multiple healthcare providers and use different pharmacies may experience polypharmacy because each provider or pharmacist may not be aware of all the drugs ordered by other prescribers. Nurses should urge patients to report all prescription and OTC products at each office visit and teach them to use one pharmacy for their prescription needs.

In addition to polypharmacy, many other factors can alter a geriatric patient's response to medication. These include physiologic changes associated with aging, changes in pharmacokinetics and pharmacodynamics, and patient adherence with the therapeutic regimen.

CONNECTION Checkpoint 10.1

From what you learned in Chapter 5, state the differences between additive, synergistic, and antagonistic effects. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Physiologic Changes Related to Aging

10.2 Anatomic and physiologic changes associated with aging may alter the patient's response to medications.

With advancing age, certain anatomic and physiologic changes occur. These predictable changes should be considered a normal part of the aging process, rather than as diseases or pathologic conditions. Awareness of the physiologic changes that occur during the lifespan is critically important in properly assessing and caring for the older adult (Figure 10.1). Failure to recognize these changes may lead to less than optimal therapeutic outcomes and may endanger patient safety.

Giving an "average dose" of a drug to an older adult may produce a very different response compared to the same dose given to a younger patient, even if the two patients weigh the same. The pharmacologic action of the drug in older adults may be enhanced or diminished. The adverse effects may be more severe or entirely different from those observed in younger patients. The older patient may experience more drug interactions. What factors are responsible for this wide variation in drug response in the geriatric population?

In general, physiologic processes slow down with advancing age. For example, the rate of absorption of nutrients from the gastrointestinal (GI) system tends to slow due to the decrease in GI motility and reduced GI blood flow. Metabolism also diminishes due to decreased liver size and reduced blood flow to this organ. Additionally, as an individual ages the production of serum albumin by the liver declines. The older adult has a decreased volume of total body water, leading to higher concentrations of substances in the serum.

Figure 10.1 Pharmacology of the older adult can be challenging due to physiologic changes that occur with aging.
Courtesy of Barabasa/Shutterstock.

Cardiovascular system changes in the older adult are related to changes in cardiac muscle and increased peripheral resistance (hypertension). These physiologic changes lead to decreased contractile force, which diminishes cardiac output and slows the circulation of nutrients and drugs.

In the nervous system, conduction velocity slows and sensory functions such as vision, hearing, and smell begin to diminish. Brain mass begins to decline, resulting in a progressive loss of cognitive ability. Additionally, as an adult ages the efficiency of the blood–brain barrier declines, allowing more substances to enter the CNS and affect the brain.

Older adults undergo a progressive decline in renal function as a result of decreased renal blood flow, decreased glomerular filtration rate, and decreased numbers of nephrons. The kidneys begin to lose their ability to effectively excrete creatinine and other wastes from the body. The body retains drugs and other substances for longer periods.

Normal, age-related physiologic changes in organ systems can greatly affect responses to medications. Selected changes, and their effects on drug response, are shown in Table 10.1.

Pharmacokinetic and Pharmacodynamic Changes in Older Adults

10.3 Normal aging processes can alter pharmacokinetic and pharmacodynamic responses to drugs.

To produce therapeutic effects, most drugs must reach their target cells in sufficient quantities. To a large extent, this depends on what the body does to the medications after they are administered, a process known as pharmacokinetics. Drug response is also dependent on pharmacodynamic factors: the mechanisms by which drugs change the body. The normal physiologic changes of aging affect pharmacokinetics and pharmacodynamics. Knowing about these changes when administering medications to the older adult helps the nurse to understand the unique actions of drugs in these patients and to predict and prevent adverse effects.

Absorption: Overall, absorption of nutrients and drugs tends to slow with aging. Fortunately, although the rate slows, absorption is usually complete because most drugs are absorbed by passive diffusion.

Because of the increased gastric pH in older adults, oral tablets and capsules that require high levels of acid for absorption may dissolve more slowly and take longer to reach their target tissues. Furthermore, decreased blood flow to and from the GI tract in the older adult delays the absorption and subsequent distribution of medications.

Table 10.1 Physiologic Factors Affecting Medication Responses in Older Adults

Body System	Changes in Physiologic Factors	Effect on Medication Response
Cardiovascular system	• Decreased force of contraction and stroke volume • Decreased oxygen uptake by tissues • Decreased serum albumin and serum-binding capacity	• Reduced cardiac output and slowed distribution • Decreased metabolism • Changed drug distribution, producing unpredictable and toxic levels of highly protein-bound drugs such as phenytoin
Central nervous system	• Decreased brain size, number of neurons, and peripheral nerve function • Declining efficiency of blood–brain barrier	• Decreased drug distribution • Increased penetration of drug in the brain
Endocrine system	• Alterations in carbohydrate metabolism • Decreased growth hormone production and altered corticosteroid activity, leading to increased body fat, decreased muscle, and decreased bone mass	• Reduced insulin secretion and increased insulin resistance, manifesting as type 2 diabetes mellitus • Increased absorption of fat-soluble drugs
Gastrointestinal system	• Decreased GI motility • Decreased emptying of gastric contents • Reduced gastric acid production • Increased gastric pH • Decreased blood flow to the GI tract • Decreased thirst perception, leading to risk for dehydration, electrolyte imbalance, and poor nutritional intake	• Slowed rate of absorption • Increased potential for adverse effects
	• Decreased liver size • Decreased blood flow to the liver • Decreased ability of the liver to metabolize drugs	• Slowed metabolism • Prolonged drug half-life, increasing the potential for adverse effects
Musculoskeletal system	• Decreased lean muscle mass and increased and redistributed body fat	• Extended and increased effect of fat-soluble drugs such as diazepam
Respiratory system	• Decreased muscle strength and endurance	• Decreased chest and lung expansion and response to hypoxia, resulting in altered rate of absorption and excretion of some respiratory drugs
Urinary system	• Decreased total fluid volume • Decreased renal blood flow, glomerular filtration, and tubular secretory function • Decreased creatinine clearance	• Higher concentrations of water-soluble drugs • Reduced rate of excretion and decreased drug clearance • Decreased drug excretion

Slowed motility allows drugs to remain longer in the GI tract, increasing the length of time for absorption and raising the risk for adverse effects such as nausea and vomiting. Physiologic changes that lead to alterations in the rate and quantity of drug absorption are listed in Table 10.1.

Distribution: As the body ages, the proportion of body fat increases, which can cause lipid-soluble drugs such as diazepam (Valium) to be stored in the body for extended periods. This may lead to lower plasma levels and increased drug concentrations in the tissues. The longer a drug remains in the tissues, the more significant the response to the drug will be and the greater the potential for adverse effects.

As the body ages, there may be a reduction in total body water resulting in water-soluble drugs such as gentamicin (Garamycin) and hydrochlorothiazide (Microzide) having less body fluid for dilution. Therefore, water-soluble drugs have higher serum concentrations and may produce more intense actions. To prevent toxicity, the peak and trough levels of drugs with a low safety index such as gentamicin are checked periodically, and drug dosages are adjusted accordingly.

Because of declining liver function, plasma protein levels are reduced in the older adult. This decrease results in fewer binding sites for certain drugs, and higher concentrations of free drugs, which may lead to toxicity. In older adults taking highly protein-bound drugs such as phenytoin (Dilantin) and warfarin (Coumadin), the nurse must carefully assess for signs of toxicity, even when the patient is receiving therapeutic doses.

Higher levels of drugs are able to enter the brain in older adults due to the inefficient blood–brain barrier. Patients taking drugs such as benzodiazepines, antipsychotic drugs, antiepileptic drugs, or tranquilizers that affect the CNS must be assessed for signs of adverse effects that often manifest as reduced cognitive function, drowsiness, confusion, and even hallucinations and psychoses.

Metabolism: Although most tissues metabolize drugs to some extent, the liver is by far the most important organ performing this function. Age-related changes in the liver include reduced hepatic function, decreased liver mass, diminished blood flow, and alteration in the activity of some hepatic enzymes.

Age-related changes in liver function are often unpredictable, causing the level of some metabolic enzymes to be reduced, whereas others remain unchanged. In general, blood flow to the liver decreases and metabolic activity of the CYP450 enzymes is diminished. Reduced metabolism

means that drugs will have extended durations of action. Drugs with a long half-life such as gentamicin, digoxin (Lanoxin), and acetaminophen (Tylenol) remain longer in the body with the potential for accumulation in tissues. Such drugs should be prescribed with longer intervals between doses or in reduced dosages, and the patient should be monitored closely.

CONNECTIONS: Lifespan Considerations

Drug Monitoring in the Older Adult

To avoid toxicity, a number of drug dosage changes should be made for the older adult:

- The older adult should be started on the smallest effective dose of medication and then be titrated upward.
- Observe the older patient for signs of drug accumulation about 3 to 5 days after new drug initiation. Consider any change in physical or emotional behavior as possible drug intoxication.
- Monitor hydration and nutritional status, especially among older patients, because dehydration and low protein in the diet are primary causes of drug toxicity in this age group.

Excretion: The kidneys are the primary site for excretion of most drugs. Renal function declines with aging, resulting in a slower clearance of drugs from the body. The half-life of drugs is increased and the dosages or frequency of administration should be decreased to avoid toxicity due to drug accumulation. Patients who are taking drugs that are excreted primarily by the kidneys should receive periodic serum creatinine tests to assess renal function. Dosages of drugs must be carefully adjusted in patients with impaired renal function. Unlike hepatic function, which is often unpredictable in older adults, diminished renal function is mostly consistent from patient to patient.

Pharmacodynamic changes: Pharmacodynamic changes are usually associated with drug receptors. Evidence suggests that older adults have decreased numbers of receptors and, possibly, changes in receptor sensitivity. In assessing the older adult, the nurse will find a decreased response to beta-adrenergic agonists and antagonists and, at the same time, an increased response to anticholinergics, CNS depressants, and drugs such as warfarin. There is limited information on how pharmacodynamic alterations actually occur in older adults.

CONNECTION Checkpoint 10.2

From what you learned in Chapter 3, what are CYP450 enzymes? State the differences between a substrate and an inducer of CYP450 enzymes. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Adherence and Drug Misuse Among Older Adults

10.4 Adherence with the therapeutic regimen is a major challenge for many older adults.

Drug adherence or compliance is the willingness and ability to take medications as instructed on the label or by the healthcare provider. Healthcare providers often assume that patients leaving the clinic or hospital will be adherent by filling their prescriptions and taking their medicines as directed. It may be surprising to learn that over a third of patients report they are often nonadherent with drug therapy. Reasons for nonadherence are many and varied and include the following: medication not with me when dose was due, ran out of medication, uncomfortable side effects, and symptoms resolved (Pasina et al., 2014).

Although nonadherence is not unique to older adults, this population is especially vulnerable. Older adult patients are more likely to have visual impairment, functional disabilities, and cognitive dysfunction that may be sources of medication errors and nonadherence. Functional hearing loss can prevent older adults from understanding the verbal instructions given by the healthcare provider. The large number of drugs taken by some older adults makes for a complicated dosing schedule that can be confusing for patients of any age.

Successful management of medical problems depends on a patient's adherence with the regimen. One of the main responsibilities of the nurse is to assess barriers to medication adherence in the older adult. Studies suggest that nonadherence is affected by three factors: the individual patient, the healthcare provider, and the patient's social support network.

Adherence at the patient level requires the patient's comprehension and commitment to the treatment. The patient must be able to afford the medication, believe in its efficacy, appropriately self-administer, and adjust to lifestyle changes that may be required. The healthcare provider must be able to effectively instruct the patient regarding a medication's efficacy, prescribe cost-effective medication, decrease the complexity of the regimen, and provide manageable and understandable instructions. Nurses play a key role in assessing the patient's understanding of the medications that have been ordered and for assessing patient concerns with cost or effects.

The nurse should provide the older adult's spouse or caregiver with adequate information regarding the patient's medication regimen, expected lifestyle changes, and the need for emotional support and monitoring. Table 10.2 lists reasons that patients give for nonadherence and provides suggestions for the nurse to promote adherence.

Drug misuse is a specific form of nonadherence that is common among older adults. Misuse includes overuse, underuse, or, in some cases, erratic use. This misuse may be unintentional or deliberate. Self-adjusting the medication

Table 10.2 Promoting Adherence in the Older Adult Patient

Reasons for nonadherence	• Unpleasant adverse effects • Forgetfulness • Cognitive or physical impairment • Poor or misunderstood instructions • Complicated regimens • Inability or refusal to purchase the medication • Health beliefs about medications
Ways the nurse can promote adherence	• Assist the older adult in comprehending and committing to the drug treatment regimen. • Communicate the instructions in such a manner that the older patient fully understands the purpose of the treatment. • Provide the older patient with social support services to obtain the medications. • Work with a pharmacist to ensure that the medication is dispensed in containers that are easily opened and in formulations that are easily taken. • Make sure all drugs are clearly labeled with instructions. • Simplify the regimen to reduce the number of drugs and doses per day. • Suggest that the older patient use a daily or weekly pill counter. • Provide the patient with a check-off calendar to document each time a medication is taken. • Engage family members or friends in supporting the older patient in efforts to comply. • Encourage the older patient to report signs of adverse effects. • Schedule periodic tests to determine plasma drug levels. • Place follow-up calls to high-risk patients.

dose is a common practice: Patients change their dose level depending on how they feel. Some believe that taking extra doses will speed their recovery. Uninsured or underinsured patients who cannot afford their medications may try to make the medications last longer by splitting doses. Patients rarely report such practices to their healthcare provider. Drug misuse may have serious consequences: Many older adult visits to emergency departments are drug related, with nonadherence accounting for a substantial percentage.

CONNECTION Checkpoint 10.3

From what you learned in Chapter 2, describe some of the benefits to older adults created by the Medicare Prescription Drug, Improvement, and Modernization Act of 2003. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Adverse Drug Reactions in Older Adults

10.5 Older adults are at high risk for experiencing adverse drug reactions and interactions.

An adverse drug effect is an undesirable and potentially harmful action caused by the administration of medications (see Chapter 5). Although older adults have many factors that predispose them to an increased risk of adverse effects, the number of drugs prescribed is probably the most important. The risk of an adverse effect greatly increases with the number of drugs taken. A survey in the United States of 2206 adults ages 62 through 85 years showed that at least one prescription medication was used by 87% of the older adults, five or more prescription medications were used by 36%, and 38% used OTC medications (Qato, Wilder, Schumm, Gillet, & Alexander, 2016).

To minimize adverse effects, prescribers should order drugs only when they are needed and for the shortest length of time necessary to produce a therapeutic effect. Medications and doses should be reviewed on a regular basis to ensure that the intervention is still necessary.

Age-related physiologic changes in renal and hepatic function are often responsible for placing older patients at greater risk for adverse effects. As the ability of the kidney to excrete drugs diminishes, serum drug levels may rise to cause toxicity. Loss of the ability of the liver to metabolize drugs can also raise serum drug levels and cause adverse effects. The nurse must be vigilant in assessing laboratory results of renal and hepatic function in older adult patients. Doses of most drugs must be adjusted with renal or hepatic impairment to prevent adverse effects.

As an individual ages it often becomes difficult for the nurse to differentiate between behaviors that may be a natural part of aging and symptoms caused by adverse effects. For example, a frail older adult who walks with an ataxic gait might be wrongly suspected of having an adverse effect from benzodiazepines or phenytoin, although the condition might be caused by normal aging. Older adults are more likely to experience CNS drug adverse effects such as dizziness and drowsiness, which are also symptoms that are often associated with normal aging processes. Medications should be considered as an underlying cause of the following symptoms in older patients:

- Sudden change in mental status
- Rapid weight loss
- Dehydration
- Restlessness
- Falls
- Anorexia
- Urinary retention or fluid retention
- Change in bowel habits
- Major change in functional status of any organ system.

Combining a thorough literature review with expert consensus, healthcare providers have compiled a list of drugs of special concern for older adults. These are sometimes referred to as **potentially inappropriate medications (PIMs)**. Known as the **Beers criteria** or Beers list, healthcare providers should avoid prescribing PIMs to older adults

Table 10.3 Selected High-Risk Drugs for Older Adults

Drug	Adverse Response
antihistamines (e.g., chlorpheniramine, diphenhydramine, hydroxyzine, promethazine)	Sedation, confusion, anticholinergic effects
antipsychotic drugs (e.g., chlorpromazine, clozapine, risperidone)	Increased mortality (in patients with dementia-related psychosis)
benzodiazepines (e.g., alprazolam, lorazepam, oxazepam)	Confusion, depression, anticholinergic effects
digoxin (Lanoxin)	Reduced renal clearance (in patients with preexisting chronic kidney disease)
GI drugs (e.g., ranitidine, cimetidine)	Liver dysfunction, blood dyscrasias (ranitidine)
	Confusion, depression (cimetidine)
muscle relaxants (e.g., carisoprodol, cyclobenzaprine, oxybutynin)	Sedation, weakness, anticholinergic effects
nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., aspirin, ibuprofen, naproxen)	Photosensitivity, nephrotoxicity, fluid retention
opioid analgesics (e.g., meperidine, morphine, oxycodone)	Sedation, confusion
phenytoin (Dilantin)	Confusion, ataxia, slurred speech, diplopia
skeletal muscle relaxants (e.g., carisoprodol, methocarbamol, cyclobenzaprine)	Sedation, confusion
tricyclic antidepressants (e.g., amitriptyline, doxepin, imipramine)	Hallucinations, confusion, anticholinergic effects

because they have been found to produce a high incidence of adverse effects in this population. In 2015, the American Geriatrics Society (AGS) updated the Beers criteria using a comprehensive, systematic review and grading of the evidence on adverse drug-related problems in older adults. The update includes lists of select drugs that should be avoided or dose adjusted based on the individual's renal function and drug–drug interactions. In the past, there was controversy around how to translate the criteria into practice and, because of this, a supplemental companion piece to the updated criteria was developed to give guidance to patients, providers, and health systems on how to use, and not use, the 2015 AGS Beers criteria. Table 10.3 provides a select list of PIMs that should be avoided in older adults along with their specific adverse effects of concern.

A drug interaction occurs when a medication interacts with another substance and the drug's actions are affected. The other substance causing the drug interaction may be another drug, a dietary supplement, an herbal product, or a food (see Chapter 5). The large number of prescription drugs and OTC products taken by older adults predisposes this population to a high risk for drug interactions.

CONNECTIONS: Preparing for Advanced Practice

Complicated Medication Routines and Older Adults

Case

Mr. Barkins is an 88-year-old who is a frequent patient in our community geriatric clinic. He has lived alone since his wife died and visits the clinic often because he is lonely and looking for conversation and company. He is a favorite patient to most of the staff. In addition to the social isolation, he has medical issues including diabetes mellitus type 2, hypertension, chronic kidney disease, peptic ulcer disease, and anemia. In fact, while doing his medication reconciliation you realize he is on 18 different medications! He tells you that he is having difficulty managing "all these pills" at home and is not taking all his prescribed medications. You inquire further and find out he is missing doses because it is "too hard to take all of them," and that by skipping some of the medications every day, he keeps the costs down. What are some of the things you can do to optimize adherence? What community resources are available for Mr. Barkins?

Discussion

Oftentimes, older patients may decide to skip doses or stop taking their medication without telling their provider, until they are asked. Medication adherence should be one of the routine health history questions for older patients. Medication reconciliation is the first step in assisting older adults to manage their medications. A "medication check-in" should be conducted annually or more often to review all the patient's medications and to determine which medications and dosage adjustments are needed.

Older patients are more likely to adhere to a prescribed medication that has a simpler dosing schedule, such as once daily, compared to another medication that has a more complex dosing schedule, such as twice daily.

Many pharmaceutical companies offer medication assistance programs to low-income older patients. These programs typically require a provider form and proof of financial status from the patient.

BenefitsCheckUp is a free service of the National Council on Aging (n.d.), a nonprofit service and advocacy organization in Washington, D.C. The online service asks a series of questions and then identifies programs that could help patients pay for prescriptions, healthcare, food, and other expenses.

Table 10.4 Nursing Responsibilities Related to Adverse Drug Reactions and Drug Interactions in Older Adults

Nursing Responsibilities	Rationales
• Review the patient's medications to determine the potential for adverse effects and drug interactions. Consider cultural and dietary issues.	• Adverse effects are common in older patients because of physiologic changes in body composition, multiple illnesses, polypharmacy, and nonadherence. • Some dietary practices may lead to adverse effects and interactions (e.g., low-salt intake may lead to lithium toxicity).
• Instruct the patient about potential adverse effects.	• A well-informed patient is better able to notify the healthcare provider as early as possible to minimize adverse effects.
• Assess the patient's fluid volume.	• Alteration in fluid volume could lead to increased sensitivity to alpha antagonists and other drugs with effects on blood pressure.
• Instruct the patient about the proper time to administer medications.	• Taking medications at the proper time will ensure optimal effectiveness and lower the chance for adverse effects.
• Ensure that the fewest number and lowest doses of medications with the simplest regimens have been prescribed for the patient.	• Polypharmacy may lead to drug toxicity.
• Monitor the patient for expected responses and any changes from normal.	• Adverse effects may not always be predictable because they may arise from sudden changes in the patient's condition.
• Discard all unused and expired medications, and instruct the patient to do the same.	• Drug effects diminish after the expiration date and some drugs can become toxic over time.
• Assess and monitor the patient's mental status for any alterations that may be caused by adverse effects.	• Delirium or confusion may be caused by adverse effects of psychoactive drugs.
• Periodically review the patient's OTC medications, nutritional supplements, and prescribed medications.	• Review of all drugs and alternative therapies can reduce the chances of adverse effects.

Another factor contributing to the increased risk for drug interactions is the presence of comorbidities (see Section 10.2). For example, the patient with both arthritis and heart disease may be using nonsteroidal anti-inflammatory drugs (NSAIDs) for pain and warfarin (Coumadin) to prevent blood clots. The NSAID may increase the effect of the warfarin, thus raising the potential for bleeding. The patient with both diabetes and hypertension may be taking thiazides and insulin. The thiazides reduce the effectiveness of insulin, thus affecting glycemic control.

The nurse plays a key role in optimizing pharmacotherapy outcomes in older adult patients, including addressing adverse effects, drug interactions, and issues of polypharmacy. One of the primary nursing responsibilities is to make a connection between the patient and family and the medication regimens. This entails assessing the level of comprehension, cultural beliefs, dietary practices, and physiologic conditions of the patient and family. Advanced age does not negate the patient's right to know the names of the prescribed medications, the reasons they are being prescribed, and the potential adverse effects. Table 10.4 highlights nursing responsibilities and rationales regarding adverse effects and drug–drug interactions in older patients.

PharmFACT

Routine vaccinations are just as important for the older adult as for younger patients—maybe even more so as immunity wanes. McIntyre, Zecevic, and Diachun (2014) explored factors that influenced older adults to either avoid or obtain the influenza vaccine. Trust in the healthcare provider's recommendation was the main reason participants in the study received the vaccine, followed by knowing others who had received it.

Understanding Chapter 10

Key Concepts Summary

10.1 Older adults take more medications than any other segment of the population.

10.2 Anatomic and physiologic changes associated with aging may alter the patient's response to medications.

10.3 Normal aging processes can alter pharmacokinetic and pharmacodynamic responses to drugs.

10.4 Adherence with the therapeutic regimen is a major challenge for many older adults.

10.5 Older adults are at high risk for experiencing adverse drug reactions and interactions.

CASE STUDY: Making the Patient Connection

Remember the patient "Mary Smith" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Mary has an IV solution of normal saline infusing in her left arm and oxygen by mask at 2 L/min. Last week she heard that her older cousin had passed away, and since then she has become extremely depressed. She refuses to eat or drink but continues to take her medications on a regular basis. This 80-year-old woman is dehydrated and somewhat confused. Her neighbor provides the history. The nurse finds that Mary has been taking a diuretic (hydrochlorothiazide), an antihypertensive (atenolol), and multivitamins daily.

Vital signs are as follows: temperature, 38.6°C (101.4°F); apical pulse, 100 beats/min; respiratory rate, 32 breaths/min; and blood pressure, 92/62 mmHg. Her skin is dry and warm to the touch, and her lips are pale, dry, and chapped. She weighs 51.3 kg (113 lb) and her height is 1.7 m (5′7″). Her speech is quiet and slurred. Mary has not eaten anything during the past 24 hours and has only taken sips of water during the past 12 hours. She has voided once in 12 hours.

The following laboratory tests are completed: urinalysis, blood urea nitrogen (BUN) and creatinine, complete blood count (CBC), and basal metabolic panel (BMP). Mary is prescribed IV rehydration fluid and is stabilized in the emergency department before being admitted to the hospital unit.

Critical Thinking Questions

1. What are some potential predisposing factors that could lead to this patient's condition? (The student may need to consult later chapters or a drug reference book for the drugs included.)
2. What are the most immediate patient care priorities for the nurse to address at this time?
3. What priority areas will the nurse assess?
4. What are some of the expected patient outcomes, including changes in vital signs, following management of dehydration?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Ms. Haynes, 88 years of age, is fiercely independent and lives in an assisted living facility in her own apartment with meals taken in a group dining room, which she clearly enjoys. She has a history of diabetes controlled with an oral antidiabetic drug, hypertension controlled with an antihypertensive drug and a mild diuretic, and occasional stomach upset for which she takes antacids. Her daughter suspects that her mother has not been taking any of her medications regularly because her blood sugar and blood pressure have been extremely variable lately and she asks the nurse for assistance.

1. What should the nurse do to assess whether Ms. Haynes is taking her medications regularly? What laboratory test will help determine diabetic control over a period of time?
2. If Ms. Haynes is not taking her medications, what would the nurse's next action be?
3. What recommendation should be given to Ms. Haynes's daughter?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. In general, drug absorption in the older adult is somewhat slowed. What physiologic changes may account for this? (Select all that apply.)
    1. Increased gastric pH
    2. Decreased rate of blood flow to the GI tract
    3. Increased gastrointestinal motility
    4. Increased body surface area
    5. Decreased cardiac output
2. The nurse completes an initial home assessment of an independent 82-year-old woman recently diagnosed with type 2 diabetes mellitus managed with insulin injections. What is the most appropriate nursing action for insulin administration for this patient?
    1. Teach the daughter how to administer the insulin to her mother.
    2. Instruct the patient how to administer the insulin.

3. Recommend daily visits by a home health aide to give the insulin.
4. Ask the healthcare provider to change the order to an oral antidiabetic medication.

3. Which age-related change in the older patient makes it necessary to reduce drug dosages?

1. Decrease in total body fat
2. Decrease in renal blood flow
3. Increase in plasma protein levels
4. Increase in total body water

4. Older adults experience adverse effects more frequently than young adults due to which of the following? (Select all that apply.)

1. Excessive prescribing
2. Multiple-drug therapy
3. Increased drug sensitivity
4. Increased body mass
5. Lack of consistent exercise

5. One third of older adult patients report that they are often nonadherent with drug therapy. Which response is given most frequently for nonadherence?

1. "The drugs prevented me from doing other things I wanted to do."
2. "I didn't have my medicine with me."
3. "I wanted to save money."
4. "I didn't believe the drugs were effective."

6. Which statement by the patient would inform the nurse that more teaching is necessary prior to discharge?

1. "It doesn't matter if the medication works as long as the doctor prescribed it."
2. "This medication is fully covered by my health insurance."
3. "I have been taking my medications by myself all my life."
4. "I don't mind making changes to my lifestyle while I am on this drug."

See Answers to Chapter Review in Appendix A.

"It was so humiliating. When I was in the hospital, no one ever called me by name. I overheard someone refer to me as the Indian woman in room 425. No one really tried to communicate with me."

Patient "Aponi Nampeyo"

Chapter 11
Individual Variations in Drug Responses

Chapter Outline

- Psychosocial Influences
- Cultural and Ethnic Variables
- Genetic Influences
- Gender Influences

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the fundamental concepts underlying a holistic approach to patient care and their importance to pharmacotherapy.
2. Identify psychosocial and spiritual factors that can affect pharmacotherapeutics.
3. Explain how ethnicity can affect pharmacotherapeutic outcomes.
4. Identify examples of how cultural values and beliefs can influence pharmacotherapeutic outcomes.
5. Convey how genetic polymorphisms can influence pharmacotherapy.
6. Explain how pharmacogenomics may lead to customized drug therapy.
7. Explain how gender can influence the actions of certain drugs.

Key Terms

culture, 134
ethnicity, 134
genetic polymorphism, 136
pharmacogenetics, 137
psychosocial, 134

Pharmacotherapy would indeed be simplified if the "average" dose given in a drug guide produced the same response in every patient. However, as presented in Chapter 4, patients can respond very differently to drug administration. For example, the same dose of an antihypertensive drug can result in a desired therapeutic effect in one patient and produce no effect or profound hypotension in other patients. The purpose of this chapter is to examine some of the factors that may cause this variability, including psychosocial influences, culture and ethnicity, genetics, and gender. Knowledge of these factors can contribute to safer and more effective pharmacotherapy.

Psychosocial Influences

11.1 Many psychosocial influences impact pharmacotherapy.

The term **psychosocial** is used in healthcare to describe the interaction between one's psychologic development and one's social environment. Psychosocial nursing is part of a holistic model that includes the examination of patients' social roles, environmental stressors, culture, values, and family, all of which contribute to health and wellness.

Psychosocial also includes the spiritual nature of an individual. *Psycho-social-spiritual* is a term that appears in the healthcare literature. Studies have established that these factors have a tremendous impact on health and well-being. Healthcare providers recognize that the close relationship among the psychologic, social, and spiritual nature of individuals strongly influences their illness and wellness.

The psychosocial history of the patient, which is often collected during the initial assessment, can influence the success of pharmacotherapy. Important assessment data include developmental needs, environmental stressors, and life transitions that could require major adaptations by the patient. The nurse also considers the patient's level of motivation to correct the health issue, because nonadherence to medication regimens and recommended lifestyle adjustments could impede the success of pharmacotherapy. For example, a highly stressed, middle-aged patient who is struggling with a new business might find it difficult to focus on wellness goals associated with maintaining normal blood pressure and cholesterol levels.

A thorough psychosocial assessment should provide the healthcare provider with a clear picture of the patient's living arrangements, family involvement and interaction, financial resources, emotional condition, physical condition, and cognitive functioning. For example, does the patient have a trusting and empathetic relationship with his or her family? Would the family be able and willing to help the patient through some difficult challenges with adverse effects or long-term therapy? Is the patient emotionally stable enough to receive prescription drugs that have a possible suicidal risk? All of this information is important to developing effective health goals and pharmacotherapeutic outcomes.

In some cases the patient assessment may indicate a need to address psychosocial interventions before pharmacotherapy is begun. Behavioral or cognitive therapies may be employed to reduce negative thoughts and behaviors that could impact therapy. In children or adolescents, attempts at psychosocial therapies may be a prerequisite to initiating pharmacotherapy for conditions such as attention-deficit/hyperactivity disorder, major depressive disorder, or bipolar disorder. The integrated use of pharmacologic and psychosocial therapies is believed to increase therapeutic success in addiction treatment.

CONNECTION Checkpoint 11.1

The frequency dose–response curve can be used to depict interpatient variability to drug response. From what you learned in Chapter 4, draw a typical frequency dose–response curve, labeling the axes and the median effective dose (ED_{50}). *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Cultural and Ethnic Variables

11.2 Cultural and ethnic variables can influence pharmacotherapy.

Although they are sometimes used interchangeably, culture and ethnicity differ in their exact definitions. An ethnic group is a community of people who share a common ancestry and similar genetic heritage. **Ethnicity** implies that people have biological and genetic similarities. **Culture** is a set of beliefs, values, and norms that provide meaning for an individual or group. People within a culture have common rituals, religious beliefs, language, and certain expectations of behavior. Cultural and ethnic variables are important aspects of patient care that directly relate to pharmacotherapy. Both can influence the occurrence of specific drug effects and patient treatment outcomes.

CONNECTIONS: Treating the Diverse Patient

Medication Refusal for Religious, Moral, or Dietary Reasons

One of the "rights" of medication administration is refusal. Patients have the right to refuse their medications due to religious or other reasons. Perhaps most familiar is the refusal to accept blood or blood products by a Jehovah's Witness member because of religious beliefs. Less familiar is refusal due to the fact that the medication or treatment contains animal-derived products. For example, acceptance or refusal of porcine (pork) and bovine (beef) drugs or surgical products by members of the Jewish, Muslim, and Hindu faiths is common; however, this may vary among individual members of the faith. People who follow vegetarian or vegan diets may also shun the use of animal-based products.

Many medications contain animal-based products, including inactive ingredients such as gelatin or lactose. Tatham and Patel (2014) found that for the top 100 drugs most commonly prescribed, 74% contained at least one animal-based product. Depending on the religious tradition, beef, pork, chicken, fish, shellfish, or all meat may be refused on religious or moral grounds or for dietary reasons. When a substitution can be made, the alternate product should be used. Sensitivity to a patient's religious beliefs, traditions, moral reasoning, or dietary needs should be maintained. When a patient questions whether or not to use an essential drug or treatment and an alternate is not available, encourage the patient to discuss the information with healthcare providers and informed religious leaders before making the decision to refuse the treatment.

For most of the history of pharmacology, the impact of cultural and ethnic variables was unknown or regarded as unimportant. This was primarily caused by a lack of diversity in the conduct of clinical trials and follow-up reporting. For example, older clinical trials enrolled mostly White males. Little attention was focused on identifying differences in pharmacologic effects in diverse ethnic or cultural groups.

The protocol for clinical trials now includes participants of different ages, genders, and ethnic groups whenever possible. Indeed, much research specifically examines differences among these populations, and findings are included in drug labels. Research has confirmed that there is a biological basis for variations or differences in metabolic response to drugs among various ethnic groups (see Section 11.3).

Certainly there are many more cultures and subcultures than ethnic groups. To have complete knowledge about the many variations in culture among a population of patients is impossible. However, nurses can strive to understand the significance of the cultural traditions and their potential impact on patients' pharmacologic regimens. Patients bring cultural (religious or ideological) beliefs that may challenge or conflict with what the healthcare provider believes to be in their best interests. How illness is defined is sometimes based on the cultural beliefs of an individual. One example that illustrates this point is the difference in belief systems between age groups—each with its own unique culture.

PharmFACT

The infant death rate of Native Americans and Alaska Natives is 60% higher than that of Caucasians. They are twice as likely to have diabetes (U.S. Department of Health and Human Services, 2016).

The nurse must keep in mind the following variables when treating patients from different cultural and ethnic groups.

- **Dietary considerations.** Cultures vary in their dietary preferences and practices, with diets that include some foods and exclude others. Patients need to understand that foods can increase or decrease the effectiveness of certain medications. Spices and herbs can be important to a patient's culture but may affect pharmacologic therapies. For example, some cultures include a diet high in foods such as cheese, pickled fish, or wine that can interact with medications to cause adverse events. Certain herbs can affect anticoagulants, beta blockers, and antidepressants. Assessing the primary foods of a patient's culture is an important component of the patient's psychosocial history.
- **Complementary and alternative medicine (CAM).** Various cultural groups use CAM therapies, such as vitamins, herbs, or acupuncture, either along with or in place of modern medicines. Some folk remedies and traditional treatments have existed for thousands of years and helped form the foundation for modern medical practice. For example, ethnic Chinese patients may consult with herbalists to treat diseases, whereas some Native Americans may collect, store, and use herbs to treat and prevent disease. Certain Hispanic cultures use spices and herbs to maintain a balance of hot and cold to promote wellness. The nurse can assess the treatments used and interpret the effect of these CAM therapies on the prescribed medications to maximize positive outcomes. The nurse can explain that certain herbs or supplements may cause potential health risks when combined with prescribed drugs.
- **Beliefs about health and disease.** Cultures view health and illness in different ways. Individuals may seek assistance from people in their own community whom they believe have healing powers. Consultation with traditional healers, prayer or laying-on-of-hands, or other culturally based strategies may be utilized as a primary source or as a supplement to more traditional

Western-based medicine practices such as drug therapy. The nurse's understanding of the patient's trust in alternative healers is important. The more nurses know about the various cultural beliefs, the better support and guidance they can provide to patients.

PharmFACT

Although access to healthcare has improved for all Americans since 2013, large differences among ethnic groups still persist. About 9% of Whites have no health insurance coverage; this number is 27% for Hispanic and Latino populations (National Center for Health Statistics, 2016).

Genetic Influences

11.3 Genetic polymorphisms can affect drug action.

Scientists have identified specific regions on various chromosomes that influence hepatic metabolism. For example, certain drugs, such as antidysrhythmics, antidepressants, and opioids, are metabolized differently in individuals of African, Native American, and Asian descent. As technology advances, nurses will likely begin to see variations in the prescribed amounts and forms of medication based on the ethnicity of the patient.

People of all races and cultures share remarkable deoxyribonucleic acid (DNA) similarities: 99.8% of our DNA sequences are identical. However, the remaining 0.2% may result in significant differences in patients' ability to handle medications. Some of these differences arise when a mutation occurs in the DNA that encodes for a certain protein. This creates a **genetic polymorphism**—two or more versions of the same protein. In pharmacology, the best characterized genetic polymorphisms have been discovered in the hepatic CYP450 enzymes that metabolize drugs and in proteins that serve as receptors for drugs.

How can a genetic polymorphism affect drug action? In the case of enzymes, the altered "mutated" form of the enzyme has a changed structure. The structure of an enzyme is intimately related to its function; even a single base mutation in DNA can cause an amino acid change in the enzyme, altering its function. The mutated version of the enzyme may increase or decrease the speed of drug metabolism and excretion, depending on the specific genetic polymorphism. In some cases, the enzyme becomes totally nonfunctional. This concept is illustrated in Figure 11.1.

As a specific example, genetic polymorphism has been discovered in the enzyme acetyltransferase, which metabolizes (deactivates) isoniazid (INH), a drug prescribed for tuberculosis. The altered form of the enzyme performs its metabolic process, known as acetylation, more slowly because of the mutation. The reduced acetylation and

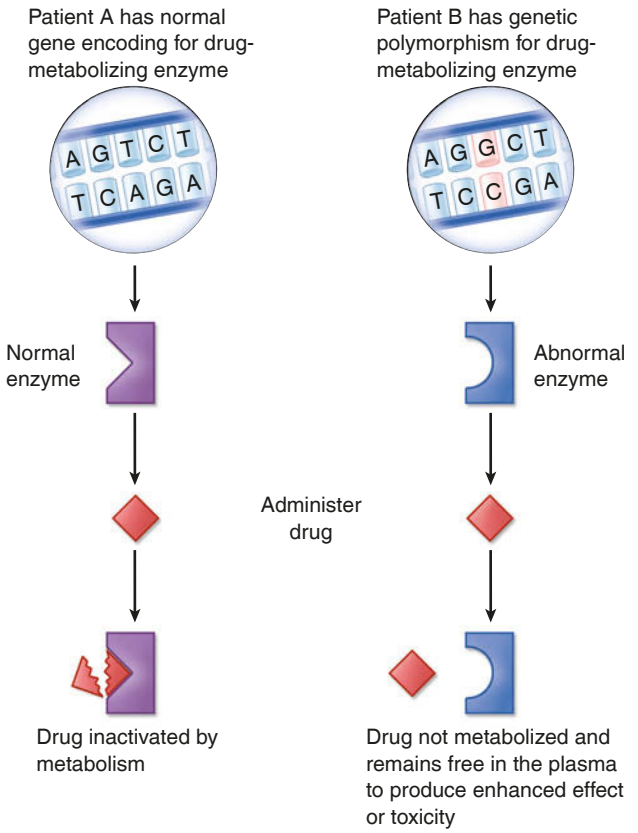

Figure 11.1 Consequences of genetic polymorphisms.

diminished clearance by the kidney can cause INH to accumulate in the blood to toxic levels. These patients, who are usually Caucasians or African Americans, are known as slow acetylators. In contrast, mutations in many patients of Japanese descent result in *rapid* acetylation. These patients will inactivate the drug so quickly that it will not produce a therapeutic effect. Procainamide, hydralazine, sulfonamide antibiotics, and dapsone are other medications that are metabolized by acetylation.

Several other enzyme polymorphisms have importance to pharmacotherapy. Asian Americans and certain other ethnic groups are slow metabolizers of codeine and morphine due to an inherent absence of the enzyme CY2D6 (debrisoquine hydroxylase). This genetic polymorphism can lead to higher than normal plasma drug levels and adverse effects. Some African Americans have decreased effects from beta-adrenergic antagonist drugs such as propranolol (Inderal) because of genetically influenced variances in plasma renin levels. Another set of oxidation enzyme polymorphisms has been found that alters the response to drugs such as warfarin (Coumadin) and diazepam (Valium).

A second type of genetic polymorphism affects receptors. Receptors are proteins that have a specific structure that accepts the drug (or other endogenous molecule) in a lock-and-key-type interaction. Small changes in the structure of the protein may result in a defective receptor that no longer "accepts" the drug. An active area of current research, receptor polymorphisms have been associated

Table 11.1 Polymorphisms of Importance to Pharmacotherapy

Type	Result of Polymorphism	Drugs Affected
Enzymes		
Acetyltransferase	Slow acetylation in African Americans and Caucasians; fast acetylation in Japanese and Eskimos	Hydralazine, INH, and procainamide, sulfonamide antibiotics
Debrisoquin hydroxylase (CYP2D6)	Poor metabolism in Asians and African Americans	Codeine, haloperidol, metoprolol, morphine, perphenazine, propranolol, tricyclic antidepressants
Mephenytoin hydroxylase (CYP2C19)	Poor metabolism in Asians and African Americans	Barbiturates, diazepam, imipramine, warfarin
Receptors or Drug Targets		
Angiotensinogen	Blood pressure reduction	Angiotensin-converting enzyme (ACE) inhibitors
$Beta_2$-adrenergic receptor	Bronchodilation	$Beta_2$ agonists
Dopamine receptor	Dyskinesias	Levodopa, antipsychotics

with an increased risk of schizophrenia, prostate cancer, breast cancer, and many other disorders. Relative to drug therapy, a few receptor polymorphisms have been shown to impact drug action, as shown in Table 11.1.

Genetic polymorphisms often occur in specific ethnic groups because members have settled in the same geographic area and have married mates within the same ethnic group for hundreds of generations. This practice results in amplified genetic polymorphisms being expressed within that specific group.

Pharmacogenetics is the study of specific genetic variations that alter patients' responses to medications. *Pharmacogenomics* is a related term that is more general in scope, referring to the network of genes that govern a patient's response to drug therapy. Both pharmacogenetics and pharmacogenomics attempt to identify genetic differences in metabolism or receptor targets that affect individual drug responses, with the ultimate goal of improving the safety and effectiveness of drug therapy through use of genetically guided treatment. It is expected that these fields will reveal data that will someday allow drug therapy that is customized for each individual patient based on his or her genetic profile, as illustrated in Figure 11.2.

CONNECTION Checkpoint 11.2

The best known genetic polymorphisms are those involving hepatic CYP450 enzymes. From what you learned in Chapter 3, explain the type of drug–drug interaction that might occur if drug A induced CYP450 enzymes and drug B was inactivated by the same enzymes. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Gender Influences

11.4 Men and women may respond differently to drugs.

There are well-established differences in the patterns of disease between men and women. Women tend to pay more attention to changes in health patterns and seek healthcare earlier than their male counterparts. However, many women do not seek medical attention for potential cardiac problems, because heart disease has traditionally been considered to be a "man's disease." Alzheimer's disease affects both men and women, but studies in various populations have shown that 1.5 to 3 times as many women have the disease. Alzheimer's disease is now recognized as a primary "woman's health issue," along with osteoporosis, breast cancer, and fertility disorders.

Adherence to the medication regimen of a particular drug class may be influenced by gender because the adverse effects affect only one gender. A common example is certain antihypertensive drugs that produce male impotence. Men may experience strokes if they abruptly stop taking their medication to avoid impotence. Some drugs

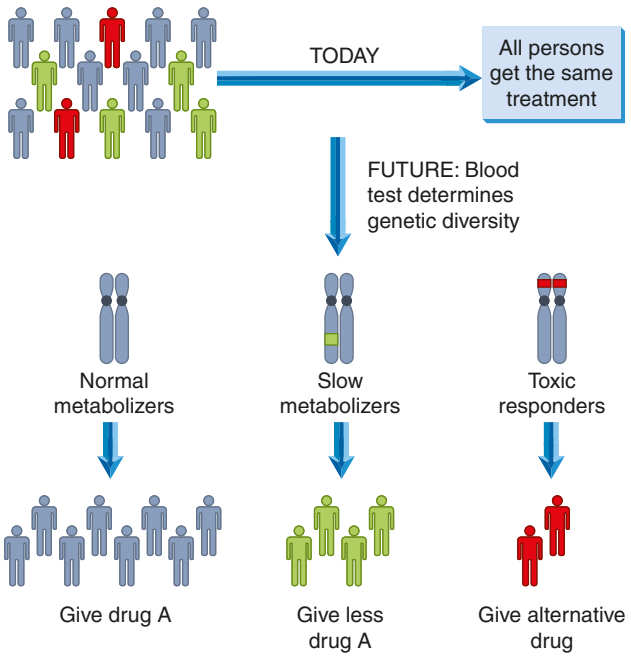

Figure 11.2 Pharmacogenomics and the future of pharmacotherapy.

can cause gynecomastia, an increase in breast size, which can be embarrassing for men. Similarly, certain drugs can cause masculine adverse effects such as hirsutism (abnormal increase in hair growth), which can be a cause of nonadherence in women taking these medications. Also in women, the estrogen contained in oral contraceptives causes an elevated risk of thromboembolic disorders.

Research has found many examples of differences in drug response between men and women. If males and females contain nearly all the same genes, how can these differences be explained? Although they may have identical genes, the "expression" of the genes differs greatly. For example, both males and females possess the same genes for hepatic metabolic enzymes, but one gender may produce more of a certain enzyme, thus producing a different degree of drug action. An example of a gender difference in a pharmacologic outcome is aspirin, which is more effective at preventing heart attacks in men than in women.

Some of the gender differences in drug response may be explained by differences in body composition, such as the fat-to-muscle ratio. Cerebral blood flow variances in genders can alter patient response to specific analgesics. An example is the benzodiazepines given for anxiety. Women experience slower elimination rates and this difference becomes more significant if a woman is concurrently taking oral contraceptives.

In the past, the majority of drug research studies were conducted using only male participants. These studies assumed that there were no differences between genders and conclusions would apply to both women and men. Current research, however, recognizes that gender differences in drug response may exist, and new drug development research now includes both males and females, as appropriate. Gender consideration is necessary in the analyses of clinical data and assessment of potential pharmacokinetic and pharmacodynamic differences.

Understanding Chapter 11

Key Concepts Summary

11.1 Many psychosocial influences impact pharmacotherapy.

11.2 Cultural and ethnic variables can influence pharmacotherapy.

11.3 Genetic polymorphisms can affect drug action.

11.4 Men and women may respond differently to drugs.

CASE STUDY: Making the Patient Connection

Remember the patient "Aponi Nampeyo" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

While traveling out of state with her husband to visit her children and grandchildren, Aponi Nampeyo became ill and was hospitalized. After being examined in the emergency department, she was diagnosed with appendicitis and underwent an emergency appendectomy. Aponi is a native of the United States and has lived most of her life in Arizona. She is well educated but she is not overly talkative and is comfortable with silence.

Aponi willingly accepts Western medical treatments. However, she also relies on traditional herbs and remedies from her youth. As the nurse caring for this patient, you are curious about her culture and health practices. However, you do not want to appear nosy or intrusive.

Critical Thinking Questions

1. Should nurses discuss cultural beliefs with patients? Explain your answer.
2. Describe how the nurse could learn about Mrs. Nampeyo's culture.
3. Are most healthcare workers culturally competent? Why? Why not?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Marjorie, a 30-year-old woman, is a single parent with three small children. She works as a self-employed housekeeper and earns minimum wage. Her annual income is $25,600, which pays for her family's housing, groceries, bus transportation, and clothing. Marjorie needs a job that pays benefits such as medical insurance. However, she fears that she will not be able to secure one because she never finished high school. She is constantly trying to save money. She has just been diagnosed with diabetes and requires insulin therapy.

1. Is it likely that Marjorie will be able to adequately care for her diabetes?
2. List the psychosocial factors that will influence this patient's ability to adhere to the therapy for her diabetes.
3. What can the nurse do to help this patient?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. In initiating holistic care with a patient who has chronic headaches, which action would the nurse take?
    1. Tell the patient to take Tylenol as directed on the label.
    2. Ask the patient what he or she believes may be contributing to the problem.
    3. Monitor the patient's pupil response to light.
    4. Refer the patient to an ophthalmologist for an eye exam.
2. Various psychosocial variables may influence nonadherence to pharmacotherapy. An example of this would occur when the patient reports that the prescribed drug:
    1. Produces an unpleasant aftertaste.
    2. Is a very large tablet and difficult to swallow.
    3. Is too expensive for the patient to afford.
    4. Potentially causes hepatotoxicity.
3. A patient of Native American descent states, "I will only take medications that are approved by the Shaman." The nurse understands that this statement reflects the patient's:
    1. Ethnicity.
    2. Cultural belief.
    3. Genetic polymorphisms.
    4. Health-related bias.
4. The nurse knows that patients characterized as slow acetylators:
    1. Are more prone to drug toxicity.
    2. Require more time to absorb enteral medications.
    3. Must be given liquid medications only.
    4. Should be advised to decrease protein intake.
5. Which of the following is considered a gender factor that may influence effective pharmacotherapy? (Select all that apply.)
    1. Fat-to-muscle ratio
    2. Cerebral blood flow
    3. Limited drug research on females
    4. Health beliefs
    5. Dietary considerations
6. Which is the most effective method for a nurse to recognize patient-specific genetic influences?
    1. Ask the patient if there have been drug-dose–related problems in the past.
    2. Consult reference books and the internet for information.
    3. Observe the effects with other patients of similar racial-ethnic background.
    4. Be cautious with all drugs and observe for individual patient responses.

See Answers to Chapter Review in Appendix A.

Chapter 12
Review of Neurotransmitters and the Autonomic Nervous System

Chapter Outline

- Overview of the Nervous System
- Structure and Function of the Autonomic Nervous System
- Synaptic Transmission
- Cholinergic Transmission
  - Cholinergic Receptors and Neurotransmitters
  - Termination of Acetylcholine Action
- Adrenergic Transmission
  - Alpha-Adrenergic Receptors
  - Beta-Adrenergic Receptors
  - Termination of Norepinephrine Action
- Regulation of Autonomic Functions
- Classifying Autonomic Drugs

Learning Outcomes

After reading this chapter, the student should be able to:

1. Distinguish between the functions of the central and peripheral nervous systems.
2. Compare and contrast the two divisions of the peripheral nervous system.
3. Compare and contrast the actions of the sympathetic and parasympathetic divisions of the autonomic nervous system.
4. Explain the process of synaptic transmission.
5. Explain mechanisms by which drugs affect synaptic transmission.
6. Describe the actions of acetylcholine at cholinergic synapses.
7. Describe the actions of norepinephrine at adrenergic synapses.
8. Compare the actions of the adrenal medulla with those of other sympathetic effector organs.
9. Explain how higher centers in the brain can influence autonomic function.
10. Design a method for classifying autonomic drugs based on which receptors are affected.

Key Terms

acetylcholine (ACh), 146
acetylcholinesterase (AChE), 150
adrenergic, 150
autonomic nervous system (ANS), 143
autonomic tone, 145
catecholamines, 150
catechol-O-methyltransferase (COMT), 151
cholinergic, 148
fight-or-flight response, 144
ganglia, 146
monoamine oxidase (MAO), 151
muscarinic, 149
neuroeffector junction, 146
neurotransmitters, 146
nicotinic receptors, 149
norepinephrine (NE), 146
parasympathetic nervous system, 145
rest-and-digest response, 145
somatic nervous system, 143
sympathetic nervous system, 144
synapse, 146
synaptic cleft, 147

Neuropharmacology represents one of the largest, most complicated, and least understood branches of pharmacology. Nervous system drugs are used to treat a large and diverse set of conditions, including pain, anxiety, depression, schizophrenia, insomnia, and seizures. Through their action on nerves, these medications are used to treat disorders affecting other body systems such as abnormalities in heart rate and rhythm, hypertension, glaucoma, asthma, and even a runny nose.

Traditionally, the study of neuropharmacology begins with the autonomic nervous system. This is because autonomic physiology lays the foundation for understanding nervous, cardiovascular, and respiratory pharmacology. This chapter serves two purposes. First, it provides a comprehensive review of autonomic nervous system physiology, a subject that is sometimes covered superficially in anatomy and physiology classes. Second, it introduces the four fundamental classes of autonomic medications, which are presented in depth in Chapters 13 through 16.

Overview of the Nervous System

12.1 The two major subdivisions of the nervous system are the central nervous system and the peripheral nervous system.

The nervous system is the master controller of most activities occurring within the body. Compared to the other major regulator, the endocrine system, the nervous system has the ability to act instantaneously to maintain homeostasis. The brain, spinal cord, and peripheral nerves act as a smoothly integrated whole to accomplish minute-to-minute changes in essential functions such as heart rate, blood pressure, pupil size, and intestinal movement. The fundamental functions of the nervous system are to:

- *Monitor* the internal and external environment of the body and alert the brain of important changes.
- *Process* and integrate the environmental changes that are perceived and determine an appropriate response.
- *Respond* to the environmental changes by producing an action or a response.

The nervous system has two major divisions: the central nervous system (CNS) and the peripheral nervous system. The CNS is made up of the brain and spinal cord, whereas the peripheral division consists of spinal nerves that carry messages to and from the CNS. Drugs used to treat disorders and conditions of the CNS are discussed in Chapters 17 through 26. The functional divisions of the nervous system are illustrated in Figure 12.1.

12.2 The peripheral nervous system is divided into somatic and autonomic components.

With its immense potential and complexity, the human brain requires a continuous flow of information to accomplish its functions. In addition, the brain would be useless without a means to carry out its commands. The peripheral nervous system provides the brain the means to communicate with and receive sensory messages from the outside world.

Neurons in the peripheral nervous system *recognize* changes to the environment (sensory division) and *respond* to those changes by moving muscles or secreting chemicals (motor division). The sensory division consists of specialized nerves that recognize touch, pain, heat, body position, light, or specific chemicals in body fluids. These sensory neurons send their messages to the spinal cord. Based on this information, the brain determines what messages are important, determines whether an action is needed, and plans an appropriate response.

The motor division is divided into two components. The **somatic nervous system** consists of nerves that provide for the voluntary control of skeletal muscle. The nerves of the **autonomic nervous system (ANS)** provide for the involuntary control of vital functions of the cardiovascular, digestive, respiratory, and genitourinary systems. The ANS controls vital life activities without people being aware of its functions. The three main activities of the ANS are:

- Contraction of smooth muscle of the bronchi, blood vessels, gastrointestinal (GI) tract, eye, and genitourinary tract
- Contraction of cardiac muscle
- Secretion of salivary, sweat, gastric, and bronchial glands.

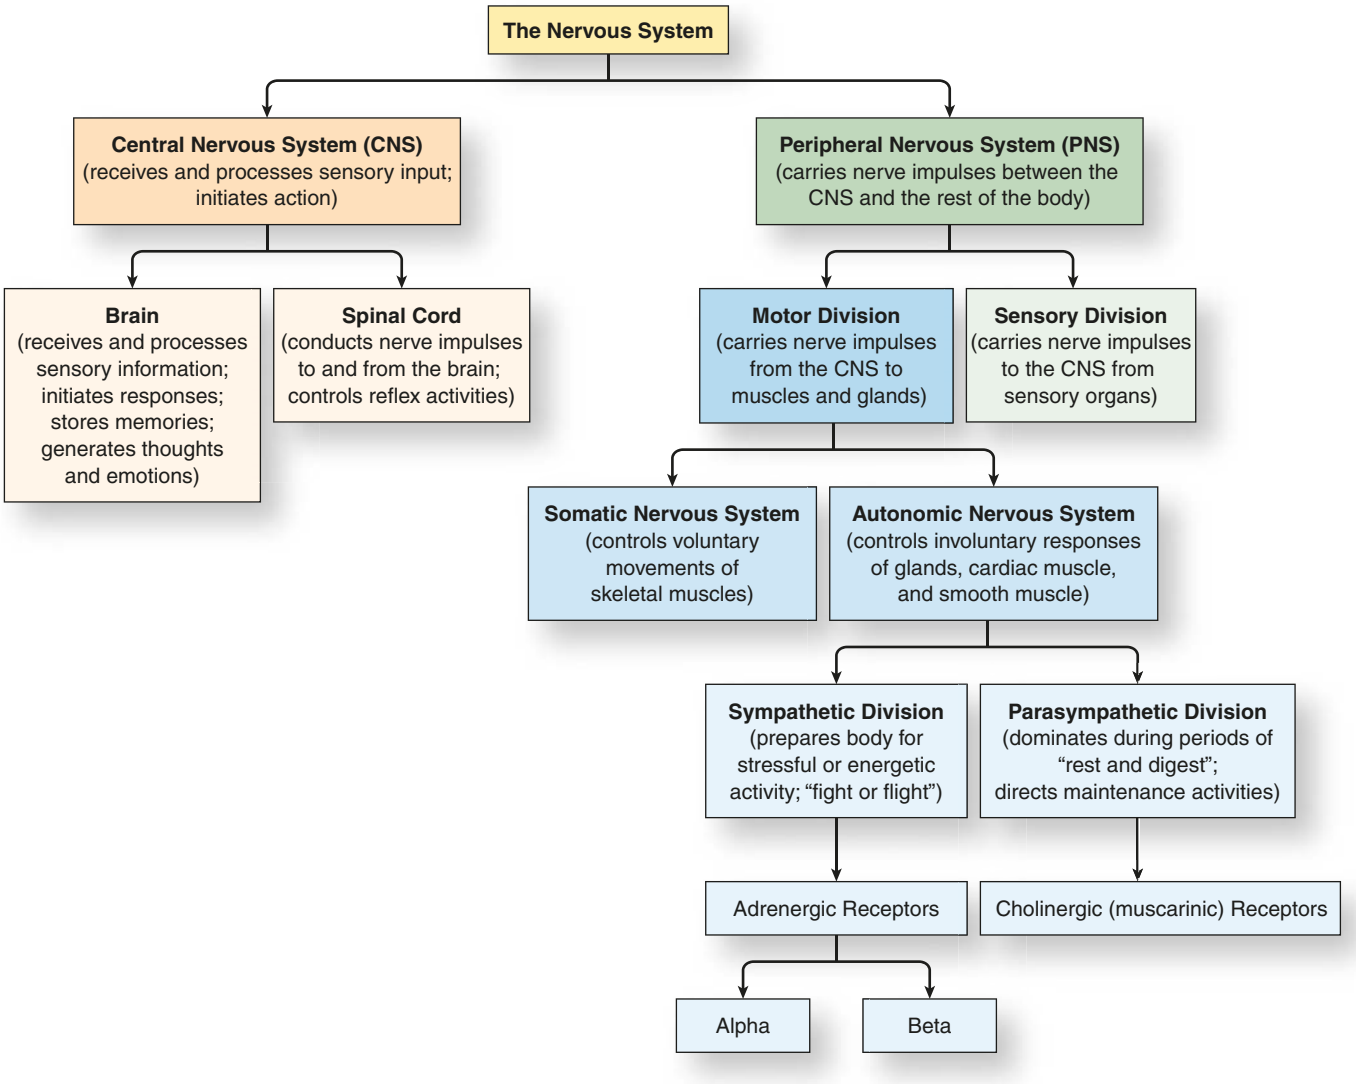

Figure 12.1 Functional divisions of the nervous system.

The ANS is particularly important to pharmacology because a large number of medications affect autonomic nerves. Some of these drug actions produce desirable, therapeutic effects, whereas others produce adverse effects. The remainder of this chapter reviews the structure and function of this complex system.

Structure and Function of the Autonomic Nervous System

12.3 The autonomic nervous system is divided into two mostly opposing components: the sympathetic and parasympathetic branches.

The ANS has two distinct divisions: the *sympathetic* nervous system and the *parasympathetic* nervous system. Most organs and glands receive nerves from both branches, and the two divisions have opposing actions. For example, one branch causes cardiac muscle to contract faster and with greater force; the other causes it to relax. The ultimate action of the cardiac muscle, smooth muscle, or gland depends on which branch is sending the most signals at any given time. The major actions of the two divisions are shown in Figure 12.2. It is essential for the student to learn these actions early in the study of pharmacology because knowledge of autonomic effects is used to predict the actions and adverse effects of many drugs.

The **sympathetic nervous system** is activated under emergency conditions or stress and produces a set of actions called the **fight-or-flight response**. Activation of this branch prepares the body for heightened activity and for an immediate response to a threat. The brain experiences an increase in alertness and readiness. Heart rate and blood pressure increase and blood is shunted to skeletal muscles, thus preparing the body for sudden, intense physical activity. The liver immediately produces more glucose for energy. The bronchi dilate to allow maximum airflow into the lungs, and breathing becomes faster and deeper. The pupils dilate to provide better vision for dealing with the emergency. The body warms and perspiration increases.

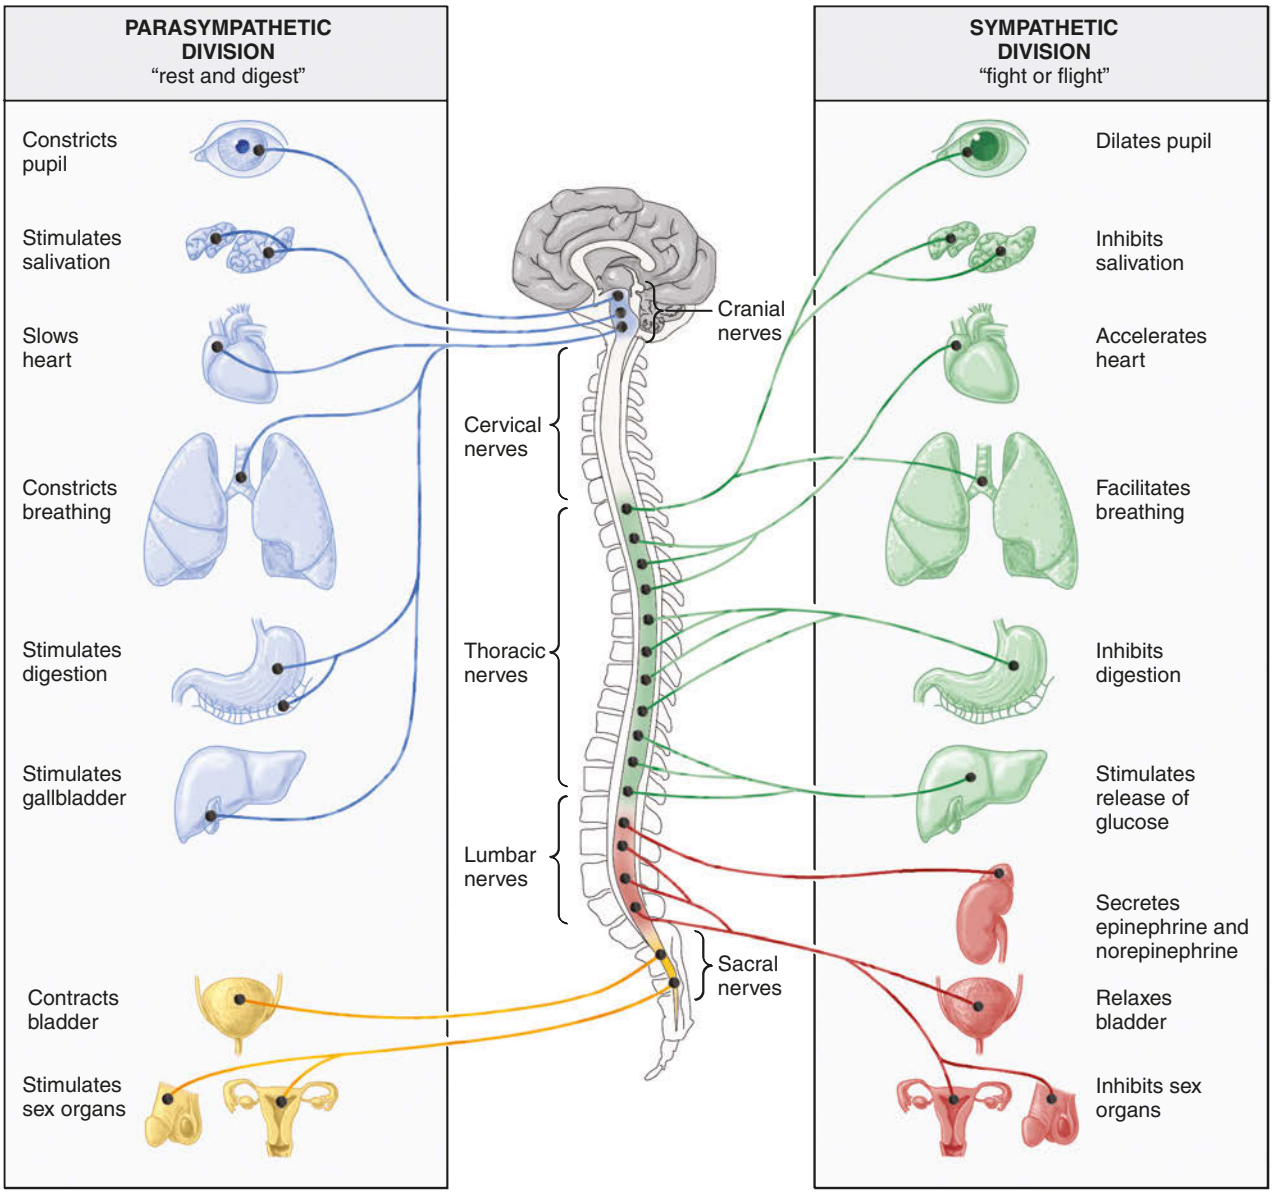

Figure 12.2 Effects of the sympathetic and parasympathetic nervous systems.
From *Biology: A Guide to the Natural World* (5th ed., Figure 27.8), by D. Krogh, © 2011. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

At the same time the body is preparing for the threat, nonemergency maintenance functions such as peristalsis and urine formation are temporarily reduced.

The **parasympathetic nervous system** is activated under less stressful conditions and produces a set of actions known as **rest-and-digest responses**, which promote relaxation and body maintenance activities. Digestive secretions increase, peristalsis propels substances along the alimentary canal, and defecation is promoted. Heart rate and blood pressure decline. Because less air is needed, the bronchi constrict and respiration slows. The student should notice that the actions of the parasympathetic division are opposite to those of the sympathetic division.

Under most conditions, the two branches of the ANS cooperate to achieve a balance of readiness and relaxation. Because they have opposite effects, homeostasis may be achieved by changing one or both branches. For example, heart rate can be increased by either increasing the firing of sympathetic nerves or by decreasing the firing of parasympathetic nerves. This allows the body to fine-tune its essential organ systems.

Some degree of autonomic activity is always occurring even in the absence of stimuli. This background level of activity is known as **autonomic tone**. For example, sympathetic nerves are constantly firing, keeping arterioles in a constant state of constriction. This sympathetic tone allows for faster changes in blood pressure because the vessels are in a constant state of readiness. On the other hand, parasympathetic tone on the smooth muscle of the alimentary and urinary tracts maintains continuous contractions and keeps intestinal peristalsis and urine flow steady. With the important exception of the vascular

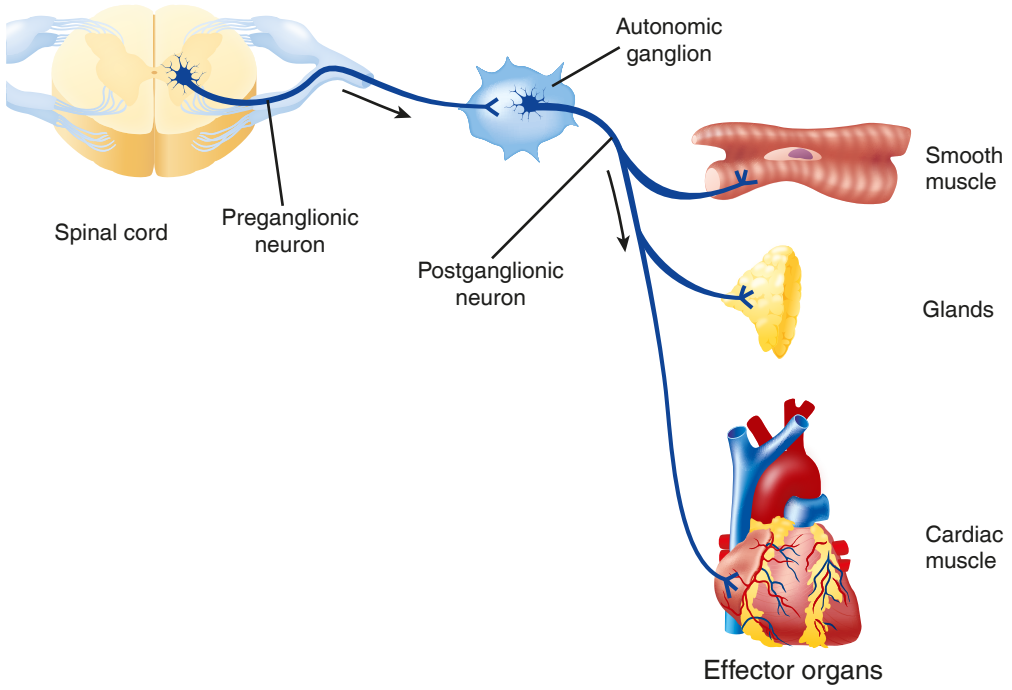

Figure 12.3 Basic structure of an autonomic pathway.

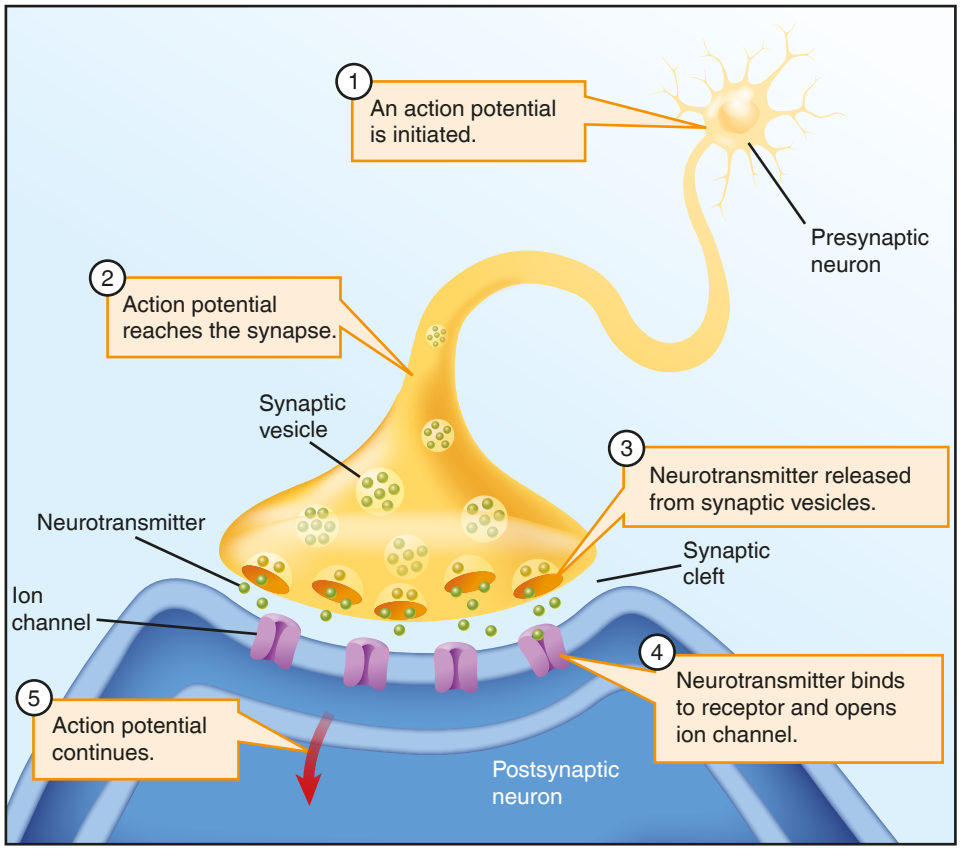
system, the predominant tone of autonomic tissues is from the parasympathetic nervous system.

The sympathetic and parasympathetic divisions do not always have opposite effects. For example, the constriction of arterioles is controlled entirely by the sympathetic branch. Sympathetic stimulation causes constriction of arterioles, whereas lack of stimulation causes vasodilation. Only sympathetic nerves control the adrenal medulla and the sweat glands. The sympathetic division is also solely responsible for the release of renin by the kidneys, an action that increases blood pressure. Metabolic effects such as increases in blood glucose and mobilization of lipids for energy are uniquely sympathetic functions. In the male reproductive system, the roles are complementary. Erection of the penis is a function of the parasympathetic division, and the sympathetic branch controls ejaculation.

Synaptic Transmission

12.4 Synaptic transmission allows information to be communicated between two nerves or from nerves to muscles or glands.

For information to be transmitted throughout the nervous system, neurons must communicate with each other and with muscles and glands. The basic unit of the ANS is a two-neuron chain. The first neuron, called the preganglionic neuron, originates in the CNS. The preganglionic neuron connects with the second nerve outside the CNS in structures called **ganglia**. A ganglion (singular of *ganglia*) contains the cell body of the postganglionic neuron, which is waiting to receive the action potential. The basic structure of an autonomic pathway is shown in Figure 12.3.



Before the message can be transferred from one nerve to another, however, it must cross the **synapse**, a physical space between the two neurons. The communication of the message from one cell to another, or synaptic transmission, utilizes chemical messengers called **neurotransmitters**. It is important to study the details of synaptic transmission because a large number of drugs affect this process. The process of synaptic transmission is illustrated in Pharmacotherapy Illustrated 12.1.

The second (postganglionic) neuron terminates on smooth muscle, cardiac muscle, or a gland at a specialized synapse called the **neuroeffector junction**. Synaptic transmission across the neuroeffector junction occurs in several steps.

1. **Synthesis of the neurotransmitter.** The neurotransmitter is synthesized in the cell body of the neuron or in the axon terminal where the synapse is located. Over 50 different neurotransmitters have been identified, the most common of which are shown in Table 12.1. Each neurotransmitter is associated with a unique set of functions and responses. The two primary neurotransmitters of the ANS are **norepinephrine (NE)** and **acetylcholine (ACh)**.
2. **Storage of the neurotransmitter.** Because nerve impulses travel rapidly from neuron to neuron, there must be an ample and continuous supply of the neurotransmitter. At the terminal ends of each axon lie millions of granules or vesicles loaded with neurotransmitters, waiting for an action potential to release them.

Pharmacotherapy Illustrated 12.1

Synaptic Transmission

3. **Release of the neurotransmitter.** When the nerve impulse reaches the end of the axon, it stimulates some of the vesicles to release their stored neurotransmitter into the synapse. The neurotransmitter enters the **synaptic cleft**, which must be bridged for the impulse to reach the postganglionic neuron or organ.

4. **Binding to the receptor.** The neurotransmitter diffuses across the synaptic cleft to reach receptors waiting on the surface of the postsynaptic cell. There is a brief delay in impulse conduction of about 0.2 to 0.5 msec for the neurotransmitter to cross the synapse. Once the neurotransmitter binds to its receptor, the message is

Table 12.1 Selected Neurotransmitters and Their Receptors: Effects and Clinical Applications

Neurotransmitter	Primary Locations of Receptors	Clinical Application (Chapter Number)
Acetylcholine	Synapses throughout the CNS; preganglionic neurons ending in the ganglia in both the sympathetic and parasympathetic nervous systems (nicotinic); postganglionic neurons ending in neuroeffector target tissues in the parasympathetic nervous system (muscarinic)	Alzheimer's disease (21); myasthenia gravis (13)
Dopamine	Limbic system and hypothalamus; some sympathetic ganglia	Attention-deficit/hyperactivity disorder (24); Parkinson's disease (21); psychoses (20)
Gamma aminobutyric acid (GABA)	Throughout the CNS	Anesthesia (26); anxiety (18); seizures (22)
Glutamate	Throughout the CNS	Seizures (22)
Nitrous oxide	CNS, adrenal gland, and nerves to the penis	Impotence (71)
Norepinephrine	Throughout the CNS; most neuroeffector target junctions in the sympathetic nervous system	Attention-deficit/hyperactivity disorder (24); cocaine and amphetamine abuse (27); depression (19)
Serotonin (5-HT)	Limbic system and hypothalamus; primary neurotransmitter in the extrapyramidal system; GI tract	Anxiety (18); depression (19); nausea and vomiting (60); psychoses (20)
Substance P	Pain pathways in the spinal cord; brain and sensory neurons	Analgesia (25)

conveyed to the postsynaptic cell. The neurotransmitter induces the target muscle cell, glandular cell, or another neuron tissue to elicit its characteristic response. Generally, the more neurotransmitter released into the synapse, the more intense and longer lasting the response.

5. **Termination of neurotransmitter action.** Once the message is transmitted, the neuron and the effector cell must quickly return to baseline conditions and ready themselves for future messages. This is accomplished by removal of the neurotransmitter. The neurotransmitter is either degraded in the synaptic cleft by enzymes, or it diffuses back into the preganglionic neuron, thus stopping the action of the muscle or gland.

Conduction of action potentials in the ANS is much slower than in the somatic nervous system. Because somatic nerves are myelinated and have no ganglia, impulses more quickly reach their target tissues. Autonomic messages must cross the synaptic cleft, and postganglionic nerves are unmyelinated, which slows the action potential.

12.5 Autonomic drugs exert their effects by acting at synapses.

The student may be wondering why it is necessary to learn ANS anatomy and physiology in such depth. The reason is that a large number of drugs act by altering neurotransmitter activity in the ANS. Some medications are identical to endogenous neurotransmitters, or have a very similar chemical structure, and are able to directly activate a gland or muscle. Other drugs are used to stimulate or block the actions of natural neurotransmitters. A firm grasp of autonomic physiology is essential to understanding the actions and adverse effects of hundreds of drugs.

The two-neuron chain of the ANS allows multiple locations at which drugs can act. Some medications affect the outflow of nervous impulses at their source—the CNS. A second potential site for drug action is at the ganglia, the synapse where the preganglionic and postganglionic neurons meet. Yet a third possible site is at the end of the chain, at the neuroeffector junction of the target organs.

Although complex, actions of drugs affecting this ANS can be grouped into just a few categories. The five general mechanisms by which drugs affect synaptic transmission in the ANS are as follows:

- Medications may affect the *synthesis* of the neurotransmitter in the preganglionic nerve. Drugs that decrease neurotransmitter synthesis inhibit autonomic responses. Those that increase neurotransmitter synthesis have the opposite effect.
- Medications can prevent the *storage* of the neurotransmitter in vesicles within the preganglionic nerve. Prevention of neurotransmitter storage inhibits autonomic actions.
- Medications can influence the *release* of the neurotransmitter from the preganglionic nerve. Promoting neurotransmitter release stimulates autonomic responses, whereas preventing neurotransmitter release has the opposite effect.
- Medications can bind to the *neurotransmitter receptors* on the postganglionic cell. Drugs that bind to receptors and stimulate the cell will increase autonomic responses. Those that attach to the postganglionic cell and prevent the natural neurotransmitter from reaching its receptors will inhibit autonomic actions.
- Medications can *prevent the destruction or reuptake* of the neurotransmitter. These drugs cause the neurotransmitter to remain in the synapse for a longer time and will stimulate autonomic actions.

It is important to understand that autonomic drugs are rarely given to correct physiologic defects in the ANS itself. Compared to other body systems, the ANS has remarkably little disease. Rather, medications are used to stimulate or inhibit target organs or glands of the ANS, such as the heart, lungs, or digestive tract. With few exceptions, the disorder lies in the target organ, not the ANS. Thus when an autonomic drug is administered, the goal is not to treat an autonomic disease; it is to correct disorders of target organs through its effects on autonomic nerves.

Cholinergic Transmission

12.6 Acetylcholine is the neurotransmitter released at cholinergic receptors, which may be nicotinic or muscarinic.

ACh was the first neurotransmitter to be identified. Neurons releasing ACh are called **cholinergic** nerves. Located on postganglionic or neuroeffector cell membranes, cholinergic receptors bind ACh and either continue the impulse (at the ganglia) or cause an autonomic action (at the neuroeffector organ). When reading the following sections, the student should refer to the sites of ACh and NE action shown in Figure 12.4.

ACh is synthesized in the preganglionic nerve terminal and stored in synaptic vesicles. A preganglionic neuron may contain 300,000 vesicles, each housing as many as 50,000 ACh molecules. When an action potential reaches the nerve terminal, a brief burst of ACh is released into the synaptic cleft, where it diffuses across to attach to its receptors on the postganglionic cell.

PharmFACT

Sir Henry Dale identified acetylcholine as a neurotransmitter in 1914, and Otto Loewi demonstrated its physiology. The pair was awarded the Nobel Prize in Physiology or Medicine in 1936 for their work (Nobelprize.org, 2016).

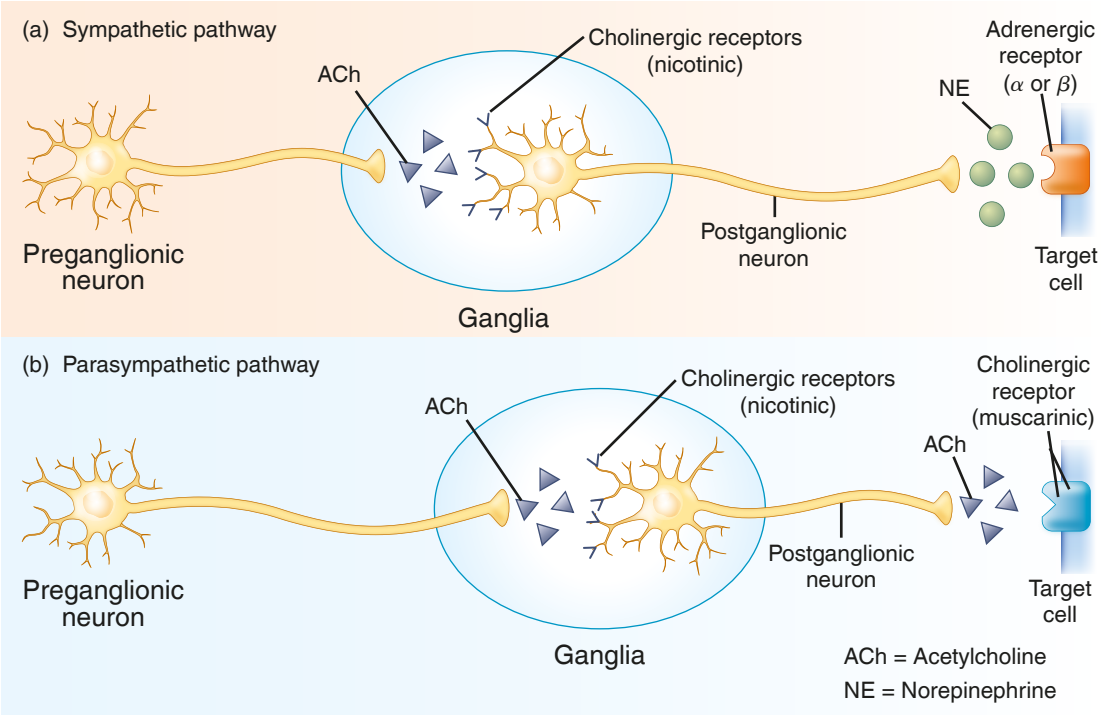


Figure 12.4 Receptors in the autonomic nervous system: (a) Sympathetic pathway: ACh is released at the ganglia (nicotinic receptor) and NE at the effector organ (adrenergic receptor). (b) Parasympathetic pathway: ACh is released at both the ganglia (nicotinic receptor) and effector organ (cholinergic receptor).

Cholinergic Receptors and Neurotransmitters

Two types of cholinergic receptors bind ACh. These are named after certain chemicals that bind to them:

- **Nicotinic receptors.** Located at preganglionic neurons ending in the ganglia in both the sympathetic and parasympathetic nervous systems
- **Muscarinic receptors.** Located at postganglionic neurons ending in neuroeffector target tissues in the parasympathetic nervous system.

Early research on laboratory animals found that the actions of ACh at the ganglia resembled those of nicotine, the active chemical in tobacco products. Because of this similarity, receptors for ACh in the ganglia are called **nicotinic** receptors. Nicotinic receptors are also found in skeletal muscle, which is controlled by the somatic nervous system, and in the adrenal medulla. Because nicotinic receptors are present in so many locations, drugs affecting these receptors produce profound effects on both the ANS and somatic nervous system. Activation of ACh nicotinic receptors always produces stimulatory actions. Nicotinic actions include increased sweat production, increased release of adrenal medullary hormones, and enhanced nerve conduction in the ganglia; and tachycardia, hypertension, and increased tone and motility in the digestive tract. Although nicotinic receptor blockers were some of the first drugs used to treat hypertension, they are rarely used for this purpose today due to the discovery of safer drugs. The primary current therapeutic application of these drugs is to produce skeletal muscle relaxation (a somatic effect) during surgical procedures. A complete discussion of nicotinic blockers can be found in Chapter 14.

CONNECTION Checkpoint 12.1

Nicotine induces hepatic microsomal (CYP450) enzymes. From what you learned in Chapter 5, how can this induction affect the actions of medications? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Activation of ACh receptors at postganglionic nerve endings in the parasympathetic nervous system results in the classic symptoms of parasympathetic stimulation shown in Figure 12.2. Early research determined that these actions closely resembled those produced after eating the poisonous mushroom *Amanita muscaria*. The active substance in this mushroom is the chemical muscarine; thus, these ACh receptors were named **muscarinic** receptors. Muscarinic receptors are also found in most sweat glands and in blood vessels serving skeletal muscles. The locations of nicotinic and muscarinic receptors are illustrated in Figure 12.4.

Unlike the actions of ACh at nicotinic receptors, which are always stimulatory, ACh action at muscarinic receptors may be stimulatory or inhibitory, depending on the target organ. For example, activation of muscarinic receptors in the heart will *decrease* the heart rate, but activation of muscarinic receptors in the intestine will *increase* peristalsis. Drugs that

Table 12.2 Types of Autonomic Receptors

Neurotransmitter	Receptor	Primary Locations	Selected Responses
Acetylcholine (cholinergic)	Muscarinic	Parasympathetic target organs (other than the heart) Heart	Stimulation of smooth muscle and exocrine gland secretions Decreased heart rate and force of contraction
	Nicotinic	Postganglionic neurons and neuromuscular junctions of skeletal muscle	Stimulation of smooth muscle and gland secretions
Norepinephrine (adrenergic)	$Alpha_1$	All sympathetic target organs except the heart	Constriction of blood vessels; dilation of pupils
	$Alpha_2$	Presynaptic adrenergic nerve terminals	Inhibition of norepinephrine release
	$Beta_1$	Heart and kidneys	Increased heart rate and force of contraction; release of renin
	$Beta_2$	All sympathetic target organs except the heart	Inhibition of smooth muscle contraction

affect muscarinic receptors have more pharmacologic applications than those affecting nicotinic receptors. Medications that block muscarinic receptors are used during ophthalmic procedures, as preanesthetic drugs, and in the pharmacotherapy of asthma and bradycardia (see Chapter 16).

Although ACh itself can stimulate both muscarinic and nicotinic receptors, some drugs are selective to only one type. Table 12.2 summarizes the types of responses produced by activation of the two types of ACh receptors.

Termination of Acetylcholine Action

The goal of nerve transmission is to produce an immediate, though transient, response. To accomplish this, ACh must be rapidly removed from the synaptic cleft after producing its effect. The enzyme that resides in the synaptic cleft and catalyzes the destruction of ACh is called **acetylcholinesterase (AChE)**, or cholinesterase (*Note:* The suffix *-erase* can be thought of as "wiping out" the ACh.) AChE is quite efficient at performing its task. It is estimated that over half the ACh molecules released from the vesicles are destroyed before they have a chance to reach their receptors. Following the breakdown of ACh, choline is reformed and is taken up by the preganglionic neuron, where it is used to synthesize more ACh. The lifecycle of ACh in the neuron is shown in Figure 12.5.

Medications can interfere with the lifecycle of ACh. Some drugs (and poisons) can prevent the inactivation of ACh by blocking the acetylcholinesterase enzyme. These drugs will cause a prolonged action of ACh at the synapse. Other medications will prevent ACh from reaching its receptors, thus blocking its actions. Medications that interfere with the lifecycle of ACh are presented in Chapters 13 and 14.

Pseudocholinesterase, also known as plasma cholinesterase, is another enzyme that destroys ACh. Found primarily in the liver, pseudocholinesterase rapidly inactivates ACh and drugs with a chemical structure similar to ACh as they circulate in the plasma. Some people are born with a genetic deficiency of this enzyme and are unable to inactivate succinylcholine, a surgical drug structurally similar to ACh. These patients are particularly sensitive to the effects of succinylcholine (see Chapter 26).

Adrenergic Transmission

12.7 Norepinephrine is the primary neurotransmitter released at adrenergic receptors, which may be alpha or beta.

In the sympathetic nervous system, NE is the neurotransmitter released at almost all postganglionic nerves. NE belongs to a class of hormones called **catecholamines**, all of which are involved in neurotransmission. Other endogenous catecholamines include epinephrine (adrenalin) and dopamine. The receptors at the ends of postganglionic sympathetic neurons are called **adrenergic**, which is derived from the word *adrenaline.*

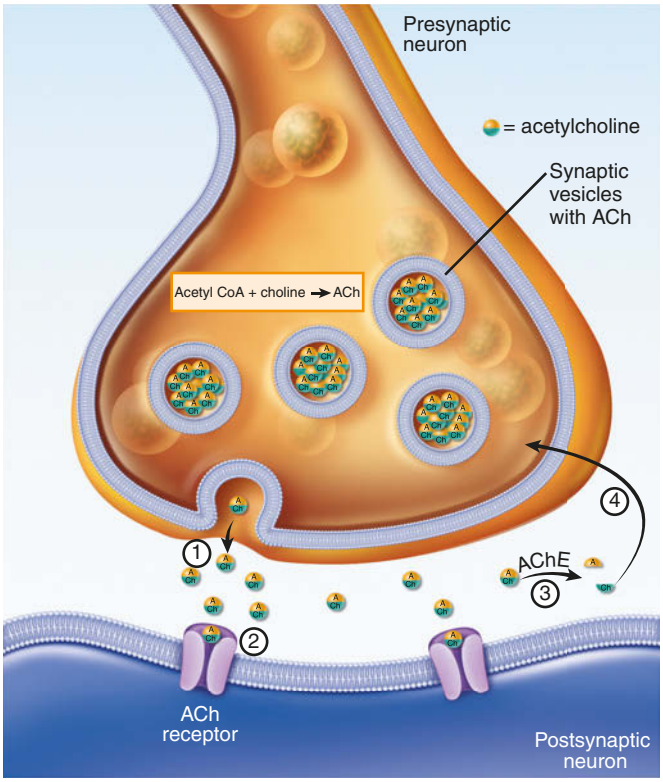

Figure 12.5 Lifecycle of acetylcholine (ACh): (1) ACh is released into the synaptic cleft. (2) ACh binds to receptors on the postsynaptic membrane. (3) ACh is broken down into acetate and choline. (4) Choline is returned to the presynaptic neuron and recycled to make additional ACh.

NE is synthesized in the nerve terminal and stored in vesicles until an action potential triggers its release into the synaptic cleft. NE then diffuses across the cleft to bind to its receptors on the effector cell.

Adrenergic receptors are of two basic types: alpha (α) and beta (β). These receptors are further divided into the subtypes $beta_1$, $beta_2$, $alpha_1$, and $alpha_2$. Activation of each type of subreceptor results in a characteristic set of physiologic responses, which are summarized in Table 12.2.

PharmFACT

According to Aronson (2000), adrenaline was isolated and identified by John Jacob Abel in 1897, who founded the very first Department of Pharmacology at the University of Michigan. The name was changed to "epinephrine" in the United States because Parke, Davis, and Co. owned the trademark rights to the word *adrenalin* (without a final "e"). It is still known as adrenaline in the rest of the world.

Alpha-Adrenergic Receptors

When alpha receptors are stimulated, enzymes on the inside of the plasma membrane are activated and a cascade of changes occurs within the cell. These changes occur due to the production of a second messenger, the G-protein, which initiates the cascade. In $alpha_1$ receptors intracellular calcium stores are released, causing excitatory effects such as smooth muscle contraction or sphincter closure. Drugs affecting $alpha_1$ receptors are primarily used for their effects on vascular smooth muscle in the treatment of hypertension (see Chapters 16 and 34). Drugs that block the $alpha_1$ receptor are used to treat benign prostatic hyperplasia (see Chapters 14 and 71).

Stimulation of $alpha_2$ receptors causes different effects due to the activation of a separate cascade of events in the target cells. By increasing cyclic adenosine monophosphate (cAMP) within the cell, activation of $alpha_2$ receptors inhibits NE release from sympathetic nerve endings, causing mostly *inhibitory* actions. In addition, activation of $alpha_2$ receptors in the CNS can suppress the outflow of sympathetic activity from the brain. Indeed, as will be discussed in Chapter 15, drugs that affect $alpha_2$ receptors are usually used for their ability to decrease blood pressure due to their effects on the CNS, not the ANS.

Beta-Adrenergic Receptors

Three subtypes of beta-adrenergic receptors have been identified, although only $beta_1$ and $beta_2$ have pharmacologic importance. Beta receptors act by increasing the second messenger cAMP in target cells. The specific response caused by activation of the beta receptor depends on its location.

The primary tissues served by $beta_1$ receptors are the heart, coronary vessels, and kidneys. Activation of these receptors increases the heart rate and strength of contraction and dilates the coronary arteries, thus preparing the heart for fight or flight. $Beta_1$ receptors in the kidney respond by releasing renin, which helps to maintain (increase) blood pressure.

$Beta_2$ receptors are more widely distributed than $beta_1$ receptors, with locations in the smooth muscle in arterioles, the GI tract, and the lungs. Activation of these receptors will dilate arteries to skeletal muscles, dilate bronchioles, slow peristalsis, and decrease urine production.

The significance of adrenergic receptor subtypes to pharmacology cannot be overstated. Some drugs are selective and activate only one type of adrenergic receptor, whereas others affect all of them. Furthermore, a drug may activate one type of receptor at low doses and begin to affect other receptor subtypes as the dose is increased. Committing the receptor types and their responses to memory is an essential step in learning autonomic pharmacology.

Other types of adrenergic receptors exist. Although the functional role of dopamine was once thought to be only a chemical precursor to NE, research has determined that this agent serves a larger role as a neurotransmitter. Five dopaminergic receptors (D1 through D5) have been discovered in the CNS. Dopaminergic receptors are important to the action of certain antipsychotic medicines (see Chapter 20) and in the treatment of Parkinson's disease (see Chapter 21). Dopamine receptors in the peripheral nervous system are located in the arterioles of the kidney and other viscera. Although these receptors likely have a role in autonomic function, their therapeutic importance has yet to be discovered.

Termination of Norepinephrine Action

The termination of NE action occurs through mechanisms different from those of ACh. The majority of the NE (50% to 80%) is taken back into the nerve terminal, a process known as *reuptake*. Following its reuptake, NE is repackaged in vesicles for future use or destroyed enzymatically by **monoamine oxidase (MAO)**. NE entering the circulation, such as that secreted by the adrenal glands or given as medication, is destroyed by the enzyme **catechol-O-methyltransferase (COMT)** in kidney and liver cells. Many drugs affect autonomic function by influencing the synthesis, storage, release, reuptake, or destruction of NE. The lifecycle of NE is shown in Figure 12.6.

Activation of the sympathetic division produces longer lasting effects than those of parasympathetic activation. This is because NE acts *indirectly* through a second messenger mechanism. Its effects are produced more slowly than ACh, which acts directly at cholinergic sites. Furthermore, the primary means of inactivation of NE is through reuptake, which is a slower process than the direct enzymatic destruction of ACh.

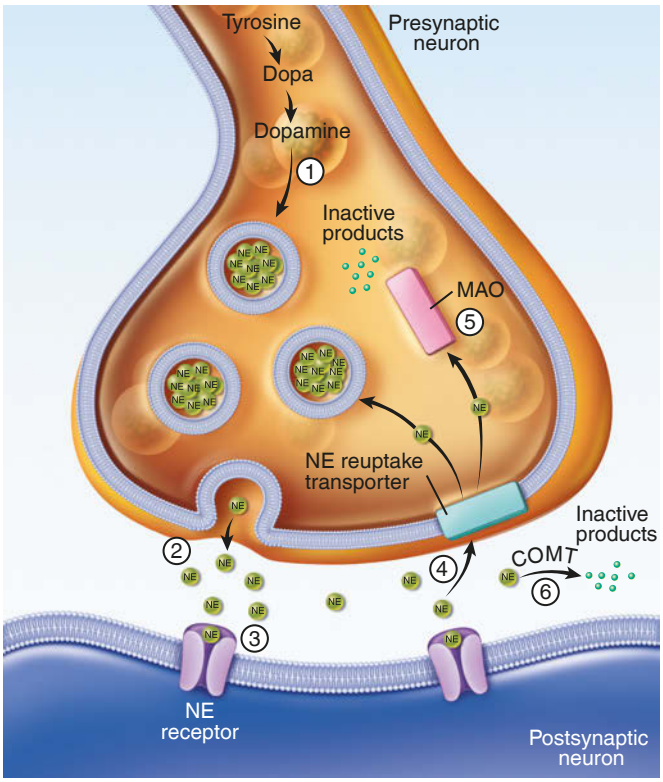

Figure 12.6 Lifecycle of norepinephrine (NE): (1) NE is synthesized from the amino acid tyrosine. (2) NE is released into the synaptic cleft. (3) NE binds to receptors on the postsynaptic membrane. (4) NE is taken back into the presynaptic neuron. (5) NE is degraded by MAO. (6) Small amounts of NE are degraded by COMT.

CONNECTION Checkpoint 12.2

The herb St. John's wort is believed to inhibit the reuptake of serotonin into presynaptic nerve terminals in the CNS. From what you learned in Chapter 7, what is the most common indication for using this herb? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

12.8 The adrenal medulla is a specialized type of sympathetic nervous system tissue that secretes epinephrine and norepinephrine.

Lying in the inner portion of each adrenal gland, the adrenal medulla is closely associated with the sympathetic nervous system but has a different anatomic and physiologic arrangement than the rest of the sympathetic branch. Early in embryonic life, the adrenal medulla is part of the neural tissue that is destined to become the sympathetic nervous system. This primitive tissue splits, however, and the adrenal medulla becomes its own functional division. Preganglionic neurons from the spinal cord terminate in the adrenal medulla and release the neurotransmitters epinephrine and NE *directly* into the blood. Approximately 80% of the secretion is epinephrine, with the other 20% being NE. Once released, these agents are widely distributed to target organs, where they elicit the classic fight-or-flight symptoms.

Once released into the systemic circulation by the adrenal gland, epinephrine and NE produce more diffuse and longer lasting effects than those produced by activation of sympathetic neurons in the ANS. In addition, the bloodstream distributes these agents to all body cells, not just those innervated by the ANS. Significant concentrations of epinephrine and NE may persist for as long as 30 seconds, and their effects on tissues may continue for several minutes until the liver eventually deactivates the hormones. It is estimated that 25% to 50% of all sympathetic nervous system responses at any given time are due to circulating hormones from the adrenal medulla.

Regulation of Autonomic Functions

12.9 The autonomic nervous system is influenced by higher levels of control in the cerebral cortex and hypothalamus.

Although it is often stated that control of the ANS is involuntary, this is an oversimplification. For example, strong emotions such as rage are seated in the brain, but they trigger the heart to race, the blood pressure to rise, and the respiration rate to increase. Mental depression can have the opposite effects. The smell of steak or chicken cooking on the grill can increase peristalsis, resulting in "grumbling" of the stomach and increased salivation. Clearly, autonomic actions can be modified by higher brain centers.

The roles of higher centers in regulating the ANS are shown in Figure 12.7. The hypothalamus is thought to be the main integration center of the ANS. This tissue receives signals from the cerebrum and sensory input, such as emotions, from the limbic system of the brain. The hypothalamus interprets the information and responds by sending messages to the various portions of the ANS, such as increasing peristalsis and salivation when the sights, sounds, and smells of the grilled steak are experienced. Messages from the hypothalamus travel along the medulla oblongata, the brainstem, and the spinal cord.

Drugs can affect the ANS by influencing these higher centers. For example, drugs that decrease anxiety or diminish the incidence of panic attacks can slow the heart rate and lower blood pressure through their ability to affect conscious thought. It is important to understand that these drugs do not necessarily act on autonomic receptors, nor do patients consciously lower their blood pressure or heart rate. The autonomic effect is indirect, caused by a reduction of stress, and it is at a subconscious level. Controlling autonomic activity through conscious thought is the principle underlying biofeedback therapy.

Classifying Autonomic Drugs

12.10 Autonomic drugs are classified by which receptors they stimulate or block.

At this point of the chapter, it is normal for students to feel overwhelmed by the complexity of the various autonomic receptors and their actions. It is the existence of these

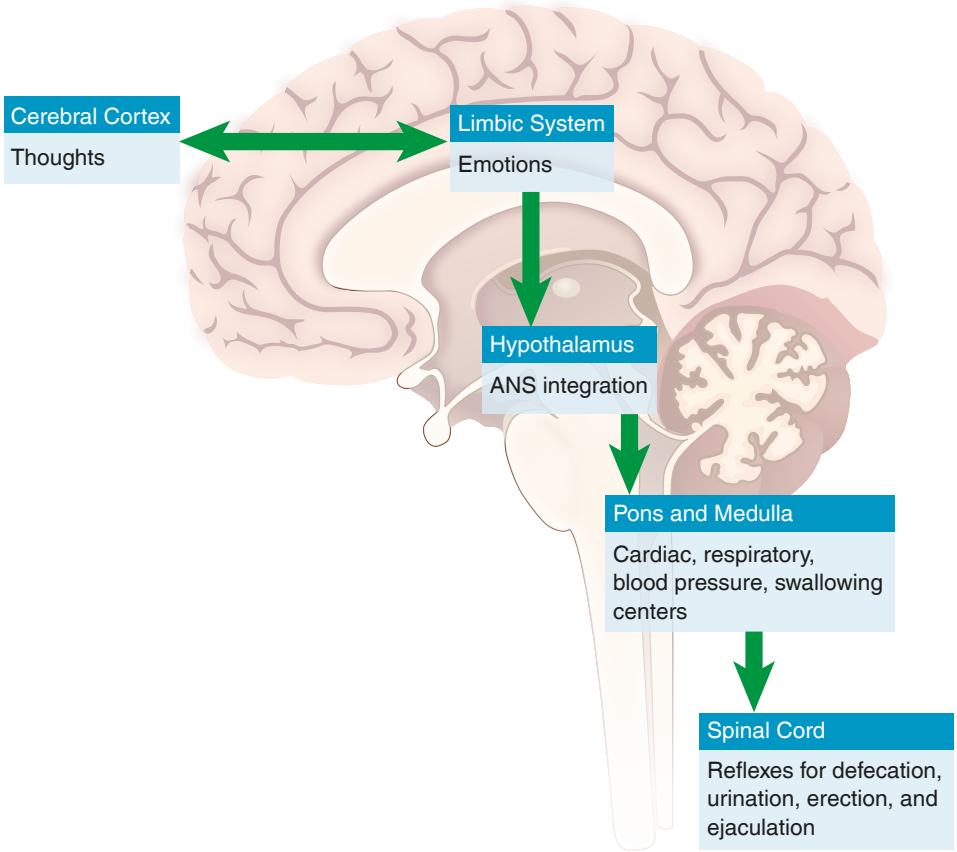

Figure 12.7 Higher centers influencing autonomic function.

different receptors, however, that allows drugs to cause very specific therapeutic actions. For example, it is desirable to have drugs that affect blood pressure without increasing heart rate, or drugs that dilate bronchi without causing hypertension. At this stage in the study of pharmacology, the student can just memorize the receptor types and actions, because applications in the coming chapters will provide clarity to this subject.

Given the opposite actions of the sympathetic and parasympathetic nervous systems, autonomic drugs are classified based on one of four possible actions:

1. **Stimulation of the sympathetic nervous system.** These drugs are called sympathomimetics or adrenergic agonists and they produce the classic symptoms of the fight-or-flight response.
2. **Stimulation of the parasympathetic nervous system.** These drugs are called parasympathomimetics or muscarinic agonists and they produce the characteristic symptoms of the rest-and-digest response.
3. **Inhibition of the sympathetic nervous system.** These drugs are called adrenergic antagonists or adrenergic blockers and they produce actions opposite to those of the sympathomimetics.
4. **Inhibition of the parasympathetic nervous system.** These drugs are called anticholinergics, parasympatholytics, or muscarinic blockers and they produce actions opposite to those of the parasympathomimetics.

Table 12.3 Indications for Autonomic Drugs

Indication	Autonomic Class	Chapter
Allergic rhinitis and the common cold	Alpha$_1$-adrenergic agonists	45
Alzheimer's disease	Cholinergic agonists	21
Angina pectoris	Beta-adrenergic blockers	35
Asthma and COPD	Beta-adrenergic agonists Anticholinergics	44
Benign prostatic hyperplasia	Alpha$_1$-adrenergic blockers	71
Dysrhythmias	Beta-adrenergic blockers	37
Eye examinations	Anticholinergics	74
Glaucoma	Alpha-adrenergic blockers Beta-adrenergic blockers Cholinergic agonists	74
Heart failure	Beta-adrenergic blockers Beta-adrenergic agonists	36
Hypertension	Alpha$_1$-adrenergic blockers Alpha$_2$-adrenergic agonists Beta-adrenergic blockers	34
Hypotension and shock	Beta-adrenergic agonists	15
Myasthenia gravis	Cholinergic agonists	13
Myocardial infarction	Beta-adrenergic blockers	35
Parkinson's disease	Anticholinergics	21
Peptic ulcer disease	Anticholinergics	59
Thyroid crisis (storm)	Beta-adrenergic blockers	67

There is a method for simplifying the learning of autonomic pharmacology. On examining the preceding four drug classes, it is evident that only one group need be learned because the others are logical extensions of the first. If the fight-or-flight symptoms of the sympathomimetics are learned, the other three groups are either the same or opposite. For example, both the sympathomimetics and the anticholinergics increase heart rate and dilate the pupils. The other two groups, the parasympathomimetics and the adrenergic antagonists, have the opposite effects of slowing heart rate and constricting the pupils. Although this is an oversimplification and exceptions exist, it is a time-saving means of learning the basic actions and adverse effects of dozens of drugs affecting the ANS. It should be emphasized again that mastering the actions and terminology of autonomic drugs early in the study of pharmacology will reap rewards later in the course when these drugs are applied to various systems. Table 12.3 shows the many applications of autonomic drugs in medicine and the chapter in this text in which each is covered.

Understanding Chapter 12

Key Concepts Summary

12.1 The two major subdivisions of the nervous system are the central nervous system and the peripheral nervous system.

12.2 The peripheral nervous system is divided into somatic and autonomic components.

12.3 The autonomic nervous system is divided into two mostly opposing components: the sympathetic and parasympathetic branches.

12.4 Synaptic transmission allows information to be communicated between two nerves or from nerves to muscles or glands.

12.5 Autonomic drugs exert their effects by acting at synapses.

12.6 Acetylcholine is the neurotransmitter released at cholinergic receptors, which may be nicotinic or muscarinic.

12.7 Norepinephrine is the primary neurotransmitter released at adrenergic receptors, which may be alpha or beta.

12.8 The adrenal medulla is a specialized type of sympathetic nervous system tissue that secretes epinephrine and norepinephrine.

12.9 The autonomic nervous system is influenced by higher levels of control in the cerebral cortex and hypothalamus.

12.10 Autonomic drugs are classified by which receptors they stimulate or block.

"It's rather embarrassing that I've had some 'accidents' these past 2 days since my surgery. They say I'm not passing my urine as I should. I just received this new prescription. What do I need to know about this bladder medicine I'm supposed to take?"

Patient "Patricia Sparks"

Chapter 13
Cholinergic Agonists

Chapter Outline

- Cholinergic Receptors
- Muscarinic Agonists

  Direct-Acting Muscarinic Agonists

  PROTOTYPE *Bethanechol (Urecholine), p. 159*

  Indirect-Acting Muscarinic Agonists (acetylcholinesterase inhibitors)
- Cholinergic Crisis
- Pharmacotherapy of Myasthenia Gravis

  PROTOTYPE *Pyridostigmine (Mestinon, Regonol), p. 163*
- Nicotinic Agonists

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the mechanisms of action for direct- and indirect-acting cholinergic agonists.
2. Identify the actions of muscarinic agonists and their pharmacologic uses.
3. Describe the pharmacotherapy of myasthenia gravis.
4. Differentiate between the treatment of cholinergic crisis and myasthenic crisis.
5. Explain the actions and pharmacologic applications of nicotine.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with cholinergic agonists.

Key Terms

acetylcholinesterase (AChE) inhibitors, 160
cholinergic agonists, 156
cholinergic crisis, 161
muscarinic agonist, 156
myasthenia gravis (MG), 161
myasthenic crisis, 163
nicotinic agonist, 156
reflex tachycardia, 159
Sjögren's syndrome, 159
xerostomia, 159

Of the four classes of autonomic drugs, the cholinergic agonists comprise the smallest and least prescribed group. Because cholinergic synapses are so widely dispersed throughout the central and peripheral nervous systems, drugs affecting these receptors will have diverse effects. A few have applications in the treatment of glaucoma, myasthenia gravis, and early Alzheimer's disease.

Cholinergic Receptors

13.1 Drugs can activate cholinergic receptors either directly or indirectly.

Recall from Chapter 12 that cholinergic receptors are located throughout the peripheral nervous system. To understand the effects of cholinergic drugs, it is important to review these locations. In the autonomic nervous system:

- At the neuroeffector junctions in the parasympathetic division
- At the ganglia in both the parasympathetic and sympathetic divisions.

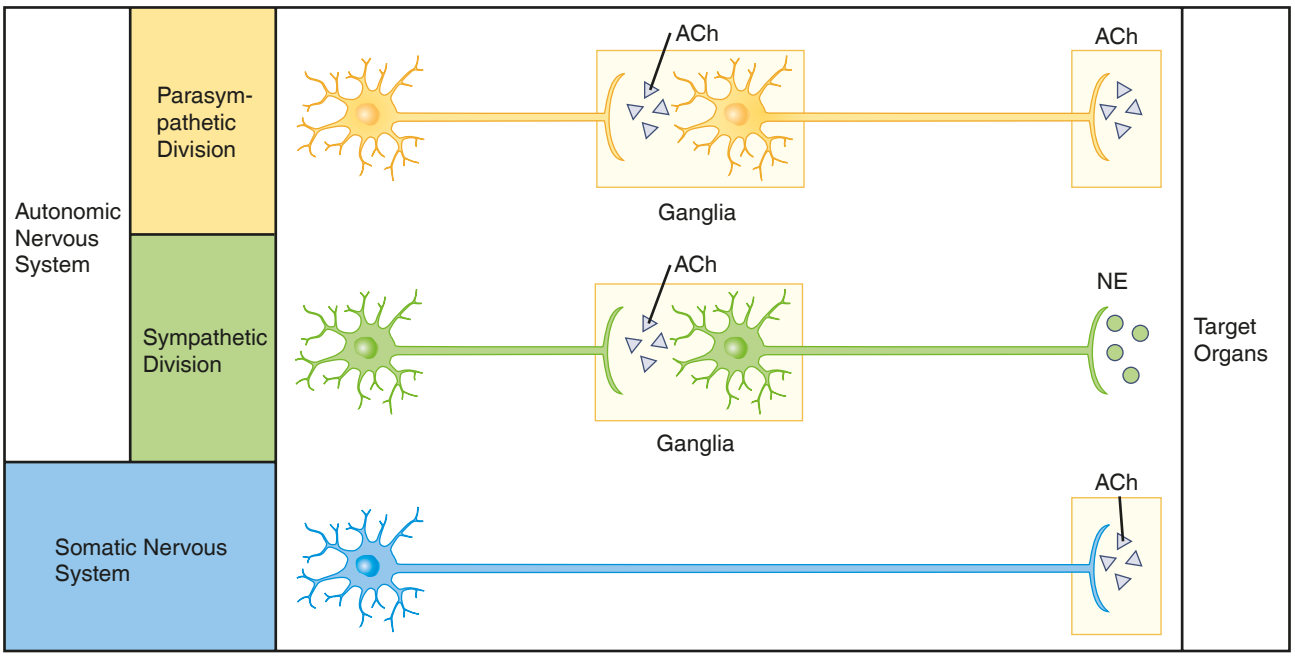
In the somatic nervous system:

- At the neuromuscular junctions, which result in skeletal muscle contraction.

In addition, cholinergic synapses are present throughout the central nervous system (CNS). These locations are summarized in Figure 13.1.

The degree of activation at a cholinergic synapse is dependent on the amount of neurotransmitter, acetylcholine (ACh), interacting with its receptors. Drugs and other chemicals that increase the action of ACh at cholinergic receptors will promote rest-and-digest responses. These substances are called **cholinergic agonists**, or parasympathomimetics.

Also recall from Chapter 12 that there are two primary types of cholinergic receptors: muscarinic and nicotinic. Although ACh itself stimulates both types of receptors, drugs may be selective for only one type. For example, bethanechol is selective for muscarinic receptors and thus it is called a **muscarinic agonist**. On the other hand, nicotine is selective for nicotinic receptors and therefore is classified as a **nicotinic agonist**. Note that both bethanechol and nicotine are considered cholinergic agonists: The terms



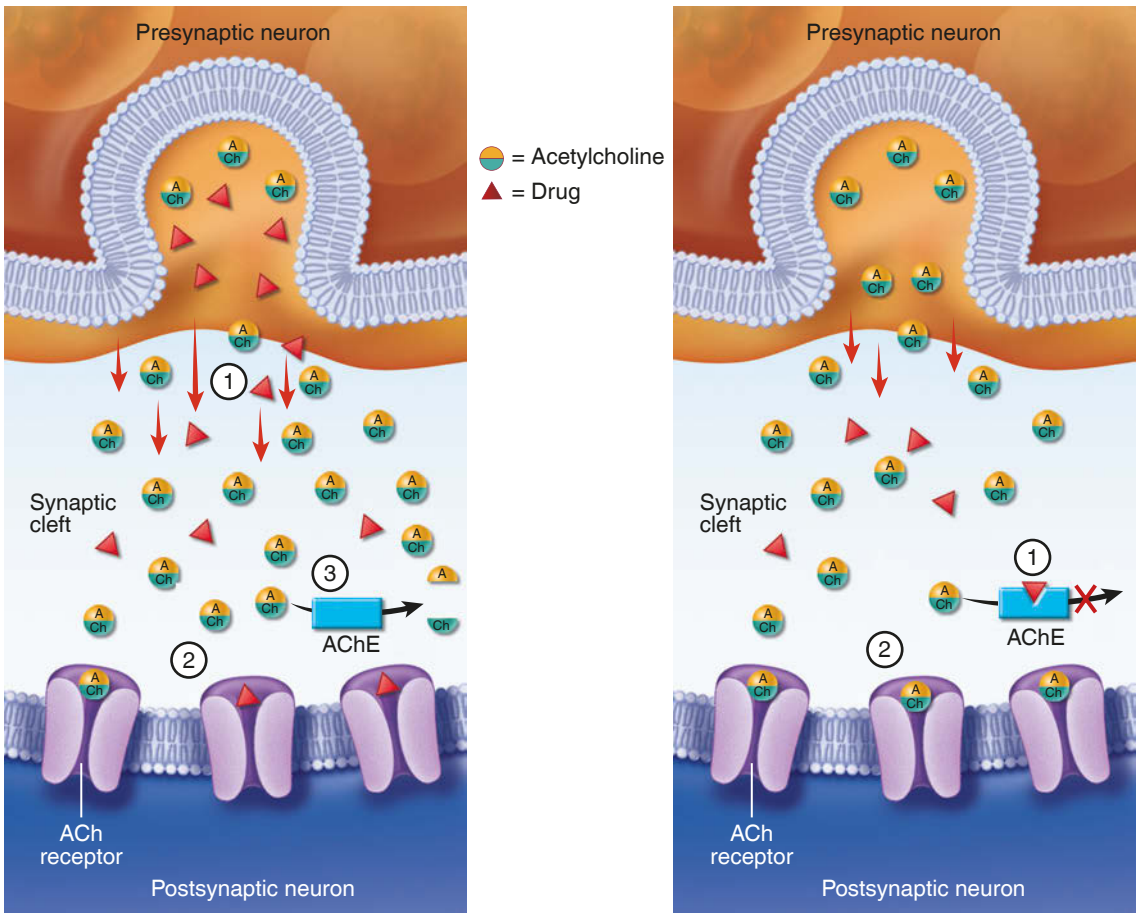


Figure 13.1 Locations of cholinergic synapses. Acetylcholine is released at the ganglia in both the parasympathetic and sympathetic divisions, at the neuroeffector junctions in the parasympathetic division, and in the somatic nervous system at neuromuscular synapses.

Table 13.1 Types of Cholinergic Receptors and Their Actions

	Muscarinic	Nicotinic
Receptor location	Glands, smooth muscle, cardiac muscle	Skeletal muscle, autonomic ganglia, brain, adrenal gland
General actions	Pupil constriction Decreased accommodation of the eye Increased GI motility Decreased heart rate Decreased blood pressure Increased glandular secretions (salivary, lacrimal, and sweat) Constriction of bronchial smooth muscle	Skeletal muscle contraction Initial stimulation of glandular secretion, followed by inhibition Increased heart rate Increased blood pressure

muscarinic and *nicotinic* are used to specify which cholinergic synapses are activated. If the student has not yet learned the differences between muscarinic and nicotinic receptors, then Section 12.6 should be reviewed before continuing. A summary of the differences is provided in Table 13.1.

Cholinergic agonists can activate cholinergic receptors directly or indirectly. Direct-acting drugs, such as bethanechol, enter the synaptic cleft and bind to ACh receptors to produce typical rest-and-digest responses. Some of these direct-acting drugs cause the release of additional ACh into the synaptic cleft, thus enhancing the normal physiologic responses caused by ACh. The direct-acting cholinergic agonists essentially act by the same mechanism as ACh itself. The direct mechanism of cholinergic activation is shown in Figure 13.2a.

(a) Direct Cholinergic Agonist

(b) Indirect Cholinergic Agonist

Figure 13.2 (a) Mechanisms of action for direct cholinergic agonists. Direct cholinergic agonists can activate the cholinergic receptor by two mechanisms: (1) The drug can cause more acetylcholine (ACh) to be released into the synaptic cleft, resulting in additional ACh occupying ACh receptors. (2) The drug can bind to ACh receptors, enhancing the action potential on the postsynaptic neuron. (3) Inactivation of drug action is achieved by acetylcholinesterase (AChE). (b) Mechanism of action for indirect cholinergic agonists: (1) The drug binds the enzyme (AChE), which prevents the ACh from being destroyed. This increases the amount of ACh remaining in the synaptic cleft, (2) thus enhancing the action potential on the postsynaptic neuron.

Table 13.2 Cholinergic Agonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Direct Acting (Muscarinic Agonists)		
bethanechol (Urecholine)	PO: 10–50 mg tid or qid (max: 200 mg/day)	*Increased salivation, abdominal cramping, sweating, flushing of the skin, miosis, blurred vision, nausea, vomiting* Orthostatic hypotension with possible syncope, bradycardia, reflex tachycardia, complete heart block, acute bronchospasm
carbachol (Miostat)	Intraocular: Instill 0.5 mL into anterior chamber of eye	
cevimeline (Evoxac)	PO: 30 mg tid (max: 90 mg/day)	
pilocarpine (Isopto-Carpine, Salagen)	Topical: 1–2 drops in affected eye tid or qid for chronic glaucoma	
	PO: 5–10 mg tid for xerostomia (max: 10 mg/dose, 30 mg/day)	
Indirect Acting (Acetylcholinesterase Inhibitors)		
donepezil (Aricept)	PO or orally disintegrating tablet (ODT): 5–10 mg (max: 10 mg/day)	*Involuntary contraction or twitching of muscles, nausea, vomiting, miosis, increased salivation* Bradycardia, hypotension, dyspnea, seizures, bronchospasm, cholinergic crisis, death due to paralysis of respiratory muscles
galantamine (Razadyne)	PO: 4 mg bid for 4 wk; may increase by 4 mg bid q4wk to target dose of 12 mg bid (max: 24 mg/day)	
neostigmine (Bloxiverz)	IM/subcutaneous: 0.5–2.5 mg q1–3 h (max: 10 mg/day) IV: 0.5–2.5 mg (max: 5 mg/day)	
physostigmine (Antilirium)	IM/IV: 0.5–2 mg (IV not faster than 1 mg/min); repeat as needed	
pyridostigmine (Mestinon, Regonol)	PO: 60 mg–1.5 g/day; sustained release: 180–540 mg 1–2 times/day at intervals of at least 6 h IV: 0.1–0.25 mg/kg	
rivastigmine (Exelon)	PO: Start with 1.5 mg bid; may increase to target dose of 3–6 mg bid (max: 12 mg/day) Transdermal: Start with one 4.6-mg patch daily (max: one 9.5-mg patch daily)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Indirect-acting drugs inhibit acetylcholinesterase (AChE) (also called cholinesterase), the enzyme in cholinergic synapses that destroys ACh. By blocking the destruction of ACh, the neurotransmitter accumulates and remains in the synaptic cleft for a longer time to produce enhanced rest-and-digest responses. Some indirect drugs such as neostigmine bind only briefly to AChE and exhibit short durations of action. These drugs are called *reversible* acetylcholinesterase inhibitors.

Certain chemicals bind *irreversibly* to AChE. For example, certain insecticides and nerve gas agents bind to AChE for prolonged periods and can cause significant mortality if ingested or absorbed. Because of the hazardous nature of these chemicals, irreversible acetylcholinesterase inhibitors are not widely used in medicine.

Note that physiologically it does not matter whether the cholinergic synapse was activated directly or indirectly: The parasympathetic responses are the same. There are some important differences, however, as will be discussed in Section 13.3. The indirect mechanism of cholinergic activation is shown in Figure 13.2b.

Muscarinic Agonists

13.2 Muscarinic agonists produce their effects by directly stimulating cholinergic receptors.

Muscarinic agonists are drugs that activate cholinergic receptors located at the neuroeffector junctions in the parasympathetic nervous system. Although ACh itself is a muscarinic agonist, it has little therapeutic value as a drug because it is rapidly destroyed both in the bloodstream and in synapses (by AChE) and produces many adverse effects. Muscarinic agonists used as medications are relatively resistant to destruction by AChE and exhibit a longer duration of action than ACh. Muscarinic agonists are poorly absorbed across the gastrointestinal (GI) tract and generally do not cross the blood–brain barrier. They have minimal effects on ACh nicotinic receptors in the ganglia. Because of the potential for serious adverse effects, few muscarinic agonists are widely used in pharmacotherapy. Available drugs are listed in Table 13.2.

Muscarinic agonists have widespread effects on the body, nearly all of which are due to parasympathetic activation. All of these drugs can increase the degree of smooth muscle tone and contractions of the GI tract. When administered before meals, stomach emptying is promoted due to increased peristalsis of the alimentary canal. Muscarinic agonists should never be administered to patients with suspected obstructive disease of the GI tract because the increased peristaltic contractions could lead to injury or rupture to the mucosa.

CONNECTION Checkpoint 13.1

From what you learned in Chapter 12, would you expect the cholinergic agonists to have similar or opposite effects to the following: adrenergic agonists, adrenergic antagonists, cholinergic antagonists? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Muscarinic agonists also stimulate the smooth muscle of the urinary tract, increasing ureteral peristalsis and

promoting emptying of the bladder. These are considered therapeutic actions in patients with urinary retention. Care must be taken not to administer muscarinic agonists when obstructive uropathy is present, however, because the increased smooth muscle contractions of the ureters and bladder could aggravate pain and bleeding.

Muscarinic agonists stimulate most exocrine glands, increasing lacrimal, sweat, digestive, and salivary secretions. This action has been used to advantage in treating patients with **xerostomia** (dry mouth) or those with **Sjögren's syndrome**, a chronic autoimmune disorder characterized by excessive dryness of mucous membranes, which is associated with rheumatoid arthritis in menopausal women. In addition to creating discomfort for the patient, xerostomia can promote dental caries, periodontal disease, oral ulcers, and candidiasis.

In the eye, muscarinic agonists cause the muscles of the iris to contract and produce pupillary constriction, or miosis. Miosis has no therapeutic application and is considered an adverse effect of muscarinic agonists. A second effect on the eye is contraction of the ciliary muscle, which causes loss of ability to focus for near vision. Although this action may cause blurred vision, ciliary muscle contraction has an indirect, beneficial effect: It allows fluid to drain from the anterior chamber of the eye, reducing intraocular pressure. When applied topically to the eye, cholinergic agonists, such as pilocarpine, can be of value in treating glaucoma. Cholinergic agonists are considered second-line drugs for glaucoma therapy, however, having been replaced by safer, more effective alternatives (see Chapter 74).

Muscarinic agonists contract bronchial smooth muscle, causing the airways to narrow. In patients with respiratory disease, bronchoconstriction may trigger episodes of breathlessness or an asthma attack. This is why muscarinic agonists are contraindicated in patients with a history of asthma.

When activated, muscarinic receptors in the cardiovascular system slow the heart rate and lower blood pressure. Baroreceptors in the carotid arteries and aortic arch, however, recognize the falling blood pressure and signal the vasomotor center in the medulla to increase the heart rate. This phenomenon, known as **reflex tachycardia**, is not unique to the cholinergic agonists; it can occur with any drug that causes blood pressure to fall. When administering cholinergic agonists by the oral (PO) or parenteral routes, the patients' heart rate must be closely monitored to avoid bradycardia. Blood pressure must also be monitored to prevent serious hypotension, particularly in those with preexisting cardiovascular disease. Patients with hyperthyroidism may experience atrial fibrillation. Serious heart disease is a contraindication to therapy with cholinergic agonists.

Occasionally, patients experience acute poisoning from eating certain species of mushrooms containing high amounts of muscarine, the original cholinergic agonist isolated from the mushroom *Amanita muscaria*. *A. muscaria* itself has only small amounts of muscarine, but several other species of fungi possess significant amounts of this toxin that can cause severe illness if ingested. Symptoms of acute poisoning appear 30 to 90 minutes after ingestion and resemble an overdose of cholinergic agonists: an exaggerated parasympathetic response. Symptoms may persist for 24 hours. *Amanita* species are sometimes intentionally ingested to obtain psychotic effects, reportedly to expand or alter spatiotemporal awareness.

PharmFACT

Muscarinic receptors are named after muscarine, which is obtained from the mushroom *Amanita muscaria*. The actual chemical that causes poisoning in patients eating this mushroom, however, is primarily ibotenic acid, which causes excitement, hallucinations, and confusion. Death from *Amanita* mushroom poisoning is rare (Rolston-Cregler, 2015).

Symptoms of parasympathetic stimulation, whether caused by medications or poisoning, may be reversed by administering an anticholinergic drug. Atropine is considered the specific antidote for these conditions. Acute symptoms of parasympathetic stimulation will begin to resolve within minutes after a subcutaneous injection of atropine. Atropine is a prototype cholinergic antagonist presented in Chapter 14.

PROTOTYPE DRUGS Bethanechol (Urecholine)

Classification

Therapeutic: Drug to treat urinary retention

Pharmacologic: Cholinergic agonist, muscarinic agonist (direct acting)

Therapeutic Effects and Uses: Approved in 1948 by the U.S. Food and Drug Administration (FDA), bethanechol is available in tablet form. Effects of bethanechol are most noted in the digestive and urinary tracts, where it stimulates smooth muscle contraction. In the urinary tract, bethanechol relaxes the sphincters and causes the detrusor muscle of the bladder to contract. These combined actions result in voiding; thus it is used to treat nonobstructive urinary retention in patients with atony of the bladder. Off-label uses include the treatment of adynamic ileus and gastric atony.

Mechanism of Action: Structurally similar to ACh, bethanechol interacts directly with muscarinic receptors to cause body responses typical of parasympathetic stimulation. This drug is selective for muscarinic receptors. Bethanechol is not destroyed by AChE; therefore, its actions are more prolonged than those of ACh.

Pharmacokinetics:

Route(s)	PO
Absorption	Poorly absorbed PO
Distribution	Widely distributed; does not cross the blood–brain barrier
Primary metabolism	Unknown
Primary excretion	Renal
Onset of action	30–60 min
Duration of action	1–6 h

Adverse Effects: The adverse effects of bethanechol are predictable knowing its parasympathetic actions. Common adverse effects include increased salivation, abdominal cramping, sweating, flushing of the skin, miosis, blurred vision, nausea, and vomiting. Serious effects include orthostatic hypotension with possible syncope, bradycardia, reflex tachycardia, complete heart block, and acute bronchospasm.

Contraindications/Precautions: Bethanechol should be used with extreme caution in patients with disorders that could be aggravated by increased contractions of the GI tract, such as suspected bowel obstruction, recent GI surgery, an active ulcer, or an inflammatory disease. Patients with suspected urinary obstruction or those who have had recent bladder surgery should not receive this drug, because the increased smooth muscle contractions could worsen these conditions. Patients with cystitis should not be given bethanechol because contractions of the bladder may force urine up the ureters to the kidneys if the sphincter fails to open. Because of the possibility of bronchoconstriction, administration of bethanechol to patients with asthma or chronic obstructive pulmonary disease (COPD) is contraindicated. Muscarinic agonists such as bethanechol can slow the heart rate; thus they are contraindicated in patients with recent myocardial infarction (MI), severe bradycardia, hypotension, or hypertension. Patients with hyperthyroidism can experience dysrhythmias with bethanechol use. Other contraindications include peritonitis, epilepsy, and Parkinson's disease.

Drug Interactions: Concurrent therapy with AChE inhibitors should be avoided because this class also stimulates muscarinic receptors, and excessive parasympathetic activity will result. Procainamide, quinidine, atropine, and epinephrine antagonize the effects of bethanechol. Concurrent administration of bethanechol with ganglionic blockers may result in a rapid fall in blood pressure. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose will result in serious cholinergic symptoms such as nausea, vomiting, abdominal cramping, diarrhea, salivation, and hypotension. Administration of subcutaneous atropine quickly reverses most symptoms.

Nursing Responsibilities: Key nursing implications for patients receiving bethanechol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Cholinergic Agonists.

Drugs Similar to Bethanechol (Urecholine)

Other direct-acting cholinergic agonists include carbachol, cevimeline, and pilocarpine.

Carbachol (Miostat): Carbachol is a direct-acting cholinergic agonist. Carbachol intraocular (Miostat) is a solution for injection into the anterior chamber of the eye to promote miosis during surgery. Vision may be clouded due to pupillary constriction. Should absorption occur, adverse effects would be those of parasympathetic stimulation. This drug is pregnancy category C.

Cevimeline (Evoxac): Cevimeline is a direct-acting cholinergic drug whose only indication is the treatment of xerostomia in patients with Sjögren's syndrome. Given orally, cevimeline increases saliva flow, relieving dry mouth. The most common adverse effect is excessive sweating, although this occurs less frequently than with pilocarpine. Other signs of parasympathetic stimulation are possible, such as diarrhea, runny nose, miosis, and bradycardia. This drug is pregnancy category C.

Pilocarpine (Isopto-Carpine, Salagen): Pilocarpine is a direct cholinergic agonist that is administered orally or as an ophthalmic solution. Salagen is an oral preparation of pilocarpine given for xerostomia due to its ability to stimulate salivary flow. When given orally, the adverse effects of pilocarpine are those expected of parasympathetic stimulation, which include diarrhea, runny nose, miosis, and bradycardia. Excessive sweating occurs in 30% to 60% of patients taking oral pilocarpine.

Pilocarpine is also approved as eyedrops to treat certain types of glaucoma and to counteract the effects of mydriatics and cycloplegics following eye examinations. This drug is pregnancy category C.

13.3 Acetylcholinesterase inhibitors are used to treat Alzheimer's disease and myasthenia gravis.

The indirect-acting cholinergic agonists inhibit the enzymatic destruction of ACh, allowing the neurotransmitter to remain on cholinergic receptors for a longer time. Like the direct-acting agonists, these drugs essentially prolong the actions of ACh. Unlike the direct-acting (muscarinic) agonists, however, the **acetylcholinesterase (AChE) inhibitors** are nonselective and affect ACh synapses located at the autonomic ganglia, muscarinic receptors, neuromuscular junctions, and synapses in the CNS.

The muscarinic actions of the AChE inhibitors are identical to those described for the direct-acting drugs. As such, these drugs would be expected to increase peristalsis in the GI and urinary tracts, and some can decrease intraocular pressure.

The AChE inhibitors have some additional nonautonomic indications due to their actions in the CNS and on motor nerve endings in skeletal muscle. AChE inhibitors used to treat mild to moderate Alzheimer's disease include galantamine (Razadyne), donepezil (Aricept), and rivastigmine (Exelon). These drugs increase the amount of ACh in cholinergic synapses in the brain, which improves memory and cognitive function. The AChE inhibitors do not cure or slow the progress of Alzheimer's disease: Improvement is limited and short lived. Donepezil is presented as a prototype drug for Alzheimer's disease in Chapter 21.

Some cholinergic agonists are used in the pharmacotherapy of myasthenia gravis. This indication is presented in Section 13.5.

Cholinergic Crisis

13.4 A cholinergic crisis may develop with overdoses of AChE inhibitors or with certain toxins.

When cholinergic receptors are overstimulated, a medical emergency known as a **cholinergic crisis** may result. Overdoses of AChE inhibitor medications, or exposure to toxic nerve gases (such as Sarin) or organophosphate insecticides (such as Malathion), may cause an acute accumulation of ACh at cholinergic synapses. The use of nerve gases as a bioterrorist threat is discussed in Chapter 75.

A cholinergic crisis is recognized by signs of intense parasympathetic stimulation such as miosis, nausea, vomiting, urinary incontinence, increased exocrine secretions, abdominal cramping, and diarrhea. As the crisis progresses, signs of sympathetic and nicotinic stimulation appear, including tachycardia, hyperglycemia, and muscle twitching, with progressive muscle weakness and possibly flaccid paralysis. In massive overdoses, mechanical ventilation may be required and paralysis of respiratory muscles may cause death. CNS effects are prominent with the organophosphates and include headache, blurred vision, anxiety, delirium, convulsions, and coma. In general, overdose with AChE drugs produces less severe and shorter duration effects than does poisoning with organophosphates.

The treatment of cholinergic crisis includes administration of atropine, the specific antidote that reverses muscarinic effects. Subcutaneous atropine can act within minutes. Because some insecticides have long-lasting effects, atropine therapy may continue for several weeks.

Pralidoxime (Protopam) is a cholinergic agonist that has primarily antinicotinic action, which can reverse muscle twitching and increase muscle strength. It is a specific antidote for poisoning by organophosphate insecticides and is used to control overdoses of the AChE inhibitors used to treat myasthenia gravis. In acute poisoning, pralidoxime is administered by IV infusion over 15 to 30 minutes. To be most effective, pralidoxime must be given as soon as possible after the suspected poisoning or overdose. Furthermore, it should always be administered concurrently with atropine (which blocks muscarinic sites). DuoDote is a drug that contains both pralidoxime and atropine combined in a single intramuscular (IM) injection.

Pharmacotherapy of Myasthenia Gravis

13.5 Acetylcholinesterase inhibitors are used in the pharmacotherapy of myasthenia gravis to increase the strength of muscular contraction.

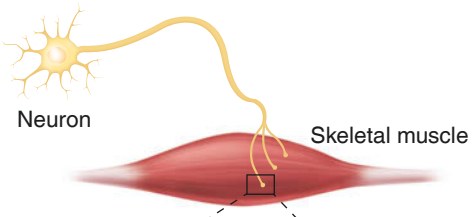
Myasthenia gravis (MG), which literally means "grave muscular weakness," first appeared in medical reports in 1672 and afflicts about 125 per million people in the United States. It is one of the best understood autoimmune diseases of the nervous system. The disease occurs when antibodies attack nicotinic synapses on skeletal muscles, resulting in symptoms of extreme fatigue, double vision, speech impairment, and difficulty chewing or swallowing. The most visible symptom is an obvious drooping of the eyelids (ptosis) due to muscular weakness. The ocular muscles may become so fatigued that the patient is unable to open the eyelids. Muscle fatigue worsens after exercise, or late in the day. MG is considered a progressive disease, although the severity of symptoms fluctuates over time.

PharmFACT

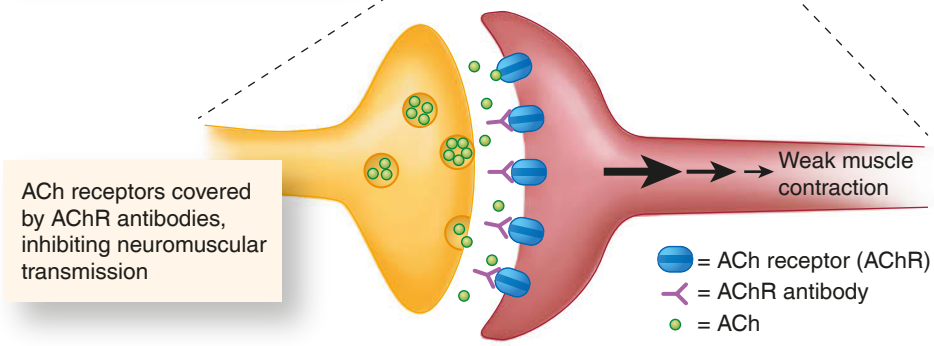
The mean age of onset of MG is 28 years in women and 42 years in men. Most mortality from the disease occurs within 3 years following diagnosis. Worsening of the disease is uncommon after 3 years (Shah, 2016).

MG is diagnosed by the anti–acetylcholine receptor (AChR) antibody test. An individual without MG should have virtually no antibodies to the acetylcholine receptor. In a patient with MG, the body forms antibodies to the ACh receptor, and these can be measured in the blood with an accuracy of almost 100%. For confirmation, an electromyelography test may be conducted to test for muscle activity and fatigue.

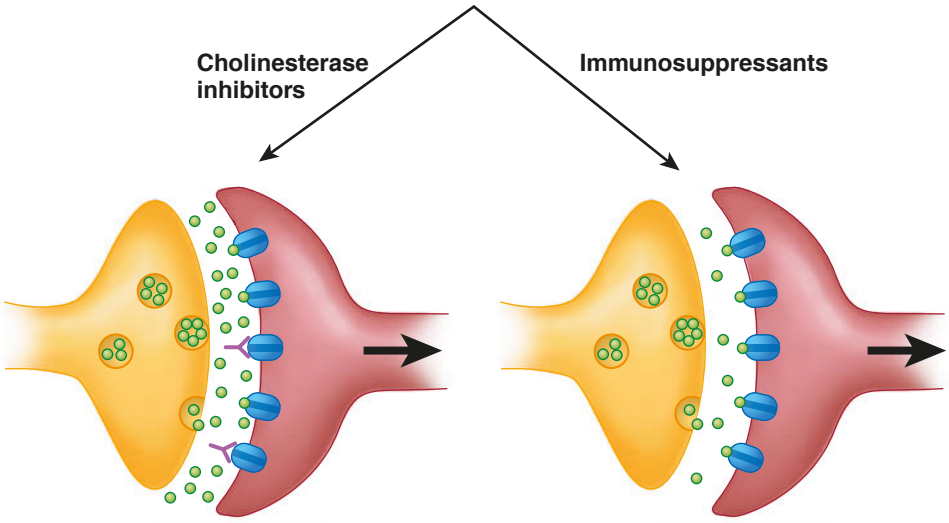
For patients with suspected MG, it is important to perform an accurate baseline physical assessment of neuromuscular and respiratory function. The patient's swallowing ability should be assessed prior to medication administration due to decreased muscle strength caused by the disease process. Subsequent assessments are important for monitoring the progress of pharmacotherapy.



Management of MG is divided into symptomatic control and immunosuppression as shown in Pharmacotherapy Illustrated 13.1. In the early stages of the disease, symptoms can be controlled successfully with AChE inhibitors, usually pyridostigmine. These drugs are effective for mild symptoms, act rapidly, and produce few serious adverse effects at low to moderate doses. Muscarinic side effects such as diarrhea and abdominal cramps are common, and muscle twitching can occur. High doses should not be used because AChE inhibitors can begin to affect



Pharmacotherapy Illustrated 13.1



Myasthenia Gravis

Patient with myasthenia gravis showing muscle fatigue.

ACh nicotinic receptors, worsening the degree of muscle weakness.

As MG progresses, immunosuppressant drugs such as corticosteroids are added to the regimen. Corticosteroids such as prednisone reduce AChE receptor antibody levels and result in symptomatic improvement. Care must be taken when initiating corticosteroid therapy because patient symptoms may dramatically worsen during the first few days of therapy. Doses of prednisone are gradually increased until the desired therapeutic effect is obtained. Unfortunately, improvement may take weeks or even months, and corticosteroids can exhibit considerable toxicity when given on a long-term basis (see Chapter 68). Therapy with corticosteroids is limited to the shortest time necessary, although some patients may require these drugs for the rest of their life.

Other immunosuppressants such as azathioprine (Imuran), cyclosporine (Sandimmune), or mycophenolate mofetil (CellCept) may be administered as alternatives to corticosteroids. Occasionally, these alternatives are administered concurrently with prednisone to allow for lower doses of the corticosteroid. Immunosuppressants are discussed in Chapter 42.

A **myasthenic crisis** may occur if a patient with MG abruptly discontinues the medication. This leads to extreme muscular weakness and symptoms similar to those of a cholinergic crisis. Rapid, correct diagnosis is essential, however, because antidotes for the myasthenic crisis and the cholinergic crisis are very different. Weakness that appears approximately 1 hour after drug administration that is accompanied by signs of muscarinic overstimulation suggests cholinergic crisis (overdose) and is treated by prompt withdrawal of neostigmine and immediate administration of atropine. Weakness that occurs 3 hours or more after drug administration without muscarinic overstimulation is more likely due to myasthenic crisis (underdose, abrupt discontinuation, or drug resistance) and is treated by more intensive AChE therapy.

It should be clearly understood that MG is a disease affecting skeletal muscle; it is not a disorder of the autonomic nervous system. It is presented in this chapter dealing with the autonomic nervous system because the primary pharmacotherapy for the disease is AChE inhibitors. Although these drugs provide symptomatic relief, they do not cure or slow the progression of MG. With treatment, however, patients may experience a near-normal life expectancy.

PROTOTYPE DRUGS Pyridostigmine (Mestinon, Regonol)

Classification **Therapeutic:** Drug for myasthenia gravis
Pharmacologic: Indirect-acting cholinergic agonist, AChE inhibitor

Therapeutic Effects and Uses: Approved in 1955, pyridostigmine is available by both oral and parenteral routes for the symptomatic treatment of MG. Affecting the neuromuscular synapses, pyridostigmine increases the strength of skeletal muscle contraction and delays fatigue. An average dose is ten 60-mg tablets per day, spaced apart to provide for maximum muscle strength. The sustained release form (Mestinon Timespan) consists of 180-mg tablets that are taken once or twice daily.

Pyridostigmine is also approved for military personnel with potential exposure to certain nerve gases. Pyridostigmine is only effective if administered several hours prior to nerve gas exposure. If exposure occurs, pyridostigmine is discontinued and the antidotes (atropine and pralidoxime) are administered.

The intravenous (IV) form of pyridostigmine (Regonol) is administered to reverse the neuromuscular blocking action of nondepolarizing muscle relaxants. When given by the IV route, extreme caution should be used to avoid overdosage, which can worsen neuromuscular blockade.

Mechanism of Action: Pyridostigmine reversibly inhibits the action of AChE at cholinergic synapses, which allows ACh to accumulate and cause a greater effect. Its use in treating MG is due to its effects on nicotinic ACh receptors in skeletal muscle.

Pharmacokinetics:

Route(s)	PO and IV
Absorption	PO: only 1–2% is absorbed; the oral dose is much higher than the parenteral dose
Distribution	Distributed to most tissues; crosses the placenta; does not cross the blood–brain barrier
Primary metabolism	Hepatic and plasma, by cholinesterases
Primary excretion	Kidneys
Onset of action	PO: 15–30 min; IV: 2–5 min
Duration of action	3–6 h (regular), 6–12 h (extended release)

Adverse Effects: In addition to its effects on nicotinic receptors, pyridostigmine also affects muscarinic receptors. At muscarinic synapses, pyridostigmine will enhance the parasympathetic response, resulting in increased peristalsis, bronchoconstriction, bradycardia, and hypotension. Common adverse effects include involuntary contraction or twitching of muscles, nausea, vomiting, miosis, and increased salivation. Potentially serious adverse effects include those of cholinergic crisis.

Contraindications/Precautions: Pyridostigmine should be used with caution in patients with disorders that could be aggravated by increased contractions of the GI tract, such as suspected bowel obstruction or active ulcers. Patients with suspected urinary obstruction should

not receive this drug because the increased smooth muscle contractions could worsen this condition. Because of the potential for bronchoconstriction, patients with asthma or COPD should be treated cautiously with cholinergic agonists. Cholinergic agonists such as pyridostigmine can cause bradycardia; thus they are used cautiously in patients with recent MI or heart failure.

Drug Interactions: Because of the potential for additive effects, other cholinergic agonists should not be administered concurrently with pyridostigmine. Drugs that interfere with neuromuscular transmission such as local anesthetics, some general anesthetics, and antidysrhythmic drugs should be used cautiously in patients with MG because severe muscular weakness may result. If administered to patients with MG, the dose of pyridostigmine should be increased. Cholinergic drugs increase gastric acid secretion and should be used with caution with other ulcer-promoting drugs such as corticosteroids or nonsteroidal anti-inflammatory drugs (NSAIDs). **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Overdose with pyridostigmine may be life threatening because the drug can cause a cholinergic crisis leading to respiratory failure. The administration of atropine reverses most overdose symptoms.

Nursing Responsibilities: Key nursing implications for patients receiving pyridostigmine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Cholinergic Agonists.

Drugs Similar to Pyridostigmine (Mestinon, Regonol)

The other AChE inhibitor for MG is neostigmine.

Neostigmine (Bloxiverz): Neostigmine has a shorter duration of action than pyridostigmine and causes a higher frequency of adverse effects. The adverse effects result from its ability to stimulate the parasympathetic nervous system.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Cholinergic Agonists

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, cerebrovascular, respiratory, musculoskeletal, or thyroid diseases, GI or genitourinary obstruction, or diabetes. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings such as hepatic or renal function studies.
- Obtain baseline vital signs, bowel sounds, urinary output, muscle strength, and mental status as appropriate. Assess the patient's ability to swallow.
- Assess the patient's ability to receive and understand instructions. Include family and caregiver as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased ease of urination, improved muscle strength and coordination, lessened ptosis, and improved swallowing).
- Continue frequent and careful monitoring of vital signs, mental status, bowel sounds, urinary output, and musculoskeletal function, including swallowing ability as appropriate.
- Assess for and promptly report adverse effects: bradycardia, hypotension, dysrhythmias, tremors, dizziness, headache, dyspnea, decreased urinary output, abdominal pain, or changes in mental status.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Ability to carry out activities of daily living [ADLs] has improved; urinary elimination and output are improved; musculoskeletal weakness, ptosis, diplopia, chewing, and swallowing are improved. A larger percentage of the dose may be needed at times of greater fatigue such as late afternoon and at mealtimes or during periods of increased stress. A decrease in dosage during remission may be needed.) **Lifespan:** Assess for subtle changes in muscle strength or voice quality or slurred speech in the older adult. (Subtle changes that occur during the day, especially if timed around drug peaks or troughs, may indicate underdosage rather than age-related changes.)	• Encourage the patient, family, or caregiver to practice supportive measures along with drug therapy to maximize therapeutic effects (e.g., adequate rest periods in MG). • Have the patient, family, or caregiver maintain a diary of variations in muscle strength, particularly periods of weakness, to assist the provider in choosing an appropriate dosage. • Instruct the patient not to self-regulate the dosage to avoid over- or underdosage. If periods of weakness occur, the provider will adjust the dosage after determining the cause (e.g., under- vs. overdosage). • **Lifespan:** Teach the patient, family, or caregiver the importance of noting even subtle changes in the diary and the timing of doses taken.
• Continue frequent monitoring of bowel sounds and urine output if drugs are given postoperatively or postpartum. (Assessments will detect early signs of adverse effects as well as monitoring for therapeutic action. Drug onset is in approximately 60 min with increased urination and peristalsis following. Drugs are not given if a mechanical obstruction is known or suspected. **Lifespan:** Be aware that the male older adult is at higher risk for mechanical obstruction due to an enlarged prostate.)	• Instruct the patient to have bathroom facilities nearby after taking the drug. The patient may need assistance to the toilet or commode if dizziness occurs.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Provide supportive nursing measures; e.g., regular toileting schedule and safety measures. (Nursing measures such as assisting the patient to normal voiding position will supplement therapeutic drug effects and optimize outcome. **Lifespan:** A home assessment is especially important for the older adult. The presence of throw rugs and other hazards that obstruct mobility increases the risk for falls.)	• Assess ability of the patient, family, or caregiver to perform ADLs at home, and explore the need for additional healthcare referrals. Evaluate home safety needs.
• Schedule activities and allow for adequate periods of rest to avoid fatigue. (Excess fatigue can lead to either a cholinergic or a myasthenic crisis in patients with MG.)	• Instruct the patient to plan activities according to muscle strength and fatigue and to allow for frequent and adequate rest periods. • Instruct the patient to report extreme fatigue immediately.
• Follow appropriate administration techniques for ophthalmic doses. Sustained release tablets should not be crushed or chewed. Administer the drug with food, milk, or small snack. (Administering with food helps to minimize adverse effects. Sustained release tablets must be swallowed whole and a change of dosage form may be needed if dysphagia is present.)	• Instruct the patient in proper administration techniques, followed by a teach-back. • Have the patient report any difficulty in swallowing if sustained release tablets are used.
Minimizing adverse effects: • Monitor for signs of excessive ANS stimulation and notify the healthcare provider if pulse is less than 60 beats/min or blood pressure is below established parameters. (Cholinergic agonists decrease heart rate and blood pressure. Atropine may be ordered to counteract drug effects.)	• Instruct the patient to promptly report tremors, palpitations, changes in blood pressure, dizziness, urinary retention, abdominal pain, or changes in behavior (e.g., confusion, depression, or drowsiness). Instruct the patient to report dyspnea, salivation, sweating, or extreme fatigue immediately, because these are signs of a potential overdose.
• Help the patient to rise from lying or sitting to standing until drug effects are assessed. (Direct-acting cholinergic agonists may cause significant orthostatic hypotension. **Lifespan:** Be aware that dizziness may increase the risk of falls in the older adult.)	• Instruct the patient to rise from lying or sitting to standing slowly and to avoid prolonged standing in one place to avoid dizziness or falls.
• Report periods of muscle weakness and association to dosage time to the provider promptly. (Muscle weakness occurring within 1 h of dose may indicate overdosage or cholinergic crisis. Weakness occurring 3 h or longer after dose may indicate underdosage, drug resistance, or myasthenic crisis.)	• Instruct the patient to report any severe muscle weakness that occurs 1 h after taking the drug or if it occurs 3 or more hours after taking the medication. • Assist the patient, family, or caregiver to record variations of muscle strength, particularly periods of weakness, and associated dose times to assist the provider in appropriate dosage.
• Continue to monitor hepatic function laboratory values. (Cholinergic agonists may cause liver toxicity, and liver enzymes may be monitored weekly for up to 6 weeks.)	• Teach the patient, family, or caregiver about the importance of returning for follow-up laboratory studies.
• Provide for eye comfort such as an adequately lighted room and appropriate safety measures. (Cholinergic agonists cause miosis with difficulty seeing in low-light levels and blurred vision.)	• Caution the patient about driving in low-light conditions, at night, or if vision is blurred. Night-light use at home and safety measures may be needed to prevent falls.
• Carefully calculate and monitor doses. (Careful calculation will avoid overdosage.)	• Ensure that the patient, family, or caregiver is administering the correct dose by observing teach-back.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug; appropriate dose and scheduling; what adverse effects to observe for and when to report them; equipment needed as appropriate and how to use that equipment; and the required length of medication therapy needed with any special instructions regarding renewing or continuing the prescription as appropriate. • Instruct the patient to wear a medic-alert bracelet or other device describing the disease and the medications used.
Patient self-administration of drug therapy: • When administering the medications, instruct the patient, family, or caregiver in proper self-administration of drugs and ophthalmic drops. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration techniques, followed by teach-back. • The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Common adverse effects include involuntary contraction or twitching of muscles, nausea, vomiting, miosis, and increased salivation. Potentially serious adverse effects include those of cholinergic crisis. If using large doses of neostigmine to treat MG, atropine (an anticholinergic) is sometimes administered concurrently to reverse the muscarinic adverse effects of neostigmine.

Patients with obstructive disorders of the GI or urinary tracts should not receive this drug because the increased smooth muscle contractions could worsen these conditions. This drug should be used with caution in patients with asthma, bradycardia, recent MI, or heart failure. This drug is pregnancy category C.

Nicotinic Agonists

13.6 Nicotine acts by activating ACh receptors at the ganglia.

Very few drugs are used for their effects on ACh nicotinic receptors located in the autonomic ganglia. These ganglia synapse with neurons leading to skeletal muscles (nicotinic receptors) as well as those leading to effector organs (muscarinic receptors). Drugs affecting the ganglia have the potential to produce widespread, nonselective effects on the autonomic nervous system.

The only drug in widespread use that activates ganglionic receptors is nicotine. The most active component of tobacco smoke, nicotine is well absorbed from the GI and respiratory mucosa as well as from the skin. Because nicotine acts at the ganglia, both parasympathetic and sympathetic responses are stimulated. Stimulation of organ activity generally occurs with low doses, such as those acquired from cigarette smoking. Within seconds after smoking, activation of the CNS increases alertness. The heart rate and blood pressure increase, although these parameters may subsequently decrease due to the baroreceptor reflex. The emetic center in the CNS is triggered, causing a feeling of nausea. As the level of nicotine in the blood falls, these same organ systems become depressed. Nicotine is pregnancy category D.

Nicotine is an extremely dangerous substance. Acute toxicity, which can occur due to the unintentional ingestion of insecticides containing nicotine, may cause death due to paralysis of the respiratory muscles. The chronic effects of nicotine in tobacco smokers such as lung cancer and emphysema are well documented and presented in Chapter 27.

As a drug, nicotine is used as nicotine replacement therapy (NRT) in tobacco cessation programs. Delivery systems include chewing gum (Nicorette), transdermal patches (Habitrol, NicoDerm), and nasal spray (Nicotrol). Use of these products reduces the uncomfortable symptoms of nicotine withdrawal, such as difficulty sleeping, lack of concentration, depression, headaches, and food cravings. As tobacco use diminishes over an 8- to 12-week period, these products are gradually withdrawn.

The goal of NRT is to gradually reduce the patient's physical dependence on nicotine. The nurse should

CONNECTIONS: Preparing for Advanced Practice

Myasthenia Gravis: Future Treatments

Case

Jane Richard is an active, busy 26-year-old mother of two young children, Amy, age 1, and Grant, age 4. One day she began to have facial weakness and reports that her "lower jaw gets tired and begins to twitch" when she chews. She has even had episodes of choking. She also mentions having double vision when she reads, especially late at night. Of most concern, however, is that she is experiencing muscle weakness and has a hard time caring for Amy, her 1-year-old. She is afraid she will drop her when she picks her up.

Her neurologic examination showed ptosis, drooping of both eyelids. Electromyographic (EMG) testing further revealed that she had progressive weakness and decreased contraction of the distal arm muscles on repeated mild shocks (5 shocks per second) of the ulnar and median nerves. Blood testing revealed high levels of an anti–acetylcholine receptor antibody in her plasma, and a diagnosis of myasthenia gravis was made.

She began treatment with pyridostigmine, a long-acting acetylcholinesterase inhibitor, and was given a prescription for prednisone to suppress the immune system and promote the formation of new acetylcholine receptors in muscle cell membranes. She also underwent occasional plasmapheresis when her symptoms became especially severe. She was given a prescription of atropine as needed to reduce the nausea, abdominal cramps, diarrhea, and excessive salivation she experienced as side effects of the pyridostigmine.

Discussion

MG is no longer considered a fatal disease, and most patients lead near normal lives with the help of either drugs or surgery. Corticosteroids suppress the immune system and may promote the formation of new acetylcholine receptors in muscle cell membranes. Patients taking corticosteroids such as prednisone for an extended time may be susceptible to bone thinning. Taking adequate amounts of calcium and vitamin D is important. Foods to include are milk products, cooked dark green vegetables, salmon, dried beans, and calcium-fortified juices and cereals. Because corticosteroids can cause fluid retention, salt substitutes or spices may be healthy alternatives to table salt. Cured or smoked meats, canned vegetables and soups, salty snacks, and pickled foods should be avoided.

Plasmapheresis, or taking the fluid part of the blood (plasma) containing the abnormal antibodies out and replacing it with other fluids, can be life changing for MG patients. Because the effects of plasmapheresis often last only 2 weeks, a series of treatments is usually necessary.

The current standard of care in MG mainly consists of generalized immunosuppression. However, the future of MG treatment will be based on increased understanding of the immune function and use of immunosuppressive drugs. Immunosuppressive drugs that were originally developed to prevent immune rejection of transplanted organs have been useful in treating MG. Additionally, the long-awaited study results from the "Randomized Trial of Thymectomy in Myasthenia Gravis" compared patients who received a thymectomy plus prednisone to a group that received only prednisone (Wolfe et al., 2016). Those who received surgery plus prednisone had an overall reduction in muscle weakness and required lower daily doses of prednisone (Kaufman et al., 2016). Based on this, treatment of MG with combined surgery and medication for those who meet surgical criteria, should be considered.

remember, however, that psychologic dependence also occurs with nicotine and that most successful smoking cessation programs include behavioral modification therapy such as self-help groups. The consistent use of NRT roughly doubles a patient's chances of quitting smoking, but a great deal of persistence and motivation is required.

CONNECTION Checkpoint 13.2

Some cholinergic agonists activate both muscarinic and nicotinic receptors. From what you learned in Chapter 12, give the locations where each of these receptors may be found. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Understanding Chapter 13

Key Concepts Summary

13.1 Drugs can activate cholinergic receptors either directly or indirectly.

13.2 Muscarinic agonists produce their effects by directly stimulating cholinergic receptors.

13.3 Acetylcholinesterase inhibitors are used to treat Alzheimer's disease and myasthenia gravis.

13.4 A cholinergic crisis may develop with overdoses of AChE inhibitors or with certain toxins.

13.5 Acetylcholinesterase inhibitors are used in the pharmacotherapy of myasthenia gravis to increase the strength of muscular contraction.

13.6 Nicotine acts by activating ACh receptors at the ganglia.

CASE STUDY: Making the Patient Connection

Remember the patient "Patricia Sparks" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Patricia Sparks is an 82-year-old patient who lives alone in a two-story house. She has been in excellent health and has required no medications other than an occasional aspirin for osteoarthritis pain. Due to the osteoarthritis, she has had a left knee replacement. Patricia bounced back relatively quickly after surgery, but required two straight-catheterizations due to urinary retention in the postoperative period.

During the past two days, she noticed leakage of urine and felt as if she was not emptying her bladder. When she returned to her provider on her third postoperative day, she reported these symptoms to the nurse. A bladder scan confirmed that Mrs. Sparks was retaining a significant amount of urine, estimated at 900 mL on this visit, and a diagnosis of "overflow incontinence" is made. Her provider gives her a short-term prescription for bethanechol and she is to return to the office in 3 days.

Critical Thinking Questions

1. As Mrs. Sparks' nurse, you will be reviewing her medications before she leaves the office. What pertinent information should she receive about bethanechol?
2. Mrs. Sparks states, "Sometimes, my memory is not so good and I forget to take my medication." What should she do if she forgets a dose? List suggestions that you could provide this patient to help remember her medication times and to ensure safe and effective administration.
3. What parameters would you use to determine the effectiveness of this drug therapy?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

The patient has smoked cigarettes for the past 25 years. She tells the nurse that she has been using nicotine replacement therapy (Nicorette) as prescribed, for the past week. However, she continues to think about and crave cigarettes, especially when she is with a group of her coworkers who smoke.

1. What should the nurse tell this patient about her continued thoughts and cravings for cigarettes?
2. Identify two websites with helpful tips that might aid this patient with smoking cessation.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is discussing the adverse effects associated with a muscarinic agonist. The nurse knows that reflex tachycardia may occur with this drug because:
   1. Baroreceptors acknowledge transient hypotension and signal the medulla to increase the heart rate.
   2. This drug stimulates the sinoatrial node in the right atrium.
   3. Aortic receptors identify episodes of systolic hypertension and stimulate heart rhythms.
   4. This drug stimulates bronchial smooth muscle contraction and a narrowing of the airway.

2. The nurse is preparing a plan of care for a patient with myasthenia gravis. Which of the following outcome statements would be appropriate for a patient receiving a cholinergic agonist such as pyridostigmine (Mestinon) for this condition? The patient will exhibit:
   1. An increase in pulse rate, blood pressure, and respiratory rate.
   2. Enhanced urinary elimination.
   3. A decrease in muscle weakness, ptosis, and diplopia.
   4. Prolonged muscle contractions and proprioception.

3. The nurse is discussing the therapeutic effects of bethanechol (Urecholine) with a patient who is receiving this drug for urinary retention. The nurse understands that bethanechol:
   1. Changes the diameter of the urethral opening.
   2. Increases the amount of urine made in the kidneys.
   3. Improves blood flow to the kidney.
   4. Increases the contractions of the bladder and structures that promote urination.

4. The nurse is monitoring the patient for which of the common adverse effects associated with bethanechol (Urecholine)? (Select all that apply.)
   1. Abdominal discomfort
   2. Sweating
   3. Flushed skin
   4. Constipation
   5. Blurred vision

5. A healthcare provider has ordered neostigmine for each of these patients. A nurse should question the order for which patient?
   1. A patient with postoperative abdominal distention
   2. A patient who is experiencing urinary retention
   3. A patient who has chronic obstructive pulmonary disease
   4. A patient who has received nondepolarizing muscle relaxants

6. A patient has been treated with pyridostigmine (Mestinon) for myasthenia gravis and has been well managed until today. He is taken to the emergency department with symptoms of a cholinergic crisis. As the nurse caring for this patient, what symptom would be indicative of this complication?
   1. Nausea and vomiting
   2. Miosis
   3. Drooling
   4. Progressively severe muscle weakness

Chapter 14
Cholinergic Antagonists

Chapter Outline

- Classification of Cholinergic Antagonists
- Muscarinic Antagonists

  PROTOTYPE *Atropine (Atropen), p. 174*
- Nicotinic Antagonists

  Ganglionic Blockers

  Neuromuscular Blockers (depolarizing type)

  PROTOTYPE *Succinylcholine (Anectine, Quelicin), p. 178*
- Neuromuscular Blockers (Nondepolarizing Type)

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe how the therapeutic actions and adverse effects of the cholinergic antagonists can be explained by their blockade of muscarinic or nicotinic receptors.
2. Identify indications for muscarinic antagonists.
3. Identify symptoms of anticholinergic syndrome.
4. Identify indications for ganglionic blockers.
5. Compare and contrast the actions of the depolarizing and nondepolarizing neuromuscular blockers.
6. Compare and contrast the indications for drugs that block nicotinic receptors at the ganglia versus those that block nicotinic receptors at the neuromuscular junction.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy with cholinergic antagonists.

Key Terms

anticholinergic syndrome, 173
belladonna, 173

ganglionic blockers, 172
malignant hyperthermia, 179
motor end plate, 177
muscarinic antagonists, 171
neuromuscular blockers, 172
nicotinic antagonists, 171
nondepolarizing neuromuscular blockers (NDNBs), 180
pseudocholinesterase, 178

Cholinergic antagonists (anticholinergics) are drugs that inhibit the action of the neurotransmitter acetylcholine (ACh) at cholinergic synapses. Because there are two different types of cholinergic synapses, muscarinic and nicotinic, the actions and therapeutic uses of these drugs are dependent on their specific site of action. Though not as widely used as the adrenergic antagonists, several anticholinergics are important to pharmacotherapy.

Classification of Cholinergic Antagonists

14.1 Cholinergic antagonists act by blocking the effects of acetylcholine at muscarinic or nicotinic receptors.

As discussed in Chapter 13, cholinergic receptors in the autonomic nervous system are found in three anatomic locations, illustrated in Figure 14.1. This results in two primary classes of cholinergic antagonists:

- **Muscarinic antagonists** are drugs that block receptors at cholinergic synapses in the parasympathetic nervous system and at a few target organs in the sympathetic nervous system.
- **Nicotinic antagonists** are drugs that block receptors at cholinergic synapses in the ganglia or in the somatic nervous system at the neuromuscular junction.

Drugs that block the action of ACh at muscarinic receptors have more therapeutic applications than those that block nicotinic receptors. These drugs are known by a number of names, including anticholinergics, cholinergic blockers, muscarinic antagonists, and parasympatholytics. Although the term *anticholinergic* is commonly used in clinical practice, the most accurate term for this group of drugs is *muscarinic antagonists*. This is because

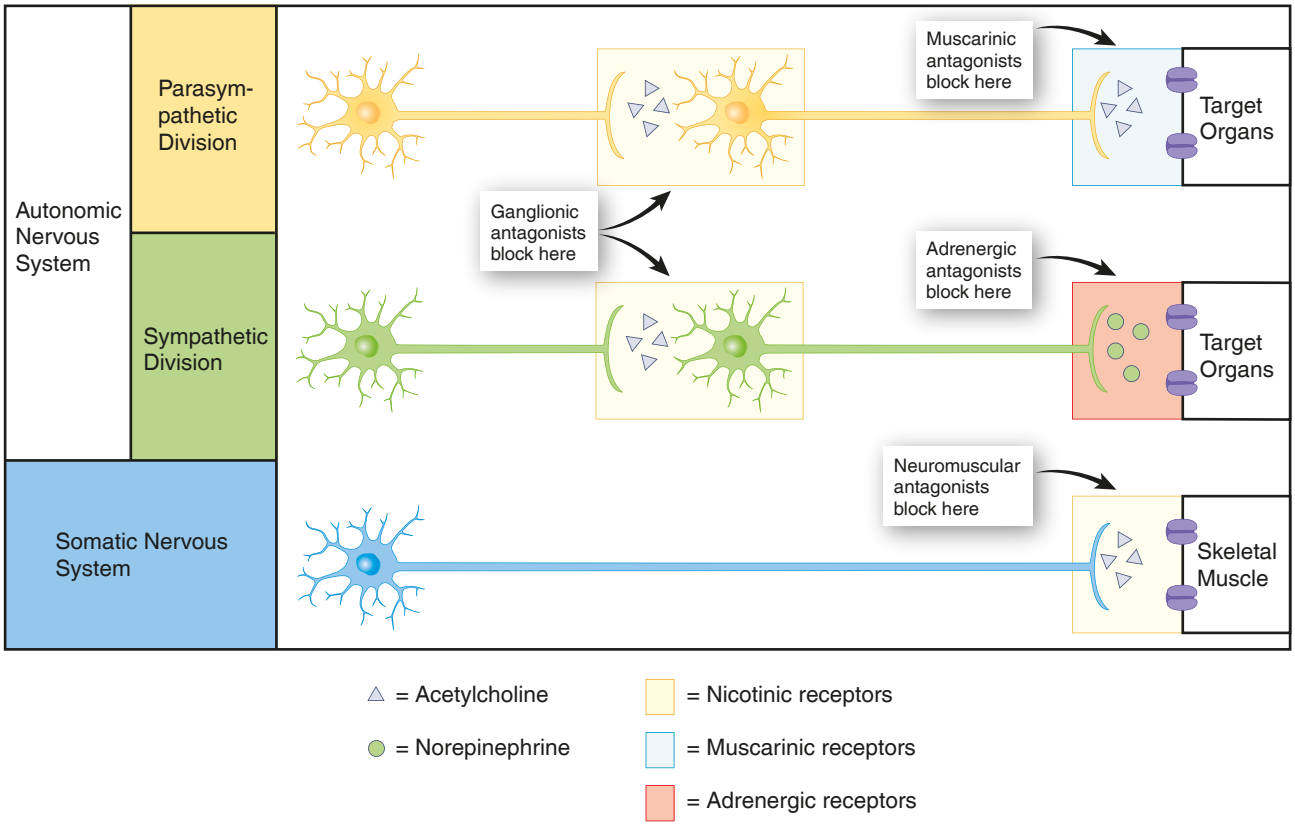

Figure 14.1 Sites of cholinergic antagonist actions. Muscarinic antagonists block cholinergic receptors in the parasympathetic nervous system. Nicotinic antagonists block cholinergic receptors at ganglia, or in the somatic nervous system at the neuromuscular junction.

these drugs are selective for ACh muscarinic receptors at therapeutic doses and have little effect on nicotinic receptors. The muscarinic antagonists are shown in Table 14.1.

The muscarinic antagonists compete with ACh for binding to muscarinic receptors. When ACh is prevented from binding, parasympathetic responses are diminished at the neuroeffector organs. Suppressing the effects of ACh at muscarinic receptors will allow symptoms of sympathetic nervous system activation to predominate (fight-or-flight response). Most therapeutic uses of the muscarinic antagonists are predictable extensions of their parasympathetic-blocking actions: dilation of the pupils, increase in heart rate, drying of secretions, and bronchodilation. Note that these are the same symptoms as fight-or-flight sympathetic activation; thus, blocking the parasympathetic division causes actions similar to those that result when activating the sympathetic division. Their actions are also *opposite* those of the cholinergic agonists discussed in Chapter 13.

Nicotinic antagonists can act at two locations. **Ganglionic blockers** inhibit transmission at the ganglia in the sympathetic and parasympathetic nervous systems, thus affecting both autonomic divisions. **Neuromuscular blockers** do not act on the autonomic nervous system at all but instead inhibit transmission at the neuromuscular junctions on skeletal muscles in the somatic nervous system. The therapeutic uses of nicotinic antagonists are more limited than those of muscarinic antagonists due to their widespread and diverse actions on body function. The specific sites of action of the ganglionic and nicotinic blockers are shown in Figure 14.1.

Muscarinic Antagonists

14.2 Muscarinic antagonists have been used for a diverse number of conditions, but they are rarely drugs of choice due to their adverse effects.

Anticholinergics are very old drugs that have been used for a large number of disorders over many centuries. The deadly

Table 14.1 Muscarinic Antagonists (Anticholinergics)

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aclidinium (Tudorza Pressair)	Inhalation: 1 inhalation (400 mcg) bid	*Headache, cough, dry mouth, blurred vision, mydriasis, constipation, insomnia, urinary retention, burning, nasopharyngitis (inhalation forms), or stinging (eyedrop forms)* Worsening of glaucoma, tachycardia, paradoxical bradycardia, dysrhythmias, paralytic ileus, urinary retention; inhalation forms may cause sinusitis, paradoxical bronchospasm, and oropharyngeal candidiasis
atropine (Atropen)	Preanesthesia: IV/IM/subcutaneous: 0.4–0.6 mg 30–60 min before surgery Dysrhythmias: IV/IM: 0.5–1 mg q1–2h prn (max: 3 mg) Cholinergic crisis: IV: 1–2 mg, repeated every 20–30 min	
benztropine (Cogentin)	PO: 0.5–1 mg/day (max: 6 mg/day) IM/IV: 1–4 mg once or twice daily	
cyclopentolate (Cyclogyl)	Topical: 1 drop of 0.5–2% solution in the eye 40–50 min before the procedure, followed by 1 drop in 5 min	
darifenacin (Enablex)	PO: 7.5–15 mg once daily	
dicyclomine (Bentyl)	PO: 20–40 mg qid IM: 10–20 mg qid	
donepezil (Aricept)	PO: 5–10 mg once daily in the evening	
fesoterodine (Toviaz)	PO: 4–8 mg once daily	
glycopyrrolate (Cuvposa, Robinul)	PO for peptic ulcer: 1–2 mg tid–bid (max: 8 mg/day) PO for excessive drooling: 0.02 mg/kg tid (max: 0.1 mg/kg tid) IM/IV: 0.1–0.2 mg tid–qid	
hyoscyamine (Anaspaz, Levsin, others)	PO: 0.0625–0.125 mg tid–qid IV/IM/subcutaneous: 0.25–0.5 mg q4h	
ipratropium (Atrovent)	Metered-dose inhaler (MDI): 2 inhalations qid (max: 12 inhalations/day) Nebulizer: 500 mcg q6–8h	
mepenzolate (Cantil)	PO: 25–50 mg qid	
methscopolamine (Pamine)	PO: 2.5 mg tid	
oxybutynin (Ditropan XL, Oxytrol)	PO (Ditropan XL): 5–10 mg once daily (max: 30 mg/day) Transdermal (Oxytrol): 1 patch twice weekly	
propantheline (Pro-Banthine)	PO: 7.5–15 mg tid–qid	
scopolamine (Transderm-Scop)	Transdermal: 1 patch q72h starting 12 h before travel	
solifenacin (VESIcare)	PO: 5–10 mg once daily	
tiotropium (Spiriva)	Inhalation/HandiHaler: 1 capsule inhaled/day	
tolterodine (Detrol)	PO: 2–4 mg once daily (sustained release)	
trihexyphenidyl	PO: 1 mg/day gradually increased to 6–10 mg/day (max: 15 mg/day)	
tropicamide (Mydriacyl)	Topical: 1–2 drops of 0.5–1% solution in each eye	
trospium (Sanctura)	PO: 20 mg bid (regular release) or 60 mg once daily (extended release)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

nightshade plant, *Atropa belladonna*, grows throughout the world and has been a natural source of alkaloids with anticholinergic activity. References to the use of **belladonna** date back to the ancient Hindus, the Roman Empire, and the Middle Ages. The name *belladonna* is Latin for "pretty woman." Roman women applied extracts of belladonna to the face and to the eyes to create the preferred female attributes of that era—pink cheeks and dilated doe-like eyes. Because of its extreme toxicity, extracts of belladonna were sometimes used for intentional poisoning, including suicide.

Although once widely prescribed, the development of safer and more effective medications has greatly decreased the current usage of muscarinic antagonists. Most muscarinic antagonists are now prescribed as alternative medications when the preferred drug is contraindicated or not well tolerated. Potential therapeutic applications of these drugs include the following:

- **Gastrointestinal (GI) disorders.** Muscarinic antagonists suppress the secretion of gastric acid and can be used to treat peptic ulcer disease (see Chapter 59). These drugs also slow intestinal motility and can reduce cramping and diarrhea associated with irritable bowel syndrome (IBS) (see Chapter 60).
- **Ophthalmic procedures.** Topical application of muscarinic antagonists to the eye causes pupil dilation (mydriasis) and paralysis of accommodation (cycloplegia), actions that are beneficial during ophthalmic examinations (see Chapter 74).
- **Cardiac rhythm abnormalities.** Muscarinic antagonists accelerate the heart rate, which is beneficial for patients experiencing bradycardia.
- **Adjuncts to anesthesia.** Combined with drugs from other classes, muscarinic antagonists can decrease excessive salivary and respiratory secretions and reverse the bradycardia caused by general anesthetics (see Chapter 26).
- **Asthma and chronic obstructive pulmonary disease (COPD).** The muscarinic antagonists ipratropium (Atrovent), tiotropium (Spiriva), and aclidinium (Tudorza Pressair) are useful in treating asthma and COPD due to their ability to dilate the bronchi (see Chapter 44).
- **Antidotes for poisoning or overdose.** These drugs are specific antidotes for overdoses with muscarinic agonists or for poisoning with muscarinic mushrooms or organophosphate insecticides (see Chapter 13).
- **Urge incontinence (overactive bladder).** A newer indication for muscarinic antagonists such as oxybutynin (Ditropan, Oxytrol), darifenacin (Enablex), and solifenacin (VESIcare) is to prevent involuntary voiding due to their antispasmodic effects on the smooth muscle of the bladder and detrusor muscle.
- **Parkinson's disease.** Muscarinic antagonists such as benztropine (Cogentin) and donepezil (Aricept) are used for their effects on the central nervous system (CNS) and are prescribed to treat mild symptoms of Parkinson's disease (see Chapter 21).

CONNECTION Checkpoint 14.1

From what you learned in Chapter 13, describe the symptoms of a cholinergic crisis and explain why muscarinic antagonists are drugs of choice in reversing this condition. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Muscarinic antagonists exhibit a relatively high incidence of adverse effects, most of which are predictable because they are associated with inhibition of the parasympathetic nervous system. Adverse effects that limit their usefulness include tachycardia and CNS stimulation. Men with prostate disorders should avoid muscarinic antagonists due to the increased risk of urinary retention. Adverse effects such as xerostomia (dry mouth) and dry eyes occur in many patients due to the blockade of muscarinic receptors on the salivary glands and lacrimal glands, respectively. Blockade of muscarinic receptors can inhibit sweating, which may lead to hyperthermia. In the eye, muscarinic antagonists can paralyze the ciliary muscle and the sphincter of the iris. These ocular effects can cause photophobia (sensitivity to bright light) and increase intraocular pressure; therefore, these drugs are usually avoided in patients with glaucoma.

Overdose with anticholinergic substances produces a set of symptoms known as **anticholinergic syndrome**. Symptoms of anticholinergic syndrome include dry mouth, blurred vision, photophobia, visual changes, difficulty swallowing, agitation, and hallucinations. Although uncommon, death may result with high doses. Drugs from several other classes have cholinergic-blocking effects, including antihistamines, antipsychotics, and tricyclic antidepressants, and can trigger these same symptoms. Certain plant substances (including belladonna) also trigger anticholinergic syndrome. Children sometimes eat the colorful, purple berries of the deadly nightshade plant, mistaking them for cherries. Plants such as henbane and angel's trumpet are sometimes intentionally ingested for their hallucinogenic effects.

The specific antidote for anticholinergic toxicity is physostigmine, a reversible cholinesterase inhibitor. Because physostigmine is capable of inducing a cholinergic crisis with high doses, it is generally only administered to patients showing severe symptoms of anticholinergic syndrome such as seizures or psychoses.

PharmFACT

- Well known in antiquity as a poison, atropine derives its name from Greek mythology: Atropos was the fiercest of the three Fates who chose how an individual was to die.
- From about 1850 to 1950 atropine was incorporated into liniments and plasters, which could be purchased at the corner apothecary or pharmacy to cure neuralgia, tuberculosis, mastitis, pleurisy, and rheumatism (Lee, 2007).

PROTOTYPE DRUGS **Atropine (Atropen)**

Classification **Therapeutic:** Drug for treatment of bradycardia, antidote for cholinergic agonist overdose
Pharmacologic: Anticholinergic, muscarinic antagonist

Therapeutic Effects and Uses: Atropine has been used for centuries for a wide variety of disorders; however, it remains a preferred drug for very few conditions because adverse effects are so common. The actions of atropine are predictable based on its ability to block muscarinic receptors. One of the most important actions of atropine is to increase the heart rate, which can be used to advantage when the drug is administered to patients with bradycardia. However, this increase in heart rate is considered an adverse effect when atropine is administered for other indications. The drug should be used with caution in patients with dysrhythmias because it can cause tachycardia.

Like other muscarinic antagonists, atropine can relax smooth muscle in the GI, genitourinary (GU), and respiratory tracts. This action has led to its use in treating hypermotility or spastic disorders of the GI tract including dysentery, abdominal cramping, and IBS. Slowing peristalsis too much, however, can lead to constipation. In the urinary tract, decreased smooth muscle tone can lead to urinary retention.

Because atropine decreases the quantity of exocrine secretions, the drug has been used to suppress secretions of the salivary glands and respiratory tract during surgical procedures. Excessive drying and thickening of bronchial secretions, however, can worsen asthma. Once widely used to produce bronchodilation in patients with asthma, atropine is now rarely prescribed for this disorder due to the development of safer drugs.

Topical administration of atropine to the eye will cause mydriasis and paralyze the ciliary muscle, causing cycloplegia. This may be used to advantage in ophthalmic examinations. When used for other indications, however, these actions on the eye are considered adverse effects and can result in blurred vision and photophobia.

Atropine is an antidote used to reverse symptoms of toxicity due to overdose of cholinergic agonists, including organophosphate insecticides and ingestion of mushrooms containing muscarine. AtroPen is an intramuscular (IM) autoinjection delivery system for poisonings due to toxic nerve agents or insecticides. Improvement in symptoms is usually noted within minutes.

Mechanism of Action: By occupying muscarinic receptors, atropine blocks the parasympathetic activation by ACh and induces symptoms of the fight-or-flight response. At therapeutic doses, atropine is specific for muscarinic receptors. At high doses, the drug may block nicotinic receptors in the ganglia and on skeletal muscle.

Pharmacokinetics:

Route(s)	PO, IV, IM, subcutaneous, inhalation, or ophthalmic
Absorption	Well absorbed by all routes
Distribution	Completely distributed; crosses the blood–brain barrier and placenta; small amounts are secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Subcutaneous/IM: 15 min; PO: 30 min; IV: 2–4 min
Duration of action	Half-life: 4 h

Adverse Effects: Common adverse effects include drying of the oral and nasal mucosa, constipation, urinary retention, increased heart rate, blurred vision, and photophobia. Serious adverse effects include ventricular fibrillation, delirium, and coma.

Contraindications/Precautions: Atropine is contraindicated in patients with acute closed-angle glaucoma because the drug may cause paralysis of the iris muscle, which can increase intraocular pressure. Safety has not been established for pregnancy and lactating mothers. Anticholinergics may cause fetal tachycardia.

Atropine should be used with caution in patients with COPD because drying of the bronchial mucosa can cause viscous mucous plugs. Blockade of cardiac muscarinic receptors can accelerate heart rate and exacerbate preexisting cardiovascular pathology. Patients with hyperthyroidism should not be given atropine because the heart rate in these patients is generally high and administration of anticholinergics can cause dysrhythmias. Atropine is contraindicated for patients with serious GI conditions such as ulcerative colitis and ileus because blockade of muscarinic receptors can decrease the tone and motility of intestinal smooth muscle, which can exacerbate intestinal conditions. Patients with gastroesophageal reflux disease (GERD) and hiatal hernia experience decreased muscle tone in the lower esophageal sphincter and delayed stomach emptying. Atropine exacerbates these symptoms, increasing the risk of esophageal injury and aspiration. Patients with Down syndrome are more sensitive to the effects of atropine due to structural differences in the CNS caused by the trisomy chromosomal abnormality. Patients with Down syndrome also tend to have disorders such as GERD and heart disease, which may be adversely affected by anticholinergics.

Drug Interactions: Care must be taken when administering atropine concurrently with other drugs with anticholinergic actions, such as antihistamines, tricyclic antidepressants, quinidine, and phenothiazines, because their anticholinergic effects will be additive. Because atropine slows GI motility, the absorption of orally (PO) administered

drugs may be altered. **Herbal/Food:** Some herbal supplements have atropine-like effects that potentiate the medication and can be harmful to the patient. For example, aloe, senna, buckthorn, and cascara sagrada may increase the effect of atropine, particularly if the herbs are used chronically.

Pregnancy: Category C.

Treatment of Overdose: Overdose with atropine is serious, with signs of parasympathetic blockade that include respiratory depression and circulatory collapse. Central signs such as hallucinations, seizures, and mania may be evident. Treatment is mostly supportive and may include drugs to control seizures and to increase respirations and heart rate.

Nursing Responsibilities: Key nursing implications for patients receiving atropine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Cholinergic (Muscarinic) Antagonists.

Drugs Similar to Atropine (Atropen)

The muscarinic antagonists are listed in Table 14.1.

Antisecretory drugs: Glycopyrrolate (Cuvposa, Robinul), mepenzolate (Cantil), methscopolamine (Pamine), and propantheline (Pro-Banthine) are called antisecretory drugs because they reduce gastric acid secretions in patients with peptic ulcer disease. Drugs with greater effectiveness and fewer adverse effects have replaced the anticholinergics for the first-line therapy of peptic ulcer disease. Rarely, some of these drugs may be used off-label to treat IBS.

Although an older drug, glycopyrrolate has been reformulated for several diverse indications. An IV form of is available to reverse neuromuscular blockade following surgery. An oral form (Cuvposa) is available to reduce excessive drooling in children ages 3 to 16 years with certain neurologic conditions. Combined with beta-adrenergic agonists such as indacaterol and formoterol, glycopyrrolate is indicated to treat symptomatic COPD (Chapter 44).

Antispasmodic drugs: All anticholinergics slow motility in the GI tract. Dicyclomine is approved by the U.S. Food and Drug Administration (FDA) to slow GI motility and for the adjunctive treatment of peptic ulcer disease and IBS. Hyoscyamine (Anaspaz, Levsin, others) has potent antispasmodic activity that is used for hypermotility disorders including IBS, spastic colitis, infant colic, renal and biliary colic, and spastic bladder. Dicyclomine (Bentyl) is given for its ability to relax bowel spasms in patients with IBS. These antispasmodic drugs should never be administered to patients with suspected obstructive disease of the GI or GU tract because they can worsen these conditions by decreasing motility and tone.

Bronchodilation drugs: Aclidinium (Tudorza Pressair), ipratropium (Atrovent), and tiotropium (Spiriva) are used for patients with COPD. Their primary action is relaxation of bronchial smooth muscle, which dilates the airways. Delivered via inhalation, these drugs produce more localized action with fewer systemic adverse effects than atropine.

Centrally acting drugs: Benztropine (Cogentin) and trihexyphenidyl are prescribed to reduce the muscular tremor and rigidity associated with Parkinson's disease. They may be used alone for mild forms of the disease or in combination with other drugs to reduce symptoms of advanced Parkinson's. Benztropine tends to produce less CNS stimulation than does trihexyphenidyl. A parenteral form of benztropine is available for treating symptoms of acute parkinsonism associated with the use of certain antipsychotic medications. Their use is limited by adverse effects such as sedation and confusion.

Ophthalmic drugs: Anticholinergics may be applied topically to the eye to produce cycloplegia and mydriasis during ophthalmic procedures. Drugs used for this purpose include tropicamide (Mydriacyl) and cyclopentolate (Cyclogyl).

Scopolamine (Transderm-Scop): Scopolamine is very similar to atropine, although scopolamine crosses the blood–brain barrier and is more likely to cause sedation at therapeutic doses. Scopolamine is very effective for preventing motion sickness. For this indication, a transdermal patch containing scopolamine is applied to the skin, usually behind the ear, for slow release of the drug. The most common adverse effect from the transdermal product is dry mouth, although sedation may be a problem in some patients. This drug is pregnancy category C.

Urge incontinence (overactive bladder) drugs: Fesoterodine (Toviaz), oxybutynin (Ditropan XL, Oxytrol), and tolterodine (Detrol) are anticholinergics used for their ability to relax smooth muscle in the urinary bladder. In patients with urge incontinence, this action limits smooth muscle spasms in the bladder, thus diminishing incidences of involuntary voiding. Oxybutynin is a first-line drug for this condition. Formulations include immediate release and extended release (XL) tablets and a transdermal patch (Oxytrol). Tolterodine is an alternative to oxybutynin and is also available in an extended release (LA) formulation. More recent additions to the pharmacotherapy for urge incontinence include darifenacin (Enablex), solifenacin (VESIcare), and trospium (Sanctura). These newer drugs are more selective for muscarinic receptors in the urinary bladder and thus have a more favorable side effect profile than the older drugs.

CONNECTION Checkpoint 14.2

From what you learned in Chapter 12, which of the following classes would give physiologic responses similar to the muscarinic antagonists: adrenergic agonists, adrenergic antagonists, or cholinergic agonists? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Nicotinic Antagonists: Ganglionic Blockers

14.3 Ganglionic blockers act at the autonomic ganglia to lower blood pressure in emergency situations.

Ganglionic blockers are drugs that interrupt the transmission of nerve impulses at nicotinic receptors at the autonomic ganglia. As discussed in Chapter 12, both the sympathetic and parasympathetic nervous systems have ganglia. This means that, unlike the muscarinic antagonists that selectively block parasympathetic actions, nicotinic antagonists nonselectively inhibit the entire autonomic nervous system. If parasympathetic and sympathetic actions are both inhibited, what types of effects will be observed?

In most cases, inhibiting the ganglia in both systems will affect the parasympathetic system more than the sympathetic. This is because the predominant, baseline autonomic tone to most organs is from the parasympathetic nervous system. When ganglionic blockers slow parasympathetic nerve impulses, symptoms characteristic of anticholinergic drugs, such as urinary retention, constipation, blurred vision, increased heart rate, and dry mouth, occur.

Although they affect all autonomic organs, the ganglionic blockers' only action that has therapeutic usefulness is vasodilation. By reducing sympathetic vasomotor tone at the arterioles, ganglionic blockers are capable of causing profound hypotension. Emergency kits must be readily available so that a vasoconstrictor such as epinephrine may be administered if blood pressure falls to a dangerous level.

Because of their potential toxicity only one ganglionic blocker, mecamylamine (Vecamyl), is approved for use. Mecamylamine is a long-acting nicotinic receptor antagonist that was originally used to reduce blood pressure in patients with severe hypertension (HTN). This drug is rarely prescribed for this purpose today due to the development of safer antihypertensives. More recently, mecamylamine was approved to treat nicotine dependence because it was found to reduce the psychologic rewarding effects of nicotine in the brain. The drug is also indicated to treat Tourette's syndrome that is unresponsive to other medications. Common adverse effects include weakness, fatigue, sedation, headache, mydriasis, blurred vision, decreased libido, impotence, and urinary retention. Serious adverse effects include orthostatic hypotension, precipitation of angina, choreiform movement, and adynamic ileus. Dosage information for mecamylamine is given in Table 14.2.

Table 14.2 Nicotinic Antagonists

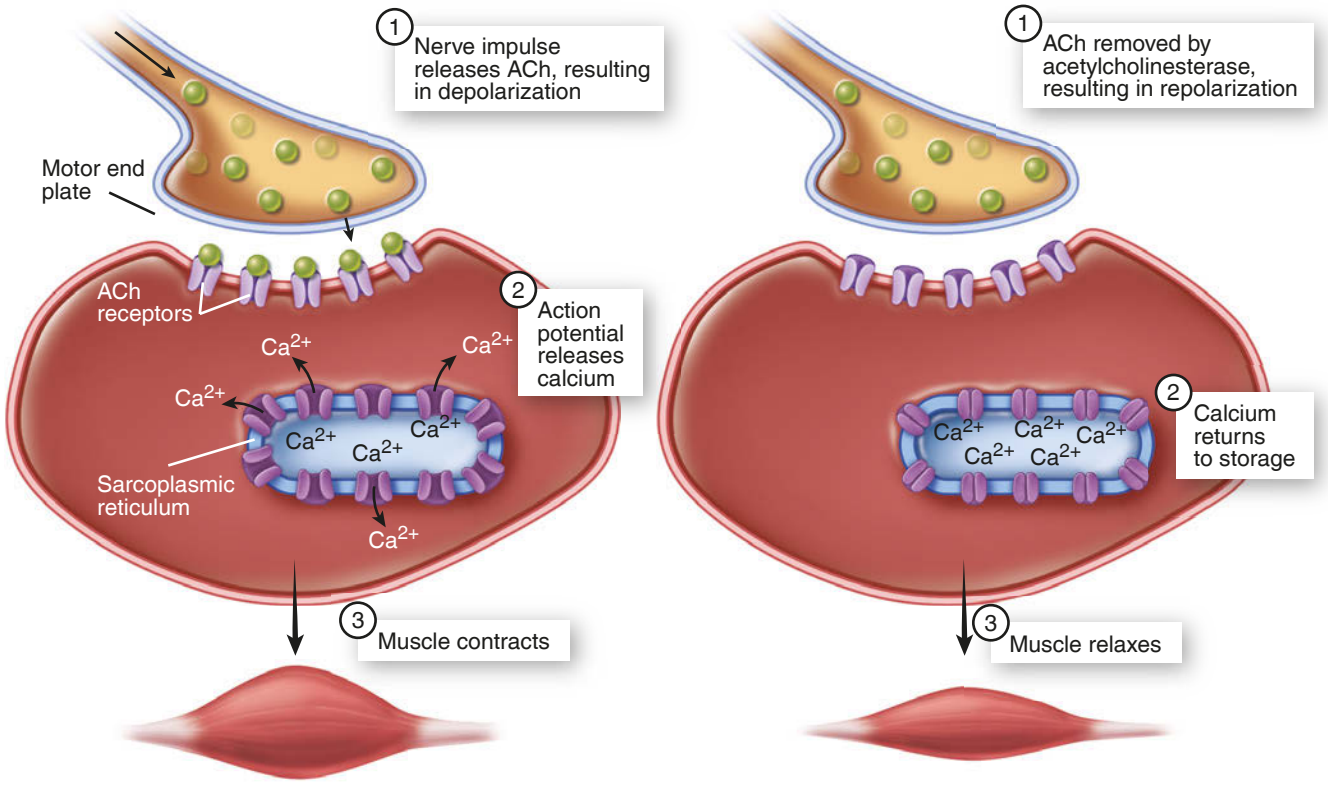
Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Ganglionic Blocker		
mecamylamine (Vecamyl)	PO: 2.5 mg, with increments of 2.5 mg until desired blood pressure reduction occurs	*Orthostatic hypotension, blurred vision, anorexia, nausea, vomiting, constipation, diarrhea, dry mouth* Adynamic ileus
Neuromuscular Blockers		
Ultrashort Acting		
succinylcholine (Anectine, Quelicin)	IV: 0.3–1.1 mg/kg over 10–30 sec	*Transient flushing of the face, neck, or chest; rash, weakness, increased salivation* Respiratory depression, anaphylaxis, prolonged apnea, cardiac arrest, bradycardia, dysrhythmias, hypotension, increases and decreases in heart rate, malignant hyperthermia, muscle paralysis
Short Acting		
mivacurium (Mivacron)	IV loading dose: 0.15 mg/kg given over 5–15 sec IV maintenance dose: 0.1 mg/kg generally every 15 min IV continuous infusion: Initial infusion of 9–10 mcg/kg/min, then 6–7 mcg/kg/min	
rocuronium (Zemuron)	IV: 0.6 mg/kg initially followed by continuous infusion of 0.01–0.012 mg/kg/min	
Intermediate Acting		
atracurium (Tracrium)	IV: 0.4–0.5 mg/kg initial dose, then 0.08–0.1 mg/kg 20–45 min after the first dose if necessary; reduce doses if used with general anesthetics	
cisatracurium (Nimbex)	IV: 0.15 or 0.20 mg/kg for intubation; 0.03 mg/kg every 20 min prn or 1–2 mcg/kg/min for maintenance	
vecuronium (Norcuron)	IV: 0.04–0.1 mg/kg initially, then after 25–40 min, 0.01–0.15 mg/kg every 12–15 min or 0.001 mg/kg/min by continuous infusion	
Long Acting		
pancuronium (Pavulon)	IV: 0.04–0.1 mg/kg initial dose; may give additional doses of 0.01 mg/kg at 30- to 60-min intervals	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Nicotinic Antagonists: Neuromuscular Blockers

14.4 Muscle contraction occurs when the motor end plate is depolarized.

The neuromuscular junction is a specialized cholinergic synapse that allows for communication between the nervous system and skeletal muscle. This synapse on the muscle, known as a **motor end plate**, receives an action potential from the axon of a motor neuron. Like other cholinergic synapses, the action potential causes the release of ACh, which travels across the synaptic cleft to its receptors on skeletal muscle. Anatomically, the neuromuscular junction is part of the somatic nervous system (not the autonomic).



Binding of ACh to its receptors changes the permeability of the muscle cell membrane and opens sodium channels, allowing sodium ions to rush in. Being a positive ion, sodium causes the inside of the muscle cell to depolarize and acquire a positive charge. This depolarization at the motor end plate triggers the release of calcium ions from internal storage areas within the muscle cell. The intense, though brief, release of calcium is quickly followed by skeletal muscle contraction.

As presented in Chapter 12, destruction of ACh by the enzyme acetylcholinesterase (AChE) removes the neurotransmitter from the motor end plate, allowing the muscle cell membrane to repolarize. Calcium returns to its internal storage depots, and muscle relaxation occurs. This process by which the action potential causes muscular contraction is known as *excitation-contraction coupling*.

When multiple action potentials arrive at a specific motor end plate, the muscle cell undergoes a series of repeated depolarizations and repolarizations. This causes a continuous depolarized state in which calcium does not return to its storage depots, and a *sustained* muscle contraction is achieved. This contraction, however, can only be sustained by a continuous cycle of depolarizations and repolarizations. If the cell is simply depolarized (without undergoing repolarization), calcium will return to its storage areas and contraction will totally cease, resulting in a flaccid muscle. This paralyzed condition is necessary when performing certain surgical procedures. The depolarization of the motor end plate is illustrated in Figure 14.2.

14.5 Depolarizing neuromuscular blockers are given to produce muscle paralysis during short medical–surgical procedures.

The nicotinic synapse at the neuromuscular junction can be affected by drugs that can act by either a depolarizing or nondepolarizing mechanism. These depolarizing and

(a) Muscle contraction (b) Muscle relaxation

Figure 14.2 Normal depolarization of the motor end plate: (a) Depolarization: ACh causes calcium to be released from storage, resulting in muscle contraction. (b) Repolarization: ACh is destroyed by acetylcholinesterase, calcium returns to storage, and muscle relaxation results.

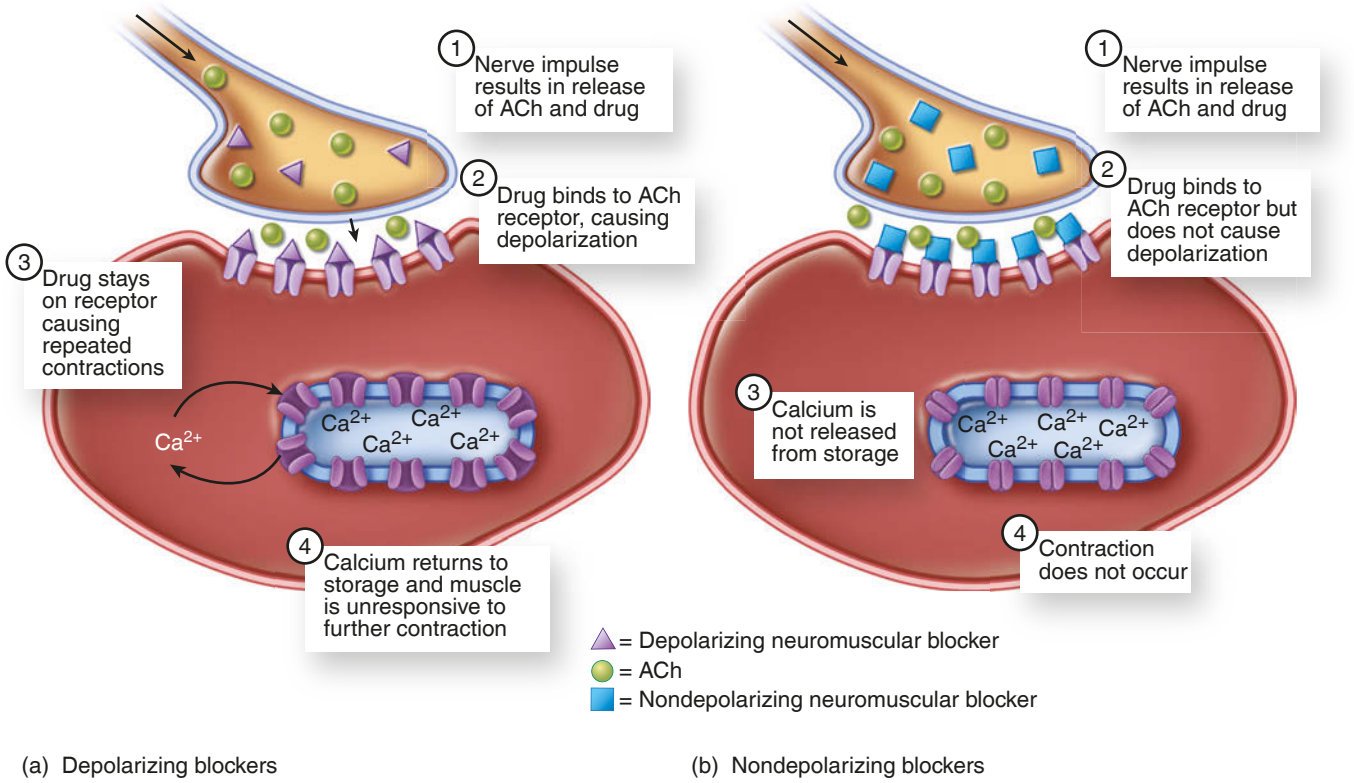


Figure 14.3 Mechanism of action of neuromuscular blockers: (a) Depolarizing neuromuscular blocker occupies ACh receptors and causes depolarization and muscle paralysis. (b) Nondepolarizing neuromuscular blocker occupies ACh receptors and causes muscle paralysis without depolarization.

nondepolarizing neuromuscular blockers produce the same result: total skeletal muscle relaxation or muscle paralysis.

Succinylcholine is the sole member of the depolarizing neuromuscular blocker class of drugs. This drug competes with ACh for nicotinic receptors on the motor end plates of skeletal muscle. Once bound to ACh receptors, succinylcholine produces muscle contraction by the same mechanism as ACh. However, succinylcholine is not destroyed by AChE, and the drug causes a prolonged and continuous depolarization of the muscle cell. Without repolarization, calcium returns to its internal storage depots and the muscle relaxes. The mechanism of action of succinylcholine is illustrated in Figure 14.3a.

It is important to note that succinylcholine does not enter the CNS. Although the drug causes muscle paralysis, it does not produce anesthesia or loss of consciousness. The patient is still able to feel pain and is aware of his or her surroundings. Thus, succinylcholine is only one component of balanced anesthesia, as discussed in Chapter 26.

CONNECTION Checkpoint 14.3

Pyridostigmine also affects nicotinic receptors in skeletal muscle. From what you learned in Chapter 13, would you expect this drug to interact with neuromuscular blockers? What is the primary indication for pyridostigmine? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUGS Succinylcholine (Anectine, Quelicin)

Classification **Therapeutic:** Skeletal muscle relaxant
Pharmacologic: Neuromuscular blocker (depolarizing type)

Therapeutic Effects and Uses: Effects of succinylcholine are first noted as muscle weakness and muscle spasms. Eventually muscle paralysis occurs. The drug is primarily used as an adjunct to surgical anesthesia to cause complete skeletal muscle relaxation of the abdominal muscles. It may also be used to relax muscles during the insertion of an endotracheal tube and to assist in the management of mechanical ventilation. Administration of succinylcholine reduces the amount of general anesthetic needed for surgical procedures. When given IV, succinylcholine induces muscle relaxation in less than a minute. When the infusion is discontinued, muscle control returns in a few minutes, because the drug is rapidly destroyed in the plasma by the enzyme **pseudocholinesterase** (also called plasma cholinesterase). This makes the drug ideal for very short procedures, such as intubation or electroconvulsive shock therapy.

Some patients have a genetic deficiency in plasma cholinesterase. In these patients, succinylcholine will have an unusually prolonged duration of action, and paralysis may

persist for hours. Because there is no specific antidote for succinylcholine overdose, the patient must receive supportive treatment until the drug is metabolized and removed by the body. This adverse effect may be avoided by assessing plasma cholinesterase levels prior to surgery. If low, succinylcholine may be contraindicated, or the dose lowered to prevent prolonged muscle paralysis.

In addition to genetic deficiency, pseudocholinesterase levels may be decreased during therapy with acetylcholinesterase inhibitors such as pyridostigmine, which is a preferred drug for treating patients with myasthenia gravis (see Chapter 13). Patients having this genetic deficiency will exhibit a prolonged duration of muscle paralysis if given succinylcholine.

Mechanism of Action: Like endogenous ACh, succinylcholine binds to cholinergic receptor sites at neuromuscular junctions (nicotinic). After repeated contractions the skeletal muscle membranes are unable to repolarize as long as the drug stays on the receptor. The result is total muscle relaxation or paralysis.

Pharmacokinetics:

Route(s)	IM, IV
Absorption	Well-absorbed IM
Distribution	Completely, including crossing the placenta
Primary metabolism	Plasma by pseudocholinesterase
Primary excretion	Renal
Onset of action	IV: less than 1 min; IM: 2–3 min
Duration of action	IV: 2–3 min; IM: 10–30 min

Adverse Effects: Succinylcholine can cause complete paralysis of the diaphragm and intercostal muscles; thus mechanical ventilation is necessary during surgery. If doses are high, succinylcholine will also inhibit nerve transmission at the ganglia, causing tachycardia, hypotension, and urinary retention. In certain susceptible patients, a rapid onset of extremely high fever with muscle rigidity may occur, a serious condition known as **malignant hyperthermia**. The high temperature is caused by excessive metabolic activity in muscles, triggered by the drug. Although rare, malignant hyperthermia may be fatal. Other serious adverse effects include respiratory depression, apnea, and dysrhythmias. **Black Box Warning:** Children with certain congenital musculoskeletal diseases (e.g., Duchenne's muscular dystrophy) are at greater risk for cardiac arrest when this drug is used and should be monitored especially closely. Because there is no way to predict which patients are at risk, the use of succinylcholine in children should be reserved for emergency intubation or instances where immediate securing of the airway is necessary.

Contraindications/Precautions: Because succinylcholine is an essential component of balanced surgical anesthesia, there are few absolute contraindications. Patients with a personal or family history of malignant hyperthermia should not receive this drug. Succinylcholine should be used cautiously in patients with preexisting electrolyte imbalances or heart failure because this drug can cause a sudden release of intracellular potassium, resulting in hyperkalemia. Patients with pulmonary or metabolic disorders should be monitored carefully because succinylcholine can cause respiratory depression and acidosis. Due to its renal excretion, succinylcholine should be used cautiously in patients with kidney disease. Because the drug can increase intraocular pressure, it is contraindicated in patients with glaucoma.

Drug Interactions: Additive skeletal muscle inhibition will occur if succinylcholine is given concurrently with clindamycin, phenothiazine, aminoglycosides, furosemide, lithium, quinidine, or lidocaine. If succinylcholine is given concurrently with the anesthetics halothane or nitrous oxide, the risk of dysrhythmias, sinus arrest, apnea, and malignant hyperthermia is increased. Use with digoxin can increase the risk of dysrhythmias due to the hyperkalemia caused by the neuromuscular blocker. If opioid analgesics are given concurrently with succinylcholine, there is an increased risk of bradycardia and sinus arrest. **Herbal/Food:** Melatonin may increase the neuromuscular blocking action of succinylcholine.

Pregnancy: Category C.

Treatment of Overdose: Overdose can lead to serious or fatal respiratory depression. The drug is discontinued and assisted ventilation is provided until the drug's effects wear off.

Nursing Responsibilities:

- Monitor vital signs frequently and keep the airway free of secretions.
- Obtain baseline laboratory tests such as serum electrolytes. Imbalances in potassium, calcium, and magnesium can potentiate the actions of neuromuscular blockers.
- Monitor for transient apnea, which usually occurs at the point of maximal drug effect (1 to 2 minutes); spontaneous respiration should return in a few seconds or, at most, 3 or 4 minutes.
- Prepare for emergency endotracheal intubation, artificial respiration, and assisted or controlled respiration with oxygen.
- Monitor temperature frequently in the postoperative patient when succinylcholine has been used.
- Provide emotional support and pain relief if needed. The drug will cause paralysis without analgesia or sedation.

Lifespan and Diversity Considerations:

- Because of postprocedural stiffness or muscle weakness, extra caution should be exercised when assisting the older patient with ambulation or activities of daily living (ADLs) to prevent falls or injury.

- When used in children, monitor vital signs, especially heart rate and rhythm, frequently due to increased risk of cardiac arrest related to certain congenital musculoskeletal diseases. The existence of these diseases may not always be known and the drug is usually avoided in children when possible.

Patient and Family Education:

- Muscle stiffness and pain that may last for as long as 24 to 30 hours may occur after the procedure.
- Understand that sore throat and hoarseness are common even when the pharyngeal airway has not been used.
- Report persistent muscle weakness.

Drugs Similar to Succinylcholine (Anectine, Quelicin)

Succinylcholine is the only depolarizing neuromuscular blocker.

14.6 Nondepolarizing neuromuscular blockers are given to produce muscle paralysis during longer surgical procedures.

The first neuromuscular blocker was **curare**, which was initially extracted from different plant species native to the rain forests of South America. Indians of the region cooked the roots and stems to produce a thick, tarry substance that could be rubbed on the tips of arrows. Once shot into the muscle of an animal, curare would rapidly cause muscle weakness, allowing the Indians to overcome and kill the game. It is these same properties that allowed medical science to use curare to reduce muscle spasms and to cause skeletal muscle paralysis during operative procedures. The active chemical extracted from curare, and which was used for medical procedures, is called tubocurarine. Tubocurarine is no longer used for medical procedures, but there are six **nondepolarizing neuromuscular blockers (NDNBs)** that have similar uses, actions, and adverse effects (see Table 14.2).

Like succinylcholine, the NDNBs are nicotinic antagonists that bind to ACh receptors at motor end plates in skeletal muscle. However, the NDNBs do not cause depolarization of the muscle cell; they act by preventing ACh from reaching its receptors. The mechanism of action of the NDNBs is illustrated in Figure 14.3b.

All NDNBs have identical actions, with their primary application being to relax skeletal muscles during operative procedures. These drugs may also be used to facilitate management of mechanical ventilation by suppressing contractions of respiratory muscles, thus eliminating resistance to mechanical ventilation. Suppressing muscular reflexes allows smoother insertion of an endotracheal tube, which is an additional indication for the use of these drugs. For patients undergoing electroconvulsive shock therapy or those who have tetanus, neuromuscular blockers can reduce the intensity and pain of severe muscle contractions.

The NDNBs are charged molecules that do not readily cross membranes. Thus, they are almost always administered IV. Because they do not cross the blood–brain barrier, they do not induce sedation, analgesia, or loss of consciousness. This allows for complete skeletal muscle paralysis without loss of consciousness. Administration of an anesthetic is necessary when diminished consciousness or analgesia is desired, such as during surgical anesthesia.

The NDNBs differ in their durations of action. This is a critical difference because the muscular relaxation induced by the drug must last long enough to complete the specific surgical procedure. The shortest acting drug, mivacurium, lasts only 12 to 18 minutes, whereas the longer acting drugs may last up to 3 hours. All NDNBs have a very rapid onset of action, inducing paralysis within 1 to 2 minutes.

The most serious concern when using NDNBs is paralysis of respiratory muscles leading to apnea and possible respiratory arrest. Excessive respiratory depression caused by NDNBs can be treated by administration of an AChE inhibitor such as neostigmine (Prostigmin). In this respect, the NDNBs differ from succinylcholine. Administration of an AChE inhibitor will not reverse the respiratory depression caused by succinylcholine.

Hypotension is another potentially serious adverse effect of NDNBs. Hypotension results when these drugs trigger the release of histamine and at higher doses when nicotinic receptors at the ganglia are activated. Some neuromuscular blockers such as pancuronium and vecuronium cause less histamine release and have little effect on the ganglia; thus these drugs pose less risk of hypotension. An antihistamine may be administered to lessen the hypotension caused by NDNBs.

Short-acting drugs: Mivacurium (Mivacron) and rocuronium (Zemuron) have the shortest duration of action, about 15 to 20 minutes. A continuous infusion may be used to maintain the neuromuscular block for a longer time.

Intermediate-acting drugs: Atracurium (Tracrium), cisatracurium (Nimbex), and vecuronium (Norcuron) have durations of action of 30 to 45 minutes. Atracurium and cisatracurium are not eliminated by the liver or kidneys

CONNECTIONS: Patient Safety

Medication Errors During Transitions of Care

The risk for a medication error increases during transitions of care, also known as "handoffs." These errors may occur with transfers between patient care units in a healthcare agency or at time of discharge (Dusek, Pearce, Harripaul, & Lloyd, 2015; Robins & Dai, 2015; Ruggiero, Smith, Copeland, & Boxer, 2015). As a nurse working in the postanesthesia care unit (PACU), how could the chance for a medication error be decreased when transferring a patient from the PACU to a surgical unit?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

and may be better choices for patients with hepatic or renal disease. Vecuronium has the advantage of causing no histamine release.

Long-acting drugs: The only long-acting drug in this class, pancuronium (Pavulon), has a duration of 60 to 90 minutes.

CONNECTION Checkpoint 14.4

From what you learned in Chapter 13, explain why a patient with myasthenia gravis might be particularly susceptible to the actions of neuromuscular blockers. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Cholinergic (Muscarinic) Antagonists

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, cerebrovascular, or respiratory disease, for acute (closed-angle) glaucoma, and the possibility of pregnancy. Assess usual elimination patterns, tearing, and salivation. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, and herbal preparations. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings such as hepatic or renal function studies.
- Obtain baseline vital signs, urinary output, bowel sounds, and cardiac rhythm if appropriate.
- Assess the patient's ability to receive and understand instruction. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased ease of breathing, cardiac rhythm stable, and blood pressure [BP] within normal range).
- Continue frequent and careful monitoring of vital signs and urinary output and cardiac activity as appropriate.
- Assess for and promptly report adverse effects: tachycardia, hypertension, dysrhythmias, tremors, dizziness, headache, decreased urinary output. Seizures or ventricular tachycardia may signal drug toxicity and are immediately reported.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects dependent on the reason the drug therapy is given. (Pulse, BP, and respiratory rate should be within normal limits or within parameters set by the healthcare provider. Gastric motility and cramping have slowed.)	• Teach the patient, family, or caregiver how to monitor pulse and BP. Ensure proper use and functioning of any home equipment obtained.
• Provide supportive nursing measures; e.g., proper positioning for dyspnea; ice chips, fluids, or hard candy for dry mouth. (Nursing measures such as raising the head of the bed during dyspnea will supplement therapeutic drug effects and optimize outcome.)	• Instruct the patient that sips of water, ice chips, oral rinses free of alcohol, or hard candies may ease mouth dryness. (Alcohol-based rinses will worsen mouth dryness.)
• Follow appropriate administration techniques for inhalant or ophthalmic doses.	• Instruct the patient in proper administration techniques, followed by teach-back.
Minimizing adverse effects: • Monitor for signs of excessive autonomic nervous system (ANS) stimulation such as anxiety, blurred vision, tachycardia, dry mouth, urinary hesitancy, and decreased sweating. (Adverse effects are due to the blockade of muscarinic receptors. Anticholinergics are contraindicated in patients with acute closed-angle glaucoma because mydriasis will increase intraocular pressure. **Lifespan:** Children and older adults may be more sensitive to the effects of anticholinergic drugs and require frequent monitoring.)	• Instruct the patient to report palpitations, shortness of breath, dizziness, dysphagia, or syncope immediately to the healthcare provider. • **Lifespan:** Older and debilitated patients should report excessive drowsiness or CNS stimulation, even at usual doses of anticholinergics.
• Notify the healthcare provider if BP or pulse exceeds established parameters. Continue frequent cardiac monitoring as appropriate (e.g., electrocardiogram) and urine output. (Anticholinergics must be closely monitored because they increase heart rate and the risk for dysrhythmias. External monitoring devices will detect early signs of adverse effects as well as therapeutic effects.)	• To allay possible anxiety, teach the patient the rationale for all equipment used and the need for frequent monitoring as applicable.
• Monitor the patient for abdominal distention and auscultate for bowel sounds. Palpate for bladder distention and monitor output. (Anticholinergics may decrease tone and motility of intestinal and bladder smooth muscle. **Lifespan:** The older adult is also at increased risk of constipation due to slowed peristalsis. Be aware that the male older adult is at higher risk for mechanical obstruction due to an enlarged prostate.)	• Teach the patient about the importance of drinking extra fluids and increasing fiber intake. Instruct the patient to notify the healthcare provider if difficulty with urination occurs or if constipation is severe.
• Minimize exposure to heat and strenuous exercise. (Anticholinergics can inhibit sweat gland secretions. Sweating is necessary for patients to cool down, so the drug can increase their risk for heat exhaustion and heatstroke. **Lifespan:** "Atropine fever"—hyperpyrexia due to suppression of perspiration and heat loss—increases the risk of heatstroke in young children and older adults. Children and older adults should be monitored frequently.)	• Instruct the patient to avoid prolonged or strenuous activity in warm or hot environments, especially on humid days. Extra-hot showers and hot tubs should also be avoided. Dizziness, change in mental status, pale skin, muscle cramping, and nausea are signs of impending heat exhaustion or stroke and should be reported immediately.
• Provide for eye comfort such as darkened room, soft cloth over eyes, sunglasses, or lubricating eyedrops. (Anticholinergic drugs cause mydriasis, dry eyes, and photosensitivity to light.)	• Instruct the patient that photosensitivity may occur and sunglasses may be needed in bright light or for outside activities. Lubricating eyedrops may soothe dryness. Caution should be taken with driving until drug effects are known.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Assessment	
Interventions and (Rationales)	**Patient-Centered Care**
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose, and scheduling; what adverse effects to observe for and when to report them; equipment needed as appropriate and how to use that equipment; and the required length of medication therapy needed with any special instructions regarding renewing or continuing the prescription as appropriate.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of an inhaler or ophthalmic drops. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.) • Childhood fatalities have occurred from systemic absorption of anticholinergic eyedrops. (Ingestion of eyedrops intended for a parent, family member, or caregiver may be fatal.)	• Instruct the patient in proper administration techniques, followed by teach-back. • The patient, family, or caregiver is able to discuss appropriate dosing and administration needs. • Instruct parents of young children to keep eyedrops and all medications secured and out of the reach of children.

Understanding Chapter 14

Key Concepts Summary

14.1 Cholinergic antagonists act by blocking the effects of acetylcholine at muscarinic or nicotinic receptors.

14.2 Muscarinic antagonists have been used for a diverse number of conditions, but they are rarely drugs of choice due to their adverse effects.

14.3 Ganglionic blockers act at the autonomic ganglia to lower blood pressure in emergency situations.

14.4 Muscle contraction occurs when the motor end plate is depolarized.

14.5 Depolarizing neuromuscular blockers are given to produce muscle paralysis during short medical–surgical procedures.

14.6 Nondepolarizing neuromuscular blockers are given to produce muscle paralysis during longer surgical procedures.

CASE STUDY: Making the Patient Connection

Remember the patient "Pete Elbertson" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Pete Elbertson is a 60-year-old man who enjoys working in his large vegetable garden. Two days ago, while watering his tomatoes, Pete noticed that insects had infested the plants. To avoid further damage, he powdered the plants with an insecticide. In his rush to finish, he unintentionally contaminated himself with the insecticide and kept working for several hours before showering.

Now, Pete presents to the local emergency department (ED) with nausea, dizziness, sweating, excessive salivation, weepy eyes, and a runny nose. He reports intermittent twitching of his upper extremities and uncoordinated movement.

His initial assessment reveals an 84-kg (185-lb) White male with a past medication history of HTN diagnosed 5 years ago. He is married and has two adult children. He smokes one pack of cigarettes per day and does not use alcohol. His vital signs are blood pressure, 158/94 mmHg; heart rate, 58 beats/min; respiratory rate, 30 breaths/min; and temperature, 37.3°C (99.2°F). His skin is pale and moist. He exhibits copious lacrimation and rhinorrhea. Both pupils are constricted. Crackles are heard bilaterally in all lung fields on inspiration. Since admission to the ED he has vomited twice and had one large diarrhea stool.

Pete is diagnosed with acute organophosphate poisoning. The patient is started on oxygen therapy, and the nurse will observe him closely for further respiratory distress.

Atropine 2 mg is administered IV every 15 minutes over the next hour.

Critical Thinking Questions

1. Discuss the mechanism of action associated with atropine.
2. Why is this drug being given to Pete?
3. What adverse effects should you expect for the patient from the administration of atropine?

Answers to Critical Thinking questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

You are caring for Nick, a 56-year-old man, in the intensive care unit. During the past 2 hours, you have been closely monitoring him due to increased respiratory distress. When the healthcare provider arrives, he informs you that Nick will need to be placed on a mechanical ventilator. The patient will be given a neuromuscular blocking drug to assist with the insertion of an endotracheal tube.

1. Describe the mechanism of action associated with this drug classification.
2. What is the rationale for the administration of neuromuscular blocking drugs for this patient?
3. Identify the problems associated with the administration of neuromuscular blocking drugs.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. Which health teaching concept should the nurse review with a patient receiving tolterodine (Detrol) for urge incontinence?
    1. Exercise daily to avoid muscle atrophy.
    2. Increase dietary fiber and water intake to avoid constipation.
    3. Consume foods high in iron to increase red blood cell production.
    4. Monitor the heart rate for bradycardia.
2. The nurse is aware that the therapeutic uses for cholinergic antagonists include (select all that apply):
    1. Ophthalmic procedures.
    2. Cardiac rhythm abnormalities.
    3. Asthma.
    4. Poisonings.
    5. Urinary retention.
3. Which factor in the patient's history would cause the nurse to question a medication order for atropine?
    1. A 42-year-old woman with a history of drug abuse
    2. An 85-year-old man with benign prostatic hyperplasia
    3. An 18-year-old man with irritable bowel syndrome
    4. A 22-year-old woman on the second day of her menstrual cycle
4. Muscarinic antagonists, such as benztropine (Cogentin), are most often contraindicated in glaucoma because these drugs can:
    1. Increase intraocular pressure.
    2. Promote ocular infections.
    3. Cause miosis, which leads to blindness.
    4. Detach the retina.
5. The patient will be taking cholinergic antagonists following discharge from the healthcare agency. Which statement, made by the patient, would indicate that additional teaching is needed?
    1. "To relieve dry mouth, I should drink plenty of water."
    2. "I will avoid activities requiring mental alertness until I know the effects of this drug."
    3. "The use of lubricating eyedrops should be avoided. I should see an eye doctor for dry eyes."
    4. "I will not breastfeed while taking this drug without consulting my healthcare provider."
6. The nurse administering succinylcholine knows that this drug causes:
    1. Muscle paralysis; it does not produce anesthesia or loss of consciousness.
    2. Loss of consciousness, along with muscle paralysis and anesthesia.
    3. Deep muscle relaxation and relief from pain.
    4. Increased mental alertness with muscle paralysis.

See Answers to Chapter Review in Appendix A.

Chapter 15
Adrenergic Agonists

Chapter Outline

- Actions of Adrenergic Agonists
- Mechanisms of Action of Adrenergic Agonists
- Classification of Adrenergic Agonists
- Nonselective Adrenergic Agonists
  PROTOTYPE *Epinephrine (Adrenalin), p. 190*
- Alpha-Adrenergic Agonists
  PROTOTYPE *Phenylephrine (Neo-Synephrine), p. 193*
- Beta-Adrenergic Agonists
  PROTOTYPE *Isoproterenol (Isuprel), p. 195*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the physiologic responses produced when a drug activates adrenergic receptors.
2. Explain the direct and indirect mechanisms by which adrenergic agonists act.
3. Compare and contrast the characteristics of catecholamines and noncatecholamines.
4. Identify indications for pharmacotherapy with adrenergic agonists.
5. Compare and contrast the types of responses that occur when a drug activates alpha$_1$-, alpha$_2$-, beta$_1$-, or beta$_2$-adrenergic receptors.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with adrenergic agonists.

Key Terms

adrenergic agonists, 186
cardiotonic drugs, 195
inotropic drugs, 195
monoamine oxidase (MAO), 188
sympathomimetics, 186
tocolytics, 196

Adrenergic agonists are drugs that activate the sympathetic nervous system and induce symptoms of the fight-or-flight response. The pharmacology of adrenergic drugs is more complex than their cholinergic counterparts due to the existence of the receptor subtypes alpha and beta. Drugs that activate these subtypes have widespread applications to the pharmacotherapy of shock, hypotension, asthma, and the common cold.

Actions of Adrenergic Agonists

15.1 Adrenergic agonists activate the sympathetic nervous system to produce fight-or-flight symptoms.

Adrenergic agonists, also called **sympathomimetics**, are agents that activate adrenergic receptors in the sympathetic nervous system. Drugs in this class include naturally occurring (endogenous) substances such as norepinephrine (NE), epinephrine, and dopamine. NE is the major neurotransmitter in the sympathetic nervous system, whereas epinephrine is the primary hormone released by the adrenal medulla. Dopamine is the immediate biochemical precursor to NE and is a key neurotransmitter in certain regions of the central nervous system (CNS). In addition to their natural physiologic roles in the body, NE, epinephrine, and dopamine are available as prescription drugs. A number of synthetic adrenergic agonists that mimic the effects of these natural neurotransmitters are also available.

When administered as drugs, the adrenergic agonists induce symptoms of the fight-or-flight response. Their most important therapeutic actions are on the cardiovascular and respiratory systems. Activation of adrenergic receptors in the myocardium increases the heart rate (positive chronotropic effect) and the force of contraction (positive inotropic effect). Cardiac output increases. Constriction of vascular smooth muscle causes a rapid increase in blood pressure. Administration by the parenteral or inhalation routes immediately relaxes bronchial smooth muscle, resulting in bronchodilation. Activation of adrenergic receptors in the smooth muscle of the gastrointestinal (GI) and urinary tracts slows peristalsis and may cause constipation and urine retention. Metabolic effects include increased oxygen consumption and increased blood glucose and lactate levels. Other adrenergic actions include reduction of glandular secretory activity and mydriasis.

It is important to remember that the symptoms of the fight-or-flight response elicited by the adrenergic agonists may be considered as therapeutic or adverse, depending on the condition of the patient and the goals of pharmacotherapy. For example, if the patient is in shock, increased blood pressure is a key therapeutic effect. However, if the patient is taking an adrenergic agonist to treat nasal congestion, an increase in blood pressure is an adverse effect. Furthermore a therapeutic effect may become an adverse effect if taken to extreme, such as raising blood pressure too much or causing excessive drying of the nasal or oral mucosa.

The actions produced by adrenergic agonists are similar to those of cholinergic (muscarinic) antagonists (see Chapter 14). This is because blocking muscarinic receptors in the parasympathetic nervous system allows sympathetic nerve impulses to predominate. However, because the sympathetic nervous system has alpha- and beta-receptor subtypes, the actions of many adrenergic agonists are more specific than the cholinergic blockers, allowing for wider therapeutic applications with a lower incidence of adverse effects.

CONNECTION Checkpoint 15.1

From what you learned in Chapter 12, where are most dopaminergic receptors located? Dopaminergic drugs would most likely be prescribed for what disorders? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

Pheochromocytomas are tumors of the adrenal medulla that secrete large amounts of adrenergic agonists including dopamine, epinephrine, and norepinephrine. As expected, signs and symptoms are those of sympathetic nervous system hyperactivity: increased heart rate and blood pressure and anxiety resembling that of a panic attack. Treatment includes pharmacotherapy with antihypertensives until surgery can be performed to remove the tumor (Blake, 2016).

Mechanisms of Action of Adrenergic Agonists

15.2 Adrenergic agonists may act directly by binding to adrenergic receptors, or indirectly by increasing the amount of norepinephrine at synapses.

Sympathomimetics exert their effects by two distinct mechanisms. Most act *directly* by binding to and activating

adrenergic receptors. Examples include the three endogenous hormones epinephrine, NE, and dopamine.

Some adrenergic agonists act *indirectly* by increasing the amount of NE available at adrenergic synapses. Any substance that increases the amount of NE in the synaptic cleft will produce an intense and prolonged fight-or-flight response. A few drugs, such as ephedrine, act by both direct and indirect mechanisms. The mechanisms of indirect-acting agents are shown in Figure 15.1. NE can be increased at the synapse by the following three means:

- **Stimulating the release of NE from its storage vesicles on the presynaptic neuron.** Drugs that act by this mechanism include ephedrine and amphetamine.
- **Inhibiting the reuptake of NE from the synaptic cleft back to the presynaptic neuron.** Examples of drugs that inhibit reuptake of NE include the antidepressant imipramine (Tofranil) and cocaine.
- **Inhibiting the destruction of NE by the enzyme monoamine oxidase (MAO).** Phenelzine (Nardil) is an example of a MAO inhibitor (MAOI).

Indirect adrenergic agonists are less commonly prescribed than the direct agents due to a higher incidence of serious adverse effects. Some indirect-acting agents such as amphetamine and cocaine are drugs of abuse that are used for their central effects on the brain rather than their autonomic effects.

Classification of Adrenergic Agonists

15.3 Adrenergic agonists may be classified as catecholamines or noncatecholamines.

The first adrenergic agonist to be identified, epinephrine, was isolated from extracts of the adrenal gland in the late 1890s. The chemical structure of epinephrine was found to have an aromatic (6-carbon) ring with two OH groups, similar to a common organic chemical known as catechol. Because the molecule also has an NH or amino group, the term *catecholamine* was assigned to epinephrine by physiologists. Several other adrenergic agonists share this core chemical structure,

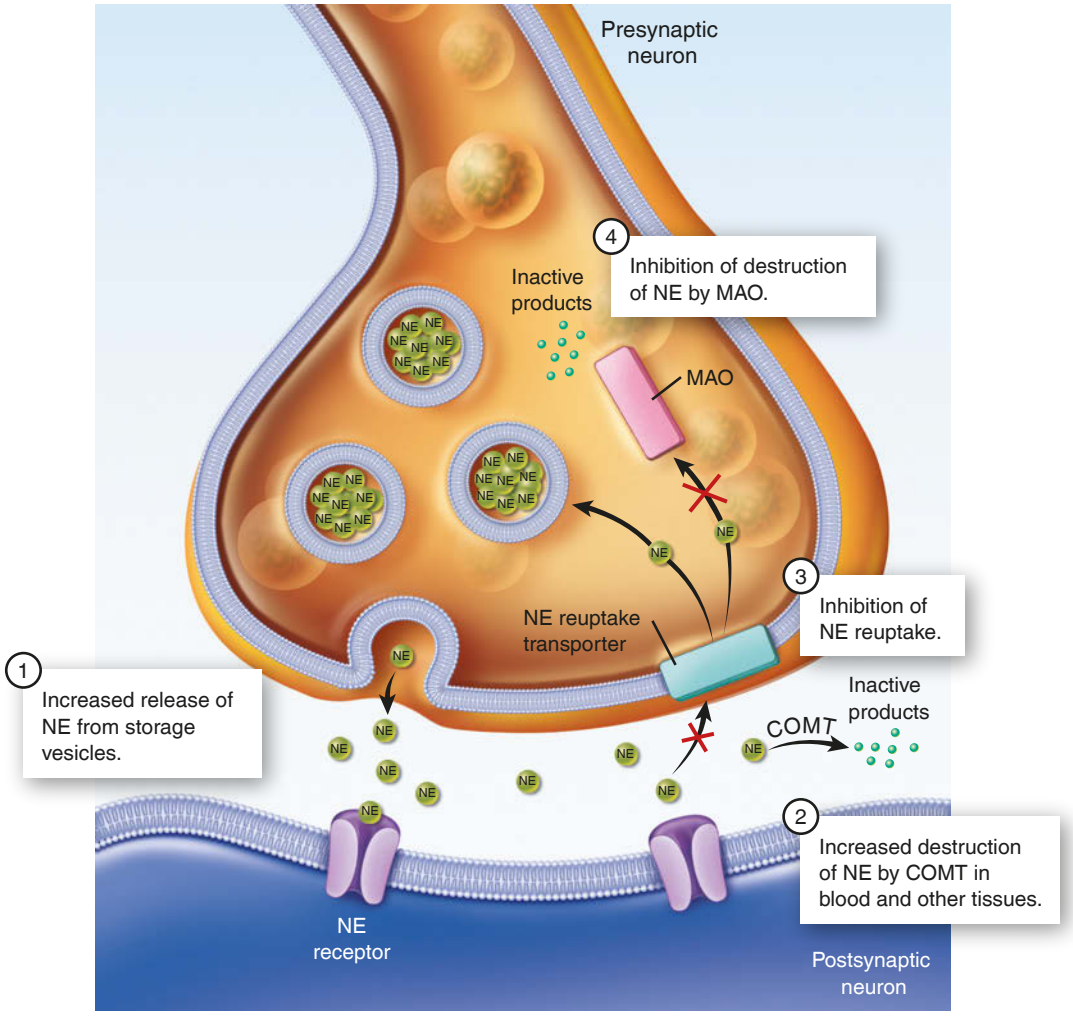

Figure 15.1 Mechanisms of action of adrenergic agonists: (1) stimulation of the release of norepinephrine (NE); (2) increased destruction of NE by catechol-O-methyltransferase (COMT); (3) inhibition of the reuptake of NE; (4) inhibition of the destruction of NE by MAO.

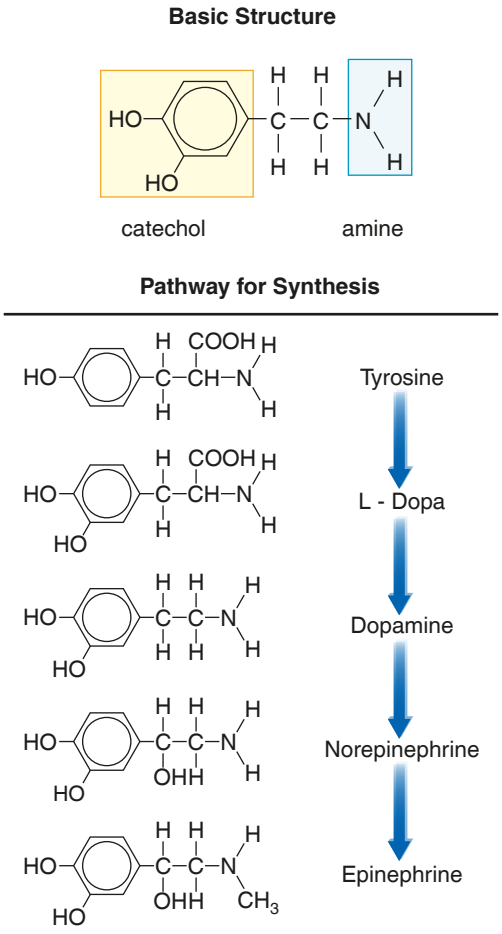

Figure 15.2 Basic chemical structure and synthesis of catecholamines. The synthesis of norepinephrine occurs in the neuron near the neuroeffector junction.

including NE, dopamine, isoproterenol, and dobutamine. This has led to a simple chemical classification of adrenergic agonists as catecholamines or noncatecholamines. Examples of noncatecholamines include phenylephrine, terbutaline, and ephedrine. The fundamental chemical structure of a catecholamine is shown in Figure 15.2.

Catecholamines and noncatecholamines have important pharmacokinetic differences. Catecholamines have a short duration of action because they are destroyed rapidly by the enzymes **monoamine oxidase (MAO)** and catechol-O-methyltransferase (COMT) (see Figure 15.1). Because these destructive enzymes are active in the mucosa of the intestinal tract, catecholamines cannot be given orally (PO) and must be administered parenterally or by inhalation. Furthermore, the OH groups on the catechol portion of the molecule make these drugs polar and prevent them from crossing the blood–brain barrier.

On the other hand, the noncatecholamines may be taken PO because they are not destroyed as readily by MAO or COMT. This also extends their duration of action. These drugs are less polar than the catecholamines; thus they are better able to enter the brain and affect the CNS.

CONNECTION Checkpoint 15.2

From what you learned in Chapter 3, how does the ionization of a drug molecule affect its absorption? How does it affect its distribution to tissues? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Nonselective Adrenergic Agonists

15.4 The nonselective adrenergic agonists activate both alpha and beta receptors and are used to treat bronchospasm, cardiac arrest, and hypotension.

Although the general actions of adrenergic agonists are predictable, based on their activation of the sympathetic nervous system, the specific effects of each drug are dependent on which receptor subtypes are stimulated. As discussed in Chapter 12, adrenergic receptors include alpha$_1$, alpha$_2$, beta$_1$, and beta$_2$ subtypes. Because the receptor responses are very different and critical to understanding drug action, the student will need to remember the specific subclass(es) of receptors activated by each adrenergic agonist drug. Therapeutic applications for the different receptor activations are summarized as follows:

- **Alpha$_1$-receptor agonists.** Generally prescribed for the pharmacotherapy of nasal congestion and hypotension, these drugs may also be used to produce dilation of the pupil (mydriasis) during ophthalmic examinations.
- **Alpha$_2$-receptor agonists.** These drugs are prescribed for the treatment of hypertension (HTN). They act through nonautonomic (centrally acting) mechanisms.
- **Beta$_1$-receptor agonists.** These critical care drugs are used for cardiac arrest, heart failure, and shock due to their powerful effects on the heart.
- **Beta$_2$-receptor agonists.** These widely used drugs are for treating asthma and reducing preterm labor contractions of the uterus.

Some sympathomimetics are nonselective, stimulating two or more adrenergic-receptor subtypes. For example, epinephrine and ephedrine stimulate all four types of adrenergic receptors. In doing so, these drugs cause widespread activation of the sympathetic nervous system and an intense fight-or-flight response (resulting in many adverse effects).

One of the most important applications of the nonselective adrenergic agonists is for the pharmacotherapy of shock and other life-threatening cardiac disorders. In certain types of shock, the most serious medical challenge facing the patient is hypotension, which may become so severe as to collapse the circulatory system. In the early stages of shock, the body compensates by activating the sympathetic nervous system; blood pressure is raised and the rate and force of myocardial contraction are increased. These compensatory measures maintain blood flow to vital organs such as the heart and brain, and decrease flow to "less vital" organs, including the kidneys and liver.

The body's ability to compensate for severe shock is limited, however, and profound hypotension may develop as the condition progresses. In minor to moderate shock, fluid replacement agents are the preferred drugs for raising blood pressure (see Chapter 33). Should fluid replacement agents prove ineffective, however, adrenergic agonists are administered to maintain blood pressure. When given intravenously (IV) these drugs immediately increase blood pressure. Because rapid, intense vasoconstriction can cause serious hypoperfusion of tissues with potential organ damage, these drugs are generally used as a last resort, when safer alternatives have failed to produce the desired therapeutic outcome. Epinephrine, NE, and dopamine are nonselective drugs for shock or anaphylaxis when blood pressure and heart rate need to be quickly restored to normal levels. The nonselective adrenergic agonists are shown in Table 15.1.

The nonselective adrenergic agonists cause more autonomic-related adverse effects than the selective drugs. Most of these adverse effects are extensions of their autonomic actions. Cardiovascular effects such as tachycardia, HTN, and dysrhythmias are particularly troublesome and may limit therapy. Blood pressure and heart rate must be monitored

Table 15.1 Selected Adrenergic Agonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
albuterol (Proventil HFA, Ventolin HFA, VoSpire ER)	Metered-dose inhaler (MDI): 2 inhalations q4–6h prn PO (extended release): 8 mg bid (max: 32 mg/day)	*Headache, dizziness, tremor, nervousness, throat irritation, drug tolerance* Tachycardia, dysrhythmias, hypokalemia, hyperglycemia
arformoterol (Brovana)	Nebulizer: 15 mcg bid (max: 30 mcg/day)	*Chest pain, back pain, diarrhea, sinusitis, leg cramps, dyspnea, flu syndrome, peripheral edema* Paradoxical bronchospasm, increased risk for asthma-related death
dobutamine	IV: Infused at a rate of 2.5–40 mcg/kg/min for a max of 72 h	*Headache, palpitations, nausea, vomiting, increased heart rate and blood pressure, anginal pain* Dysrhythmias, gangrene, severe HTN
dopamine	IV: 2–5 mcg/kg/min initial dose; may be increased to 20–50 mcg/kg/min	*Headache, palpitations, nausea, vomiting, changes in blood pressure (hypo- or hypertension)* Dysrhythmias, gangrene, severe HTN
droxidopa (Northera)	PO: 100 mg tid (max: 600 mg tid)	*Headache, dizziness, nausea* Supine hypertension, hyperpyrexia, confusion
ephedrine	PO: 2.5–25 mg qid (max: 150 mg/24 h) IM/IV/subcutaneous: 12.5–25 mg	*Headache, nervousness, palpitations, nausea, vomiting* Dysrhythmias, severe HTN, decreased urine output
epinephrine (Adrenalin)	Subcutaneous: 0.1–0.5 mL of 1:1000 every 10–15 min prn IV: 0.1–0.25 mL of 1:1000 every 10–15 min	*Headache, palpitations, nausea, vomiting, tremors, changes in blood pressure (hypo- or hypertension)* Dysrhythmias, gangrene, severe HTN, pulmonary edema
indacaterol (Arcapta Neohaler)	Inhalation: One 75-mcg capsule daily using the Neohaler	*Cough, oropharyngeal pain, nasopharyngitis, headache, nausea* Hypersensitivity, bronchospasm
isoproterenol (Isuprel)	IV: 0.01–0.02 mg prn	*Headache, nervousness, palpitations, tachycardia* Ventricular dysrhythmias, unstable blood pressure
levalbuterol (Xopenex)	Nebulizer: 0.63 mg tid MDI: 90 mcg (2 inhalations) q4–6h	*Headache, dizziness, tremor, nervousness, throat irritation, drug tolerance* Tachycardia, dysrhythmias, hypokalemia, hyperglycemia
midodrine (ProAmatine)	PO: 10 mg tid (max: 20 mg/dose)	*Paresthesia, pruritus* HTN, urinary retention
mirabegron (Myrbetriq)	PO: 25–50 mg q8h	*Paresthesia, nasopharyngitis, urinary tract infection, pruritus* HTN, urinary retention
norepinephrine (Levophed)	IV: Initially 0.5–1 mcg/min, titrate slowly to therapeutic response; usual range 8–30 mcg/min	*Restlessness, anxiety, palpitations, nausea, vomiting, headache* Tachycardia or bradycardia (overdose), severe HTN, hepatic necrosis, cerebral hemorrhage
olodaterol (Striverdi Respimat)	Inhalation: 2 inhalations daily	*Upper respiratory tract infection, bronchitis, urinary tract infection, cough* Paradoxical bronchospasm, increased risk for asthma-related death
phenylephrine (Neo-Synephrine)	IV: 0.1–0.18 mg/min until blood pressure stabilizes, then 0.04–0.06 mg/min for maintenance	*Palpitations, tingling or coldness of extremities, nervousness* Severe peripheral vasoconstriction, tachycardia or bradycardia (overdose), HTN, dysrhythmias, necrosis at injection site

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

continuously during parenteral administration of these drugs. Large doses can induce CNS excitement and seizures. Patients with diabetes may experience a significant increase in blood glucose levels due to an increased breakdown of glycogen in the liver and skeletal muscle. Care must be taken to avoid extravasation because this can cause severe tissue injury. Should extravasation occur, the antidote is phentolamine, an alpha-adrenergic blocker, which will help to counteract the vasoconstriction caused by the catecholamine at the site. Other adverse effects associated with sympathetic activation include dry mouth, nausea, and vomiting.

Amphetamine is a nonselective adrenergic agonist with a marked CNS stimulant effect. Amphetamine also causes anorexia, which has led to its historical use as an appetite suppressant. Because of prominent cardiovascular adverse effects, nervous system effects such as paranoia and psychosis, and the risk of physical dependence, the drug is no longer routinely prescribed for weight loss. In 2015, amphetamine (Evekeo) was approved as an adjunct for the short- term (a few weeks) treatment of obesity when combined with a strict dietary regimen. Amphetamine and amphetamine-like drugs are widely prescribed to treat attention-deficit/hyperactivity disorder. In children with this disorder, amphetamine has less stimulatory effect; instead, it increases children's attention span, allowing them to focus more on tasks. Additional details on amphetamine may be found in Chapters 24 and 27.

PROTOTYPE DRUG Epinephrine (Adrenalin)

Classification **Therapeutic:** Antishock and antianaphylaxis drug, bronchodilator
Pharmacologic: Nonselective adrenergic agonist, catecholamine

Therapeutic Effects and Uses: Epinephrine has several therapeutic applications, all of which are the result of adrenergic-receptor activation. It can be administered parenterally, topically, by inhalation, or by instillation.

Epinephrine is a preferred drug for cardiac arrest after cardiopulmonary resuscitation (CPR) has failed. Given as an IV infusion or by intracardiac injection, the drug has the potential to immediately restore cardiac rhythm. Epinephrine also constricts arterioles, raising cerebral and cardiac perfusion pressure, which discourages cardiovascular collapse. The intracardiac route is used only under extreme conditions, usually during open cardiac massage, or when no other route is possible.

Epinephrine can reverse many of the distressing symptoms of anaphylaxis within minutes. Almost immediately after injection, blood pressure increases due to stimulation of $alpha_1$ receptors. Activation of $beta_2$ receptors in the bronchi dilates the airways to relieve shortness of breath. Epinephrine can also be administered by inhalation, which has the potential to immediately terminate acute bronchospasm.

Epinephrine is sometimes added to cartridges of local anesthetics to cause vasoconstriction of local vessels. This forces the anesthetic to remain localized in the tissues for a longer period, prolonging analgesia and slowing the absorption of anesthetic. Epinephrine can also be applied topically to control superficial bleeding along a surgical incision. Repeated injection or application to the same site can result in tissue necrosis due to the diminished blood supply to the area.

Ophthalmic administration of epinephrine causes mydriasis and the outflow of fluid from the anterior chamber of the eye, making the drug an adjunct to the pharmacotherapy of open-angle glaucoma. Intranasal administration can be used to reduce nasal congestion.

Mechanism of Action: Epinephrine is a nonselective adrenergic agonist, stimulating both alpha- and beta-adrenergic receptors throughout the body. Actions typical of the fight-or-flight response are induced.

Pharmacokinetics:

Route(s)	Subcutaneous, IV, intramuscular (IM), inhalation, topical, ophthalmic
Absorption	Not absorbed PO; minimal absorption by inhalation; rapidly absorbed by IM and subcutaneous routes
Distribution	Widely distributed; does not cross the blood–brain barrier; crosses the placenta; secreted in breast milk
Primary metabolism	Rapidly metabolized by MAO and COMT in the liver and most tissues
Primary excretion	Small amount excreted unchanged in the kidneys
Onset of action	Subcutaneous: 3–5 min; IM: 5–10 min; inhalation: 1 min (for local respiratory effects); IV: immediate onset
Duration of action	1–4 h

Adverse Effects: The most common adverse effects of epinephrine are nervousness, tremors, palpitations, tachycardia, dizziness, headache, and stinging at the site of application. Serious adverse effects include HTN, dysrhythmias, pulmonary edema, and cardiac arrest. Intense CNS stimulation including hallucinations, panic attacks, and aggression may occur, especially in patients with preexisting psychiatric disorders. Extravasation of epinephrine can produce an injection site reaction, causing severe tissue damage and necrosis.

Contraindications/Precautions: Contraindications for epinephrine include hypersensitivity to other adrenergic agonists, closed-angle glaucoma, severe shock (other than anaphylaxis), and dysrhythmias. The drug should be used with caution in patients with coronary artery disease because intense angina symptoms may result. Due to its

ability to relax uterine smooth muscle, epinephrine will delay labor. Patients with hyperthyroidism or HTN are more sensitive to the effects of administered epinephrine (and other catecholamines). In life-threatening conditions such as anaphylaxis or cardiac arrest, there are no absolute contraindications for the use of epinephrine.

Drug Interactions: Additive cardiovascular effects will occur if epinephrine is used concurrently with other sympathomimetics or antihypotensive drugs. MAOIs block the destruction of catecholamines and will intensify the effects of epinephrine. Tricyclic antidepressants block the reuptake of catecholamines, which is the primary way by which epinephrine is inactivated; thus doses of epinephrine should be lowered in patients using these depressants. Alpha- and beta-adrenergic antagonists inhibit the actions of epinephrine. Epinephrine will decrease the effects of beta blockers. Digoxin and some general anesthetics may sensitize the heart to the effects of epinephrine. Two drugs used for Parkinson's disease, entacapone and tolcapone, are inhibitors of COMT, the enzyme that degrades epinephrine; concurrent use may cause increased effects of epinephrine on the heart and blood pressure. **Herbal/Food:** Caffeine and ephedra should be avoided because they may increase blood pressure and heart rate.

Pregnancy: Category C.

Treatment of Overdose: Overdose of epinephrine is life threatening and the immediate administration of an alpha- or beta-adrenergic blocker is indicated. If blood pressure remains high, a direct vasodilator may be administered.

Nursing Responsibilities: Key nursing implications for patients receiving epinephrine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Agonists.

Drugs Similar to Epinephrine (Adrenalin)

Other nonselective adrenergic agonists include dopamine, droxidopa, ephedrine, and NE.

Dopamine: Approved as a drug by the U.S. Food and Drug Administration (FDA) in 1974, dopamine is an endogenous catecholamine that has both alpha- and beta-agonist activity. It is administered by the IV route and has a brief 10-minute duration of action. Doses are slowly increased until the desired therapeutic effects have been achieved. Vital signs should be monitored continuously during the infusion.

Dopamine is primarily used to treat hypovolemic and cardiogenic shock. Whenever possible, hypovolemia is corrected with fluid-expanding agents before starting a dopamine infusion. At low doses (1–5 mcg/kg/min), the drug selectively stimulates dopaminergic receptors, especially in the kidneys, leading to vasodilation and thus increasing renal blood flow and enhancing urine output. This helps to prevent renal failure, which can occur during shock conditions. At higher doses (more than 10 mcg/kg/min), dopamine stimulates $beta_1$-adrenergic receptors, causing the heart to beat more forcefully, increasing cardiac output. Also at higher doses, dopamine stimulates $alpha_1$-adrenergic receptors, causing vasoconstriction and increased blood pressure.

Headache, nausea, and vomiting are common adverse effects. High doses can produce ventricular tachycardia. Severe necrosis or gangrene can result if extravasation occurs; thus phentolamine should be readily available. Dopamine is pregnancy category C.

Droxidopa (Northera): Approved in 2014, droxidopa is a prodrug that is metabolically converted to NE after oral administration. As such, it shares the same vasoconstrictor action as NE. The drug is approved to treat orthostatic hypotension that is associated with neurogenic disorders such as Parkinson's disease. The most common adverse events of droxidopa include headache, dizziness, nausea, HTN, and fatigue. The drug carries a black box warning that the patient should be monitored carefully for supine HTN during therapy because this increases the risk for serious cardiovascular events. Droxidopa is pregnancy category C.

Ephedrine: Ephedrine is a noncatecholamine, originally obtained from the *Ephedra* plant species, that activates both alpha and beta receptors. Although ephedrine was approved by the FDA in 1939, extracts from the ephedra plant have been used to treat various ailments for thousands of years. In Chinese medicine, the herb ma huang contains ephedrine as one of its active ingredients.

Ephedrine acts by two mechanisms: directly, by binding to adrenergic receptors, and indirectly, by causing the release of NE from storage vesicles in the nerve terminals. Ephedrine has been used for its ability to relieve respiratory congestion caused by allergies and to prevent bronchospasm in patients with asthma. It is available by the PO and parenteral routes, is readily absorbed from the GI tract, and crosses the blood–brain barrier. Once in the brain, ephedrine exhibits prominent stimulatory effects, keeping patients alert and awake. It was once used as an over-the-counter (OTC) appetite suppressant, but this indication is not legal in the United States. The CNS stimulation has also been used to alleviate the CNS depression caused by opioid or barbiturate overdose. This stimulatory effect of ephedrine is also the cause of the major adverse effects of the drug such as nervousness, insomnia, palpitations, and tachycardia. Like the closely related drug pseudoephedrine, ephedrine is highly regulated because it can be used to make methamphetamine. This drug is pregnancy category C.

Norepinephrine (Levophed): Approved in 1938, NE is a nonselective catecholamine that has actions similar to epinephrine, except that is does not activate $beta_2$ receptors. Approved to treat shock and hypotension, NE acts directly

on alpha-adrenergic receptors in vascular smooth muscle to immediately raise blood pressure. It also stimulates $beta_1$ receptors in the heart to increase cardiac output. It is given by the IV route and has a duration of only 1 to 2 minutes after the infusion is terminated. Because NE is a powerful vasoconstrictor, continuous monitoring of blood pressure is required to avoid HTN. When first administered, reflex bradycardia is sometimes experienced, and the drug has the ability to produce various dysrhythmias. Blurred vision and photophobia are signs of overdose. Like other drugs in this class, NE produces symptoms of CNS stimulation such as nervousness, insomnia, and confusion. Severe tissue necrosis can result if extravasation occurs; thus phentolamine should be readily available. The primary indications for NE are acute shock and cardiac arrest. This drug is pregnancy category C.

CONNECTIONS: Patient Safety

Prompt Use of the Epinephrine Autoinjector in the School Setting

The EpiPen autoinjector contains epinephrine and is used to prevent and treat anaphylaxis and severe allergic reactions to insect stings, foods, or drugs. This device is designed to be easy to operate, although the word *auto* sometimes gives people a false sense of security that the injector is foolproof. It is crucial that a potential anaphylactic reaction be treated as quickly as possible. Because anaphylaxis may occur with the first exposure to an antigen, children in school settings may be particularly vulnerable if there are not sufficient numbers of adequately trained staff to administer the epinephrine.

In a study of over 6000 schools throughout the United States, Hogue, Goss, Hollis, Silvia, and White (2016) found that 11% of the schools surveyed reported at least one anaphylactic event within a year's time. Over 50% of the schools reported that a school nurse or select staff members were trained, whereas less than 38% of schools had trained all staff on the use of an epinephrine autoinjector.

Nurses working in school settings, as well as with their local pediatrician's offices and communities, can support regulations that require the training of all school staff in the use of the epinephrine autoinjector and supplying all schools with the drug. Early recognition and treatment of anaphylaxis is essential, and having the training and available drug supplies can ensure treatment will be given as soon as a reaction is noted.

Alpha-Adrenergic Agonists

15.5 Alpha-adrenergic agonists are used to relieve nasal decongestion and elevate blood pressure.

Activation of alpha-adrenergic receptors causes a number of important physiologic responses, most of which relate to contraction of vascular smooth muscle. Like the nonselective adrenergic agonists, several of the selective alpha agonists are used to treat hypotension associated with shock and other critical care conditions. Alpha agonists may also be administered to treat patients who are susceptible to orthostatic hypotension.

A second application of alpha-adrenergic agonists is for the treatment of nasal congestion. During upper respiratory infections or allergic rhinitis, arterioles in the nose dilate and produce excess mucus. $Alpha_1$ agonists relieve nasal congestion by constricting vessels of the nasal mucosa. Intranasal drugs such as phenylephrine work within minutes and are highly effective at clearing the nasal passages. The intranasal route causes few systemic side effects because absorption is limited. Oral decongestants such as phenylephrine take longer to act and the risk for systemic side effects is higher; however, they are less damaging to the nasal mucosa than the intranasal drugs. The pharmacotherapy of upper respiratory congestion is presented in Chapter 45.

Topical instillation of $alpha_1$ agonists to the eye has two applications. $Alpha_1$-adrenergic receptors are present on the radial muscle of the iris. When these receptors are activated, the radial muscle contracts and the pupil dilates, allowing the healthcare provider to better examine the interior structures of the eye. Although the $alpha_1$ agonists are effective at producing mydriasis, they are generally second-line drugs for ophthalmic exams. Another ophthalmic application of $alpha_1$ agonists is to relieve conjunctival congestion and redness. The mechanism behind this effect is through $alpha_1$-receptor activation of arterioles in the eye, causing vasoconstriction. Tetrahydrozoline (Tyzine) is widely used for minor eye irritation and redness and is available OTC. The pharmacotherapy of ophthalmic conditions is discussed in detail in Chapter 74.

Most adverse effects of the $alpha_1$-adrenergic agonists are logical extensions of their autonomic actions. Their intense vasoconstrictive effect can lead to HTN. This increase in blood pressure can activate the baroreceptor reflex, causing reflex bradycardia. Because of the potential for cardiovascular adverse effects, patients should be continuously monitored when receiving high doses or infusions of these drugs. Should extravasation occur, the intense local vasoconstriction caused by these drugs can lead to tissue necrosis. Major adverse effects or overdose with drugs in this class may be treated by administering a specific alpha-adrenergic antagonist such as phentolamine. Bradycardia can be prevented or reversed by administration of an anticholinergic drug such as atropine. In low doses, many of the alpha agonists can be safely used as OTC drugs for symptoms of the common cold, minor allergies, or ophthalmic conditions.

Activation of $alpha_2$-adrenergic receptors produces very different responses than $alpha_1$ activation. The most important responses to $alpha_2$-receptor agonists occur in the brain rather than the peripheral nervous system. Unlike $alpha_1$ agonists, which increase sympathetic nervous system activity, $alpha_2$ agonists act in the CNS to *decrease* sympathetic activity. Methyldopa (Aldomet) and clonidine

(Catapres, Duraclon) are two drugs in this class. Because they decrease blood pressure, their primary therapeutic application is for the treatment of HTN (see Chapter 34).

PROTOTYPE DRUG **Phenylephrine (Neo-Synephrine)**

Classification **Therapeutic:** Nasal decongestant, vasoconstrictor
Pharmacologic: Alpha-adrenergic agonist

Therapeutic Effects and Uses: Approved in 1938, the actions and indications of phenylephrine are predictable extensions of its sympathetic activation. Its most frequent application is for the relief of congestion associated with the common cold and allergies. Historically, pseudoephedrine was the preferred drug for these indications. Phenylephrine has now largely replaced pseudoephedrine in OTC multisystem cold, allergy, and sinus remedies because it cannot be used by illicit drug dealers to synthesize methamphetamine. Formulations containing phenylephrine are exempt from regulations in most states that require pseudoephedrine products to be kept behind the pharmacy counter. For congestion, phenylephrine is available via oral and intranasal routes. When applied intranasally by spray or drops, it reduces nasal congestion by constricting small blood vessels in the nasal mucosa.

Parenteral administration of phenylephrine causes systemic vasoconstriction that can prevent or reverse acute hypotension caused by spinal anesthesia or vascular shock. Its long duration of activity and lack of significant cardiac adverse effects gives phenylephrine advantages over epinephrine or NE in treating acute hypotension. Unlike epinephrine, which markedly increases the heart rate, phenylephrine tends to slow the heart rate, probably due to reflex bradycardia. In situations in which reflex bradycardia is undesirable, this action may be blocked by the administration of atropine.

Phenylephrine is also available for topical use. Applied topically to the eye during ophthalmic examinations, phenylephrine can dilate the pupil, without causing significant cycloplegia. Applied to swollen hemorrhoidal tissue, the drug can relieve itching and burning associated with hemorrhoids.

Mechanism of Action: Phenylephrine directly activates alpha$_1$-adrenergic receptors in the peripheral nervous system. It has weak beta-adrenergic activity at high doses, but this is usually not of clinical significance.

Pharmacokinetics:

Route(s)	PO, IM, subcutaneous, IV, intranasal, and ophthalmic solutions
Absorption	Readily absorbed in the GI tract; well absorbed when given IM or subcutaneously
Distribution	Widely distributed; does not cross blood–brain barrier or enter breast milk in significant amounts
Primary metabolism	Intestinal and hepatic by MAO
Primary excretion	Unknown
Onset of action	Oral: peaks in 1–2 h; subcutaneous/IM: 10–15 min; IV: immediate
Duration of action	Oral: 3 h; subcutaneous/IM: 30–120 min; IV: 15–20 min

Adverse Effects: Phenylephrine causes few serious adverse effects when taken by the PO, intranasal, or ophthalmic routes. Common adverse effects with intranasal phenylephrine use include stinging of the nasal mucosa, sneezing, and rebound congestion. Ophthalmic use can cause closed-angle glaucoma or photophobia. Parenteral use can lead to symptoms of CNS stimulation such as anxiety, restlessness, and tremor. Serious adverse effects include reflex bradycardia and reduced blood flow to peripheral tissues due to severe vasoconstriction. OTC cough and cold products containing phenylephrine or pseudoephedrine should not be given to children under age 2 years because overdose has caused serious illness and several infant deaths.

Contraindications/Precautions: Phenylephrine is contraindicated in patients with severe HTN because the drug will raise blood pressure to dangerous levels. Because it causes reflex bradycardia, patients with preexisting bradycardia should not receive phenylephrine. Phenylephrine causes vasoconstriction, which can reduce coronary blood flow in patients with advanced coronary artery disease, causing angina attacks. Phenylephrine also reduces the effectiveness of nitrates such as nitroglycerin that are taken to prevent anginal episodes. Because of its effects on the eye, it should not be administered to patients with closed-angle glaucoma. Phenylephrine should be used with caution in patients with hyperthyroidism or diabetes because these patients are more sensitive to the potential cardiac adverse effects.

Drug Interactions: Phenylephrine will reduce the effectiveness of antihypertensive medications. A hypertensive crisis may occur in patients receiving MAOIs; phenylephrine should not be administered within 21 days of a MAOI. Increased effects of phenylephrine may occur in patients taking ergot alkaloids and tricyclic antidepressants. Additive effects may occur if phenylephrine is given concurrently with other adrenergic agonists, including amphetamines or cocaine. Concurrent administration with oxytocin during the postpartum period may cause persistent HTN. Concurrent use with halothane or digoxin may increase the risk of dysrhythmias. **Herbal/Food:** Phenylephrine should be used with caution with

St. John's wort because this combination may result in HTN. Ingestion of substances with high amounts of caffeine will worsen the CNS stimulation caused by phenylephrine.

Pregnancy: Category C.

Treatment of Overdose: When given by the parenteral route, overdose will result in HTN and possible dysrhythmias. Phentolamine is a specific alpha antagonist that can be used to lower blood pressure, and antidysrhythmic drugs may be indicated.

Nursing Responsibilities: Key nursing implications for patients receiving phenylephrine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Agonists.

Drugs Similar to Phenylephrine (Neo-Synephrine)

Most drugs with predominant alpha-adrenergic agonist activity can be grouped into subclasses based on their indications: intranasal or ocular decongestants.

Intranasal decongestants: Oxymetazoline (Afrin), pseudoephedrine (Sudafed), xylometazoline (Neo-Synephrine II, Long-Acting), and tetrahydrozoline (Tyzine) are given by the intranasal route to diminish nasal congestion caused by allergies or the common cold. Use of these medications is generally limited to 3 to 5 days. If the drug is abruptly discontinued, congestion may worsen, a phenomenon known as *rebound congestion*. Although these drugs may also have some beta-adrenergic activity, they are only used for their effects on alpha-adrenergic receptors in the nasal mucosa. The pharmacotherapy of nasal decongestants is presented in Chapter 45.

Pseudoephedrine is an intranasal decongestant that deserves special attention because of its potential for misuse. Pseudoephedrine is the starting chemical for the synthesis of illegal methamphetamine by drug traffickers. Most states have enacted laws to regulate the sale of solid tablet formulations containing pseudoephedrine, requiring that pseudoephedrine be placed behind the pharmacy counter so that only pharmacists can provide the product. Most states also require the pharmacist to record the name and address of the buyer. Note that these precautions are not being taken because pseudoephedrine itself is a dangerous drug, but to limit the availability of the drug to illicit makers of methamphetamine. A prototype feature for pseudoephedrine can be found in Chapter 45.

Ocular decongestants: Naphazoline (Naphcon, Clear Eyes), oxymetazoline (Afrin 12 Hour), and tetrahydrozoline (Visine) are available as ophthalmic solutions to relieve redness due to minor eye irritations, such as those caused by the common cold, swimming, allergies, or contact lenses. These drugs act by constricting arteries in the conjunctiva. Other than local stinging, they rarely cause adverse effects. The pharmacotherapy of ocular medications is presented in Chapter 74.

Midodrine (ProAmatine): Approved in 1996, midodrine is converted into an active metabolite that has alpha$_1$-agonist actions. It is given PO for the symptomatic treatment of orthostatic hypotension. The drug increases standing, sitting, and supine systolic and diastolic blood pressure. Because marked elevation of supine blood pressure occurs in as many as 13% of patients taking the drug, it carries a black box warning that supine and sitting blood pressures should be monitored during therapy and that it should not be used in patients with an initial supine systolic pressure greater than 180 mmHg. Signs of supine HTN include pounding sensations in the ears or chest, blurred vision, and headache. The most common adverse effects are paresthesia, goose bumps, dysuria, and pruritus of the scalp. Midodrine is contraindicated in patients with heart failure, severe cardiac disease, or excessive supine HTN. The drug is pregnancy category C.

CONNECTION Checkpoint 15.3

Parenteral phenylephrine can cause reflex bradycardia. From what you learned in Chapter 14, would the administration of an anticholinergic such as atropine improve or worsen this condition? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Beta-Adrenergic Agonists

15.6 Beta-adrenergic agonists are used to treat asthma, shock, heart failure, and other cardiac disorders.

Activation of beta-adrenergic receptors can produce a wide variety of physiologic responses, depending on the location of the receptor and which subtype is stimulated. Some beta-adrenergic agonists are more selective for beta$_1$ receptors, whereas others affect primarily beta$_2$. The indications for the beta$_1$ activators are very different from those of the beta$_2$ activators:

- **Beta$_1$ applications:** cardiac arrest, heart failure, atrioventricular (AV) heart block, and shock
- **Beta$_2$ applications:** asthma, chronic obstructive pulmonary disease (COPD), and delay of preterm labor.

Beta$_1$-adrenergic agonists: Pharmacologically, the most significant site having beta$_1$ receptors is cardiac muscle. Activation of beta$_1$ receptors results in cardiac actions typical of the fight-or-flight response: increased heart rate (positive chronotropic effect), force of contraction (positive inotropic effect), and velocity of impulse conduction across the myocardium (positive dromotropic effect). These cardiac effects may be considered beneficial or adverse,

depending on the condition of the patient and the therapeutic goals.

Drugs used for their $beta_1$-agonist actions are sometimes called **cardiotonic drugs** because they increase the force of contraction of the heart. In the treatment of heart failure or shock, they are administered to increase cardiac output. Another name applied to these drugs is **inotropic drugs**, because they reverse the cardiac symptoms of shock by increasing the strength of myocardial contraction. The use of $beta_1$ agonists in treating heart failure is presented in Chapter 36.

Most drugs used for their strong $beta_1$-agonist activity are nonselective and activate other receptor subtypes. For example, although epinephrine is often used for its $beta_1$ activation of the heart following cardiac arrest, the drug has effects on all receptor subtypes. Similarly, although NE is used for its $beta_1$-agonist actions during cardiac arrest, the drug also activates alpha receptors. Dopamine is somewhat unique in that at low doses the drug activates dopamine receptors, and at moderate doses it stimulates both $beta_1$ and dopamine receptors. At high doses dopamine activates all three receptor types: dopamine, alpha, and $beta_1$. Dobutamine is selective for $beta_1$ receptors and isoproterenol activates both $beta_1$ and $beta_2$ receptors.

Beta$_2$-adrenergic agonists: Beta$_2$-adrenergic receptors are more widely distributed than $beta_1$ receptors. Pharmacologically, the most important site is in the lung, where activation of $beta_2$ receptors leads to relaxation of bronchial smooth muscle. Beta$_2$-adrenergic agonists, commonly referred to as bronchodilators, are used extensively in the treatment of asthma, COPD, and other pulmonary disorders. The following discussion is limited to autonomic bronchodilators; information on other classes of drugs used in the pharmacotherapy of asthma is presented in Chapter 44.

Autonomic drugs used as bronchodilators include nonselective adrenergic agonists as well as those that are selective for $beta_2$ receptors. Epinephrine is the best example of a nonselective drug that is an effective bronchodilator. Unfortunately, epinephrine exhibits a high incidence of adverse effects, such as HTN and dysrhythmias, due to its stimulation of multiple receptor subtypes throughout the body. Likewise, isoproterenol is an effective bronchodilator; however, it also affects $beta_1$ receptors, which increases its potential for producing cardiovascular adverse effects. Selective $beta_2$ agonists were developed to minimize these adverse effects. Selective $beta_2$ agonists such as albuterol are now important drugs in the pharmacotherapy of asthma and other conditions characterized by bronchospasm. A drug prototype feature for albuterol can be found in Chapter 44.

When given for asthma, $beta_2$ agonists are administered by either the inhalation or PO route. Inhalation administration of these medications relieves acute bronchospasm within minutes. Some of the inhaled $beta_2$ agonists, such as albuterol (Proventil, Ventolin, VoSpire) and pirbuterol (Maxair), have a rapid onset; however, their duration of action is only 3 to 5 hours. Others, such as formoterol (Xopenex), have longer onsets of action, but their effects can last up to 12 hours. The preferred drug and dosage schedule are individualized for the particular pattern of asthma exhibited by each patient.

Albuterol and terbutaline are $beta_2$ agonists available by the PO route. An extended release form of albuterol (Proventil Repetabs) allows for the convenience of twice a day dosing. Terbutaline is given 3 or 4 times per day. Because the PO forms take up to 30 minutes to act, they are not indicated for the relief of acute bronchospasm.

Adverse effects of the $beta_2$ agonists are predictable extensions of their autonomic activation. Tachycardia, palpitations, flushing, insomnia, and tremor are possible adverse effects with all $beta_2$ agonists. The oral forms have some $beta_1$ activity; thus systemic adverse effects are more common than the inhaled drugs, which act locally and produce few systemic adverse effects. Beta agonists should be used cautiously in patients with dysrhythmias or heart failure. These drugs antagonize the actions of beta-adrenergic blockers.

PROTOTYPE DRUG Isoproterenol (Isuprel)

Classification

Therapeutic: Bronchodilator, drug for shock

Pharmacologic: Nonselective beta-adrenergic agonist

Therapeutic Effects and Uses: Isoproterenol is a catecholamine that has been available as a drug for over 50 years. The drug activates both $beta_1$- and $beta_2$-adrenergic receptors but has minimal effect on alpha receptors. Given by the IV route, isoproterenol immediately activates $beta_1$ receptors to increase the strength of myocardial contraction and improve cardiac output. The cardiac actions of isoproterenol are used to advantage in the pharmacotherapy of cardiogenic or bacteremic shock, cardiac arrest, Adams–Stokes syndrome, and certain types of ventricular dysrhythmias. Dobutamine has largely replaced isoproterenol as a cardiac drug because it is more specific to $beta_1$ receptors in the heart.

Isoproterenol was once available by inhaler for asthma pharmacotherapy and was a preferred drug due to its bronchodilation effects caused by activation of $beta_2$ receptors in the airways. The development of selective $beta_2$ agonists with fewer cardiac adverse effects, however, led to a significant decline in the use of isoproterenol for treating asthma. This drug is no longer available via inhalation devices. Other types of acute bronchospasm, such as that caused by anesthesia, may be reversed by IV isoproterenol.

Mechanism of Action: Isoproterenol is a potent activator of both beta$_1$- and beta$_2$-adrenergic receptors throughout the body.

Pharmacokinetics:

Route(s)	IV
Absorption	N/A
Distribution	Distributed to most tissues; it is unknown if it crosses the placenta or is secreted in breast milk
Primary metabolism	Hepatic by COMT
Primary excretion	Renal: 40–50% unchanged
Onset of action	Immediate
Duration of action	Less than 1 h

Adverse Effects: Adverse effects of isoproterenol are predictable based on its activation of beta-adrenergic receptors. Common adverse effects include headache, nausea, vomiting, and symptoms of CNS stimulation such as tremors, anxiety, and insomnia. Adverse effects affecting the heart include serious dysrhythmias.

Contraindications/Precautions: Because isoproterenol increases the myocardial workload, it should be used with extreme caution in patients with severe cardiac disease, dysrhythmias, or HTN. The drug should be used with caution in patients with hyperthyroidism or diabetes because these patients are more sensitive to the potential cardiac adverse effects.

Drug Interactions: Concurrent administration with a beta-adrenergic blocker diminishes the bronchodilation effect of isoproterenol and may induce bronchospasm in patients with asthma. Use with other bronchodilators or adrenergic agonists such as epinephrine or dopamine may result in additive effects. MAOIs and tricyclic antidepressants should be discontinued at least 2 weeks prior to isoproterenol therapy to avoid possible hypertensive crisis. Isoproterenol should not be concurrently administered with potassium-wasting diuretics because hypokalemia may result. Isoproterenol may lower serum levels of digoxin and induce dysrhythmias.

Pregnancy: Category C.

Treatment of Overdose: Overdose with isoproterenol will cause tachycardia and other dysrhythmias. Blood pressure usually falls. Due to the relatively short half-life of the drug, discontinuing the infusion is often enough to reverse symptoms, although supportive cardiac drugs may be necessary.

Nursing Responsibilities: Key nursing implications for patients receiving isoproterenol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Agonists.

Drugs Similar to Isoproterenol (Isuprel)

Beta-adrenergic agonists may be grouped into two primary subclasses: bronchodilators and tocolytics.

Bronchodilators: Albuterol (Proventil, Ventolin, VoSpire ER), levalbuterol (Xopenex), and pirbuterol (Maxair) are short-acting beta-adrenergic agonists given by inhalation to terminate acute bronchospasm. They are first-line drugs for terminating acute asthma attacks. Patients can be dosed every 20 to 30 minutes until control is achieved. Arformoterol (Brovana), formoterol (Foradil, Perforomist), indacaterol (Arcapta Neohaler), olodaterol (Striverdi Respimat), and salmeterol (Serevent) are also given by inhalation but the long onset of action of these drugs makes them unsuitable for relieving acute bronchospasm. The longer acting drugs are used in combination with inhaled corticosteroids in the pharmacotherapy of chronic asthma. In addition, formoterol and indacaterol are used in combination with glycopyrrolate in the symptomatic relief of COPD.

Albuterol and terbutaline are available in tablet form. Because the PO route results in more delayed onset of action, these drugs should not be used to terminate an asthma attack in progress. When given 15 minutes before exercise, albuterol may be used for the prophylaxis of exercise-induced bronchospasm. A complete discussion of bronchodilators may be found in Chapter 44.

Dobutamine: Dobutamine is a selective beta$_1$-adrenergic agonist that has value in the short-term treatment of certain types of shock due to its ability to cause the heart to beat more forcefully. Dobutamine is especially beneficial in cases where the primary cause of shock is related to heart failure, not hypovolemia. In fact, hypovolemia should be corrected before administering adrenergic agonists such as dobutamine. The resulting increase in cardiac output assists in maintaining blood flow to vital organs; renal blood flow is enhanced, and urine output increased. Dobutamine has a brief half-life of 2 minutes and is only given as an IV infusion. The patient should be monitored continuously during the infusion for abnormal changes in heart rate or rhythm. Dobutamine is a pregnancy category C drug.

Tocolytics: Terbutaline is a beta$_2$ agonist that relaxes uterine smooth muscle. Drugs used to delay preterm labor are called **tocolytics**. Although not approved by the FDA as a tocolytic, terbutaline is sometimes used off-label for this purpose. It is administered as an IV infusion, subcutaneous injection, or by a portable infusion pump programmed to deliver small amounts of the drug at prescribed intervals. Tocolytics may cause the fetus to experience transient tachycardia. Tocolytics are presented in greater detail in Chapter 69.

Beta$_3$-adrenergic agonists: The beta$_3$-adrenergic receptor has been known for about a decade but has largely been ignored as a pharmacologic target. This receptor is primarily located in adipose tissue and skeletal muscle, though it

has subsequently been found in the gallbladder and the urinary bladder. The first drug acting on the beta$_3$ receptor, mirabegron (Myrbetriq), is an oral drug approved in 2012 for the treatment of overactive bladder. The most commonly observed side effects are HTN, nasopharyngitis, urinary tract infection, and headache. This drug is pregnancy category C.

CONNECTION Checkpoint 15.4

A patient has severe bronchoconstriction due to an acute allergic attack. From what you learned in Chapter 3, which route of administration—oral, subcutaneous, or inhalation—would likely give the fastest onset of drug action for this patient? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Adrenergic Agonists

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, cerebrovascular, respiratory disease, or diabetes. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings such as hepatic or renal function studies.
- Obtain baseline vital signs, weight, electrocardiogram (ECG), and urinary and cardiac output as appropriate.
- For treatment of nasal congestion, assess the nasal mucosa for excoriation or bleeding prior to beginning therapy.
- Assess the patient's ability to receive and understand instructions. Include family and caregiver as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased ease of breathing, blood pressure [BP] within normal range, nasal congestion improved).
- Continue frequent and careful monitoring of vital signs and urinary and cardiac output as appropriate, especially if IV administration is used.
- Assess for and promptly report adverse effects: tachycardia, HTN, dysrhythmias, tremors, dizziness, headache, or decreased urinary output. Severe HTN, seizures, or angina may signal drug toxicity and are immediately reported.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. (Pulse, BP, and respiratory rate should be within normal limits or within the parameters set by the healthcare provider. Nasal congestion should be decreased, and reddened, irritated sclera improved.)	• Teach the patient, family, or caregiver how to monitor pulse and BP as appropriate. Ensure proper use and functioning of any home equipment, obtained using return demonstration or teach-back.
• Provide supportive nursing measures, e.g., proper positioning for dyspnea or shock. (Nursing measures such as raising the head of the bed during dyspnea will supplement therapeutic drug effects and optimize the outcome.)	• Teach the patient to report increasing dyspnea despite medication therapy, and to not take more than the prescribed dose unless instructed otherwise by the healthcare provider.
Minimizing adverse effects: • Monitor for signs of excessive autonomic nervous system (ANS) stimulation and notify the healthcare provider if BP or pulse exceeds established parameters. Continue frequent cardiac monitoring (e.g., ECG, cardiac output) and urine output if IV adrenergic agonists are given. (Because adrenergic drugs stimulate heart rate and raise BP, they must be closely monitored to avoid adverse effects. External and invasive monitoring devices will detect early signs of adverse effects as well as monitor for therapeutic effects. **Lifespan:** The older adult may be at greater risk due to previously existing cardiovascular disease. **Diverse Patients:** Research suggests African Americans may experience an impaired [diminished] vascular response to isoproterenol and vital signs should be monitored frequently during administration.)	• Instruct the patient to report palpitations, shortness of breath, chest pain, excessive nervousness or tremors, headache, or urinary retention immediately. • Teach the patient to limit or eliminate the use of caffeine-containing foods and beverages because these may cause excessive nervousness, insomnia, and tremors.
• Closely monitor the IV infusion site when using IV adrenergic agonists. All IV adrenergic drips should be given via infusion pump. (Blanching at the IV site is an indicator of extravasation with intense vasoconstriction. The IV infusion should be immediately stopped and the provider contacted for further treatment orders. Infusion pumps will allow precise dosing of the medication.)	• To allay possible anxiety, teach the patient the rationale for all equipment used and the need for frequent monitoring.
• Monitor oral and nasal mucosa and breath sounds in patients taking inhaled adrenergic drugs. (Inhaled epinephrine and other adrenergic drugs may reduce bronchial secretions, making removal of mucus more difficult.)	• Teach the patient to increase fluid intake to moisten airways and assist in the expectoration of mucus, unless contraindicated.
• Continue to monitor blood glucose level and appropriate laboratory values. (Adrenergic agonists affect a wide range of body systems. Patients with diabetes may need a change in diabetic medication or dosing if glucose remains elevated.)	• Teach patients with diabetes to monitor their blood glucose level more frequently and to notify the healthcare provider if a consistent increase is noted.
• Provide for eye comfort such as a darkened room, soft cloth over eyes, or sunglasses. Transient stinging after instillation of eyedrops may occur. (Adrenergic agonists can cause mydriasis and photosensitivity to light. Localized vasoconstriction may cause stinging of the eyes.)	• Instruct the patient that photosensitivity may occur and sunglasses may be needed in bright light or for outside activities. The provider should be notified if irritation or sensitivity occurs beyond 12 h after the drug has been discontinued. Soft contact lens users should check with the provider before using, as some solutions may stain lenses. • **Lifespan:** Assist the older adult with ambulation if blurred vision or light sensitivity occurs, to prevent falls.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Inspect nasal mucosa for irritation, rhinorrhea, or bleeding after nasal use. Avoid prolonged use of adrenergic nasal sprays. (Vasoconstriction may cause transient stinging, excessive dryness, or bleeding. Rebound congestion with chronic rhinorrhea may result after prolonged treatment.)	• Instruct the patient not to use nasal spray longer than 3–5 days without consulting the provider. OTC saline nasal sprays may provide comfort if mucosa is dry and irritated. Increasing oral fluid intake may also help with hydration. • **Lifespan:** Teach the family or caregiver that adrenergic nasal sprays and other decongestants are not recommended in children and should be used only under a provider's supervision.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug; appropriate dose and scheduling; what adverse effects to observe for and when to report them; equipment needed as appropriate and how to use that equipment; and the required length of medication therapy needed, with any special instructions regarding renewing or continuing the prescription as appropriate.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration of an inhaler, epinephrine autoinjector, nasal spray, or ophthalmic drops. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration techniques, followed by teach-back. Inhalation forms should be dispensed only when the patient is upright to properly aerosolize the drug and prevent overdosage from excessively large droplets.
	• Teach the patient, family, or caregiver proper technique for the autoinjection epinephrine device and to have on hand for emergency use at all times. If the autoinjector is needed and used, 911 and the healthcare provider should be called immediately after use. • Teach the patient, family, or caregiver to not share nasal sprays with other people to prevent infection. • The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 15

Key Concepts Summary

15.1 Adrenergic agonists activate the sympathetic nervous system to produce fight-or-flight symptoms.

15.2 Adrenergic agonists may act directly by binding to adrenergic receptors, or indirectly by increasing the amount of norepinephrine at synapses.

15.3 Adrenergic agonists may be classified as catecholamines or noncatecholamines.

15.4 The nonselective adrenergic agonists activate both alpha and beta receptors and are used to treat bronchospasm, cardiac arrest, and hypotension.

15.5 Alpha-adrenergic agonists are used to relieve nasal decongestion and elevate blood pressure.

15.6 Beta-adrenergic agonists are used to treat asthma, shock, heart failure, and other cardiac disorders.

CASE STUDY: Making the Patient Connection

Remember the patient "Alexia Howard" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Alexia Howard is a 22-year-old woman with a history of asthma since childhood. She is presently a student at the local university where she lives in a dormitory. Since the beginning of the semester, Alexia has experienced tremendous stress trying to manage school and part-time employment. Her roommate, an animal lover, has kept stray dogs and cats in their room several times during the past few months until she could find them good homes.

Today Alexia arrives at the University Health Center with tachypnea and acute shortness of breath with audible wheezing. She has not consistently taken her prescribed medications to avoid asthma attacks. A physical examination revealed a heart rate of 110 beats/min and a respiratory rate of 40 breaths/min with signs of accessory muscle use. Auscultation revealed decreased breath sounds with inspiratory and expiratory wheezing. The patient was coughing up small amounts of white sputum. Her saturated oxygen is 93% on room air.

An aerosol treatment with albuterol (Proventil) was ordered, using a small-volume nebulizer for 15 minutes. Peak flow measures after the treatment showed marked improvement of airflow. On auscultation there was clearing of bilateral breath sounds. Alexia's respiratory rate at the time of discharge was 20 breaths/min and her heart rate was 108 beats/min. The patient verbalized that she felt much better but a little nervous.

Alexia was discharged from the University Health Center. She was given a prescription for inhaled steroids and instructed to resume her home medications and use them consistently.

Critical Thinking Questions

1. Discuss the mechanism of action associated with albuterol (Proventil).
2. Why is albuterol being given to Alexia, and why is this route of administration being used?
3. What adverse effects is Alexia demonstrating as a result of the administration of albuterol (Proventil)?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Bill Jennings, a 55-year-old man, has been using an epinephrine inhaler for asthma for several months. He is attending a community health fair at a local church, and you are the nurse screening his blood pressure.

When you take Bill's blood pressure, you discover it is 172/94 mmHg. As you talk with him, the patient reveals that he is also self-medicating with OTC pseudoephedrine 60 mg 3 times per day for seasonal allergies. Bill says his blood pressure is usually 120/80 mmHg.

1. Explain why the increased blood pressure might be related to the drug combination.
2. What patient teaching should occur in this situation?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A patient who uses over-the-counter phenylephrine (Neo-Synephrine) nasal spray asks the nurse how the medication works. The nurse's response would be:
    1. "It helps to shrink the swelling in your nose by tightening the blood vessels there."
    2. "It works to locally destroy invading organisms that cause colds and flu."
    3. "It coats the nasal passages to reduce swelling."
    4. "It is absorbed after you swallow it to act as a decongestant."

2. The nurse is teaching the patient about the use of an adrenergic agonist nasal spray at home. What patient teaching is needed related to this medication? (Select all that apply.)
    1. Do not share the nasal spray with another individual.
    2. Use this drug only for 3 to 5 days unless directed otherwise by a healthcare provider.
    3. Symptoms of excessive use of this drug are lethargy and fatigue.
    4. Infants and children should not use this medication unless directed to do so by a healthcare provider.
    5. This drug can be safely used by individuals with diabetes.

3. The healthcare provider prescribes epinephrine (Adrenalin) to a patient who was stung by several wasps 30 minutes ago. The nurse knows that the primary purpose of this medication for this patient is to:
    1. Stop the systemic release of histamine produced by the mast cells.
    2. Counteract the formation of antibodies in response to an invading antigen.
    3. Increase the number of white blood cells produced to fight the primary invader.
    4. Increase a declining blood pressure and dilate constricting bronchi associated with anaphylaxis.

4. A patient takes a dose of albuterol (Ventolin) prior to bedtime. Which effect would the nurse consider normal for this drug?
   1. Insomnia
   2. Sleepiness
   3. Urticaria
   4. Tinnitus

5. To evaluate the effectiveness of high-dose dopamine, the nurse would assess the:
   1. Pupillary response.
   2. Blood pressure.
   3. Level of consciousness.
   4. Gag reflex.

6. A beta-adrenergic agonist is prescribed for each of the following conditions. A nurse would question the order for which condition? (Select all that apply.)
   1. Hyperthyroidism
   2. Asthma
   3. Shock
   4. Dysrhythmias
   5. Heart failure

Chapter 16
Adrenergic Antagonists

Chapter Outline

- Actions of Adrenergic Antagonists
- Alpha-Adrenergic Antagonists

  PROTOTYPE *Prazosin (Minipress), p. 205*
- Beta-Adrenergic Antagonists

  Nonselective Beta-Adrenergic Antagonists

  PROTOTYPE *Propranolol (Inderal, InnoPran XL), p. 208*

  Selective $Beta_1$-Adrenergic Antagonists

  PROTOTYPE *Metoprolol (Lopressor, Toprol XL), p. 211*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the physiologic responses produced when a drug blocks $alpha_1$-, $alpha_2$-, $beta_1$-, and $beta_2$-adrenergic receptors.
2. Identify indications for pharmacotherapy with $alpha_1$ and $alpha_2$-adrenergic antagonists.
3. Identify indications for pharmacotherapy with nonselective beta-adrenergic antagonists.
4. Identify indications for pharmacotherapy with selective $beta_1$-adrenergic antagonists.
5. Explain the advantages of selective beta antagonists versus nonselective beta antagonists.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with adrenergic antagonists.

Key Terms

adrenergic antagonists, 202
alpha-adrenergic antagonists, 202
beta-adrenergic antagonists, 206
first-dose phenomenon, 204
intrinsic sympathomimetic activity (ISA), 206
orthostatic hypotension, 204
pheochromocytoma, 204
Raynaud's disease, 204

Adrenergic antagonists inhibit the sympathetic nervous system and produce many of the same rest-and-digest symptoms as the cholinergic agonists. They have wide therapeutic applications in the management of hypertension (HTN), angina pectoris, myocardial infarction, and heart failure (HF). They also serve limited roles in the pharmacotherapy of benign prostatic hyperplasia, thyroid crisis, and glaucoma.

Actions of Adrenergic Antagonists

16.1 Adrenergic antagonists act by blocking the effects of norepinephrine at adrenergic receptors.

When the adrenergic receptor binds norepinephrine (NE), symptoms typical of the fight-or-flight response are induced. Drugs that activate these receptors are used to treat shock, cardiac arrest, nasal congestion, and asthma. If the student is not yet thoroughly familiar with the actions at the adrenergic receptor, Chapters 12 and 15 should be reviewed before continuing.

Adrenergic antagonists are drugs that compete with NE for adrenergic receptors, as shown in Figure 16.1. By blocking NE from reaching its receptors, symptoms of the fight-or-flight response are *prevented*. With reduced sympathetic activation, nerve impulses from the parasympathetic nervous system will predominate. In fact, most of the symptoms produced by adrenergic antagonists are those of parasympathetic activation. In other words, adrenergic antagonists and cholinergic agonists result in many of the same actions.

CONNECTION Checkpoint 16.1

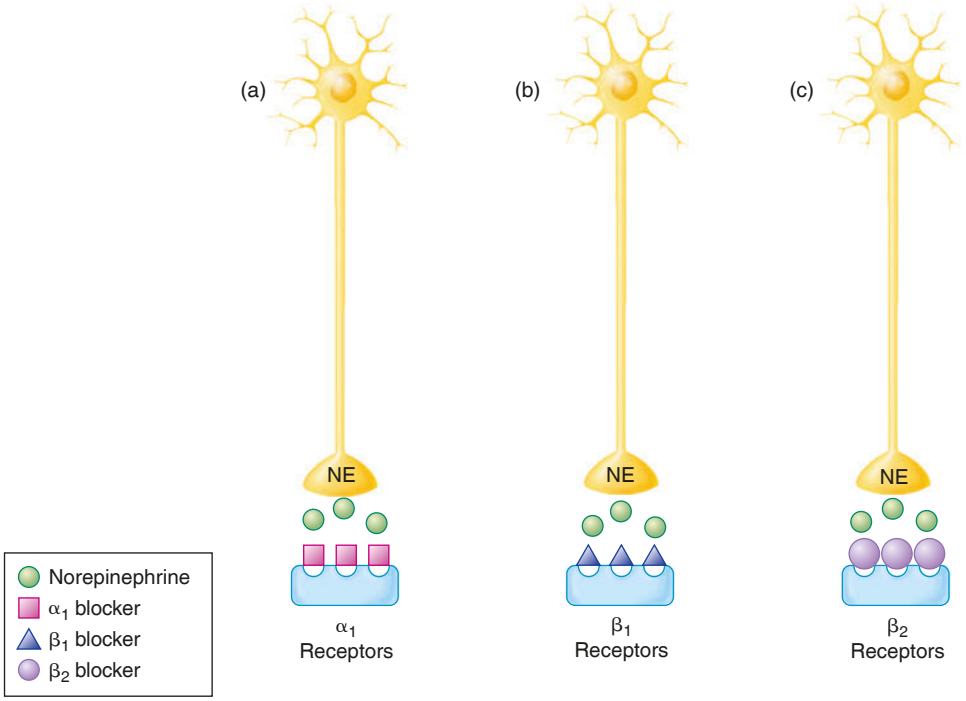
Although cholinergic agonists and adrenergic antagonists may produce similar physiologic actions, their indications are very different. From what you learned in Chapter 13, what are the primary indications for pharmacotherapy with cholinergic agonists?

Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.

The presence of the alpha- and beta-adrenergic receptor subtypes in the sympathetic nervous system allows for more specific pharmacologic responses. For example, with the adrenergic agonists, epinephrine activates both alpha and beta receptors, whereas albuterol activates only $beta_2$ receptors. The same type of division occurs with adrenergic antagonists. Actions of these drugs are specific to either alpha blockade or beta blockade. Beta blockade is further divided into those drugs that inhibit both $beta_1$ and $beta_2$ receptors and those that selectively inhibit only $beta_1$ receptors. The therapeutic uses and adverse effects of each drug are dependent on which receptor subtype is activated.

Adrenergic antagonists have wide therapeutic application. They are the most frequently prescribed class of autonomic drugs. Most of their therapeutic applications relate to the cardiovascular system.

Alpha-Adrenergic Antagonists



16.2 $Alpha_1$-adrenergic antagonists are used to treat hypertension and benign prostatic hyperplasia.

Alpha-adrenergic receptors are primarily located on smooth muscle, and their activation results in contraction. Most blood vessels, including those serving the myocardium, genitourinary (GU) system, gastrointestinal (GI) system, and brain, have alpha receptors. Because of their key locations on arterial smooth muscle, the most important effects of **alpha-adrenergic antagonists**, or alpha blockers, are on the cardiovascular system. Blockade of alpha receptors will dilate blood vessels, thus lowering blood pressure.

The specific actions of each alpha-adrenergic antagonist depend on its degree of selectivity for $alpha_1$ or $alpha_2$ receptors. Drugs selective for $alpha_1$ receptors have greater therapeutic application and are listed in Table 16.1. The selective $alpha_1$ blockers doxazosin (Cardura), prazosin (Minipress), and terazosin have very similar actions, indications, and adverse effects.

Phentolamine (Regitine) and phenoxybenzamine (Dibenzyline) are the only alpha blockers that are nonselective, activating both $alpha_1$ and $alpha_2$ receptors. These drugs have very limited usefulness because they exhibit a high incidence of adverse effects, such as hypotension, tachycardia, nausea, vomiting, and diarrhea.

Selective $alpha_1$ antagonists are primarily used to treat HTN. Their most significant action is blocking vasoconstriction in arterioles and veins, which decreases peripheral resistance. Their ability to block $alpha_1$ receptors on

	α_1 Receptors	β_1 Receptors	β_2 Receptors
Pharmacologic Effects	Inhibition of ejaculation Pupil constriction Relaxation of smooth muscles in prostate and bladder neck Vasodilation	Decreased force of cardiac contraction Decreased heart rate Slowed cardiac conduction	Bronchoconstriction Increased intestinal motility Uterine contraction
Indications	Benign prostatic hyperplasia Hypertension Raynaud's disease	Angina pectoris Heart failure Hypertension Myocardial infarction	Dysrhythmias Glaucoma Heart failure Hypertension Migraine Myocardial infarction

Figure 16.1 Pharmacologic effects and indications of adrenergic antagonists: (a) blockade of alpha$_1$ receptors; (b) blockade of beta$_1$ receptors; (c) blockade of beta$_2$ receptors.

Table 16.1 Alpha-Adrenergic Antagonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
alfuzosin (Uroxatral)	PO: 10 mg once daily	*Orthostatic hypotension, dizziness, headache, fatigue* First-dose phenomenon, tachycardia, dyspnea
doxazosin (Cardura)	PO: 1 mg/day; may increase to 16 mg/day in 1–2 divided doses (max: 16 mg/day)	
phenoxybenzamine (Dibenzyline)	PO: Initially 10 mg bid, may increase by 10 mg at 4-day intervals to 20–40 mg bid or tid	
phentolamine (Regitine)	IV/IM: 5 mg 1–2 h prior to surgery; repeat as needed Intradermal: 5–10 mg diluted in 10 mL of normal saline injected into the affected area within 12 h of catecholamine extravasation	
prazosin (Minipress)	PO: 1 mg/day; may increase to 1 mg bid–tid (max: 20 mg/day)	
silodosin (Rapaflo)	PO: 8 mg once daily	
tamsulosin (Flomax)	PO: 0.4–0.8 mg/day (max: 0.8 mg/day)	
terazosin	PO: 1–5 mg/day (max: 20 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

arterial smooth muscle lowers blood pressure directly. Their ability to dilate veins lowers blood pressure indirectly by decreasing venous return to the heart. This reduces cardiac output, resulting in a reduction in systemic blood pressure. When used to treat HTN, the alpha blockers are often administered concurrently with other classes of antihypertensives, such as diuretics (see Chapter 32).

In addition to dilating vascular smooth muscle, alpha$_1$ blockers relax smooth muscle in the trigone and sphincter muscles at the base of the urinary bladder and in the prostate. Relaxation of these muscles promotes an increase in urine flow in patients who have difficulty voiding due to strictures in this region. This action has resulted in the use of alpha blockers in the treatment of benign prostatic hyperplasia (BPH), a nonmalignant condition in which the prostate gland enlarges to restrict urine flow through the urethra. These drugs increase urine flow and decrease residual urine volume in patients with BPH. Selective alpha$_1$ antagonists used for this indication include alfuzosin (Uroxatral), doxazosin (Cardura), silodosin (Rapaflo), tamsulosin (Flomax), and terazosin. Alpha$_1$ blockers do not cure this disorder, and patients with moderate to severe BPH usually require surgery to correct the restriction in urinary flow. A complete discussion on the pharmacotherapy of BPH is found in Chapter 71.

Alpha$_1$ antagonists are occasionally used to treat pheochromocytoma and Raynaud's disease. **Pheochromocytoma** is a tumor, usually benign, arising from the adrenal medulla that is characterized by excessive secretion of catecholamines. A patient with a pheochromocytoma will exhibit extreme HTN, palpitations, dyspnea, anxiety, and profuse sweating. All are signs of excessive amounts of catecholamines. Although surgical removal is the usual treatment, alpha$_1$-receptor antagonists may be administered to block the peripheral vascular effects of natural (endogenous) catecholamines. This reduces the profound HTN in patients who are high surgical risks.

In **Raynaud's disease**, vasospasms of vessels serving the fingers and toes can lead to intermittent pain and cyanosis of the digits. Emotional stress or cold temperatures usually exacerbate the disorder. The primary treatment is nonpharmacologic: warming techniques and avoidance of cold. For those who require pharmacotherapy, administration of alpha$_1$ antagonists can diminish the vasospasm and bring symptomatic relief. Long-acting calcium channel blockers (see Chapter 30) such as nifedipine (Procardia XL) are also used to relieve Raynaud's vasospasms.

PharmFACT

Raynaud's disease is more common in women than men and can occur secondary to other diseases, usually autoimmune disorders. For example, 90% of individuals with scleroderma also develop Raynaud's disease. Systemic lupus erythematosus may also occur concurrently with Raynaud's phenomenon (Hansen-Dispenza, 2016).

The adverse effects of alpha$_1$ antagonists are predictable based on their mechanism of action. When the sympathetic nervous system is blocked, parasympathetic tone will predominate; thus most of the significant adverse effects of alpha blockers are due to increased parasympathetic activity.

The limiting adverse effect of pharmacotherapy with alpha$_1$ antagonists is hypotension. The vasodilation caused by alpha$_1$ blockers is more intense when the patient is upright, as compared to recumbent. Significant **orthostatic hypotension** can occur when the patient abruptly changes from a recumbent to an upright position, resulting in diminished blood flow to the brain. Much of this effect is caused by blockade of alpha$_1$ receptors in the veins. As the patient moves to an upright position, blood accumulates in the veins, cardiac output decreases, and blood pressure falls. Orthostatic hypotension is especially pronounced at the beginning of pharmacotherapy and when increasing the dose. This adverse effect is called the **first-dose phenomenon**. Because the first-dose phenomenon can cause syncope due to reduced blood flow to the brain, initial therapy is begun with low doses, usually administered at bedtime.

The fall in blood pressure during alpha$_1$-antagonist therapy may be accompanied by reflex tachycardia, which occurs when the baroreceptor reflex is triggered. Reflex tachycardia can be particularly troublesome in patients who are susceptible to dysrhythmias. A beta-adrenergic antagonist is sometimes administered concurrently with alpha blockers to reduce the risk of reflex tachycardia. A less serious, though annoying, adverse effect of alpha antagonists is nasal congestion, which is caused by vasodilation of blood vessels serving the nasal mucosa.

A number of noncardiovascular adverse effects may also occur during alpha$_1$-blocker pharmacotherapy. Because smooth muscle contraction is inhibited in the vas deferens and ejaculatory ducts, these drugs can cause an inability to ejaculate during intercourse. This is a major cause for discontinuation of alpha-antagonist therapy in sexually active men. Increased smooth muscle activity in the GI tract may cause nausea, vomiting, or abdominal cramping. Incontinence or increased urinary frequency may occur due to more active smooth muscle contractions in the urinary tract. These medications cross the blood–brain barrier and can cause central nervous system (CNS) effects such as depression, lethargy, and vivid dreams. Alpha blockers increase urinary metabolites of vanillylmandelic acid (VMA) and NE, which can result in false-positive test results for pheochromocytoma.

Although a few drugs selectively block alpha$_2$-adrenergic receptors, they currently have no clinical application. Yohimbine, approved by the U.S. Food and Drug Administration (FDA) in 1938 for the treatment of erectile dysfunction, selectively blocks alpha$_2$ receptors but is not prescribed for this purpose today due to the availability of safer and more effective drugs. Yohimbe (converted to yohimbine in the body) is a natural product obtained from the bark of a West African tree and may be purchased by patients over the counter (OTC) as an herbal supplement. Claims that

this herb is a sexual stimulant or aphrodisiac have not been supported by controlled research studies.

PROTOTYPE DRUG **Prazosin (Minipress)**

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Selective alpha$_1$-adrenergic antagonist

Therapeutic Effects and Uses: The primary therapeutic action of prazosin is a rapid decrease in peripheral resistance that reduces blood pressure. The drug has very little effect on cardiac output or heart rate and it causes less reflex tachycardia than some other drugs in this class. Approved in 1976, its most common use is in combination with other drugs, such as beta blockers or diuretics, in the pharmacotherapy of HTN. Optimal therapeutic effects may require 4 to 6 weeks of therapy. Off-label indications include symptomatic BPH, treatment of Raynaud's disease, and hypertensive emergencies associated with pheochromocytoma. An additional off-label use of prazosin is to treat sleep disturbances and nightmares related to post-traumatic stress disorder (PTSD). Prazosin has a relatively short half-life that requires it to be administered 2 to 3 times per day.

Mechanism of Action: Prazosin competes with NE at alpha-adrenergic receptors on vascular smooth muscle in arterioles and veins. It is selective for alpha$_1$-adrenergic receptors and has no activity at alpha$_2$- or beta-adrenergic receptors.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Completely distributed; small amounts secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Primarily bile and feces, with small amounts by the kidneys
Onset of action	2 h
Duration of action	Less than 24 h

Adverse Effects: The most common adverse effects of prazosin include dizziness, drowsiness, fatigue, weakness, palpitations, orthostatic hypotension, and headache. Nausea, vomiting, and other GI effects occur in about 5% of patients. Most patients develop tolerance to these adverse effects as therapy progresses. The first-dose phenomenon may cause syncope. Erectile dysfunction, including priapism, is rare but can present a barrier to patient adherence.

Contraindications/Precautions: The only contraindication to the use of prazosin is prior sensitivity to the drug. The drug should be used with caution in older patients and those with renal impairment because these groups tend to exhibit more pronounced orthostatic hypotension and syncope. Patients with coronary artery disease should be treated with caution because prazosin may worsen angina symptoms in these patients.

Drug Interactions: Additive hypotensive effects may occur when prazosin is used concurrently with other antihypertensives and diuretics. This additive effect is used to advantage in the pharmacotherapy of HTN, in which the dose of each individual drug may be lower than if a single drug were used as monotherapy. Ingestion of alcohol or use with erectile dysfunction drugs such as sildenafil (Viagra) may cause increased hypotension. Use with sympathomimetics having alpha-agonist activity will antagonize the therapeutic effects of prazosin. **Herbal/Food:** Hawthorn may cause an additive drop in blood pressure when used with antihypertensive drugs such as prazosin.

Pregnancy: Category C.

Treatment of Overdose: Overdose will lead to hypotension and possibly sudden loss of consciousness; thus it is important to keep the patient supine. Fluid expanders may be administered to raise blood pressure, and renal function should be monitored. Vasopressors such as levarterenol or dopamine may be necessary to increase blood pressure. Drowsiness may also be prominent.

Nursing Responsibilities: Key nursing implications for patients receiving prazosin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Antagonists.

Drugs Similar to Prazosin (Minipress)

Other alpha-adrenergic blockers used for HTN include doxazosin, phenoxybenzamine, phentolamine, silodosin, and terazosin. Two alpha-adrenergic blockers, alfuzosin and tamsulosin, are indicated only for BPH.

Alfuzosin (Uroxatral): Alfuzosin was approved in 2003 to treat BPH as an extended release tablet that permits once-daily dosing. Both tamsulosin and alfuzosin relax smooth muscle in the bladder and prostate gland, which reduces pressure on the urethra, thus enhancing urine flow. The drug is well tolerated, with the most common adverse effects being dizziness, fatigue, headache, and upper respiratory infection. Hypotension may be a serious problem in patients taking antihypertensive drugs or erectile dysfunction drugs such as sildenafil (Viagra). Caution should be used in patients with moderate or severe hepatic or renal impairment. This drug is pregnancy category B.

Doxazosin (Cardura): Approved in 1990, doxazosin is an oral drug used to treat both HTN and BPH. It has the longest duration of action of the selective alpha$_1$ blockers, allowing for once-daily dosing. The most frequent adverse effects are dizziness, fatigue, headache, and edema.

Orthostatic hypotension occurs in about 10% of patients taking the drug, especially when therapy is initiated or with changes in dose. Patients who ingest alcohol or use this drug with erectile dysfunction drugs such as sildenafil (Viagra) may experience increased hypotension. The drug should be used cautiously in older adults because they tend to experience more hypotension-related adverse effects. Doxazosin should be taken at bedtime to avoid the first-dose phenomenon. This drug is pregnancy category B.

Phenoxybenzamine (Dibenzyline): Phenoxybenzamine is an older drug, approved in 1954, that blocks both alpha$_1$- and alpha$_2$-adrenergic receptors. The drug has a very prolonged duration of action, and its effects may last up to a week after the drug is discontinued. Because it has the potential to cause extended alpha blockade and serious cardiovascular adverse effects, its use is limited to managing the HTN caused by pheochromocytoma. Off-label indications include symptomatic BPH, Raynaud's disease, and frostbite. The drug is pregnancy category C.

Phentolamine (Regitine): Like phenoxybenzamine, phentolamine blocks both alpha$_1$ and alpha$_2$ receptors. Approved in 1952, it is the only alpha blocker that is given parenterally. Phentolamine may be administered to treat or prevent hypertensive crises during surgical removal of pheochromocytomas. Phentolamine is considered an antidote for treating hypertensive emergencies caused by catecholamine overdose. The drug may be injected subcutaneously to prevent or treat dermal necrosis or sloughing caused by extravasation of catecholamines such as NE and dopamine. Although the drug has been used in the past to diagnose pheochromocytoma, safer measures such as urinary or blood assays of catecholamine levels are more accurate indicators of this disease. This drug is pregnancy category C.

Silodosin (Rapaflo): Approved in 2008, silodosin is a selective alpha$_1$-adrenergic antagonist that is indicated for the management of BPH. The most common adverse effects are retrograde ejaculation, dizziness, diarrhea, orthostatic hypotension, headache, nasopharyngitis, and nasal congestion. It should be taken with food to lessen the risk of adverse effects. This drug is pregnancy category B.

Tamsulosin (Flomax): Like alfuzosin and silodosin, tamsulosin has only one indication: BPH. Approved in 1997, it is administered orally (PO) and should be taken with food to reduce the incidence of orthostatic hypotension. The drug is generally well tolerated and exhibits adverse effects similar to other alpha blockers. Significant numbers of patients may experience headache, rhinitis, and orthostatic hypotension. Tamsulosin is extensively metabolized by hepatic CYP enzymes and may interact with drugs that are inducers or substrates of these enzymes. This drug is pregnancy category B.

Terazosin: Approved in 1987, terazosin has a long duration of action and is indicated for both HTN and symptomatic BPH. Given PO, its prolonged half-life permits once-daily dosing. Common adverse effects include dizziness and fatigue. Tolerance develops to most adverse effects as therapy progresses. Like other drugs in this class, terazosin should be taken at bedtime to avoid the first-dose phenomenon. Older adults are more sensitive to the hypotensive and adverse effects of terazosin, such as dry mouth and drowsiness. The drug is pregnancy category C.

Beta-Adrenergic Antagonists

16.3 Nonselective beta-adrenergic antagonists affect both beta$_1$ and beta$_2$ receptors and are prescribed for HTN, angina, and other cardiovascular disorders.

Beta-adrenergic antagonists, or beta blockers, are classified as nonselective or selective. Nonselective beta-adrenergic antagonists, such as propranolol, block both beta$_1$ and beta$_2$ receptors. Selective drugs that block only beta$_1$ receptors are sometimes called cardioselective agents and are discussed in Section 16.4.

Some beta blockers, such as carvedilol (Coreg), also have some alpha-antagonist activity, which adds to their ability to lower blood pressure. A few beta blockers such as pindolol (Visken) exhibit mixed beta-antagonist and beta-agonist activity. This low level of beta-agonist activity is called **intrinsic sympathomimetic activity (ISA)**. Theoretically, the agonist action of these drugs may result in fewer adverse effects in patients who have bradycardia, HF, or compromised pulmonary function. Regardless of their receptor specificity, most therapeutic applications of the beta blockers relate to their effects on the cardiovascular system (Table 16.2).

Because their mechanism of action is to antagonize the effects of endogenous catecholamines, all beta blockers have the potential to reduce the heart rate (negative chronotropic effect), decrease the force of myocardial contraction (negative inotropic effect), and slow conduction velocity through the atrioventricular node (negative dromotropic effect). These effects are modest when the heart is at rest. During periods of stress or exercise, however, beta blockers tend to prevent the normal increase in sympathetic stimulation to the heart, which is supposed to bring more blood flow to this organ. In some cases, this results in an undesirable short-term decrease in cardiac output, and the sympathetic nervous system responds by activating alpha receptors and raising blood pressure. In time, peripheral resistance returns to normal or below-normal levels, particularly in patients with HTN, and blood pressure falls.

Table 16.2 Beta-Adrenergic Antagonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Selective Beta$_1$-Adrenergic Antagonists		
acebutolol (Sectral)	PO: 200–800 mg/day in divided doses (max: 1200 mg/day)	*Fatigue, insomnia, diarrhea, constipation, drowsiness, impotence or decreased libido, hypotension, bradycardia, confusion* Bronchospasm, Stevens–Johnson syndrome, anaphylaxis, worsening of HF; if the drug is abruptly withdrawn, palpitations, rebound HTN, dysrhythmias, MI
atenolol (Tenormin)	PO: 25–50 mg daily (max: 100 mg/day)	
betaxolol	PO: 10–20 mg daily (max: 40 mg/day)	
bisoprolol	PO: 2.5–5 mg once daily (max: 20 mg/day)	
esmolol (Brevibloc)	IV: 500 mcg/kg loading dose followed by 50 mcg/kg/min; may increase dose every 5–10 min (max: 200 mcg/kg/min)	
metoprolol (Lopressor, Toprol XL)	PO: 12.5–20 mg once daily (max: 200 mg/day for HF; 400 mg/day for HTN or angina)	
nebivolol (Bystolic)	PO: 5 mg once daily (max: 40 mg)	
Alpha$_1$ and Beta Blockers (Centrally Acting)		
nadolol (Corgard)	PO: 40 mg once daily (max: 240–320 mg/day)	*Headache, dizziness, fatigue, drowsiness, anxiety, depression, lethargy, impotence, peripheral vascular insufficiency, hypoglycemia* Bradycardia, bronchospasm, laryngospasm, respiratory disturbances, may worsen HF and mask symptoms of hypoglycemia, Stevens–Johnson syndrome (propranolol), toxic epidermal necrolysis (propranolol), exfoliative dermatitis (propranolol), dysrhythmias (sotalol)
penbutolol (Levatol)	PO: 10–20 mg/day (max: 80 mg/day)	
pindolol (Visken)	PO: 5 mg bid (max: 60 mg/day)	
propranolol (Inderal, InnoPran XL)	PO (extended release): 80–120 mg once daily IV: 0.5–3 mg q4h prn for dysrhythmias	
sotalol (Betapace, Sorine)	PO: Initial dose of 80 mg bid (max: 320 mg/day)	
timolol	PO: 10 mg bid (max: 60 mg/day for HTN)	
Mixed Alpha$_1$- and Beta-Adrenergic Antagonists		
carvedilol (Coreg)	PO (immediate release): start with 3.125 mg bid (max: 50 mg/day) PO (extended release): start with 10–20 mg once daily (max: 80 mg/day)	Same as the above two classes
labetalol (Trandate)	PO: 100 mg bid (max: 2400 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

The primary use of beta-adrenergic antagonists is the treatment of HTN. The following multiple mechanisms are believed to contribute to their antihypertensive effect:

- Diminished myocardial contractility decreases cardiac output.
- The release of renin by the kidney, normally stimulated by catecholamines, is prevented.
- The nonselective adrenergic antagonists block alpha$_1$-adrenergic receptors, relaxing arteriolar smooth muscle.
- Central actions reduce sympathetic output from the vasomotor center in the brain.

The student should refer to Chapter 34 for additional details on the use of beta blockers in HTN management.

Beta-adrenergic antagonists have several other important applications, although they are not always first-line drugs for these conditions. By decreasing cardiac workload and oxygen demand, beta blockers can ease the acute chest pain characteristic of angina pectoris (see the prototype feature for atenolol in Chapter 35). Because they slow cardiac conduction, beta blockers are used in the pharmacotherapy of certain types of dysrhythmias (see Chapter 37). Some nonselective beta blockers have the ability to reduce intraocular pressure when given as ophthalmic solutions in the pharmacotherapy of glaucoma (see Chapter 74). Other

CONNECTIONS: Treating the Diverse Patient

Ethnic Differences in Antihypertensive Response

One of the largest clinical trials of drug therapy for hypertensive disease, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) (Gupta et al., 2010) noted differences in response to antihypertensive drugs among Whites, Blacks, and Asian Americans. Although Blacks experienced less of a response to the use of a beta blocker (atenolol) than other patients, adding a diuretic increased the blood pressure–lowering effects. Asian Americans experienced a greater antihypertensive effect when an ACE inhibitor (perindopril) was added to the medication routine.

Subsequent studies have supported the original findings and drugs used, with a thiazide diuretic being a first-line drug for most patients (Alderman et al., 2016). In addition to blood pressure control, it has also been noted that the use of lisinopril, one of the drugs in the study, reduced the risk of conduction system disease (Dewland et al., 2016).

Because most patients with HTN may need more than one drug to adequately control their blood pressure, different ethnic groups will respond differently to the various drug categories and "one size does *not* fit all."

therapeutic uses include the treatment of HF (see Chapter 36), myocardial infarction (MI) (see Chapter 35), and migraine prophylaxis (see Chapter 25). Beta blockers such as propranolol have been used off-label to treat the anxiousness, sweating, and tachycardia associated with stage fright and PTSD.

Pharmacotherapy with nonselective beta antagonists usually produces more adverse effects than treatment with selective $beta_1$ antagonists. Because of this, the use of the nonselective drugs has diminished. One of the more serious adverse effects with the nonselective beta blockers is that inhibition of $beta_2$ receptors in the lung can cause bronchoconstriction, which can result in acute shortness of breath, in patients with chronic obstructive pulmonary disease (COPD) or asthma.

The metabolic effects of beta-adrenergic antagonists can be important for patients with diabetes mellitus. Under normal conditions, catecholamines break down glycogen, which frees glucose to enter the blood to be used as an energy source. Many body tissues, particularly skeletal muscles, must receive a continuous source of glucose, especially during prolonged physical activity or heavy exercise. Beta blockers prevent this hyperglycemic effect of the catecholamines, and patients with diabetes may develop hypoglycemia. In addition, beta blockers will prevent tachycardia, an important warning sign of impending hypoglycemia. Beta-blocker therapy in patients with diabetes must be carefully monitored.

A second metabolic effect of nonselective beta-adrenergic antagonists relates to lipid metabolism. Catecholamines normally stimulate lipolysis, the breakdown of stored lipid in adipose tissue, resulting in the release of free fatty acids into the blood. Like glucose, these fatty acids serve as an essential energy source for skeletal muscle. By blocking the actions of catecholamines, beta antagonists decrease the amount of free fatty acids available during periods of metabolic stress. Nonselective beta blockers may also increase serum triglycerides and decrease high-density lipoproteins. During the course of therapy with beta blockers, patients with preexisting lipid disorders should have their lipid profiles monitored periodically to prevent hyperlipidemia.

Overdoses with nonselective beta blockers are potentially serious and treatment involves maintaining or restoring cardiovascular function. An anticholinergic such as atropine or a beta-adrenergic agonist such as isoproterenol may be administered to reverse severe bradycardia and cause bronchodilation. Cardiac failure caused by beta-antagonist overdose may be treated by administering digoxin (Lanoxin) or diuretics. Severe hypotension may require the administration of a vasopressor such as epinephrine or NE.

Beta blockers should always be withdrawn gradually over several weeks. If discontinued abruptly, the heart displays hypersensitivity to catecholamines, resulting in sweating, palpitations, headache, and tremors. This phenomenon is called *rebound cardiac excitation*. Some of the beta blockers have a black box warning to discontinue the drug gradually because patients with coronary artery disease may experience a worsening of angina symptoms, or MIs may occur.

PROTOTYPE DRUG Propranolol (Inderal, InnoPran XL)

Classification **Therapeutic:** Antihypertensive, antidysrhythmic
Pharmacologic: Nonselective beta-adrenergic blocker

Therapeutic Effects and Uses: Approved in 1967, propranolol reduces heart rate and slows conduction velocity through the atrioventricular (AV) node by blocking $beta_1$ receptors in cardiac muscle. The decrease in cardiac output, as well as its suppression of renin activity, results in a reduction in blood pressure. Cardiac workload and myocardial oxygen demand are decreased due to the slower heart rate and decreased cardiac output. Propranolol is prescribed for a wide variety of indications (some off-label), including the following:

- **Hypertension.** For the treatment of HTN, propranolol has largely been replaced by angiotensin-converting enzyme (ACE) inhibitors and calcium channel blockers, which are more effective at preventing the long-term consequences of HTN such as stroke and MI. Propranolol is still widely used in patients with HTN who have angina, prior MI, or heart failure.
- **Angina pectoris.** Beta blockers are the preferred drugs for treating chronic angina. The nonselective drugs such as propranolol are less frequently used than the cardioselective agents.
- **Dysrhythmias.** Propranolol is one of the few beta-adrenergic antagonists approved to treat dysrhythmias. As an antidysrhythmic, propranolol is most effective at preventing tachycardia caused by excessive sympathetic stimulation.
- **Migraine prophylaxis.** Propranolol has been one of the most frequently prescribed drugs for the prevention of migraines.
- **Prophylaxis of MI.** When given following an MI, propranolol reduces cardiovascular mortality and the risk of reinfarction.

Propranolol has a number of other indications. By lowering venous pressure, it may be useful in reducing portal HTN and bleeding due to esophageal varices. Propranolol is sometimes used to reduce the tachycardia, palpitations, tremor, and nervousness associated with thyroid crisis (storm). It has been used to treat panic attacks, PTSD,

chronic agitation, and aggressive behavior. Lastly, it has been used to manage involuntary, rhythmic movements of essential tremor.

Both immediate release and extended release forms of propranolol are available. InnoPran XL has a timed delivery system that is designed for bedtime dosing, with a peak effect in the morning.

Mechanism of Action: Propranolol is a nonselective beta-adrenergic antagonist, affecting both $beta_1$ receptors in the heart, and $beta_2$ receptors in the lung and other locations throughout the body. It has no ISA.

Pharmacokinetics:

Route(s)	Usually PO; IV for severe dysrhythmias
Absorption	Completely absorbed
Distribution	Widely distributed, including the CNS and placenta; secreted in breast milk; 90% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	90–95% renal
Onset of action	PO: 1–2 h; IV: immediate
Duration of action	Half-life: 3–5 h

Adverse Effects: Propranolol is well tolerated and common adverse effects, such as nausea, vomiting, and diarrhea, generally diminish as therapy progresses. Other frequent adverse effects include fatigue, insomnia, drowsiness, bradycardia, and confusion. Impotence or loss of libido occurs in a small percentage of patients. Serious adverse effects include agranulocytosis, bronchospasm, Stevens–Johnson syndrome, and anaphylaxis. If the drug is abruptly withdrawn, palpitations, rebound HTN, life-threatening dysrhythmias, or myocardial ischemia may occur. **Black Box Warning:** Abrupt withdrawal is not advised in patients with angina or heart disease. Dosage should gradually be reduced over 1 to 2 weeks and the drug should be reinstituted if angina symptoms develop during this period.

Contraindications/Precautions: Because of its depressive effects on the heart, propranolol is contraindicated in cardiogenic shock, sinus bradycardia, greater than first-degree heart block, and severe HF. Patients with cardiac impairment must be monitored carefully to prevent worsening of their condition. Due to its constriction of smooth muscle in the airways, the drug is contraindicated in patients with COPD or asthma. Propranolol should be used cautiously in patients with diabetes because it interferes with glucose metabolism and can cause hypoglycemia. The drug can also mask signs of impending hypoglycemia such as tachycardia and tremors. Propranolol should be used with caution in patients with reduced renal output, because the drug may accumulate to toxic levels in the blood and cause dysrhythmias.

Drug Interactions: Propranolol interacts with many other drugs. When given with other beta blockers, effects on the cardiovascular system may be additive and bradycardia or hypotension may result. Because both propranolol and calcium channel blockers such as verapamil (Calan) and diltiazem (Cardizem) suppress myocardial contractility, concurrent use may lead to additive bradycardia. Use with antidysrhythmic drugs that slow conduction through the AV node such as amiodarone may lead to AV block. Phenothiazines can add to the hypotensive effects of propranolol. Because monoamine oxidase (MAO) inhibitors deplete endogenous catecholamines, concurrent administration with propranolol could result in severe bradycardia and hypotension.

Use of ethanol or antacids containing aluminum hydroxide gel will slow the absorption of propranolol and reduce its therapeutic effects. Administration of beta-adrenergic agonists such as albuterol (Proventil) will antagonize the antihypertensive action of propranolol. **Herbal/Food:** Hawthorn may cause an additive drop in blood pressure when used with antihypertensive drugs such as propranolol. Large doses of vitamin C may reduce the absorption of propranolol.

Pregnancy: Category C.

Treatment of Overdose: Overdose will cause bradycardia, hypotension, and bronchospasm. Treatment may require the use of plasma volume expanders or vasopressors to raise blood pressure to normal levels and atropine to counteract the bradycardia. Isoproterenol (a beta agonist) may be administered to reverse bronchospasm.

Nursing Responsibilities: Key nursing implications for patients receiving propranolol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Antagonists.

Drugs Similar to Propranolol (Inderal, InnoPran XL)

Many beta blockers are available. All nonselective beta-adrenergic blockers have the same actions but differ in their pharmacokinetics and therapeutic applications. Those prescribed for glaucoma, including betaxolol, carteolol, levobunolol, metipranolol, and timolol, are discussed in Chapter 74.

Carvedilol (Coreg): Approved in 1995, carvedilol is a PO medication approved for the management of HTN and HF and to reduce mortality in patients who have survived the acute phase of an MI. It may be used off-label to treat angina. In addition to being a nonselective beta-receptor

blocker, carvedilol blocks alpha$_1$-adrenergic receptors. Because of its alpha-antagonist action, carvedilol shares similar adverse effects, such as orthostatic hypotension, with the alpha$_1$ blockers. Like most beta blockers, fatigue and dizziness are common adverse effects. Patients with asthma or chronic lung disorders may experience dyspnea or wheezing due to the bronchoconstriction effects of the drug. This drug is pregnancy category C.

Labetalol (Trandate): Like carvedilol, labetalol has nonselective beta-blocking action as well as the ability to selectively block alpha$_1$-adrenergic receptors. Approved in 1984, it is available by both the oral and IV routes for the therapy of HTN. When treating HTN, the drug may be given concurrently with a thiazide diuretic. The most common adverse effects are generally mild and include insomnia, drowsiness, fatigue, decreased libido, and tingling of the scalp. Orthostatic hypotension is greatest 2 to 4 hours after the drug is administered. When given by the IV route for hypertensive emergencies, as many as 60% of patients will experience orthostatic hypotension. This drug is pregnancy category C.

Nadolol (Corgard): Approved in 1989, nadolol is a nonselective beta-adrenergic blocker that is used to treat HTN and for the long-term management of angina. Off-label uses of nadolol include suppression of ventricular dysrhythmias, migraine prophylaxis, treatment of essential tremor, and anxiety. Given by the oral route, it has a long half-life of 20 to 24 hours, which offers the benefit of once-daily dosing. Unlike many beta blockers, it is not metabolized by the liver and is excreted mostly unchanged by the kidneys. Adverse effects are generally mild and similar to those of propranolol and include drowsiness, fatigue, and decreased libido. This drug is pregnancy category C.

Penbutolol (Levatol): Penbutolol is a nonselective beta-adrenergic antagonist that has a long duration of action, which offers the benefit of once-daily dosing. Approved in 1987, it is used in the pharmacotherapy of HTN as monotherapy, or in combination with other antihypertensives. Treatment of chronic stable angina is an off-label use of penbutolol. The drug has higher lipid solubility than most other drugs in its class and thus has a greater potential for causing CNS adverse effects such as dizziness and fatigue. Other common adverse effects include nausea, vomiting, and diarrhea. The drug is pregnancy category C.

Pindolol (Visken): Approved in 1982, pindolol is an oral, nonselective beta blocker that is used in the pharmacotherapy of HTN, usually in combination with a thiazide diuretic. It is used off-label for the management of chronic stable angina. Pindolol has the highest degree of ISA of any beta blocker, which gives it some beta-agonist action in addition to antagonist activity. Adverse effects are generally mild and temporary and include nausea, vomiting, insomnia, fatigue, and dizziness. Maximum antihypertensive action may take up to 2 weeks to achieve. This drug is pregnancy category B.

Sotalol (Betapace, Sorine): Although all nonselective beta blockers affect heart rate and rhythm, sotalol is one of the few drugs in this class used exclusively as an antidysrhythmic. By slowing the action potential crossing the myocardium, the heart is able to regain normal rhythm. Therapy with sotalol is begun in a setting where the electrocardiogram (ECG) can be continuously monitored for a minimum of 3 days because this drug can cause or worsen certain dysrhythmias. Adverse effects are those typical of beta blockers but they occur more frequently. For example, fatigue may occur in 20% of patients, dyspnea in 21%, and sinus bradycardia in 16%. Patients with a history of dysrhythmias are more likely to experience serious adverse effects. Abrupt discontinuation of the drug can cause dysrhythmias and MI. Other adverse effects include insomnia, nausea, vomiting, and drowsiness. Approved in 1992, the role of sotalol in the pharmacotherapy of dysrhythmias is presented in Chapter 37. This drug is pregnancy category B.

Timolol: When given PO, timolol is indicated for HTN, migraine prophylaxis, and reduction of mortality following an acute MI. Chronic, stable angina is an off-label indication for the drug. Systemic adverse effects are generally mild and transient and include nausea, vomiting, diarrhea, bradycardia, fatigue, and dizziness. Abrupt discontinuation of PO timolol can cause dysrhythmias and MI. Approved in 1978, timolol (Timoptic) is available as a 0.25% and 0.5% ophthalmic solution to treat glaucoma and is presented as a prototype for glaucoma in Chapter 74. When given PO, timolol is pregnancy category C.

16.4 Beta$_1$-adrenergic antagonists are selective for beta$_1$ receptors in the myocardium and are used to treat HTN and other cardiovascular disorders.

Because of their specificity for beta$_1$ receptors in the myocardium, the beta$_1$-adrenergic antagonists exert fewer noncardiac adverse effects than nonselective agents such as propranolol. This selectivity is not absolute, however; some of these drugs affect beta$_2$ receptors at higher doses, and a few have intrinsic sympathomimetic activity.

The primary indication for selective beta$_1$ antagonists is HTN. Some are also used in the pharmacologic management of chronic angina pectoris and HF. Although used for the same indications as the nonselective agents, the beta$_1$ blockers have certain advantages. The major advantage is that they have little effect on beta$_2$ receptors in bronchial smooth muscle. This allows the beta$_1$ blockers to be administered to patients with asthma or COPD with a lower risk

of bronchospasm. The $beta_1$ blockers also have less effect on glucose and lipid metabolism than the nonselective drugs.

Beta blockers should be used with great caution in patients with a history of HF because both the nonselective and selective $beta_1$ blockers slow the speed of impulse conduction across the myocardium. In patients with healthy hearts, this effect is a clinical problem only at high doses. In patients with diseased hearts, however, this depression can worsen cardiac impairment and lead to HF. This cardiac impairment may develop gradually in patients taking beta blockers for prolonged periods; therefore, the patient should receive regular assessments of cardiac function during therapy. Generally, beta blockers are discontinued or their doses adjusted as soon as HF is suspected.

Overdose with $beta_1$ antagonists is treated in a manner similar to the nonselective beta blockers. An anticholinergic drug such as atropine or a beta agonist such as isoproterenol may be given to promote bronchodilation and increase the heart rate. Digoxin (Lanoxin) or diuretics may be indicated if HF develops. Severe hypotension may require the administration of an emergency vasopressor such as dopamine (a beta agonist).

CONNECTION Checkpoint 16.2

Dopamine is a catecholamine. From what you learned in Chapter 15, identify other catecholamines that are used to quickly raise blood pressure in acute care situations. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Metoprolol (Lopressor, Toprol XL)

Classification **Therapeutic:** Antihypertensive
Pharmacologic: Selective $beta_1$-adrenergic antagonist

Therapeutic Effects and Uses: Approved in 1978, the primary indication for metoprolol is HTN, as monotherapy or in combination with other antihypertensives. It is also indicated for angina and for the treatment of stable, symptomatic HF.

The therapeutic actions of metoprolol include decreases in heart rate (both resting and during exercise), cardiac output, and blood pressure (both systolic and diastolic). Fixed-dose combination formulations are available for HTN: Lopressor HCT combines metoprolol with the diuretic hydrochlorothiazide in a single tablet. Because it slows the rate and force of myocardial contraction, metoprolol can reduce oxygen demands on the heart and benefit patients with angina and stable HF. Off-label uses include essential tremor, migraine prophylaxis, and the control of heart rate in patients with atrial dysrhythmias.

Metoprolol reduces the mortality associated with recent MI. Following an acute MI, metoprolol is infused slowly until a target heart rate between 60 and 90 beats/min is reached. This reduces myocardial oxygen demand at a time when the heart is at high risk for a subsequent MI or life-threatening dysrhythmias. On hospital discharge, patients continue metoprolol therapy by switching to the PO form of the drug.

Mechanism of Action: Metoprolol is a selective $beta_1$-adrenergic antagonist that competes with endogenous catecholamines at adrenergic receptors in cardiac muscle. At high doses, it may affect $beta_2$ receptors in bronchial smooth muscle.

Pharmacokinetics:

Route(s)	Usually PO; IV for MI
Absorption	Well absorbed
Distribution	Completely, including CNS and placenta; secreted in breast milk; 12% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	PO: 15 min; IV: immediate
Duration of action	13–19 h

Adverse Effects: Metoprolol is well tolerated and adverse effects generally diminish as therapy progresses. Nausea and vomiting are the most common adverse effects. Other common adverse effects include dizziness, fatigue, insomnia, bradycardia, heartburn, and dyspnea. Serious adverse effects include agranulocytosis, laryngospasm, complete heart block, and thyroid storm in patients with thyrotoxicosis. Bronchospasm and dyspnea are rare because the drug has little effect on $beta_2$ receptors in bronchial smooth muscle. Dysrhythmias, severe HTN, or MI may occur if the drug is abruptly withdrawn. **Black Box Warning:** Abrupt withdrawal is not advised in patients with angina or heart disease. Dosage should gradually be reduced over 1 to 2 weeks and the drug should be reinstituted if angina symptoms develop during this period.

Contraindications/Precautions: Because of its multiple effects on the heart, patients with preexisting cardiac disease such as HF should be carefully monitored. This drug is contraindicated in cardiogenic shock, severe bradycardia, and heart block greater than first degree. Metoprolol should be used with caution in patients with severe hepatic disease because its major route of excretion is the liver. Metoprolol should be used with caution in patients with asthma and those with a history of bronchospasm because the drug may affect $beta_2$ receptors at high doses.

Drug Interactions: $Beta_1$ blockers such as metoprolol have the potential to interact with many different drugs. The nurse should always be cautious when administering a beta blocker with any other medication that affects the heart, particularly those that depress AV node conduction.

Because certain calcium channel blockers such as verapamil suppress myocardial contractility, concurrent use with metoprolol can lead to additive bradycardia and even heart block. Use with other antihypertensive drugs may cause additive hypotension. Certain drugs, including cimetidine and oral contraceptives, can also add to the hypotensive effect of metoprolol. Metoprolol should not be given with sympathomimetics because the actions of the drugs will cancel each other. Metoprolol can reduce the clearance of lidocaine and cause lidocaine toxicity.

Pregnancy: Category C.

Treatment of Overdose: Overdose of metoprolol will cause bradycardia, hypotension, and bronchospasm. Treatment may require the use of plasma volume expanders or vasopressors to raise blood pressure to normal levels and atropine to counteract the bradycardia. Isoproterenol may be administered for bronchospasm.

Nursing Responsibilities: Key nursing implications for patients receiving metoprolol are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Adrenergic Antagonists.

Drugs Similar to Metoprolol (Lopressor, Toprol XL)

Other $beta_1$-adrenergic antagonists include acebutolol, atenolol, betaxolol, bisoprolol, esmolol, and nebivolol. The $beta_1$-adrenergic antagonists are very similar but differ in their pharmacokinetics and specific indications.

Acebutolol (Sectral): Approved in 1984, acebutolol is a cardioselective $beta_1$ antagonist similar to metoprolol that is given PO for HTN and recurrent ventricular dysrhythmias. An off-label indication is chronic stable angina. In addition to being a selective $beta_1$ blocker, it exhibits mild ISA. Because of its 3- to 4-hour half-life, it is usually administered twice daily. Common adverse effects include CNS effects such as fatigue, dizziness, and headache. Higher doses can produce hypotension and bradycardia. Like other beta blockers, care must be taken when using acebutolol with other drugs that depress myocardial conduction because bradycardia and hypotension may result. This drug is pregnancy category B.

Atenolol (Tenormin): Approved in 1981, atenolol is available PO for HTN and for the long-term management of chronic stable angina. It is also given by the IV route to reduce the risk of sudden death in patients with an acute MI. Off-label indications include migraine prophylaxis and the prevention of symptoms in patients undergoing ethanol withdrawal. Atenolol has a long half-life, which allows for once-daily dosing. Common adverse effects are the same as those of other drugs in this class, such as nausea, vomiting, fatigue, dizziness, and headache. The risk of bradycardia is low at normal doses. Like other beta blockers, care must be taken to avoid abrupt discontinuation of therapy, especially in patients with coronary artery disease. Tenoretic is a combination of atenolol and the diuretic chlorthalidone that is approved for HTN. Atenolol is presented as a prototype drug for angina in Chapter 35. This drug is pregnancy category D and is not recommended during pregnancy or lactation.

Betaxolol: Approved in 1985, betaxolol is available in tablet form for the pharmacotherapy of HTN, sometimes given concurrently with thiazide diuretics. The drug is one of the most potent and selective of the beta blockers; it is nine times more potent than atenolol. It has no ISA, and it inhibits $beta_2$-adrenergic receptors in the lung only at very high doses. When given PO, adverse effects such as nausea, vomiting, dizziness, fatigue, and headache are typical of the beta blockers. The risk of bradycardia increases with higher doses. Like other beta blockers, care must be taken to avoid abrupt discontinuation of therapy, especially in patients with coronary artery disease, because myocardial ischemia, MI, HTN, or dysrhythmias may result.

Betaxolol is also available as a 0.25% ophthalmic suspension (Betoptic) for reducing intraocular pressure in patients with chronic open-angle glaucoma. Adverse effects are limited to the eye and include burning and transient blurred vision. This drug is pregnancy category C.

Bisoprolol: Approved in 1992, bisoprolol is approved only for HTN, although HF and chronic stable angina are off-label indications. Given PO, bisoprolol has a longer half-life than metoprolol, which allows for less frequent dosing. The cardioselective nature of bisoprolol action only applies to low doses; at higher doses it also blocks $beta_2$ receptors to cause dyspnea and wheezing. Common adverse effects are the same as those of other drugs in this class, such as fatigue, dizziness, and headache. Like other beta blockers, care must be taken to avoid abrupt discontinuation of therapy, especially in patients with coronary artery disease. Ziac combines bisoprolol with the diuretic hydrochlorothiazide in a single tablet. Bisoprolol is pregnancy category C.

Esmolol (Brevibloc): Approved in 1986, esmolol is very different from other $beta_1$-adrenergic blockers. It is administered by continuous IV infusion in emergency situations, usually postoperative or perioperative, to rapidly correct supraventricular tachycardia or severe HTN. It has a very short half-life of only 8 minutes, and the patient must be monitored for hypotension and bradycardia during the infusion. Although it has the same actions and adverse effects as other beta blockers, the actions of esmolol begin to diminish within minutes after discontinuation of the infusion. Esmolol should be used with extreme caution in patients with severe bradycardia, AV block, or cardiogenic shock. Hypotension occurs in about 40% of patients receiving the drug but resolves quickly following completion of the infusion. The drug is pregnancy category C.

Nebivolol (Bystolic): Approved in 2007, nebivolol is a selective beta$_1$-adrenergic blocker that is indicated for the treatment of HTN, either as monotherapy or in combination with other antihypertensives. Nebivolol is highly cardioselective but may activate beta$_2$ receptors at higher doses. It has no ISA activity. Nebivolol has equal effectiveness to other drugs in its class, but it appears to produce fewer adverse effects. The drug is well tolerated, with the most frequently observed adverse effects being headache, fatigue, paresthesia, dizziness, hypotension, and bradycardia. Like other beta blockers, care must be taken to avoid abrupt discontinuation of therapy, especially in patients with coronary artery disease. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Adrenergic Antagonists

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, cerebrovascular, or respiratory disease, or diabetes. Obtain a drug history including allergies, current prescriptions and OTC drugs, herbal preparations, and alcohol use. Be alert to possible drug interactions.
- Evaluate appropriate laboratory findings including electrolytes, glucose, and hepatic and renal function studies.
- Obtain baseline weight, vital signs, and cardiac monitoring (e.g., ECG, cardiac output as appropriate).
- For treatment of BPH, assess urinary output.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., blood pressure [BP] within normal range, dysrhythmias or palpitations relieved, greater ease in urination).
- Continue frequent and careful monitoring of vital signs, daily weight, and urinary and cardiac output as appropriate, especially if IV administration is used.
- Assess for and promptly report adverse effects: bradycardia, hypotension, dysrhythmias, reflex tachycardia (from too rapid decrease in BP or hypotension), dizziness, headache, or decreased urinary output. Severe hypotension, seizures, dysrhythmias, or palpitations may signal drug toxicity and are immediately reported.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. Daily weights should remain at or close to baseline weight. (Pulse, BP, and respiratory rate should be within normal limits or within the parameters set by the healthcare provider. Urinary hesitancy or frequency should be decreased and urine output improved. An increase in weight over 1 kg [2 lb] per day may indicate excessive fluid gain. **Diverse Patients:** Research indicates differing responses to antihypertensive therapy, including with adrenergic-blocking drugs, in ethnically diverse populations compared to non-Hispanic Whites.)	• Teach the patient, family, or caregiver how to monitor pulse and BP as appropriate. The pulse rate should be taken for one full minute at a pulse point most easily felt. Ensure proper use and functioning of any home equipment obtained. • Have the patient weigh self daily along with BP and pulse measurements, ideally at the same time each day. Report weight gain or loss of more than 1 kg (2 lb) in a 24-hour period.
• Follow appropriate administration techniques for ophthalmic doses.	• Instruct the patient, family, or caregiver in proper administration techniques, followed by teach-back.
Minimizing adverse effects: • Continue to monitor vital signs. Take BP lying, sitting, and standing to detect orthostatic hypotension. Notify the healthcare provider if BP or pulse decreases beyond the established parameters or if hypotension is accompanied by reflex tachycardia. (Adrenergic antagonists decrease heart rate and cause vasodilation, resulting in lowered BP. Orthostatic hypotension may increase the risk of falls. **Lifespan:** Be aware that dizziness may increase the risk of falls in the older adult. Reflex tachycardia may signal that the BP has dropped too quickly or too substantially.)	• Teach the patient to rise from lying to sitting or standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Instruct the patient to stop taking medication if BP is 90/60 mmHg or below, or below the parameters set by the healthcare provider, and immediately notify the provider.
• Continue cardiac monitoring (e.g., ECG) as ordered for dysrhythmias in the hospitalized patient. (External monitoring devices will detect early signs of adverse effects as well as monitor for therapeutic effects.)	• Instruct the patient to report palpitations, chest pain, or dyspnea immediately.
• Weigh patient daily and report weight gain or loss. (Daily weight is an accurate measure of fluid status and takes into account intake, output, and insensible losses. Weight gain or edema may signal BP has lowered too quickly, stimulating renin release, or is an adverse effect.)	• Instruct the patient to weigh self daily, ideally at the same time of day, and record weight along with BP and pulse measurements. Have the patient report weight gain or loss of more than 1 kg (2 lb) in a 24-hour period.
• Monitor for breath sounds and for increasing dyspnea or adventitious breath sounds. (Nonselective beta-adrenergic blockers may cause bronchoconstriction.)	• Instruct the patient to immediately report any increasing or severe shortness of breath.
• Monitor urine output and symptoms of dysuria such as hesitancy or retention when given for BPH. (Alpha$_2$- and beta-adrenergic blockers may impair urinary sphincter function. Alpha$_1$ blockers given for BPH cause bladder and urinary sphincter relaxation. **Lifespan:** Be aware that the older adult men are at higher risk for mechanical obstruction due to an enlarged prostate.)	• Have the patient report urinary hesitancy, feelings of bladder fullness, or difficulty starting urinary stream promptly.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Give the first dose of the drug at bedtime. (A first-dose response may result in a greater initial drop in BP than subsequent doses.)	• Instruct the patient to take the first dose of medication immediately before going to bed, and to avoid driving for 12 to 24 hours after the first dose or when the dosage is increased until the effects are known.
• Continue to monitor blood glucose levels and appropriate laboratory work. (Adrenergic antagonists affect a wide range of body systems. They may also interfere with some oral diabetic drugs or change the way a hypoglycemic reaction is perceived.)	• Teach patients with diabetes to monitor their blood sugar more frequently and to be aware of subtle signs of possible hypoglycemia (e.g., nervousness, irritability). Patients on oral antidiabetic drugs should report any consistent changes in their blood sugar levels to the healthcare provider promptly.
• Assess the patient's mental status and mood. (Adrenergic antagonists may cause depression or dysphoria.)	• Teach the patient to report unusual feelings of sadness, despondency, apathy, or depression that may warrant a change in medication.
• Provide for eye comfort such as adequately lighted room. (Adrenergic antagonists can cause miosis and difficulty seeing in low-light levels.)	• Caution the patient about driving or other activities in low-light conditions or at night until the effects of the drug are known.
• Assess for cold, painful, or tender feet or hands or other symptoms of Raynaud's disease such as cyanosis, intermittent pallor, redness, or paresthesia. (These symptoms may accompany Raynaud's disease or suggest that treatment is not effective. Alternate drug therapy may be required.)	• Teach the patient to report any hand or feet pain, pallor, coldness, numbness, or cyanosis to the healthcare provider.
• Do not abruptly stop the medication. (Rebound HTN and tachycardia may occur.)	• Teach the patient, family, or caregiver not to stop the medication abruptly and to call the healthcare provider if the patient is unable to take medication for more than one day due to illness.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug; appropriate dose and scheduling; what adverse effects to observe for and when to report them; equipment needed as appropriate and how to use that equipment; and the required length of medication therapy needed with any special instructions regarding renewing or continuing the prescription as appropriate.
Patient self-administration of drug therapy: • When administering medications, instruct the patient, family, or caregiver in proper self-administration of drugs and ophthalmic drops. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration techniques, followed by teach-back. • The drug should be taken at the same time each day when possible. • The patient, family, or caregiver is able to discuss appropriate dosing and administration needs.

Understanding Chapter 16

Key Concepts Summary

16.1 Adrenergic antagonists act by blocking the effects of norepinephrine at adrenergic receptors.

16.2 Alpha$_1$-adrenergic antagonists are used to treat hypertension and benign prostatic hyperplasia.

16.3 Nonselective beta-adrenergic antagonists affect both beta$_1$ and beta$_2$ receptors and are prescribed for HTN, angina, and other cardiovascular disorders.

16.4 Beta$_1$-adrenergic antagonists are selective for beta$_1$ receptors in the myocardium and are used to treat HTN and other cardiovascular disorders.

CASE STUDY: Making the Patient Connection

Remember the patient "Amos Tucker" from the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Amos Tucker is a 48-year-old executive who lives a very active life. He has a wife and two teenage children. His job requires frequent travel for up to 2 weeks at a time. Every

year, Amos's company recommends a complete health physical as part of the executive benefits package. Amos has not taken advantage of this opportunity in the past. However, this year his wife has insisted that he have a checkup.

Amos arrives at the employee health clinic for the physical examination. On arrival he is visibly anxious and has accepted three calls on his cell phone since entering the clinic. During the initial health history session, Amos reveals that he smokes one pack of cigarettes per day and does not drink alcohol. He states that he has no time for exercise and has gained weight during the past year. Most nights Amos sleeps 4 to 6 hours. He states that he frequently wakes up during the night with thoughts of what he needs to do the next day. He finds it difficult to return to sleep after waking.

His medical and family histories indicate that both of his parents died within the past 10 years. His father died of a stroke and his mother died of a heart attack. Amos states that he has been prescribed prazosin (Minipress) in the past but he stopped taking it. When questioned about why he chose not to take the medication, Amos reluctantly confides in you that he suspected that the medication was causing sexual adverse effects.

The physical examination reveals that Amos is 1.9 m (6´2˝) tall and weighs 119 kg (262 lb). His body temperature is 37°C (98.6°F), heart rate is 88 beats/min, respiratory rate is 18 breaths/min, and blood pressure is 160/90 mmHg. During the examination an ECG and laboratory test results were all within normal limits.

Critical Thinking Questions

1. Identify the mechanism of action associated with prazosin (Minipress).
2. Discuss the physiology of sexual disorders associated with alpha-adrenergic antagonists.
3. As this patient's nurse, how would you approach the topic of medication-induced sexual dysfunction?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Richard Perry is a 64-year-old patient who has been successfully treated for HTN for over 15 years with propranolol (Inderal). Mr. Perry is allergic to cats, and he recently visited his grandson who has a new kitten. He now has weepy eyes and a runny nose. He is considering taking the OTC medication pseudoephedrine (Sudafed) to relieve the allergic symptoms.

1. Is it safe for Mr. Perry to take this OTC medication? Why or why not?
2. Is there another OTC medication that would be safer for this patient?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is started on propranolol (Inderal). Which is the most important action to be included in the plan of care for this patient related to this medication?
   1. Monitor apical pulse and blood pressure.
   2. Elevate the head of the bed during meals.
   3. Take the medication after meals.
   4. Consume foods high in potassium.

2. Which of the following should the nurse instruct a patient with diabetes who is prescribed a beta-adrenergic blocker for the treatment of hypertension to do?
   1. Increase insulin intake by 2 to 3 units daily each morning.
   2. Decrease the intake of carbohydrates while on the antihypertensive medications.
   3. Elevate the lower extremities to promote venous drainage.
   4. Monitor blood glucose levels frequently and report hypoglycemia.

3. To avoid the first-dose phenomenon, the nurse knows that the initial dose of prazosin (Minipress) should be:
   1. Very low and given at bedtime.
   2. Doubled and given before breakfast.
   3. The usual dose and given before breakfast.
   4. Doubled and given immediately after breakfast.

4. A patient who is taking an adrenergic antagonist for hypertension reports being dizzy when first getting out of bed in the morning. The nurse should advise the patient to:
   1. Move slowly from the recumbent to the upright position.
   2. Drink a full glass of water before rising to increase vascular circulatory volume.
   3. Avoid sleeping in a prone position.
   4. Stop taking the medication.

5. A healthcare provider has ordered an alpha$_1$-adrenergic antagonist for each of these patients. A nurse should question the order for the patient with which disorder?
   1. Benign prostatic hyperplasia
   2. Pheochromocytoma
   3. Raynaud's disease
   4. Tachycardia

6. The nurse is caring for a patient with chronic hypertension. The patient is receiving a beta-adrenergic blocker daily. Which patient manifestations would the nurse conclude are adverse effects of this medication? (Select all that apply.)
   1. Anorexia
   2. Increased serum triglycerides
   3. Hypoglycemia
   4. Decreased libido
   5. Thrombocytopenia

See Answers to Chapter Review in Appendix A.

Chapter 17
Review of the Central Nervous System

Chapter Outline

- Scope of Central Nervous System Pharmacology
- Neurons and Neurotransmission
- Structural Divisions of the Central Nervous System
- Functional Systems of the Central Nervous System

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify disorders for which central nervous system medications are prescribed.
2. Illustrate the major components of a synapse within the central nervous system.
3. Identify the major neurotransmitters in the central nervous system and their functions.
4. Describe the major structural regions of the brain and their primary functions.
5. Explain the major functional systems of the brain and their primary functions.

Key Terms

basal nuclei, 225
dopamine, 221
extrapyramidal system, 225
gamma aminobutyric acid (GABA), 221
glutamate, 221
limbic system, 224
neuron, 220
reticular activating system (RAS), 224
serotonin, 221
synapses, 220

Chapters 12 through 16 introduced the autonomic nervous system (ANS)—the system that provides involuntary control over vital functions of the cardiovascular, digestive, respiratory, and genitourinary systems. This chapter launches Unit 4, which examines the pharmacology of the central nervous system (CNS). The two components of the CNS, the brain and spinal cord, are collectively responsible for receiving all sensory information, interpreting that data, and formulating appropriate responses. Typical responses may include thinking (deciding if the sensory information is harmful or pleasurable), emotions (anger, depression, euphoria), or movement (running away, pounding a fist, or hugging). The purpose of this chapter is to provide a brief review of concepts of CNS anatomy and physiology that are relevant to neuropharmacology.

Scope of Central Nervous System Pharmacology

17.1 Medications affect the central nervous system by stimulating or suppressing the firing of specific neurons.

CNS pharmacology is one of the largest and most important divisions in medicine, encompassing 11 chapters in this text. Medications are administered to treat a large number of neurologic and psychiatric disorders of the CNS. In addition, many drugs cause CNS adverse effects, while others are self-administered to produce pleasurable psychoactive effects. At high doses, a large number of drugs affect the brain, and CNS toxicity is a dose-limiting factor in the pharmacotherapy of many diseases.

Of all divisions of pharmacology, CNS drug mechanisms are the least understood. For some medications, pharmacologists know only that the drug acts on the CNS and produces a therapeutic effect, but its mechanism of action remains largely unknown. There are two primary reasons for this lack of understanding about how CNS drugs produce their effects: the uniqueness of the human brain and the complexity of the disorders affecting it.

The human brain is truly unique, with no other species having the same complexity. It is not known if animals experience the same types of mental disorders as humans, and objective measurement of hallucinations, euphoria, or depression is difficult, if not impossible, in most species. If a drug does induce changes in animal behavior such as depression or anxiety, it is not known whether these data apply to humans because of the enormous differences in brain physiology as well as human social networks that can profoundly influence mental health conditions. Pharmacologists are certainly able to measure changes in brain activity or in the amounts of neurotransmitters in specific regions of the brain, but these do not adequately explain complex changes in thinking, mood, or behavior. Without good animal models, pharmacologists must rely largely on empirical observations—evidence derived from giving the drugs to patients and determining what works rather than how it works.

Also complicating the study of CNS pharmacology is that mental disorders themselves are incompletely understood. The physiologic basis for disorders such as schizophrenia, major depression, bipolar disorder, panic attacks, or post-traumatic stress disorder is not well established. There is great patient variability in symptoms and disease progression with these disorders, and social factors play important roles. Without a complete understanding of the etiology and pathophysiology of mental disorders, pharmacotherapy of these conditions and the development of new drug therapies for CNS disorders will remain challenging.

The next nine chapters present the major classes of drugs whose pharmacotherapeutic goal is to modify the activity of some portion of the CNS. A 10th chapter examines substances that are abused for their effects on the CNS. In a few cases, CNS drugs affect the function of very specific regions of the brain. Most CNS drugs, however, are nonspecific and affect multiple brain regions.

In simplest terms, CNS drugs have two basic actions: They either stimulate (activate) or suppress (inhibit) the firing of neurons. In some cases, CNS drugs may have both actions: activation of some neurons and inhibition of others. The pharmacologic effects of a CNS drug observed in a patient are the result of precisely which neurons are changed, and how many are affected. As a result of neuron modification, the following beneficial effects of CNS medications are observed and are studied in this unit:

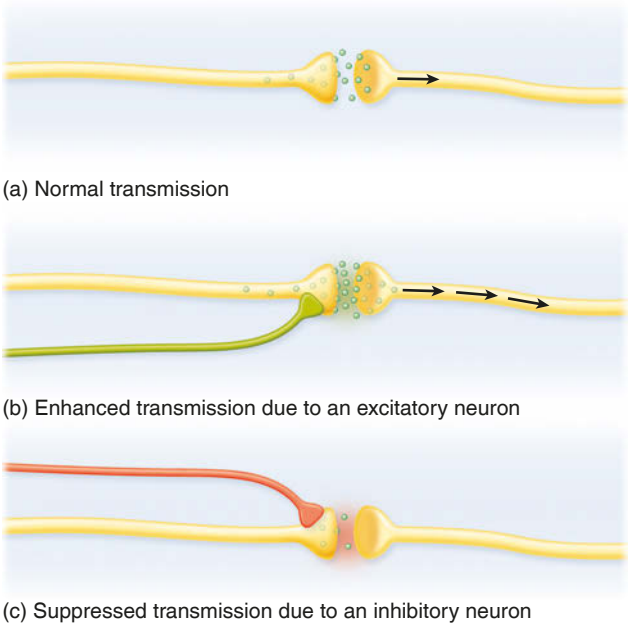
- Reduction in anxiety
- Improved sleep patterns
- Elevated mood

- Management of psychotic symptoms
- Slowing the progression of chronic degenerative diseases of the brain
- Termination and prevention of seizures
- Reduction in muscle spasms and spasticity
- Reduction of hyperactivity and mania
- Reduction in pain
- Induction of anesthesia.

CONNECTION Checkpoint 17.1

From what you learned in Chapter 12, what are the two divisions of the peripheral nervous system and what are their primary functions?

Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.



Neurons and Neurotransmission

17.2 Neurons in the central nervous system communicate with each other and with body tissues, using neurotransmitters.

The **neuron** is the primary functional cell in all portions of the nervous system. The function of the 100 billion neurons making up the nervous system is to communicate messages through conduction of an action potential. In the CNS, the vast majority of neurons communicate with other neurons. These neuronal pathways or circuits are extremely complex and provide the basis for the higher level functions of the brain such as thinking, memory, and intelligence. Although a single neuron in the CNS serves no practical function, the interconnections among 100 billion neurons are a major part of what distinguishes the human brain from that of all other species.

Communication between neurons in the brain, as well as that between the brain and other organs, is provided through **synapses**. Synapses are junctions between two neurons, or between a neuron and a muscle or gland. Synapses in the ANS are presented in detail in Chapter 12. The student should review that chapter before proceeding.

Synapses within the CNS operate by the same basic principles as those in the ANS. An action potential from the presynaptic neuron releases a neurotransmitter that moves across the synaptic cleft to activate receptors on the postsynaptic neuron, as illustrated in Figure 17.1a. In some cases, the neuron may be excitatory, enhancing neural transmission (Figure 17.1b). In other cases the impulse inhibits a neurotransmitter from being released, or it causes the release of an inhibitory neurotransmitter that suppresses neuronal conduction (Figure 17.1c). All interconnections in the CNS depend on transmission of the action potential from one neuron to another neuron, or to multiple neurons at synapses.

(a) Normal transmission

(b) Enhanced transmission due to an excitatory neuron

(c) Suppressed transmission due to an inhibitory neuron

Figure 17.1 Modification of neural transmission in the central nervous system: (a) normal transmission; (b) enhanced transmission; (c) suppressed transmission.

In the ANS only two neurotransmitters account for nearly all synaptic transmission: acetylcholine (ACh) and norepinephrine (NE). Although these two chemicals also are found in the CNS, more than 30 additional substances have been identified as neurotransmitters in the brain, making the study of neuronal communication in this organ very complex. Some neurotransmitters such as glutamate are primarily stimulatory, whereas others such as gamma aminobutyric acid (GABA) inhibit neuronal activity. NE can activate or inhibit neuronal activity, depending on its location in the brain. A summary of relevant brain neurotransmitters is shown in Table 17.1.

PharmFACT

Male brains are about 10% larger than female brains, due to differences in average body sizes. However, there is no correlation between brain size and intelligence (Martini, Nath, & Bartholomew, 2014).

Adrenergic synapses: Adrenergic synapses utilize NE as the neurotransmitter. Adrenergic synapses in the CNS are abundant in the hypothalamus, the limbic system, and the reticular activating system (RAS). NE activates parts of the brain to heighten alertness and is prominent during waking hours. Adrenergic neurons likely play a role in mood disorders such as depression and anxiety. Drugs used to modify adrenergic synapses in the CNS include caffeine, amphetamines, and tricyclic antidepressants.

Cholinergic synapses: Cholinergic synapses utilize ACh as the neurotransmitter. In the brain, these synapses

Table 17.1 Selected Central Nervous System Neurotransmitters and Their Functions

Neurotransmitter	Abundance	Effect	Clinical Significance
Acetylcholine (ACh)	Widely distributed in the CNS; a major transmitter in the ANS	CNS: May be excitatory or inhibitory; controls voluntary skeletal muscle movement ANS: Activates the parasympathetic nervous system	Myasthenia gravis, Alzheimer's disease
Dopamine	Basal ganglia and limbic system	Usually excitatory; locomotion, attention, learning, and the reinforcing effects of abused drugs	Parkinson's disease; psychoses; motivation, pleasure
Endorphins and enkephalins	Widely distributed in the CNS and peripheral nervous system (PNS)	Usually inhibitory; reduction of pain	Opioids bind to endorphin receptors
Gamma aminobutyric acid (GABA)	Widely distributed in the CNS	Most common inhibitory CNS neurotransmitter	Seizure and anxiety disorders
Glutamate	Widely distributed in the CNS	Most common excitatory CNS neurotransmitter	Memory
Norepinephrine (NE)	Widely distributed in the CNS; a major transmitter in the ANS	CNS: May be excitatory or inhibitory ANS: Activates the sympathetic nervous system	Depression, memory, panic attacks
Serotonin	Common in the brainstem but also found in the limbic system, gastrointestinal tract, and platelets	Usually inhibitory	Anxiety, bipolar disorder, depression

are most often stimulatory. Cholinergic synapses are abundant in the motor cortex and basal ganglia but are uncommon in other areas. Cholinergic synapses are especially important in the pathophysiology of Parkinson's disease and Alzheimer's disease.

Dopaminergic synapses: These synapses utilize dopamine as the neurotransmitter. **Dopamine** is a chemical precursor in the synthesis of NE and, like epinephrine and NE, is classified chemically as a catecholamine. Dopaminergic synapses are generally excitatory and affect arousal and wakefulness. However, two major receptor subtypes exist: D1 is stimulatory, and D2 is inhibitory. Cocaine and amphetamines produce their stimulatory actions by affecting dopamine receptors; marijuana is also thought to exert some of its psychoactive effects by increasing dopaminergic activity. Dopamine receptors are important in the pharmacotherapy of psychosis and Parkinson's disease.

CONNECTION Checkpoint 17.2

The neurotransmitter dopamine is also available as a drug. From what you learned in Chapter 15, what are the indications for dopamine therapy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Endorphins and enkephalins: Endorphins and enkephalins are small peptides secreted by neurons in the hypothalamus, pituitary, limbic system, and spinal cord. The receptor for these molecules is the opioid receptor, which is involved in pain transmission. Endorphins and enkephalins are sometimes called natural opiates because they produce effects very similar to those of morphine and other opioid drugs. Drugs used to modify the types of synapses in the CNS include opioids such as codeine and morphine.

Gamma aminobutyric acid synapses: These synapses utilize **gamma aminobutyric acid (GABA)** as a neurotransmitter. GABA synapses are the second most common type in the CNS, accounting for 30% to 40% of all brain synapses. GABA is the primary inhibitory neurotransmitter in the CNS and is found throughout the brain, with greatest abundance in the basal ganglia and hypothalamus. Several GABA receptor subtypes have been identified. GABA receptors are the primary site of action for several classes of drugs, including the benzodiazepines and barbiturates.

Glutamate synapses: Glutamate synapses utilize the amino acid **glutamate** (glutamic acid) as a neurotransmitter. Glutamate is the most common neurotransmitter in the CNS, and its synapses are always excitatory in nature. It is found in nearly all regions of the brain. Several glutamate receptor subtypes have been identified, with the N-methyl-D-aspartate (NMDA) receptor being particularly important to memory and learning. In addition to glutamate, zinc, magnesium, glycine, and even phencyclidine (a hallucinogen) bind to the NMDA receptor, thus modulating neuronal activity. High amounts of glutamate can cause neuron death and may be the mechanism responsible for certain types of neurotoxicity.

Serotonergic synapses: Serotonergic synapses utilize **serotonin**, also known as 5-hydroxytryptamine (5-HT), as a neurotransmitter. Although some serotonergic synapses are located in the CNS, 98% of the serotonergic receptors are found outside the CNS in platelets, mast cells, and other peripheral cells. Serotonergic receptors are found throughout the limbic (emotional) system of the brain, often in close association with adrenergic synapses. Serotonin is used by the body to synthesize the hormone melatonin in the pineal gland. Low serotonin levels in the CNS are associated with anxiety and impulsive behavior, including suicidal ideation. Serotonergic receptors play an important role in the mechanism of action of antidepressant drugs.

PharmFACT

Conduction of nerve impulses in large-diameter myelinated neurons can reach speeds up to 268 miles/h (120 m/s) (Silverthorn, 2015).

Structural Divisions of the Central Nervous System

17.3 The central nervous system is divided into several major structural components.

The brain consists of dozens of structural divisions that serve common functions. Identification of the many anatomic components in the CNS is complex and beyond the scope of this text. This section focuses on regions of the CNS that have applications to neuropharmacology. For a more complete discussion of CNS anatomy, the student should consult anatomy and physiology textbooks. Basic brain structures are illustrated in Figure 17.2.

Cerebrum: The cerebrum is the "thinking" part of the brain responsible for perception, speech, conscious motor movement, movement of skeletal muscles, memory, and smell. It is the largest part of the brain, by weight, and the most advanced. Portions of the cerebrum are organized for specialized functions. For example, the occipital lobe is associated with vision and the frontal lobes are concerned with reasoning and planning. Other areas are specific to language, hearing, motor, or sensory functions.

Disorders of the cerebrum may be focal or generalized. Focal abnormalities, often the result of a stroke, occur in specific regions and may affect a single brain function such as vision, hearing, or movement of a particular limb. Generalized disorders of the cerebrum affect widespread areas or multiple regions and can produce drowsiness, coma, hallucinations, depression, or generalized anxiety.

Thalamus: The thalamus is the major relay center in the brain that sends sensory information such as sounds, sights, pain, touch, and temperature to the cerebral cortex for analysis. To reach the cerebrum, all sensory information must travel through the thalamus. Portions of the thalamus comprise the limbic system, an area that controls mood and motivation. Abnormalities of the thalamus have been associated with diverse mood disorders such as obsessive-compulsive disorder, bipolar disorder, anxiety, and panic disorder.

Hypothalamus: The hypothalamus is the major visceral control center in the body. Regulation of hunger, thirst, water balance, and body temperature is a function of this region. The hypothalamus is also part of the limbic system, which is associated with emotional balance. Some neurons in the hypothalamus connect to the brainstem to affect vital centers such as heart rate, respiratory rate, blood pressure, and pupil size. These responses are associated with the fight-or-flight response of the ANS. The many endocrine functions of the hypothalamus are discussed in Chapter 65. Disorders of the hypothalamus may affect some or all of these essential functions.

CONNECTION Checkpoint 17.3

From what you learned in Chapter 12, describe the symptoms of the fight-or-flight response. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Cerebellum: The cerebellum controls muscle movement, balance, posture, and tone. It is involved in learning fine motor skills that make muscular movements smooth and continuous. The cerebellum receives sensory information, including vision, position, equilibrium, and touch, and calculates the strength and extent of muscle movement needed to maintain posture and coordinate complex tasks such as walking, driving, or playing a musical instrument. Injury or disease in this region results in uncoordinated, jerky body movements.

Brainstem: The brainstem, consisting of the medulla oblongata, pons, and midbrain, connects the spinal cord to the brain. Because of its critical location, it serves as the major relay center for messages traveling to and from the brain. In addition, it contains major reflex and control centers involving breathing, heart rate, vision, swallowing, coughing, and vomiting. Injury to the brainstem can be fatal if vital centers are disrupted. The brainstem contains clusters of scattered neurons, known as the reticular formation, that help maintain alertness.

Spinal cord: The spinal cord is essentially a conduction pathway to and from the brain. Disruptions of these pathways will prevent transmission of nerve impulses and cause loss of sensory (paresthesia) or motor (paralysis) function.

Blood–brain barrier: The brain must receive a continuous supply of oxygen and glucose; interruptions for even brief periods may cause loss of consciousness. At the same time it needs large quantities of nutrients, the brain must also protect itself from pathogens or toxins that may have entered the blood. Capillaries in most regions of the brain are not as porous as those in other organs; the endothelial cells form tight junctions, creating a seal or barrier to many substances. This is important to pharmacology because CNS drugs must have the ability to penetrate the blood–brain barrier to produce

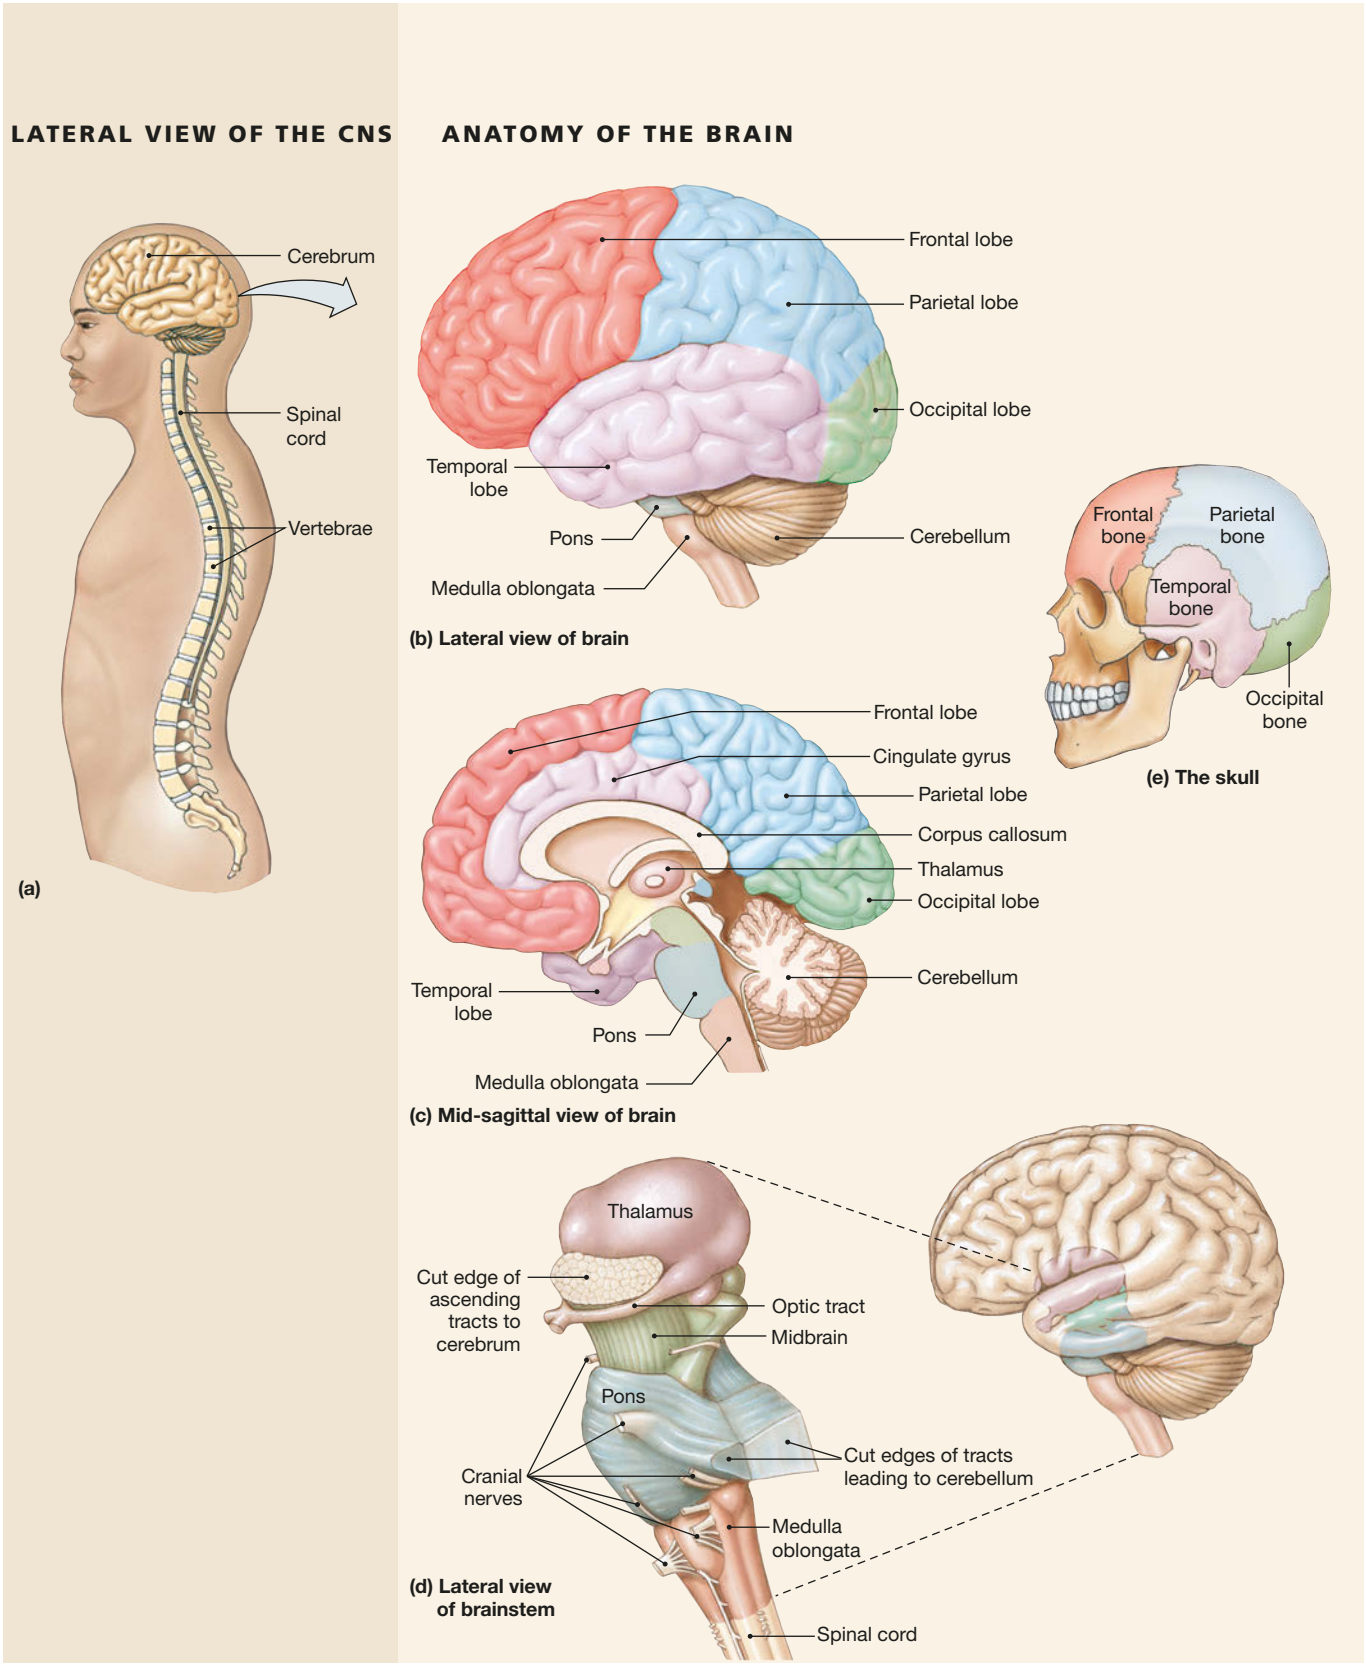


Figure 17.2 Basic anatomy of the brain.

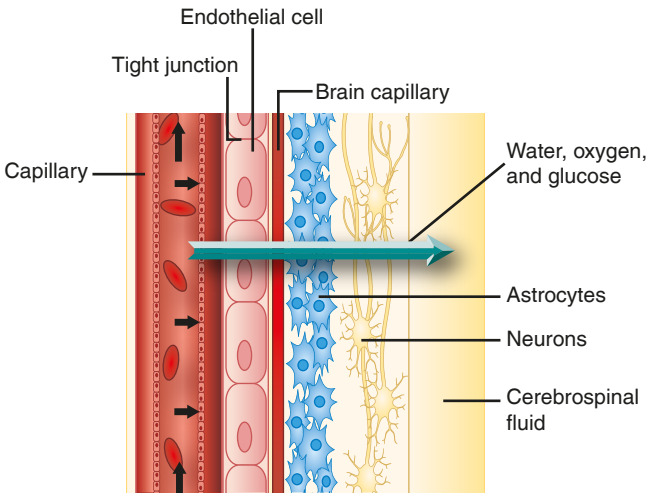

Figure 17.3 Blood–brain barrier.

their effects. The blood–brain barrier is illustrated in Figure 17.3.

Functional Systems of the Central Nervous System

17.4 Several functional divisions of the central nervous system are important to pharmacotherapy.

Functional brain systems are clusters of neurons that work together to perform a common function. These clusters may be located far apart from each other in the CNS but they form a network that acts as a coordinated unit. Some CNS drugs produce their effects by modifying the functions of these systems.

Limbic system: The **limbic system** is a group of structures deep in the brain that are responsible for emotional expression, learning, and memory. Emotional states associated with this system include anxiety, fear, anger, aggression, remorse, depression, sexual drive, and euphoria. Signals routed through the limbic system ultimately connect with the hypothalamus (see Section 17.3). Through its connection with the hypothalamus, autonomic actions such as rapid heart rate, high blood pressure, or peptic ulcers are associated with intense emotional states. The limbic system also communicates with the cerebrum, which allows people to think and reflect on their emotional states. The connection to the cerebrum allows one to use logic to "override" emotional reactions that might be inappropriate or harmful. Parts of the limbic system also allow people to remember emotional responses. The components of the limbic system are illustrated in Figure 17.4.

Reticular activating system: The reticular formation, a network of neurons found along the entire length of the brainstem, is shown in Figure 17.5. Stimulation of the

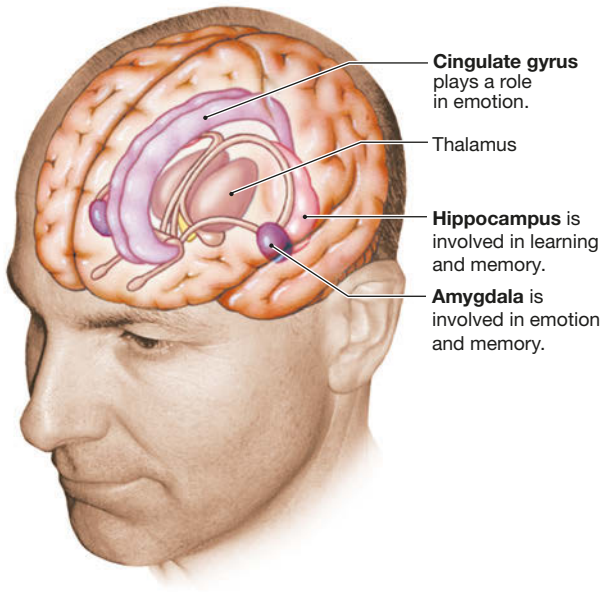

Figure 17.4 Limbic system.
From *Human Physiology: An Integrated Approach* (4th ed.), by D. U. Silverthorn, 2007. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, NJ.

reticular formation causes heightened alertness and arousal of the brain as a whole. Inhibition causes general drowsiness and the induction of sleep.

The larger area in which the reticular formation is found is called the **reticular activating system (RAS)**. This

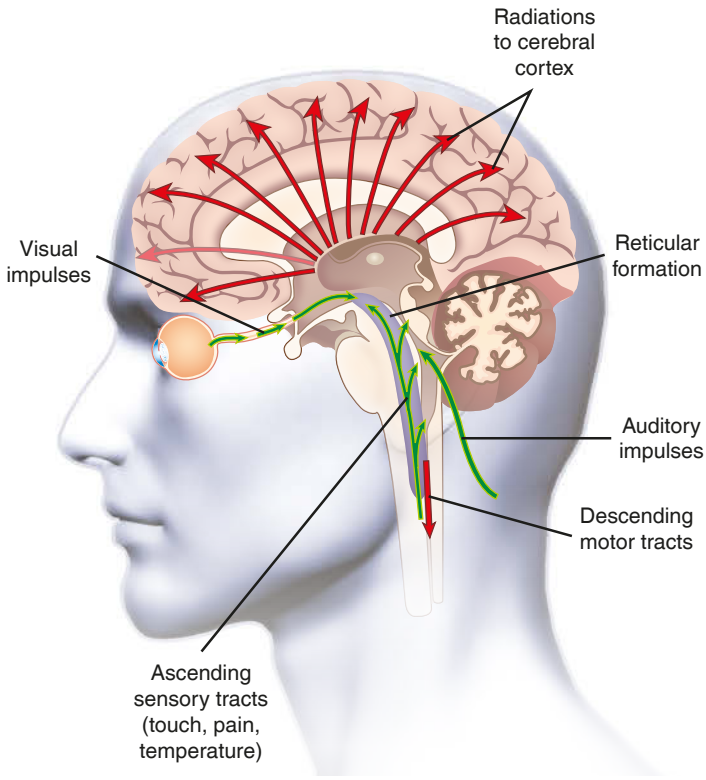

Figure 17.5 With input from sensory neurons, activation of the reticular activating system causes arousal of the cerebral cortex, thus maintaining the awake-and-alert state.

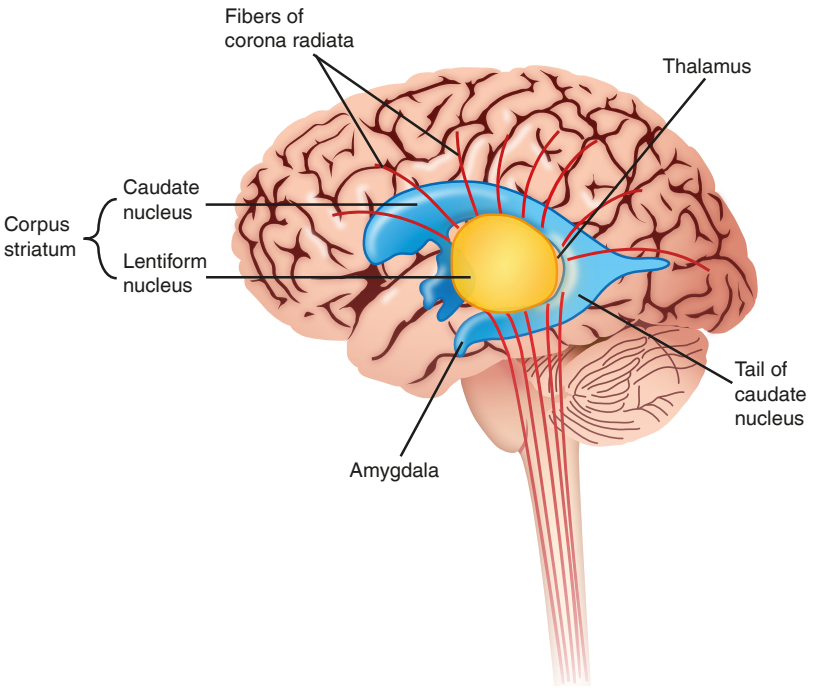

Figure 17.6 The basal ganglia are clusters of gray matter that control learned movement and are involved with the subconscious control of skeletal muscle tone.

structure projects from the brainstem to the thalamus. The RAS is responsible for sleeping and wakefulness and performs an alerting function for the cerebral cortex. It also acts as a filter, allowing people to ignore weak, repetitious, or unimportant sensory stimuli and to focus attention on individual tasks by transmitting information to higher brain centers. This is important in busy, noisy environments when an individual must concentrate on a specific task, such as studying or reading. In any given situation, as much as 99% of all sensory information may be filtered and never reach consciousness.

The RAS has particular importance to pharmacology because many drugs act by decreasing neuronal activity in this system to cause drowsiness or sleep. Examples include alcohol and sedative–hypnotics. Lysergic acid diethylamide (LSD) interferes with portions of the RAS, causing unusual sensory experiences such as seeing odors or hearing colors.

Basal nuclei: The **basal nuclei**, also called basal ganglia, are a cluster of neurons in the brain that help regulate the initiation and termination of skeletal muscle movement. They also help initiate and terminate certain cognitive functions such as memory, learning, planning, and attention. Connections between the basal ganglia and the limbic system are thought to be associated with psychoses, attention-deficit/hyperactivity disorder, and obsessive-compulsive disorder. Reduced dopaminergic transmission through the basal ganglia is the most common etiology for Parkinson's disease. The basal ganglia are illustrated in Figure 17.6.

Extrapyramidal system: Messages controlling the voluntary movement of skeletal muscle originate in the cerebrum and travel down the CNS in tracts or pathways. The two motor pathways, traveling through the brain, brainstem, and spinal cord, are called pyramidal (direct) and extrapyramidal (indirect). The pyramidal tracts are voluntary tracts involved with the movement of skeletal muscles. The **extrapyramidal system** controls locomotion, complex muscular movements, and posture. The extrapyramidal system has particular importance to pharmacology because it is adversely affected by certain medications, especially the conventional antipsychotic drugs (see Chapter 20). Adverse extrapyramidal symptoms include jerking motions, muscular spasms of the head, face, and neck, and akathisia, an inability to remain at rest. Some extrapyramidal symptoms resemble those of Parkinson's disease (see Chapter 21).

PharmFACT

Some of the postsynaptic neurons connect with and receive information from as many as 150,000 presynaptic neurons (Silverthorn, 2015).

Understanding Chapter 17

Key Concepts Summary

17.1 Medications affect the central nervous system by stimulating or suppressing the firing of specific neurons.

17.2 Neurons in the central nervous system communicate with each other and with body tissues, using neurotransmitters.

17.3 The central nervous system is divided into several major structural components.

17.4 Several functional divisions of the central nervous system are important to pharmacotherapy.

Chapter 18
Pharmacotherapy of Anxiety and Sleep Disorders

Chapter Outline

- Anxiety Disorders
- Sleep Disorders
- Management of Anxiety and Sleep Disorders
- Pharmacotherapy of Anxiety and Insomnia

  Benzodiazepines

  PROTOTYPE *Lorazepam (Ativan), p. 238*

  Nonbenzodiazepine Anxiolytics and Miscellaneous Drugs

  PROTOTYPE *Zolpidem (Ambien, Edluar, Others), p. 241*

  Antidepressants

  Barbiturates

  PROTOTYPE *Phenobarbital (Luminal), p. 246*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Explain why it is important to obtain an accurate diagnosis of anxiety.
2. Compare and contrast the five major categories of anxiety disorders.
3. Identify the regions and systems of the brain associated with anxiety, sleep, and wakefulness.
4. Describe the normal stages of sleep and explain how they are affected by anxiety and stress.
5. Identify sleep disorders that may benefit from pharmacotherapy.
6. Explain the association between insomnia and anxiety.
7. Describe nonpharmacologic methods for managing anxiety and sleep disorders.
8. Identify the major classes of medications used to treat anxiety and sleep disorders.
9. Describe the nurse's role in the pharmacologic and nonpharmacologic management of anxiety and sleep disorders.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Develop a plan of care for patients receiving pharmacotherapy for anxiety and sleep disorders.

situational anxiety, 229
social anxiety disorder, 230

Anxiety is a generalized feeling of worry, fear, or uneasiness over a perceived threat. This threat may be clearly identifiable, such as an upcoming divorce or pharmacology test, or it may be an unfocused, general feeling of worry or dread. Anxiety is a normal, adaptive response to stress that prepares an individual to deal, both physically and emotionally, with a perceived threat. However, when the anxiety is excessive or irrational, the patient's quality of life may become seriously affected and there will be an increased risk of developing chronic gastrointestinal (GI) and cardiovascular disorders. This chapter deals with medications that treat anxiety, cause sedation, or help patients sleep.

Anxiety Disorders

18.1 Proper diagnosis of anxiety disorders is important to identifying the most effective treatment option.

Anxiety disorders are the most common mental health illnesses encountered in clinical practice. Patients with anxiety often present with multiple symptoms and describe their condition in diverse ways. They often describe their feelings using terms such as *apprehension*, *dread*, *fear*, or *worry*. Anxiety activates the sympathetic nervous system and triggers symptoms of the flight-or-fright response such as rapid heart rate, shortness of breath, hypertension, pounding in the ears, excessive sweating, or dry mouth. Most patients readily admit that their feelings of anxiety are disproportionate to any real threats or dangers. A diagram of how people typically deal with stressful events is shown in Figure 18.1.

Nurses may find it challenging to sort through the many diverse and subjective patient symptoms to determine the etiology of the anxiety. Patients may be unclear as to why they are feeling anxious, or they may be reluctant to discuss the causes because they may be deeply personal. The healthcare provider must accurately diagnose the condition, however, because treatment differs among the various types of anxiety disorders. In some cases pharmacotherapy may not be the best option. Anxiety is a disorder that may respond to complementary and alternative medicine (CAM), and the nurse is a key individual to recommend and teach patients nonpharmacologic stress-reduction techniques. Some patients benefit from individual or group psychotherapy, which can help to identify and overcome the root causes of their worry and fear. Some anxiety disorders, however, are debilitating and require effective pharmacotherapy.

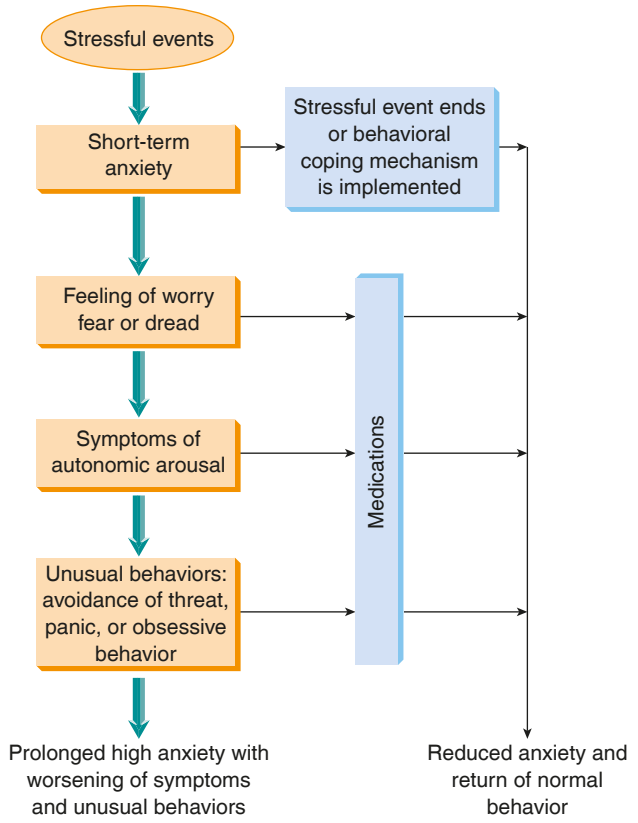

Figure 18.1 Anxiety model. Stressful events lead to physical and mental symptoms, which can be resolved by coping mechanisms or medication.

When obtaining a comprehensive medication history during the initial patient assessment, the nurse should note any substances that the patient is taking that may worsen or cause anxiety symptoms. Sometimes discontinuing or substituting alternate drugs for these "anxiety-promoting" medications can lessen patient symptoms. A simple example is substituting decaffeinated beverages for those containing caffeine. In addition, many medical conditions are associated with anxiety symptoms. For example, knowing that one has cancer or has a high risk for myocardial infarction (MI) certainly creates high stress for a patient. In these cases, the anxiety is considered secondary and may resolve once the underlying medical condition is treated. Drugs and medical conditions associated with anxiety disorders are shown in Table 18.1.

CONNECTION Checkpoint 18.1

From what you learned in Chapter 12, which classes of autonomic drugs would be most likely to cause anxiety as a side effect: sympathomimetics, parasympathomimetics, adrenergic blockers, or cholinergic blockers? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

18.2 Anxiety disorders may be divided into five major categories.

The anxiety experienced by people faced with a temporary stressful environment is called **situational anxiety**. Situational anxiety is not considered a major anxiety disorder because it is not disabling or persistent. To a degree, situational anxiety is beneficial because it motivates people to accomplish tasks in a prompt manner—if for no other reason than to eliminate the source of nervousness. Everybody experiences situational stress at some time in their lives and, although it may be intense, it does not generally require pharmacotherapy.

Anxiety requires treatment when it becomes chronic, interferes with activities of daily living (ADLs), or begins to result in long-term physical damage such as heart disease. Anxiety disorders are classified into several major categories: generalized anxiety disorder, panic disorder, social anxiety disorder, obsessive-compulsive disorder, and posttraumatic stress disorder. Not all anxiety experienced by patients is easily classified, and patients often present with multiple types of anxiety, such as generalized anxiety disorder along with panic attacks.

Table 18.1 Medications and Medical Conditions Associated with Anxiety

Medications
Antibiotics: isoniazid, fluoroquinolones
Antidepressants: bupropion, selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs)
Antihypertensives: felodipine, methyldopa
Antiseizure drugs: carbamazepine
Bronchodilators: albuterol, theophylline
Hallucinogens: ecstasy, LSD
Hormones: prednisone, thyroid hormone
Nonsteroidal anti-inflammatory drugs (NSAIDs): ibuprofen
Stimulants: amphetamines, caffeine, cocaine, methylphenidate
Sympathomimetics: pseudoephedrine
Medical Conditions
Cardiovascular: angina, dysrhythmias, heart failure, MI, pulmonary embolus, stroke
Endocrine: Cushing's disease, hyperthyroidism, hypoglycemia
Neurologic: dementia, epilepsy, Parkinson's disease, severe or chronic pain
Others: anemias, cancer, impotence, nausea, vertigo, withdrawal from abused substances
Respiratory: asthma, chronic obstructive pulmonary disease (COPD), pneumonia

PharmFACT

About 40 million Americans, or 18% of the population, are affected by anxiety disorders. Of these cases, almost 24% are classified as severe (National Institute of Mental Health [NIMH], n.d.b)

Generalized anxiety disorder (GAD) is excessive anxiety that persists for 6 months or longer. GAD has a gradual onset and is most prevalent in the 20- to 35-year-old age group. The characteristic feature of GAD is excessive worry or fear regarding life events or activities, frequently focusing on family, money, or health. Symptoms include restlessness, fatigue, muscle tension, nervousness, inability to focus or concentrate, an overwhelming sense of dread, and sleep disturbances. Signs of sympathetic nervous system activation that accompany GAD include blood pressure elevation, heart palpitations, varying degrees of respiratory change, and dry mouth. Parasympathetic responses may consist of abdominal cramping, diarrhea, fatigue, and urinary urgency. Some patients experience symptoms for over a decade before seeking help for their condition.

Panic disorder is a type of anxiety characterized by intense feelings of immediate apprehension, fearfulness, terror, or impending doom, accompanied by increased autonomic nervous system activity such as sweating, racing heart rate, shortness of breath, and trembling. To be diagnosed with panic disorder, the patient must present with at least 1 month of ongoing concern or worry about experiencing subsequent episodes. Panic attacks typically last only 1 to 10 minutes, although one attack may quickly follow another and patients may describe the episode as seemingly endless. Up to 5% of the population will experience one or more panic attacks during their lifetime, with women being affected about twice as often as men. Patients with panic disorder usually modify their behavior to try to avoid another attack. Some develop **agoraphobia**, an extreme avoidance of closed places where a panic attack might occur

such as airplanes, public meetings, or elevators. Panic attacks are often associated with major depression.

Social anxiety disorder, also called social phobia, is an unreasonable and persistent fear of being judged, ridiculed, or embarrassed by others. Performing and speaking in public are two common examples of activities that may trigger social anxiety disorder. Patients will either avoid the situation entirely or tolerate it with great discomfort. Symptoms include sweating, blushing, tachycardia, trembling, and bowel cramping or diarrhea. The average age of onset is the midteens, and the disorder may persist for decades before the individual seeks treatment. Social anxiety disorder is a type of **phobia**, a fearful feeling attached to situations or objects. In addition to social anxiety disorder, specific phobias include fear of snakes, spiders, high altitudes, exposure to blood, or fear of speaking or performing in public. Panic attacks may occur when an individual encounters his or her specific phobia.

Obsessive-compulsive disorder (OCD) involves recurrent, intrusive thoughts or repetitive behaviors. To be diagnosed with OCD, the behavior or thought must occupy more than 1 hour each day and negatively impact the patient's normal daily activities or relationships. The obsession portion of this behavior involves thoughts, whereas the compulsion portion involves actions. Most patients with this disorder have both obsessions and compulsions. One common example is repetitive thoughts about the fear of exposure to germs. The patient may think about the presence of germs constantly and what can be done to decrease exposure (obsession). The individual may engage in repetitive hand washing, possibly to the point of doing damage to the skin of the hands (compulsion). This repetitive activity can occur so frequently that it severely intrudes on the individual's ability to do any other activity during the day, including work or school. Other obsessions or compulsions include viewing sexually explicit pictures, doubting whether the iron or stove was turned off, repeating the same words silently, or repetitive counting. Most commonly, the age of onset is the teen years or early adulthood.

Post-traumatic stress disorder (PTSD) is a type of situational anxiety that develops in response to reexperiencing a previous life event. Witnessing or experiencing traumatic events such as combat, physical or sexual abuse, torture, natural disasters, or murder may lead to a sense of helplessness and reexperiencing of the event. The reexperience may take the form of nightmares, hallucinations, or flashbacks, accompanied by uncomfortable physical signs such as tachycardia and extreme nervousness or panic attacks. If the reaction occurs immediately and resolves within 1 month of the event, it is classified as acute stress disorder. To be diagnosed with PTSD, the patient must experience distressing symptoms for more than 1 month.

The average lifetime prevalence of PTSD in the United States is about 7%. Among veterans, however, the prevalence is about 30% for Vietnam veterans, and 10% to 14% for Gulf War, Iraqi, and Afghanistan veterans. Among veterans, the incidence is approximately equal in both sexes (Gore, 2015).

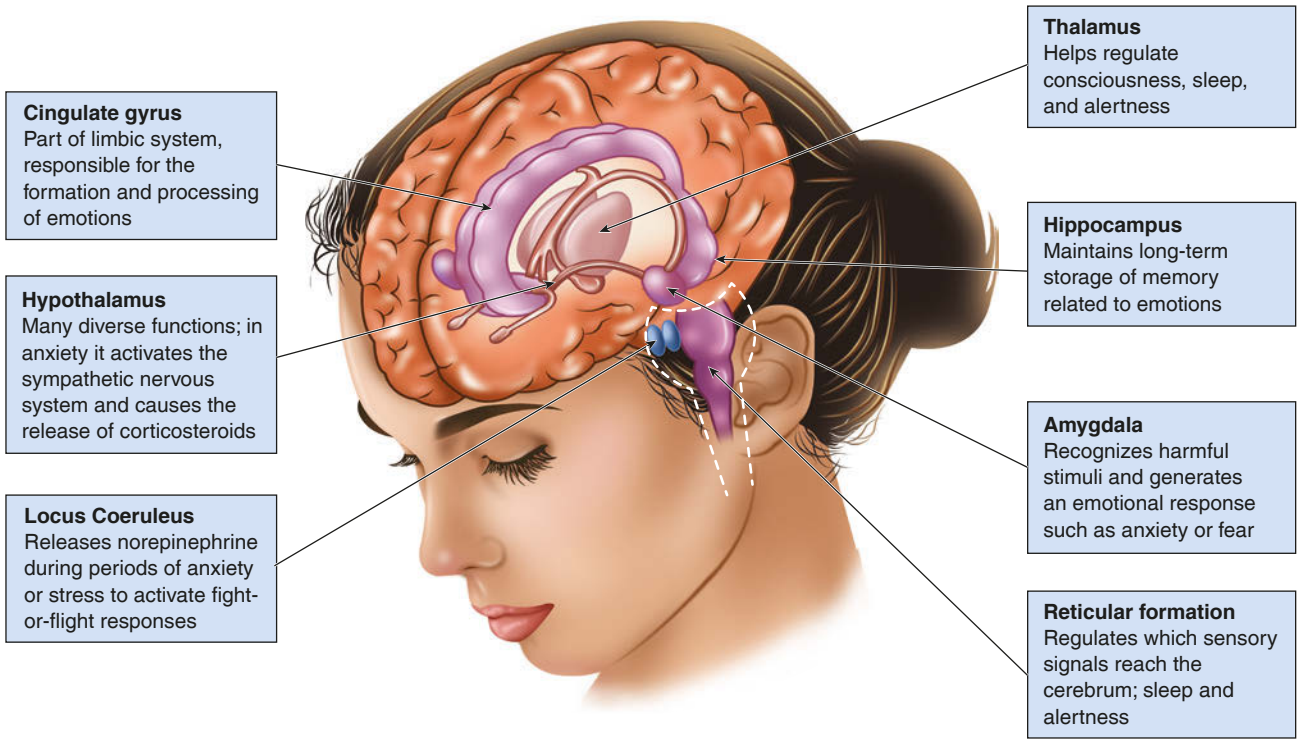
PharmFACT

For three anxiety disorders, women are twice as likely to be affected as men. These disorders include GAD, panic disorder, and specific phobias (Anxiety and Depression Association of America, 2016).

18.3 Specific regions of the brain have been identified that are responsible for anxiety.

Research has clearly demonstrated that the modulation of anxiety is accomplished in specific brain regions and by multiple neurotransmitter systems. Neural pathways associated with GAD, social anxiety disorder, and panic disorder are different.

Neural systems in the brain that are associated with anxiety include the limbic system and the reticular activating system. These are shown in Pharmacotherapy Illustrated 18.1. The student should read Section 17.4 in Chapter 17 for a brief review of these two systems before proceeding.



The limbic system is a cluster of structures in the middle of the brain that is responsible for governing emotions, behavior, and long-term memory. A key part of the limbic system that is involved in the pathogenesis of anxiety is the **amygdala**, located in the temporal lobe. The amygdala is essential for the ability to feel certain emotions and to perceive them in other people. The amygdala receives sensory inputs from many parts of the brain, which allows it to recognize and react to stimuli in the environment that could threaten survival. Once activated the amygdala generates feelings of anxiety and fear and stimulates several regions of the brain that begin the stress response. For example, the midbrain and brainstem may be activated, resulting in stress symptoms related to the autonomic nervous system, such as high blood pressure, elevated breathing rate, and dilated pupils.

The amygdala has neural connections to the hippocampus. The hippocampus is a memory storage area. It allows us to retrieve specific memories associated with a stressful event. For example, the sight of large crowds may trigger social phobia, or a loud firecracker may trigger PTSD. The hippocampus thus can retrieve negative memories that, once sent to the amygdala, can reinforce anxiety symptoms.

Activation of the amygdala also sends signals to the hypothalamus, an important command center responsible for modulating the fight-or-flight response of the autonomic nervous system. Symptoms typical of sympathetic activation result, such as increased heart rate and blood pressure. The hypothalamus responds to chronic stress by causing the release of corticosteroids from the adrenal glands. Corticosteroids are major modulators of the long-term stress

Pharmacotherapy Illustrated 18.1

Regions of the Brain Affected by Antianxiety Medications

response (see Chapter 68), keeping the body on continual "high alert" for stressors. High levels of corticosteroids can lead to irritability, anxiety, and depression.

Within the brainstem, the **locus coeruleus** maintains close neural connections to the amygdala and hypothalamus. The locus coeruleus monitors internal and external signals and is the principal site for norepinephrine synthesis in the brain. Release of norepinephrine from this region activates the brain for fight or flight. Dysfunction of the locus coeruleus has been associated with excessive anxiety and PTSD. Certain medications inhibit this area of the brain, preventing anxiety-related behaviors.

The hypothalamus connects with the reticular formation, a collection of neurons found along the core of the brainstem. The reticular formation receives input from nearly all sensory organs as well as from the cerebrum and cerebellum. Ascending fibers project to the cerebrum to form the reticular activating system (RAS). The RAS is responsible for regulating sleep and wakefulness and it performs an alerting function for the entire cerebral cortex.

If signals coming from the hypothalamus are allowed to proceed, then those signals are further routed through the RAS and on to higher brain centers. This is the neural mechanism thought to be responsible for feelings of anxiety, fear, restlessness, and an interrupted sleeping pattern. Drugs that stimulate the RAS cause heightened alertness, arousal, and focus. If signals are prevented from passing through the RAS, there is a reduction in general brain activity; thus inhibitory drugs cause general drowsiness and the induction of sleep.

Sleep Disorders

18.4 Sleep occurs in distinct stages.

The process of sleep has been well studied. It has been established that all people need an adequate amount of sleep to function optimally, although the amounts change throughout the lifespan. For middle-aged adults, 7 to 8 hours of sleep appear to be adequate. Most older adults sleep less than 8 hours, and infants and babies require much more sleep. Although it is known that sleep is essential for wellness, scientists are unsure of its function or how much is needed to maintain optimal health. Following are some theories:

1. Physical inactivity during sleep gives the body time to repair itself.
2. Sleep is a function that evolved as a protective mechanism. Throughout history, nighttime was the safest time of day for resting.

3. Sleep involves electrical charging and discharging of the brain. The brain needs time for processing and filing information collected throughout the day. When this is done without interference from the outside environment, these vast amounts of data can be retrieved later through memory.

Sleep occurs in two basic phases: rapid eye movement (REM) sleep and non–rapid eye movement (NREM) sleep. NREM sleep is further subdivided into four distinct stages based on the depth of sleep. Drugs may affect the length of time spent in the different stages of sleep. Decreases in the neurotransmitters acetylcholine, norepinephrine, and serotonin signal the change from wakefulness to **non–rapid eye movement (NREM) sleep**. During this phase, respirations slow, heart rate and blood pressure decrease, oxygen consumption by muscles decreases, and urine formation decreases. NREM accounts for about 75% to 85% of total sleep time. The four stages of NREM sleep are described in Table 18.2.

Rapid eye movement (REM) sleep is considered the active dreaming stage of sleep, although dreams may also occur in NREM sleep. As the name implies, the eyes move during this stage. Muscle tone diminishes and heart rate and breathing become irregular. Penile erections and clitoral enlargement may occur. Although adults spend about 25% of their sleep in REM sleep, newborns may spend as much as 80% of their sleep in this phase.

Table 18.2 Stages of Sleep

Stage of Sleep	Description
NREM stage 1	At the onset of sleep, the patient experiences drowsiness for 1–7 min. During this time, the patient can be easily awakened. This stage of sleep is so light that when awakened from it, individuals often deny that they were asleep. Respirations slow, muscles relax. This stage lasts for about 4–5% of total sleep time.
NREM stage 2	Although deeper than stage 1, the patient can still be easily awakened. This stage constitutes the greatest amount of total sleep time, 45–55%.
NREM stage 3	This is the period in which an individual may experience nightmares, bedwetting, or sleepwalking. Heart rate and blood pressure fall; GI activity rises. This stage lasts for about 4–6% of total sleep time.
NREM stage 4	The deepest stage of sleep, this comprises about 12–15% of total sleep time. Dreams that occur are usually thoughtlike and revolve around current concerns or recent events with little story line. This is the stage during which nightmares occur in children. Sleepwalking is also a common behavior for this stage. Heart rate and blood pressure remain low; GI activity remains high.
REM sleep	This stage, which lasts for about 25% of sleep time, is characterized by eye movement and a loss of muscle tone. Eye movement occurs in bursts of activity. Dreaming takes place in this stage; dreams are vivid, emotional, story-like, and frequently bizarre. The mind is very active and resembles a normal waking state.

Sleep occurs in cycles, alternating between REM and NREM sleep about 4 to 5 times each night, with each sleep cycle lasting approximately 90 minutes. More time is spent in NREM in early cycles, with REM sleep increasing in the later cycles. When the individual moves from NREM to REM sleep, acetylcholine levels increase and serotonin and norepinephrine levels further decrease. As REM sleep continues, the body progressively increases the levels of serotonin and norepinephrine until the amounts are adequate to stop REM sleep. For a brief time, the individual may awaken until the next cycle begins.

PharmFACT

Studies suggest that there is a connection between sleep and cognition in the older adult. Cognitive impairment has been found to correlate to sleep duration, sleep fragmentation, and sleep-disordered breathing in this population (Yaffe, Falvey & Hoang, 2014).

Patients who are deprived of stage 4 NREM sleep experience depression and a feeling of apathy and fatigue. Stage 4 NREM sleep appears to be linked to repair and restoration of the physical body, whereas REM sleep is associated with learning, memory, and the capacity to adjust to changes in the environment. The body requires the dream state associated with REM sleep to keep the psyche functioning normally. When deprived of REM sleep, people experience a sleep deficit and become frightened, irritable, paranoid, and even emotionally disturbed. Judgment is impaired, and reaction time is slowed. It is speculated that to make up for their lack of dreaming, these individuals experience far more daydreaming and fantasizing throughout the day. The stages of sleep are shown in Table 18.2.

The sleep patterns of adults vary widely. Some people do very well with less sleep, whereas others require above-average amounts to feel refreshed and mentally alert. Most people, even young adults, awaken at least once during the night; older adults awaken more frequently. The nurse can be a valuable ally to the patient experiencing sleep disturbances by explaining these normal variations and by assisting the patient to reach a desirable sleep pattern.

The acts of sleeping and waking are synchronized with many different bodily functions. Body temperature, blood pressure, hormone levels, and respiration all fluctuate on a cyclic basis throughout the 24-hour day, known as the **circadian rhythm**. Even without realizing it, those who are "day people" or "night people" structure their activities, even their occupations, around what they recognize as their best individual pattern of sleep and wakefulness. *Circadian dysrhythm* refers to the psychologic and biological stress an individual undergoes when traveling rapidly through several time zones, such as during a long airplane

Table 18.3 Types of Sleep Disorders

Type	Example(s)
Circadian rhythm sleep disorders	Time zone syndrome (jet lag), shift work sleep disorder
Hypersomnias of central origin	Narcoplexy (with or without cataplexy)
Insomnia	Acute, chronic, transient
Parasomnias	Sleepwalking, sleep terrors, nightmares
Sleep-related breathing disorders	Sleep apnea
Sleep-related movement disorders	Restless leg syndrome

journey. "Jet lag" is a very real, and sometimes disabling, phenomenon, although not a permanent dysfunction. When this cycle becomes impaired, pharmacologic or other interventions may be needed to readjust it. Circadian rhythms are based on many complex variables, including light–dark cycles and secretion of hormones such as melatonin. Biological rhythms likely exist in all living things and have even been identified in bacteria.

18.5 Sleep disorders affect a large percentage of the population.

A sleep disorder is a disturbance in the normal pattern, quality, or quantity of sleep. It is estimated that 40 million Americans experience sleep disorders. Although about 70 specific types of sleep-related disorders have been identified, pharmacotherapy is beneficial in treating only a few of them. Examples of common sleep disorders are shown in Table 18.3.

Insomnia is the most common sleep disorder and the one that is the most frequent indication for pharmacotherapy. Insomnia can be simply defined as the lack of adequate sleep; however, the disorder can be better explained by the following terms:

- **Sleep-onset insomnia.** Inability to fall asleep within a reasonable time, usually more than 30 minutes
- **Sleep-maintenance insomnia.** Frequent awakenings during the night or the inability to fall back asleep
- **Sleep-offset insomnia.** Premature, early morning awakenings
- **Nonrestorative sleep.** Persistent sleepiness during the day, despite adequate sleep duration.

The diagnosis of chronic insomnia is determined by its duration (at least 30 days or more) and the degree to which it affects ADLs. The most frequent symptom reported by patients is excessive daytime drowsiness.

Insomnia has multiple causes and often presents secondary to an underlying disorder. Examples of conditions causing secondary insomnia are shown in Table 18.4. The best approach to resolving secondary insomnia is to treat the underlying disorder. Insomnia not associated with another medical, psychiatric, or medication-related cause is considered to be *primary*.

Table 18.4 Causes of Secondary Insomnia

Cause	Description
Drugs	Amphetamines, cocaine, caffeinated beverages, corticosteroids, sympathomimetics, antidepressants, alcohol use, nicotine or tobacco use
Medical disorder	Dementia, anxiety disorder, epilepsy, Parkinson's disease, Tourette's syndrome, psychosis, mania, migraines, asthma, sleep apnea, chronic or severe pain, COPD, gastroesophageal reflux, hyperthyroidism
Poor sleep hygiene	Noisy environment; too much light in the bedroom; large meals; working or exercising just prior to sleeping; partner who snores, talks, or moves frequently during sleep
Stressful situation	Major life event such as marriage, divorce, death of a loved one, chronic or terminal disease, stressful job

A thorough medical history can sometimes distinguish between primary and secondary insomnia; however, for objective testing patients are referred to sleep disorder specialists for polysomnography and actigraphy. Polysomnography is a series of tests that record physiologic changes occurring during sleep, including eye movement, muscle tension, respiration, cardiac rhythm, and brain wave activity. Polysomnography can also determine the amount of REM and NREM sleep. Brain wave activity is measured using an electroencephalogram (EEG). Actigraphy is another frequently used diagnostic test that measures the motor activity of a patient during waking and sleeping hours. The results of these comprehensive tests can be used to diagnose most sleep disorders.

In addition to insomnia, **narcolepsy** is a sleep disorder that may respond to pharmacotherapy. Narcolepsy is characterized by severe daytime sleepiness such that the patient is unable to stay awake and may fall asleep quickly and at inappropriate times. An episode of narcolepsy, called a "sleep attack," may last from a few seconds to about 30 minutes. In addition to the sleep attack, the following four "classic" symptoms are often observed in patients with narcolepsy:

- **Cataplexy** is a sudden loss of muscle strength manifested as slurred speech, sagging of the jaw, head nodding, or even complete collapse of the body. The condition is triggered by strong emotions.
- **Hypnagogic hallucinations** are vivid, fearful sensory illusions that may be experienced at the onset of sleep or on awakening.
- Muscular paralysis may result in the temporary inability to move or speak on awakening.
- Automatic behavior may include actions such as talking or repetitive movements during the sleep episode. The individual has no memory of the behavior on awakening.

CONNECTIONS: Community-Oriented Practice

Risks Associated with Drugs for Sleep

Antihistamines, particularly the older first-generation sedating forms such as diphenhydramine (Benadryl, Sominex, others), are commonly found in over-the-counter (OTC) sleep remedies. Newer drugs such as zolpidem (Ambien) and zaleplon (Sonata), as well as older benzodiazepine drugs, are prescribed drugs. Although both types of drugs are beneficial in treating sleep disorders, they come with serious risks, even with short-term use.

Although daytime drowsiness is a common and expected adverse effect for drugs used for sleep, anxiety and psychiatric disorders are also possible effects. Benzodiazepines are more likely to cause these effects than the newer "Z drugs" such as zolpidem (Weich et al., 2014), and an increased risk of fractures related to falls has also been noted with anxiolytics, hypnotics, and even melatonin (Frisher, Gibbons, Bashford, Chapman, & Weich, 2016). Antihistamines, particularly older first-generation drugs, are known to reduce REM sleep, have cognitive effects on learning, and, because they are readily available OTC, are of particular concern in the older adult (Hess, Linnebur, Rhyne, & Valdez, 2016).

Patients who use OTC antihistamines or melatonin, or prescribed sleep aids should be cautioned about the potential for daytime drowsiness and more subtle effects that may occur, such as slowed reaction time, impaired cognitive function, and other systemic effects. For the older adult, these drugs may significantly increase the risk of falls and fractures, and special precautions should be taken, especially at night when drowsiness may impede mobility.

Pharmacologic treatment for narcolepsy includes stimulants such as amphetamines, methylphenidate, and modafinil (Provigil), which is considered a first-line drug for the disorder. Modafinil is well tolerated and adverse effects such as headache, nausea, nervousness, and anxiety are generally mild. This drug is a Schedule IV controlled substance due to its stimulant properties.

Stimulants such as modafinil are not effective for cataplexy symptoms. Older therapies for cataplexy include antidepressants such as tricyclic antidepressants (TCAs) or selective serotonin reuptake inhibitors (SSRIs). A more recent therapy utilizes sodium oxybate (gamma hydroxybutyrate [GHB], Xyrem). This drug appears to be effective in managing symptoms of both narcolepsy and cataplexy. This substance is very unusual because (as GHB) it has been used illegally to produce euphoria and to enhance sexual stimulation. GHB can cause amnesia and has been implicated in sexual assaults as a "date-rape" drug. Because of these abuses, GHB is listed as a Schedule I drug. However, the same chemical substance, marketed as Xyrem to treat narcolepsy, is a Schedule III drug. It is only available using the Xyrem Success Program, which requires the patient to obtain the drug through a central pharmacy, have regular office visits, and demonstrate understanding about the safety and proper use of the drug. Common adverse effects include headache, nausea, dizziness, and somnolence.

Management of Anxiety and Sleep Disorders

18.6 There is a link between insomnia and anxiety.

The student may be wondering why two seemingly different conditions, anxiety and insomnia, are being presented in the same chapter. There are two fundamental reasons. First, there is a pathophysiologic link between sleep and anxiety, and, second, many of the drugs used to treat anxiety are also effective for treating insomnia.

Research has shown a high incidence of serious insomnia in patients with comorbid mental health conditions such as depression and anxiety. Patients with insomnia are likely to report symptoms of nervousness and anxiety. But which comes first, the anxiety or the insomnia? In some patients, insomnia can lead to anxiety and worry about lack of restful sleep. In other patients, anxiety and worry can cause someone to lie awake and experience insomnia. Thus, it is not a matter of which came first or which caused the other. Anxiety and insomnia should be recognized as a continuous, destructive cycle with each "feeding" on the other. Recognizing this link makes insomnia therapy more than just a nighttime problem. It involves treating anxiety during the day while improving sleep at night. The nurse should assess patients for anxiety when they report sleeplessness, and vice versa.

Three primary classes of drugs are used for treating both anxiety and insomnia: benzodiazepines, nonbenzodiazepine antianxiety drugs, and antidepressants. The benzodiazepines are used for the short-term therapy of anxiety and for the treatment of patients who are unable to fall asleep due to excessive worrying at bedtime. Some of the nonbenzodiazepines and the newer antidepressants are effective for the longer term therapy of insomnia and anxiety. A second approach is to use combined therapy for the two disorders. Treating both conditions concurrently may result in better sleep outcomes than treating insomnia only.

Long-term use of sleep medications is likely to worsen insomnia, and many of these medications cause physical or psychologic dependence. Patients may experience a phenomenon referred to as **rebound insomnia**. This condition occurs when a sedative drug is discontinued abruptly after it has been taken for several months or longer. Symptoms of sleeplessness, anxiety, and daytime drowsiness become markedly worse for a few days before the original insomnia symptoms return.

PharmFACT

Studies of more than 16,000 university students found that insomnia is a common problem among students. While the prevalence is about 7% in the general population, almost 19% of the university students studied experienced insomnia (Jiang et al., 2015).

18.7 Management of anxiety and sleep disorders utilizes a combination of pharmacologic and nonpharmacologic therapies.

Various treatments for anxiety and insomnia are available. The choice of therapy depends primarily on the severity of the symptoms. In some cases, several therapies may be combined to achieve optimal results. The three types of therapies include complementary and alternative therapies, nonprescription drugs, and prescription drugs.

Complementary and alternative therapies: In mild cases of anxiety or insomnia, patients should be encouraged to explore and develop nonpharmacologic coping strategies to deal with the underlying causes. Such strategies may include cognitive behavioral therapy, counseling, biofeedback techniques, yoga, and meditation. Complementary and alternative treatments that may be useful in reducing anxiety and enhancing sleepiness are listed in Table 18.5.

Many natural products and supplements are claimed to promote relaxation and sleep. The best studied natural remedy is melatonin. Research studies have demonstrated that melatonin supplementation may improve both sleep onset and sleep duration. Melatonin is a natural hormone; however, taking too much can disrupt homeostasis and cause adverse effects such as headaches, mental impairment, and nightmares.

Two herbal products with demonstrated efficacy in promoting relaxation are kava and valerian. Although kava appears to be effective, high doses have been associated with liver damage. This has prompted some countries to withdraw kava from the market. While still available in the United States, the U.S. Food and Drug Administration (FDA) has issued a warning that kava should not be used unless recommended by a healthcare provider.

Table 18.5 Complementary and Alternative Treatments for Anxiety and Insomnia*

Alternative therapies	Acupuncture, aromatherapy, prayer, massage, meditation, biofeedback therapy, hypnosis, guided imagery, music therapy
Exercise and nutrition	Exercise therapy, nutrition therapy, deep breathing, yoga
Herbal therapies	Kava, valerian, chamomile, ginseng, lemon balm, passionflower, St. John's wort, lavender

*Safety and effectiveness have not been demonstrated for most complementary and alternative therapies.

Valerian is effective at producing drowsiness and promoting sleep and has not been shown to cause major adverse effects. Other herbs are claimed to have relaxation and sleep-promoting properties (often by those marketing the products), but research has not proved their validity or safety in treating anxiety or insomnia.

Nonprescription drugs: Antihistamines are drugs used to treat cold or allergy symptoms. One of the side effects of antihistamines is drowsiness. This is used to advantage in OTC sleep aid products such as Sominex and Nytol. In addition, products indicated as "p.m." or "nighttime" contain antihistamines that promote sleep. The two antihistamines most frequently used to produce drowsiness are diphenhydramine and doxylamine.

Antihistamines can have a long duration of action (up to 12 hours) and may leave the patient feeling drowsy the next day. They also cause drying of the nose and mouth, which is the reason they are included in cold and flu remedies. Some patients experience dizziness and blurred vision. Antihistamines should not be taken for prolonged periods for insomnia because patients become tolerant to the drowsiness effect of the drugs. The use of antihistamines in treating allergic rhinitis and the common cold is presented in Chapter 45.

Prescription drugs: The remainder of this chapter examines the classes of prescription drugs used to treat anxiety and insomnia. These medications are used when the anxiety or sleep disorder is severe or when the condition is unresponsive to nonpharmacologic therapies.

The first drugs used to treat anxiety and insomnia were *general* central nervous system (CNS) depressants. Ethanol and opium were the two CNS depressants most widely used for treating these disorders until the discovery of the barbiturates in the early 1900s. Other nonselective CNS depressants such as chloral hydrate, methaqualone (Quaalude), and meprobamate (Miltown) were also widely prescribed in the mid-20th century. Because general CNS depressants suppress most neuronal functions, they have serious adverse effects and are very dangerous in overdose situations. Methaqualone was removed from the U.S. market in 1984 because of its addictive potential and widespread illegal use in the 1960s and 1970s. Starting in the 1960s and continuing until present day, more *selective* CNS depressants have been developed that target specific areas of the brain controlling anxiety and sleep, without causing the serious adverse effects of the older drugs.

The terminology used to describe these drugs can be confusing. An **anxiolytic** is any drug that has the ability to relieve anxiety. In the broadest definition, anxiolytics include drugs from a large number of different pharmacologic classes. In clinical practice, however, the term *anxiolytic* is often more narrowly defined to include just the benzodiazepine and nonbenzodiazepine antianxiety drugs.

A *sedative* is a CNS depressant that produces relaxation, calmness, and a reduction in anxiety and excitement. *Tranquilizer* is an older term, though still often used, to describe a sedative. A *hypnotic* is a drug that produces sleep. A sedative is most often administered during the day to induce a feeling of calm or relaxation without causing sleep, whereas hypnotics are used during the night to induce sleep. The term **sedative–hypnotic** is used to describe a drug with the ability to produce a calming effect at lower doses and sleep at higher doses. Very high doses of sedative–hypnotics may produce coma and death due to respiratory failure. All of these drugs—anxiolytics, tranquilizers, sedatives, and hypnotics—are classified more broadly as CNS depressants.

The overlap in meaning can easily be seen with the preceding definitions. Some medications may be used as an anxiolytic, a sedative, or a hypnotic, depending on the dose administered. This is because CNS depression is a continuum ranging from relaxation to sedation to the induction of sleep and anesthesia. To avoid this confusion in terminology, drugs for anxiety and insomnia are usually referred to by their chemical or pharmacologic classifications. The four general classifications of drugs used for patients experiencing anxiety or sleep disorders are as follows:

- Benzodiazepines
- Nonbenzodiazepine anxiolytics
- Antidepressants
- Barbiturates.

Many CNS depressants have the potential to cause physical and psychologic dependence and nearly all of them are controlled substances. The withdrawal syndrome for some CNS depressants such as the barbiturates can cause life-threatening neurologic reactions (see Chapter 27). Drugs for treating anxiety and insomnia are listed in Table 18.6.

Table 18.6 Benzodiazepines and Nonbenzodiazepine Anxiolytics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Benzodiazepines for Anxiety		
alprazolam (Xanax)	Anxiety: PO (immediate release): 0.25–0.5 mg tid (max: 4 mg/day) Panic disorder: PO (extended release): 3–6 mg once daily in the morning (max: 10 mg/day)	*Drowsiness, lethargy, ataxia, confusion, dizziness, headache, blurred vision, slurred speech* Physical dependence, seizures (following abrupt withdrawal of high doses), birth defects, suicidal ideation, sleepwalking or sleep-driving (with insomnia therapy). With overdose: coma, respiratory depression, paradoxical anxiety, hypotension, dyspnea, cardiac arrest (IV forms)
chlordiazepoxide (Librium)	PO: 5–25 mg tid or qid IM/IV: 50–100 mg 1 h before a medical procedure	
clonazepam (Klonopin)	PO: 0.25–1 mg/day in divided doses (max: 4 mg/day)	
clorazepate (Tranxene)	PO: 15–30 mg/day in divided doses or a single dose at bedtime (max: 60 mg/day)	
diazepam (Valium)	PO: 2–10 mg bid–qid or 15–30 mg/day sustained release IM/IV: 2–10 mg, repeat if needed in 3–4 h	
lorazepam (Ativan)	PO: 2–6 mg/day in divided doses (max: 10 mg/day)	
oxazepam	PO: 10–30 mg tid or qid	
Benzodiazepines for Insomnia		
estazolam	PO: 0.5–1 mg at bedtime (max: 2 mg/day)	
flurazepam	PO: 15–30 mg at bedtime	
quazepam (Doral)	PO: 7.5–15 mg at bedtime	
temazepam (Restoril)	PO: 7.5–30 mg at bedtime	
triazolam (Halcion)	PO: 0.125–0.25 mg at bedtime (max: 0.5 mg/day)	
Nonbenzodiazepine Anxiolytics		
buspirone	PO: 7.5–15 mg in divided doses; may increase by 5 mg/day every 2–3 days (max: 60 mg/day)	*Dizziness, headache, nausea, vomiting, drowsiness, fatigue, dry mouth, headache, dream disturbances, unpleasant taste (eszopiclone, ramelteon), decreased testosterone and increased prolactin levels (ramelteon)* Paradoxical excitation, mood changes, tachycardia, blurred vision, confusion, myalgia
eszopiclone (Lunesta)	PO: 2–3 mg/day at bedtime	
ramelteon (Rozerem)	PO: 8 mg/day at bedtime (max: 8 mg/day)	
suvorexant (Belsomra)	PO: 5–20 mg once daily 30 min before bedtime	
tasimelteon (Hetlioz)	PO: 20 mg/day at bedtime	
zaleplon (Sonata)	PO: 5–10 mg at bedtime (max: 20 mg/day)	
zolpidem (Ambien, Edluar, others)	PO (immediate release): 5–10 mg at bedtime for 7–10 days (max: 10 mg/day); PO (extended release): 12.5 mg at bedtime SL: 1.75–3.5 mg (Intermezzo) or 5–10 mg (Edluar) once per night	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

CNS depressants are very effective drugs. If a patient does not respond to these medications with improved relaxation or sleep, the presence of a serious underlying psychiatric or medical condition should be considered that requires further assessment by behavioral specialists. This is especially true if the drug worsens insomnia or produces bizarre thinking or unusual behaviors. Examples of such behaviors that should be immediately reported to the healthcare provider include aggressiveness, hallucinations, suicidal thinking, and unusual extroversion or depersonalization.

Pharmacotherapy of Anxiety and Insomnia

18.8 Benzodiazepines are preferred drugs for generalized anxiety disorder and the short-term therapy of insomnia.

The benzodiazepines are versatile drugs used for a diverse collection of medical conditions, including anxiety, seizure disorders, muscle spasms, premedication for medical procedures and anesthesia, and alcohol withdrawal. Diazepam (Valium) is featured as a prototype drug in Chapter 22 for its use in treating acute seizure disorders.

The benzodiazepines are preferred drugs for GAD and for the short-term management of insomnia. Since the introduction of the first benzodiazepines—chlordiazepoxide (Librium) and diazepam (Valium)—in the 1960s, the class has become one of the most widely prescribed in medicine. Benzodiazepines account for approximately three fourths of all prescriptions for anxiety because they are effective, have a low incidence of drug interactions, and have less abuse potential compared to the older sedative–hypnotic drugs. There is a relatively wide margin of safety between therapeutic and lethal doses.

Although about 15 benzodiazepines are available, all have very similar actions and adverse effects; the various benzodiazepines differ primarily in their onset and duration of action. Although their actions are similar, drugs in this class have different indications, which are listed in Table 18.7.

Benzodiazepines bind to the gamma-aminobutyric acid (GABA) receptor and intensify the effect of GABA, the natural inhibitory neurotransmitter found throughout the brain. Most are metabolized in the liver to active metabolites and are excreted primarily in urine. One major advantage of the benzodiazepines is that they do not produce respiratory depression when taken in therapeutic doses. Death due to overdose is unlikely unless the benzodiazepines are taken in extreme quantities in combination with other CNS depressants, or if the patient has sleep apnea.

The benzodiazepines are categorized as Schedule IV drugs; their use may lead to physical and psychologic dependence. The risk of dependence increases with higher doses and more prolonged therapy. Abrupt termination of treatment can result in withdrawal symptoms that include headaches, confusion, irritability, insomnia, and restlessness. Preexisting mental health conditions such as depression or suicidal tendencies may emerge or worsen during benzodiazepine therapy.

Most benzodiazepines are given orally (PO). Those that can be given parenterally, such as diazepam (Valium) and lorazepam (Ativan), the prototype drug in this category, should be monitored carefully due to their rapid onset of CNS effects and possible hypotension and respiratory depression. Benzodiazepines are given parenterally for conditions such as status epilepticus or severe symptoms of acute schizophrenia. Midazolam (Versed) is administered parenterally because it can act within minutes to

CONNECTIONS: Complementary and Alternative Therapies

Melatonin

Description

Melatonin is a natural hormone produced during the night by the pineal gland. Melatonin production in the brain is related to time of day, falling in the morning with light inhibiting its release and rising in the evening (National Center for Complementary and Integrative Health [NCCIH], 2015).

History and Claims

The secretion of melatonin is stimulated by darkness and inhibited by light. As melatonin production rises, alertness decreases, and body temperature starts to fall, both of which make sleep more inviting. Melatonin production is related to age. Children manufacture more melatonin than older adults; however, melatonin production begins to drop at puberty. Supplemental melatonin, 0.5 to 3 mg at bedtime, is alleged to decrease the time required to fall asleep and to produce a deep and restful sleep.

Standardization

Melatonin is commonly marketed as 1- to 3-mg tablets. Melatonin is one of only two hormones not regulated by the FDA and sold OTC without a prescription (dehydroepiandrosterone [DHEA] is the other).

Evidence

Melatonin appears to help people, particularly the older adult, to fall asleep faster. The NCCIH (2015) cites evidence that melatonin also appears to be useful in people with insomnia related to disrupted circadian rhythm cycles. It is believed that melatonin helps to reset the circadian rhythm for these patients, rather than cause drowsiness. Melatonin appears to be safe for short-term use; however, an increased risk of falls and fractures has been noted with long-term use, although further study is needed to confirm this finding (Frisher et al., 2016).

Table 18.7 Indications for Benzodiazepines

Drug	GAD	Panic Disorder	Insomnia	Seizures	Alcohol Withdrawal	Preanesthetic Medication	Other
alprazolam (Xanax)	A	A	O				Premenstrual dysphoric disorder
chlordiazepoxide (Librium)	A				A	A	
clonazepam (Klonopin)	O	A	O	A			
clorazepate (Tranxene)	A		O	A	A		
diazepam (Valium)	A		O	A	A	A	Muscle spasms
estazolam	O		A				
flurazepam	O		A				
lorazepam (Ativan)	A	O	O	A (IV form)	O	A (IV form)	
midazolam (Versed)				O		A	Conscious sedation
oxazepam	A		O		A		
quazepam (Doral)	O		A				
temazepam (Restoril)			A				
triazolam (Halcion)			A				

Note: A = FDA approved for this indication; O = off-label use.

Note: Off-label uses are highly dependent on the prescriber and change frequently. The student should refer to current reference sources for updated information on approved and off-label indications.

produce conscious sedation in patients undergoing minor medical–surgical procedures.

The benzodiazepines have replaced the barbiturates for the short-term treatment of insomnia caused by anxiety because of their greater margin of safety. Benzodiazepines shorten the length of time it takes to fall asleep and reduce the frequency of interrupted sleep. Initially, patients will report an increase in refreshed, deep sleep. Although most benzodiazepines increase total sleep time, some reduce stage 4 sleep, and some affect REM sleep. With chronic use, the patient will experience a gradual increase of REM sleep as tolerance develops to the REM-suppressant effects of the medication.

The benzodiazepines approved to treat short-term insomnia are different from those indicated for GAD (see Table 18.6). These anti-insomnia benzodiazepines are administered as hypnotics to induce sleep. Like other benzodiazepines tolerance develops to their therapeutic effects, and all have the potential for physical and psychologic dependence. Most produce excessive daytime drowsiness, although this diminishes after a few days of therapy. They are indicated for short-term therapy of insomnia, approximately 4 weeks, although in clinical practice they may be used for longer periods. Rebound insomnia may be significant if these drugs are used for prolonged therapy.

Sedative–hypnotic medications such as the benzodiazepines have the potential to cause sleep-related behaviors that the patient does not remember. These include sleepwalking, sleep-eating, and even making phone calls or driving a car (sleep-driving) while not fully awake. Patients often deny that these events occurred.

Flumazenil (Romazicon) is an antidote for benzodiazepine overdose. Given by rapid IV injection, flumazenil competes with benzodiazepines for the GABA receptor and reverses benzodiazepine-induced sedation within minutes. It has a very short duration of action, and multiple doses, given every 30 to 45 seconds, may be necessary. If there is no response after the maximum dose (3 mg/h) has been administered, the patient's sedation was likely caused by a drug other than a benzodiazepine. Flumazenil must be used cautiously because the patient may awaken abruptly with dysphoria, agitation, and even seizures. Flumazenil does not reverse the depressed respiration characteristic of benzodiazepine overdose and it is not an antidote for the serious CNS depression caused by barbiturates or opioids. It does, however, reverse the CNS effects of some of the nonbenzodiazepine drugs such as zolpidem and eszopiclone.

PROTOTYPE DRUG Lorazepam (Ativan)

Classification **Therapeutic:** Antianxiety drug, sedative–hypnotic, antiseizure drug
Pharmacologic: Benzodiazepine, GABA receptor agonist

Therapeutic Effects and Uses: Approved in 1977, lorazepam is administered as oral tablets, concentrated oral solution, or by the intramuscular (IM) or intravenous (IV) routes. It is well absorbed by all routes. Lorazepam is approved for the routine management of GAD and to reduce anxiety prior to surgical or medical procedures. As a preanesthetic drug, it is administered by the IV route

15 to 20 minutes prior to surgery or by the IM route 2 hours prior to the procedure. Mechanically ventilated patients may receive lorazepam infusions to manage excessive anxiety and agitation that commonly occur while connected to a ventilation device.

Lorazepam is also used for several off-label indications, including insomnia, seizures, and the prevention or control of acute symptoms associated with ethanol withdrawal. Although used off-label for this indication, it is a preferred drug for treating life-threatening status epilepticus. For this indication it is administered by slow IV injection over a 2- to 4-minute period.

Mechanism of Action: Lorazepam potentiates the actions of GABA, an inhibitory neurotransmitter in the CNS. It is capable of causing all levels of CNS depression, from simple relaxation, to the induction of sleep, to coma.

Pharmacokinetics:

Route(s)	PO, IM, IV
Absorption	Readily absorbed
Distribution	91% bound to plasma proteins; widely distributed, including crossing the placenta; secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Peak effect: PO: 1–6 h; IM: 1–1.5 h; IV: 1–5 min
Duration of action	12–24 h

Adverse Effects: The most frequently reported adverse effects, such as dizziness, ataxia, drowsiness, blurred vision, vertigo, sedation, and confusion, are CNS related. These effects are dose related and tolerance to them may develop as therapy progresses. Less common adverse effects include hepatotoxicity (including jaundice), alopecia, anaphylaxis, orthostatic hypotension, cardiac changes (tachycardia, hypotension, cardiac arrest following rapid IV administration), constipation, dry mouth, nausea, vomiting, and anorexia. Paradoxical CNS stimulation can occur in psychiatric patients, older adults, and hyperactive children. Patients may experience nightmares, talkativeness, mania, sleep disorders, acute rage reactions, anxiety, restlessness, and euphoria.

Contraindications/Precautions: Like other benzodiazepines, use of lorazepam may cause fetal malformations; thus this drug is contraindicated during pregnancy unless the patient's condition is life threatening. It is also contraindicated in lactating women because the drug is secreted in breast milk. Those with a hypersensitivity to benzodiazepines or who have closed-angle glaucoma, psychosis, or chronic obstructive pulmonary disease (COPD) should not take lorazepam. Precautions must be taken in older adults, those who are debilitated, or those who have hepatic or renal dysfunction. Safe use in children has not been established. Lorazepam is a Schedule IV controlled substance and can cause both physical and psychologic dependence. Those with a history of drug abuse should be monitored carefully.

Drug Interactions: There are many potential drug interactions with lorazepam. Most notably, additive CNS depression will occur if the drug is given concurrently with other CNS depressants, such as alcohol, opiates, or other sedative–hypnotics. Oral contraceptives inhibit the metabolism of benzodiazepines that undergo oxidation (alprazolam, chlordiazepoxide, diazepam, and others); thus the effectiveness of these antianxiety drugs may be increased. On the other hand, oral contraceptives increase the metabolism of benzodiazepines that undergo conjugation (e.g., lorazepam, oxazepam, and temazepam) such that the antianxiety effects of these drugs may be reduced. Sedation effects may be increased if lorazepam is taken concurrently with disulfiram. Valproic acid may decrease the effects of lorazepam. **Herbal/Food:** Kava, melatonin, and valerian may cause excessive drowsiness if taken with lorazepam. Excessive ingestion of caffeinated food and drinks may decrease the effectiveness of lorazepam.

Pregnancy: Category D.

Treatment of Overdose: Overdose will cause sedation, lethargy, and coma. Supportive care should be provided while the patient is recovering. Gastric lavage and activated charcoal may be administered. The benzodiazepine antagonist flumazenil may be administered to reverse sedation.

Nursing Responsibilities: Key nursing implications for patients receiving lorazepam are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders.

Drugs Similar to Lorazepam (Ativan)

Benzodiazepines for anxiety: Benzodiazepines that are primarily used to treat anxiety are discussed next and include alprazolam, chlordiazepoxide, clorazepate, diazepam, and oxazepam. Benzodiazepines that are primarily indicated for seizures (clonazepam, clorazepate, diazepam, and lorazepam) are presented in Chapter 22. Midazolam is used as an adjunct to anesthesia and is presented in Chapter 26.

Alprazolam (Xanax): Approved in 1981, alprazolam is available in several oral formulations and is indicated for the management of GAD and panic disorder. It is used off-label for the short-term treatment of insomnia and for premenstrual dysphoric disorder that is unresponsive to nonpharmacologic therapies. An extended release form

(Xanax XR) is administered once daily. An orally disintegrating tablet (ODT) form is also available (Niravam). The drug is well tolerated, with drowsiness being the most common adverse effect. Patients are encouraged to refrain from consuming grapefruit and grapefruit juice while taking alprazolam, because the combination may inhibit the metabolism of the drug. Older adults should receive a small dose, which can then be gradually increased as indicated, to prevent ataxia or excessive sedation. Care must be taken when treating women of childbearing age because alprazolam is a pregnancy category D drug.

Chlordiazepoxide (Librium): Chlordiazepoxide is a long-acting benzodiazepine that has been available for almost 50 years. It is available as capsules for oral administration; the parenteral formulations are no longer marketed in the United States. It is approved to manage GAD, acute anxiety situations, and symptoms associated with acute alcohol withdrawal. Off-label uses include treatment of panic disorder, tremors, and tension headaches. The use of chlordiazepoxide has markedly declined in favor of the shorter acting drugs in this class such as lorazepam and alprazolam. Drowsiness is the most common adverse effect. Precautions should be used in those with impaired hepatic or renal function. Children and older adults are more likely to experience adverse effects and should be started with a low dose, which may then be gradually increased as needed. Chlordiazepoxide is a pregnancy category D drug and is secreted in breast milk.

Clorazepate (Tranxene): Approved in 1972, clorazepate is available by the oral route to treat GAD, partial seizures, and symptoms associated with ethanol withdrawal. It may be used off-label for the short-term management of insomnia. Clorazepate is essentially a prodrug that is converted into the same active metabolites as diazepam; thus these drugs share the same actions and adverse effects. They are both pregnancy category D drugs.

Diazepam (Valium): Diazepam is an older benzodiazepine that is available for PO, IM, and IV administration. It is FDA approved to treat GAD, seizures, and muscle spasms and for the relief of symptoms associated with acute alcohol withdrawal. It is also approved to produce relaxation or sedation prior to medical procedures. Off-label uses include reduction of agitation, treatment of acute chloroquine overdose, and treatment of withdrawal symptoms associated with benzodiazepine abuse. Diazepam has the same actions and adverse effects as other drugs in its class.

Oxazepam: Approved in 1965, oxazepam is indicated for managing the symptoms of acute alcohol withdrawal and for treating mild to moderate GAD associated with depression. It may be used off-label for the short-term management of insomnia associated with situational anxiety. Available only PO, its actions and adverse effects are the same as other benzodiazepines. This is a pregnancy category D drug.

Benzodiazepines primarily for insomnia: Benzodiazepines primarily used as hypnotics to treat insomnia include estazolam, flurazepam, quazepam, temazepam, and triazolam.

Estazolam: Approved in 1990, estazolam is an intermediate-duration benzodiazepine approved as a hypnotic in the short-term management of insomnia. This drug should be given at bedtime because it causes significant drowsiness and promotes sleep. The most common adverse effects are somnolence, hypokinesia, abnormal coordination, and dizziness. After several weeks of therapy, patients may exhibit tolerance to the sedative effects of the drug and will experience difficulty sleeping during the early morning hours. Estazolam is a pregnancy category X drug and is contraindicated during lactation.

Flurazepam: Flurazepam, the oldest benzodiazepine hypnotic, was approved in 1970. This drug is only available PO and should be taken immediately before bedtime because it rapidly produces significant drowsiness. Flurazepam has a longer duration of action than some drugs in this class because it is converted to long-acting active metabolites in the liver. Its longer duration has the potential to extend drowsiness into the morning hours. Because of the development of tolerance to the sedative effects of this drug and the potential for physical and psychologic dependence, therapy is usually limited to 4 weeks. Flurazepam is a pregnancy category X drug.

Quazepam (Doral): Approved in 1985, quazepam is a benzodiazepine hypnotic drug available only by the PO route. It is administered just before bedtime because it rapidly produces significant drowsiness. This drug has a long duration of action because it is converted to several active metabolites in the liver that extend the drug's half-life. Patients may experience daytime sedation, although tolerance develops to this adverse effect after a few days. Therapy is usually limited to 4 weeks because of the development of tolerance and the potential for dependence. Quazepam is a pregnancy category X drug.

Temazepam (Restoril): Approved in 1981, temazepam is indicated for the short-term therapy (7–10 days) of insomnia. It is administered PO and should be taken at bedtime due to its rapid onset of action. Unlike flurazepam and quazepam, the metabolism of temazepam does not result in active metabolites; thus the drug may be safer for use in patients with hepatic impairment. Like the other benzodiazepine hypnotics, however, temazepam is a pregnancy category X drug.

Triazolam (Halcion): Approved in 1982, triazolam is similar to other benzodiazepine hypnotics. Because of its rapid onset, it should be taken immediately prior to sleep. It has a relatively short half-life and has no active metabolites.

Daytime drowsiness is less of a problem with triazolam because of its relatively short half-life. It is approved for the short-term therapy (7–10 days) of insomnia. Anterograde amnesia may occur more frequently with triazolam than with other benzodiazepine hypnotics. Triazolam is a pregnancy category X drug.

CONNECTION Checkpoint 18.2

Differences in sleep patterns and ability to sleep may be apparent in different age groups. From what you learned in Chapter 8, should sleeping difficulties in the pregnant or lactating woman be treated with medications? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

18.9 Nonbenzodiazepine anxiolytics have become popular choices for treating anxiety and sleep disorders.

Several CNS depressants are used for anxiety and sleep disorders that are chemically unrelated to benzodiazepines. These drugs come from multiple classes and are grouped together as nonbenzodiazepine anxiolytics.

Older CNS depressants, such as paraldehyde (Paracetaldehyde), ethchlorvynol (Placidyl), chloral hydrate, meprobamate (Equanil), and glutethimide (Doriglute), have only historic interest because they are so rarely prescribed due to their potential for serious adverse effects. The student should refer to drug guides or older pharmacology references for information on these medications.

A few nonbenzodiazepine drugs have antianxiety properties but their primary use is for indications other than anxiety. For example, valproic acid (Depakote) is a commonly prescribed antiseizure medication that is used off-label to treat agitation in older adults or anxiety in patients with bipolar disorder. Atenolol (Tenormin), metoprolol (Toprol), and propranolol (Inderal) are beta blockers that reduce the autonomic nervous system symptoms of anxiety such as nervousness, tremor, and tachycardia. Similarly, clonidine (Catapres) is an adrenergic antagonist that can block the autonomic symptoms that accompany anxiety. Diphenhydramine (Benadryl) and hydroxyzine (Vistaril) are antihistamines that produce drowsiness and may be beneficial in calming patients. They offer the advantage of not causing dependence, although their use is often limited by their anticholinergic adverse effects. Diphenhydramine is a common component of OTC sleep aids and medications used to treat seasonal allergies. Because anxiety is a secondary indication for these drugs, they are discussed in other chapters of this text.

The most frequently prescribed nonbenzodiazepine anxiolytics are newer drugs that produce more selective CNS depression. Buspirone is commonly prescribed for its anxiolytic effect. Zolpidem (Ambien, Edluar, others), ramelteon (Rozerem), zaleplon (Sonata), suvorexant (Belsomra), and eszopiclone (Lunesta) are used for their hypnotic effects. Other than their use in treating anxiety or insomnia, these drugs share little in common with each other and are discussed individually next.

PROTOTYPE DRUG **Zolpidem (Ambien, Edluar, Others)**

Classification **Therapeutic:** Sedative–hypnotic, drug for insomnia
Pharmacologic: Nonbenzodiazepine anxiolytic

Therapeutic Effects and Uses: Approved in 1992, zolpidem is approved for the short-term (7–10 days) treatment of insomnia. Zolpidem decreases sleep-onset time and the number of nighttime awakenings and improves the length and quality of sleep. Muscle relaxation and anticonvulsant effects occur at doses much higher than the hypnotic dose. Immediate release (Ambien), extended release (Ambien CR), oral spray (Zolpimist), and sublingual (Edluar, Intermezzo) forms are available. The sublingual and oral spray forms have a more rapid onset than tablets and eliminate the requirement for water or the need to swallow.

Zolpidem should be administered just prior to expected sleep due to its rapid onset of action. Its lack of active metabolites and short half-life reduce the incidences of excessive daytime drowsiness and rebound insomnia.

Mechanism of Action: Zolpidem has a similar mechanism of action as the benzodiazepines: enhancing the action of GABA, the inhibitory neurotransmitter. Whereas the benzodiazepines bind nonselectively to all three known subtypes of the GABA receptors, zolpidem binds to only one specific type (omega-1). This explains why the drug shares some actions of the benzodiazepines, such as antianxiety and hypnotic effects, but has no effects on muscle relaxation or reducing seizures.

Pharmacokinetics:

Route(s)	PO
Absorption	70% absorbed
Distribution	Widely distributed; unknown if it crosses the placenta; small amounts are secreted in breast milk; 92% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal, small amounts in bile and feces
Onset of action	7–27 min; peak effect: 90 min
Duration of action	Duration: 6–8 h; half-life: 1.4–4.5 h

Adverse Effects: Adverse reactions to zolpidem are usually mild and include dizziness, diarrhea, and daytime drowsiness. Other adverse effects include nausea,

vomiting, depression, confusion, and amnesia. As with other hypnotic drugs, a small percentage of patients experience abnormal thinking, behavioral changes, and complex behaviors such as sleep-eating, sleep-driving, and hallucinations. Very high doses may cause severe ataxia, bradycardia, altered vision, severe nausea, vomiting, drowsiness, difficulty breathing, and coma. Abrupt withdrawal after long-term use may result in asthenia, diaphoresis, vomiting, tremor, or facial flushing. **Black Box Warning:** Zolpidem is a Schedule IV controlled substance that can be abused and lead to dependency. Store in a safe place to prevent misuse and abuse. Tell your doctor if you have ever abused or been dependent on alcohol, prescription drugs, or street drugs.

Contraindications/Precautions: Other than hypersensitivity to zolpidem, there are no contraindications to the use of this drug. As with other CNS depressants, it should be used cautiously in patients with respiratory impairment and in older adults, who are generally more sensitive to the depressive effects of the drugs; lower dosages may be necessary. Because zolpidem is metabolized in the liver and excreted by the kidneys, impaired liver or kidney function can increase serum drug levels and doses should be lowered. Zolpidem should be used with caution in individuals with depression and suicidal ideation because there is a potential for intentional overdose in these patients. The safety and effectiveness in patients under age 18 have not been established.

Drug Interactions: Zolpidem is a substrate for hepatic CYP3A4 enzymes and thus may interact with drugs that induce or inhibit this enzyme system. Concurrent use with other CNS depressants, including alcohol and fentanyl, will cause additive sedation. When given concurrently with certain SSRIs, disorientation or worsening of depression may occur. **Herbal/Food:** The presence of food will reduce absorption of the drug; thus it should be taken on an empty stomach. St. John's wort may cause confusion and, rarely, hallucinations. Valerian, kava, and melatonin supplements may cause additive sedation.

Pregnancy: Category B (immediate release) or C (extended release).

Treatment of Overdose: Overdose with zolpidem can cause serious impairment of consciousness and may be fatal. The benzodiazepine antagonist flumazenil will reverse the sedative effects of zolpidem but may precipitate seizures. Other treatment involves supportive care, such as gastric lavage.

Nursing Responsibilities: Key nursing implications for patients receiving zolpidem are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders.

Drugs Similar to Zolpidem (Ambien, Edluar, Others)

Other drugs in this category include buspirone, eszopiclone, ramelteon, suvorexant, tasimelteon, and zaleplon.

Buspirone: Buspirone is a nonbenzodiazepine anxiolytic approved in 1986 for the short-term management (up to 1 month) of GAD. Available PO, it should be taken consistently either with or without food because food affects its absorption. Grapefruit juice may increase the effects of the drug and should be avoided. The mechanism of action for buspirone is unclear but appears to involve two pathways: enhancing dopamine (D_2) receptors and suppressing serotonin receptors in the brain. It is less likely to affect cognitive and motor performance than benzodiazepines and rarely interacts with other CNS depressants. The most common adverse effects include dizziness, drowsiness, nausea, vomiting, and headache. When switching from a benzodiazepine to buspirone, the patient may experience withdrawal symptoms or anxiety; therefore, the dose of benzodiazepine should be gradually tapered while buspirone is increased. Safety and efficacy have not been established in children. Unlike other CNS depressants, buspirone does not cause dependence or have withdrawal symptoms. Therapy may take 2–4 weeks to achieve optimal results. Buspirone is sometimes used off-label to treat symptoms of nicotine withdrawal and premenstrual syndrome. It is a pregnancy category B drug.

Eszopiclone (Lunesta): Although not structurally related to other sedative–hypnotics, eszopiclone shares certain properties with zolpidem and the benzodiazepines. Approved in 2004, eszopiclone has a long elimination half-life, about twice as long as that of zolpidem, which offers an advantage in maintaining sleep and decreasing early-morning awakening. On the other hand, the long half-life is more likely to cause sleepiness to carry over into the morning hours and result in daytime sedation. Adverse effects are mild and include headache, dizziness, dry mouth, and an unpleasant taste that may persist into the following day. It is only available PO and should be taken immediately before bedtime due to its rapid onset of action. Eszopiclone is metabolized by hepatic CYP3A4 enzymes; thus potential drug–drug and drug–herb interactions exist for substances that induce or inhibit these enzymes. The onset of action may be reduced if taken with or immediately following a high-fat meal. Older adults with impaired hepatic or renal function may need a lower dose. Eszopiclone may be used for the long-term treatment of insomnia. However, tolerance develops to the sedative effects after a few weeks of therapy and rebound insomnia may occur on withdrawal. Eszopiclone is a Schedule IV controlled substance. It is a pregnancy category C drug.

Ramelteon (Rozerem): Approved in 2005, ramelteon is approved to treat chronic insomnia in people who have problems falling asleep. It appears to be safe for long-term use. Ramelteon has a unique mechanism of action: It activates melatonin receptors, specifically MT1 and MT2, which are mediators of the normal sleep–wake cycle. With an onset of action of 30 minutes and a short duration of action, it is helpful in treating sleep onset but it does not maintain sleep. It is less effective if taken with or immediately after a high-fat meal. There is little next-day residual drowsiness owing to its short half-life. Adverse effects of ramelteon are mild and include dizziness, fatigue, and somnolence. Ramelteon can affect the levels of sex hormones in the body, so the patient may experience amenorrhea, decreased libido, galactorrhea, and problems with fertility. Alcohol should be avoided because it may cause additive CNS depression. Fluvoxamine (Luvox) can greatly increase (more than 50 times) the levels of ramelteon so it should not be used concurrently. Ramelteon is a pregnancy category C drug.

Suvorexant (Belsomra): Approved in 2014 to treat insomnia, suvorexant is the only drug in a class called orexin receptor antagonists. Orexin is a neurotransmitter found in the brain that helps regulate sleep–wake cycles by maintaining wakefulness. Loss of orexin neurons is associated with narcolepsy. By blocking orexin receptors, suvorexant promotes drowsiness and sleep. Caution must be used when combining suvorexant with alcohol or other CNS depressants due to additive sedation. Use with inhibitors of hepatic CYP3A4, including grapefruit juice, should be avoided. The primary side effect is daytime drowsiness. Worsening of depression or suicidal thinking has been reported. Suvorexant is a Schedule IV controlled substance. It is pregnancy category C.

Tasimelteon (Hetlioz): Tasimelteon was approved in 2014 for non–24-hour sleep–wake disorder. This is a condition that occurs in people who are totally blind. Because no light is perceived, these patients are unable to synchronize the timing of sleep to a 24-hour light–dark cycle. This may result in the patient being active when others are sleeping or drowsy when others are awake. Several weeks or months of therapy may be needed to improve the sleep–wake cycle. The most common adverse effects are headache, elevated alanine aminotransferase (ALT), and nightmares. This drug is pregnancy category C.

Zaleplon (Sonata): Approved in 1999, zaleplon is an oral nonbenzodiazepine sedative–hypnotic whose only indication is for the short-term treatment (7–10 days) of insomnia. Zaleplon decreases time to sleep onset. Like zolpidem, it binds specifically to the omega-1 GABA receptor, but it has a faster onset and shorter duration of action than zolpidem. Zaleplon should be taken immediately before bedtime due to its rapid onset of action. Administration immediately following a high-fat meal slows the absorption of zaleplon and reduces its effectiveness. The drug is well tolerated and causes few adverse effects. High doses produce symptoms characteristic of other sedative–hypnotics such as drowsiness, confusion, dizziness, and lethargy. As with other sedative and hypnotic drugs, worsening of depression or suicidal thinking has been reported. Long-term use does not result in tolerance and, although it is a Schedule IV drug, dependence potential is low. It is a pregnancy category C drug.

PharmFACT

The prevalence of insomnia appears to be increasing, especially in patients with diabetes. From 2002–2010, the overall prevalence increased slightly from 17.4% to 18.8%, but the increase in patients with diabetes was 27% (Ford, Cunningham, Giles, & Croft, 2015).

18.10 Antidepressants are widely prescribed for anxiety disorders.

Until the 1980s, antidepressants were used mainly to treat major depressive disorder, a condition characterized by chronic low mood and loss of interest or pleasure in activities that were previously enjoyable. During the past 20 years, however, pharmacologists have discovered the value of these drugs in treating other disorders, including anxiety. Today, antidepressants are frequently used to treat various anxiety disorders and are the preferred drugs in some cases. Given the effectiveness of antidepressants for these conditions, many believe that in the future, anxiolytics and antidepressants will eventually merge into a single drug class.

Antidepressants act by altering the levels of two important neurotransmitters in the brain: norepinephrine and serotonin. Restoration of normal neurotransmitter balances reduces symptoms associated with depression, panic attacks, obsessive-compulsive behavior, PTSD, and phobias. A more detailed treatment of these drugs and their use in treating depression is presented in Chapter 19. The following section focuses on their applications to treating anxiety disorders and insomnia.

For most patients, panic attacks and other intense anxiety symptoms come in two stages. In the first stage, termed anticipatory anxiety, the patient begins to think about an upcoming challenge and starts to experience feelings of dread. The second stage is when physical symptoms such as shortness of breath, accelerated heart rate, and muscle tension start to emerge as a consequence of activation of the autonomic nervous system. For panic attacks or phobias, the most useful therapy is to help motivate the patient to face his or her fear and to suppress symptoms in one or both of these stages. If drugs can reduce the negative thoughts associated with the anticipatory component of panic, then there is less likelihood that

Table 18.8 Indications for Antidepressants Used for Anxiety or Insomnia

Drug	GAD	Panic Disorder	Social Anxiety Disorder	OCD	PTSD	Insomnia
Atypical Antidepressants, Including the SNRIs						
duloxetine (Cymbalta)	A					
trazodone (Oleptro)	O	O				O
venlafaxine extended release (Effexor XR)	A	A	A	O		
Selective Serotonin Reuptake Inhibitors (SSRIs)						
citalopram (Celexa)	O	O	O	O	O	
escitalopram (Lexapro)	A	O	O			
fluoxetine (Prozac)	O	A		A	O	
fluvoxamine (Luvox)	O	O	A	A	O	
paroxetine (Paxil)	A	A	A	A	A	
sertraline (Zoloft)	O	A	A	A	A	
Tricyclic Antidepressants (TCAs)						
amitriptyline (Elavil)		O	O			O
clomipramine (Anafranil)				A		
desipramine (Norpramin)	O	O				
doxepin (Silenor)	A					A
imipramine (Tofranil)		O	O			
nortriptyline (Pamelor)		O	O			

Note: A = FDA approved for this indication; O = off-label use.

Note: Off-label uses are highly dependent on the prescriber and change frequently. The student should refer to current reference sources for updated information on approved and off-label indications.

the patient will become stressed. Drugs can also be used to reduce neuronal activity and suppress the autonomic nervous system, helping the patient to remain calm. The patient can then use self-help coping skills to control the negative behavior.

The antidepressants used to reduce symptoms of panic and anxiety are usually the SSRIs and atypical antidepressants. Older classes such as the TCAs and monoamine oxidase inhibitors (MAOIs) are less commonly employed due to a greater potential for adverse effects. The SSRIs treat symptoms of panic attacks, OCD, and phobias. Indications for these medications are shown in Table 18.8. Following is a brief summary of additional important considerations for each antidepressant class. Individual drug information, patient teaching, and nursing responsibilities are presented in Chapter 19.

Selective serotonin reuptake inhibitors: This is the most widely prescribed antidepressant class because these drugs are safer than those from other classes and cause fewer sympathomimetic effects (increased heart rate and hypertension) and anticholinergic effects. Some SSRIs can, however, cause weight gain and sexual dysfunction. Overdoses can cause confusion, anxiety, restlessness, hypertension, tremors, sweating, fever, and lack of muscle coordination.

Five SSRIs are approved for anxiety disorders although other drugs in this class are often used off-label. The indications for each drug are given in Table 18.8.

- **Generalized anxiety disorder.** Paroxetine (Paxil) and escitalopram (Lexapro) are considered first-line drugs for patients with GAD and anxiety that is associated with depressive disorders. Unlike the benzodiazepines that act immediately, onset for the antianxiety effects of the SSRIs may take several weeks.
- **Panic disorder.** The three SSRIs approved for panic disorder, fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft), are considered preferred drugs for this disorder. They reduce both the frequency and intensity of panic attacks.
- **Obsessive-compulsive disorder.** Four SSRIs are approved to treat OCD, although others in this class may be used off-label. Paroxetine (Paxil), fluvoxamine (Luvox), fluoxetine (Prozac), and sertraline (Zoloft) are first-line drugs for this disorder. Optimal therapeutic effects may take several months to achieve.
- **Social anxiety disorder.** Paroxetine (Paxil), fluvoxamine (Luvox), and sertraline (Zoloft) are SSRIs approved for the long-term therapy of social anxiety disorder. Because several months may be necessary for optimal therapeutic benefit, the benzodiazepines

are better choices for acute symptoms of social anxiety disorder.

- **Post-traumatic stress disorder.** Paroxetine (Paxil) and sertraline (Zoloft) are the two SSRIs approved for the therapy of PTSD. Therapy should be initiated as soon after the traumatic event as possible, and several months may be necessary for optimal results.

Atypical antidepressants: These include serotonin–norepinephrine reuptake inhibitors (SNRIs). Adverse effects are similar to those of the SSRIs and include insomnia, abnormal dreams, sweating, constipation, dry mouth, loss of appetite, weight loss, tremor, abnormal vision, headaches, nausea, vomiting, dizziness, and loss of sexual desire. Two atypical antidepressants are used for anxiety disorders:

- **Duloxetine (Cymbalta).** Approved in 2007 for GAD, duloxetine has the potential to become a first-line drug for this disorder due to its safety and effectiveness, especially in patients with accompanying major depression. It is also approved to treat fibromyalgia, chronic musculoskeletal pain, and diabetic peripheral neuropathic pain.
- **Venlafaxine (Effexor XR).** The extended release form of venlafaxine was the first antidepressant approved for GAD. It is also beneficial in treating panic attacks and social anxiety disorder. It is widely used for anxiety disorders that are accompanied by depression.

Tricyclic antidepressants (TCAs): TCAs are older drugs that, although effective, generally produce more adverse effects than SSRIs. Patients often have annoying anticholinergic effects such as dry mouth, blurred vision, urine retention, and hypertension (see Chapter 14). They are not recommended for patients with a history of heart attack, heart block, or dysrhythmia. Concurrent use with alcohol or other CNS depressants should be avoided, and patients with asthma, GI disorders, alcoholism, schizophrenia, or bipolar disorder should take TCAs with extreme caution. Most TCAs are pregnancy category C or D. Although several drugs in this class are used off-label, only two TCAs are approved for anxiety disorders:

- **Clomipramine (Anafranil).** The only drug in this class approved for OCD, clomipramine is very effective but tends to cause more adverse effects than SSRIs. It is considered an alternative for patients who are unable to tolerate SSRIs.
- **Doxepin (Silenor).** Originally approved for anxiety associated with depressive disorders, doxepin produces a rapid antianxiety effect. However, because of significant anticholinergic adverse effects, it is not a first-line drug for anxiety. This drug is also approved to treat insomnia characterized by difficulty with sleep maintenance (staying asleep). Unrelated to its actions on the CNS, doxepin (Zonalon) has antihistamine actions that reduce itching due to atopic dermatitis when used as a cream over the affected area.

Monoamine oxidase inhibitors: Once commonly prescribed, it is rare to find these drugs used today due to their high incidence of potential adverse effects. No MAOIs are FDA approved for anxiety disorders, although some may be occasionally used off-label when other therapies fail to produce satisfactory results. The student should refer to Chapter 19 for more information on drugs in this class.

CONNECTION Checkpoint 18.3

Fluvoxamine, fluoxetine, and duloxetine have similar sounding names and may look alike when written as prescriptions. From what you learned in Chapter 6, describe means that you should implement to avoid these types of medication errors. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

18.11 Barbiturates are effective sedative–hypnotics but have potentially serious adverse effects that limit their use.

Used in pharmacotherapy since the early 1900s, barbiturates are powerful CNS depressants prescribed for their sedative, hypnotic, and antiseizure effects. Until the discovery of the benzodiazepines, barbiturates were the preferred drugs for patients with anxiety and insomnia. They are now rarely prescribed for anxiety or insomnia because of their significant adverse effects and because of the availability of more effective medications. The risk of psychologic and physical dependence is high—several are Schedule II drugs. If a patient does become physically dependent on barbiturates, the withdrawal syndrome is extremely severe and can be fatal. Overdose results in profound respiratory depression, hypotension, and shock. Barbiturates have frequently been used to commit suicide, and death due to overdose was common when these drugs were frequently prescribed in the 1960s and 1970s.

Barbiturates are capable of depressing CNS function at all levels. Like benzodiazepines, barbiturates act by binding to GABA receptor-chloride channel molecules, intensifying the effect of GABA throughout the brain. At low doses they reduce anxiety and cause drowsiness. At moderate doses they inhibit seizure activity (see Chapter 22) and promote sleep by inhibiting brain impulses traveling through the limbic system and the RAS. At higher doses, some barbiturates can induce anesthesia (see Chapter 26). Barbiturates are classified by their duration of action: short acting, intermediate acting, or long acting. Selected barbiturates used to treat sleep disorders are shown in Table 18.9.

Table 18.9 Selected Barbiturates for Insomnia

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
butabarbital (Butisol)	Sedative: PO: 15–30 mg tid or qid Hypnotic: PO: 50–100 mg at bedtime	*Somnolence, hangover, confusion, nausea, vomiting, rebound insomnia* CNS depression, coma, death, bradycardia, liver damage, hypocalcemia, Stevens–Johnson syndrome, severe respiratory depression, birth defects
pentobarbital	Preoperative sedation: IM: 150–200 mg in two divided doses Hypnotic: IM: 150–200 mg; IV: 100 mg every 1–3 min up to 500-mg dose	
phenobarbital (Luminal)	Sedative: PO: 30–120 mg/day IV/IM/subcutaneous: 100–320 mg/day	
secobarbital (Seconal)	Sedative: PO: 100–300 mg/day in three divided doses Hypnotic: PO: 100–200 mg	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

When taken for prolonged periods, barbiturates induce the synthesis of hepatic CYP450 enzymes and can stimulate their own metabolism as well as that of hundreds of other drugs that use these enzymes for their breakdown. This significantly increases the risk for drug–drug interactions. After 2 weeks, tolerance begins to develop to the sedative effects of barbiturates; this includes cross-tolerance to other CNS depressants such as the opioids. Tolerance does not develop, however, to the respiratory depressant effects. Thus, the patient may take higher and higher doses to produce sleep while approaching dangerous and even lethal dosage levels.

PROTOTYPE DRUG Phenobarbital (Luminal)

Classification **Therapeutic:** Sedative–hypnotic, antiepileptic drug
Pharmacologic: Barbiturate, GABA receptor agonist

Therapeutic Effects and Uses: A Schedule IV drug, phenobarbital is available as tablets or elixir for PO doses and as injection for IM or IV administration. By the IV route, phenobarbital is reserved for emergency situations such as status epilepticus. It is effective for treating generalized and partial seizures, which are likely the most common indications for the use of the drug. The drug is FDA approved for the short-term treatment of insomnia, although there are many safer and equally effective medications available for this indication. Therapeutic serum phenobarbital concentrations range from 15 to 40 mcg/mL. As a sedative–hypnotic, phenobarbital decreases time to sleep onset and lengthens total sleep time. The number of nighttime awakenings diminishes. Significant rebound insomnia occurs when the drug is discontinued.

Mechanism of Action: Phenobarbital binds to GABA receptors, where it enhances the activity of GABA.

Pharmacokinetics:

Route(s)	PO, IM, and IV
Absorption	Well absorbed by all routes
Distribution	Rapidly and widely distributed; may cross the placenta; secreted in breast milk; 20–45% bound to protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	IV: 5 min; PO: 8–12 h
Duration of action	Half-life: 53–118 h

Adverse Effects: Many adverse effects are reported with phenobarbital. Serious ones include coma, Stevens–Johnson syndrome, angioedema, and thrombophlebitis. Adverse reactions related to CNS depression include oversedation, "hangover" effect, lethargy, and hallucinations. Other adverse effects can include blood dyscrasias, hypocalcemia, hepatic disease, nausea, vomiting, diarrhea, or constipation. Deficiency in folic acid, calcium, and vitamin D may result in osteomalacia. Phenobarbital can cause paradoxical excitation in older adults or children, especially during the first 2 weeks of treatment. If abruptly discontinued after prolonged use, the patient may experience nightmares, insomnia, tremor, hallucinations, nausea, and vomiting.

Contraindications/Precautions: Phenobarbital is contraindicated in patients with hypersensitivity to barbiturates, suicidal ideation or previous suicide attempt, preexisting CNS depression, severe respiratory disease,v severe pain, or hyperthyroidism. Patients with impaired hepatic, renal, and cardiovascular function should not receive phenobarbital, or the dose should be lowered to prevent toxicity. Patients with COPD may experience profound respiratory depression, even at therapeutic doses, and should not receive phenobarbital. A patient who has a familial history of porphyria should not be administered phenobarbital. Porphyria is a metabolic disorder in which neurologic disturbances are noted. Phenobarbital should be used cautiously in patients with hyperthyroidism, diabetes mellitus, and severe anemia. Phenobarbital can cause birth defects and physical dependence in the neonate, and thus it is contraindicated during pregnancy. Phenobarbital is secreted in breast milk and can cause profound effects

on the neonate; thus it should not be administered during lactation.

Drug Interactions: Phenobarbital induces CYP450 enzymes and has the potential to interact with drugs that are metabolized by the liver such as corticosteroids, oral contraceptives, and anticonvulsants. Use with other CNS depressants, including alcohol, will cause additive sedation. Valproic acid may increase the risk of phenobarbital toxicity. Phenobarbital may decrease the effectiveness of digoxin, TCAs, metronidazole, quinidine, or oral anticoagulants. **Herbal/Food:** St. John's wort may lead to decreased barbiturate effect. Use of kava, chamomile, eucalyptus, lemon balm, or valerian may increase additive CNS depression.

Pregnancy: Category D.

Treatment of Overdose: Overdosage of phenobarbital is a medical emergency and may be fatal. Activated charcoal is administered followed by gastric lavage. Alkalinization of the urine with sodium bicarbonate increases the renal elimination of phenobarbital.

Nursing Responsibilities: Key nursing implications for patients receiving phenobarbital are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders.

Drugs Similar to Phenobarbital (Luminal)

The barbiturates are classified by duration of action, and all have the same actions and adverse effects as phenobarbital. None are in common use.

Ultra-short acting: With a half-life of less than 10 minutes, methohexital (Brevital) is administered by the IV route to induce or maintain anesthesia, as preoperative sedation, or in the emergency management of seizures.

Short acting: With half-lives of 15 to 40 minutes, secobarbital (Seconal) and pentobarbital are oral drugs that have been used to treat insomnia and as preoperative medications. These are Schedule II drugs and have been the most widely abused barbiturates.

Intermediate acting: With slightly longer half-lives, amobarbital (Amytal) and butabarbital (Butisol) are oral drugs that have been used as sedative–hypnotics and to provide preanesthesia sedation.

Long acting: Phenobarbital is the only long-acting barbiturate. Mephobarbital (Mebaral) was withdrawn from the U.S. market in 2012.

CONNECTIONS: Preparing for Advanced Practice

Treating Childhood Anxiety Disorders

Case

Frankie, a 16-year-old adolescent, arrives for her follow-up therapy appointment. She had been diagnosed 2 months ago with GAD after having symptoms of fatigue, irritability, and sleep disturbance. She was having trouble engaging in school, and many days was absent or would leave early. She asked the school counselor for help after she had a panic attack in the school health clinic. She is currently in therapy and continues to have difficulty managing the symptoms. The inability to sleep is interfering with her school success. You and the therapist recognize the importance of a holistic treatment focus and begin working with Frankie on progressive muscle relaxation, breathing techniques, and diet management. What pharmacologic interventions should the provider be considering for Frankie?

Discussion

Children and adolescents may experience intense fear and worry that can lead to the same types of anxiety disorders experienced by adults. Signs may include excessive worrying about ordinary school activities; physical symptoms such as sweating, headaches, trembling, and palpitations; social withdrawal; and sleep disturbances. If not recognized and treated, childhood anxiety disorders may lead to low self-esteem, poor interpersonal relationships, drug or alcohol use, or repeated school absences. Worldwide it is estimated that 6.5% of 6- to 18-year-olds experience anxiety, with girls being affected more than boys (Polanczyk, Salum, Sugaya, Caye, & Rohde, 2015).

Cognitive–behavioral therapy and relaxation techniques are usually the first treatments used for childhood anxiety. If medication is indicated in addition to these therapies, the SSRIs are the preferred drugs for children (Cousins & Goodyer, 2015). The use of any antidepressant in children must be carefully considered, with the risks versus benefits weighed before the drugs are prescribed and carefully monitored thereafter. In 2004, the FDA issued a black box warning that applied to most antidepressants, citing the possibility of increased risk of suicide in children and adolescents. In 2007, this warning was extended to include young adults up to age 25. Prescribing of SSRIs has dropped by 20% in the United States since 2004, likely due to increased awareness of this suicide risk (Anxiety and Depression Association of America, 2016; NIMH, n.d.a). Caregivers must be diligent in monitoring for signs of potential suicidal thoughts in children taking SSRI antidepressants and report any such changes to the healthcare provider immediately. Signs include unusual changes in behavior, sleeplessness, agitation, and social withdrawal.

Recent studies have shown that the use of vitamin C in the treatment of depression may reduce the severity of symptoms in both children and adult patients (De Oliveira, De Souza, Motta, & Da-Silva, 2015), although further studies are needed to substantiate this finding.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, respiratory, cardiovascular or neurologic disease, mental status, closed-angle glaucoma, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, and caffeine and alcohol use. Be alert to possible drug interactions.
- Assess stress and coping patterns (e.g., existing or perceived stress, duration, coping mechanisms, or remedies).
- Obtain a sleep history (e.g., quality and quantity of sleep, restlessness or frequent wakefulness, snoring or apnea, remedies used for sleep, concerns).
- Evaluate appropriate laboratory findings (e.g., hepatic or renal function studies).
- Obtain baseline vital signs and weight. Assess fall risk.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., statements of improvement in anxiety, appetite, ability to carry out ADLs, and sleep patterns normalize).
- Continue periodic monitoring of liver and renal function studies.
- Assess vital signs and weight periodically or if symptoms warrant.
- Assess for and promptly report adverse effects: excessive dizziness, drowsiness, lightheadedness, confusion, agitation, palpitations, tachycardia, or musculoskeletal weakness.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (If the drug is given for anxiety, the patient reports decreased anxiety, improved sleep and eating habits, improved coping, and ability to carry out ADLs without anxiety. If the drug is given for sleep, the patient reports being able to fall and remain asleep; improved daytime wakefulness.) **Diverse Patients:** Barbiturates induce CYP450 enzymes and may interact with other drugs. Ethnically diverse populations may also experience less than optimal effects of the drug. Nonbenzodiazepine sedative–hypnotic drugs are also metabolized through the CYP450 pathways. Women may metabolize some sublingual drugs (e.g., zolpidem [Edluar, Intermezzo]) more slowly, and dosage may need to be halved by the provider.	• Assist the patient in developing healthy coping strategies and sleep habits with referral to appropriate healthcare providers as needed. • Encourage the patient to keep a sleep diary of bedtime, time involved trying to fall asleep, quality and quantity of sleep, daytime sleepiness. • **Diverse Patients:** Teach ethnically diverse patients to observe for either excessive or less than optimal therapeutic effects and report promptly.
Minimizing adverse effects: • Continue to monitor vital signs, mental status, coordination, and balance periodically. **Lifespan:** Be particularly cautious with older adults who are at increased risk for falls. Many benzodiazepines and all barbiturates are included on the Beers list of potentially inappropriate drugs for older adults and warrant careful monitoring. (Drugs used for anxiety and sleep may cause excessive drowsiness and dizziness, increasing the risk of falls and injury.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Ensure patient safety, especially of older adults. Observe for lightheadedness or dizziness. Monitor ambulation until effects of the drug are known. (Dizziness and drowsiness for a prolonged period may occur, depending on the drug's half-life. Daytime drowsiness may impair walking or the ability to carry out usual ADLs. Subtle changes in mental alertness and cognitive functioning may occur, even in the absence of sleepiness.)	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Assess for changes in level of consciousness, disorientation or confusion, or agitation. (Neurologic changes may indicate overmedication or effects of sleep deprivation.)	• Instruct the patient or caregiver to report increasing lethargy, disorientation, confusion, changes in behavior or mood, slurred speech, or ataxia immediately. • Have caregivers observe for nighttime behavioral activities such as sleepwalking, sleep-eating, or sleep-driving if nonbenzodiazepine sedative–hypnotic drugs are given, and report immediately. The patient may not remember or be aware of these activities.
• Assess for changes in visual acuity, blurred vision, loss of peripheral vision, seeing rainbow halos around lights, acute eye pain, or any of these symptoms accompanied by nausea and vomiting and report immediately. (Increased intraoptic pressure in patients with closed-angle glaucoma may occur in patients taking benzodiazepines.)	• Instruct the patient to report any visual changes or eye pain immediately.
• Monitor affect and emotional status. (Drugs may increase the risk of mental depression, especially in patients with suicidal tendencies. Concurrent use of alcohol and other CNS depressants increases the effects and the risk.)	• Instruct the patient to report significant mood changes, especially depression, and to avoid alcohol and other CNS depressants while taking the drug. • Teach the patient about the need for continued monitoring, especially if preexisting depression is present.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Encourage appropriate lifestyle changes: lowered caffeine intake including OTC medications that contain caffeine, increased exercise during the day but not immediately before bedtime, limited or no alcohol intake, and smoking cessation. (Healthy lifestyle changes will support and minimize the need for drug therapy. Caffeine and nicotine may decrease the effectiveness of the drugs. Alcohol and other CNS depressants may increase the adverse effects of the drugs.)	• Encourage the patient to adopt a healthy lifestyle of decreased use of or abstinence from caffeine, nicotine, and alcohol, and increased exercise. Avoiding caffeine, decreasing stimulation (e.g., TV, internet use) before bedtime, and regular bedtime habits help to promote sleep. • Advise the patient to discuss all OTC medications with the healthcare provider to ensure caffeine or alcohol is not included in the formulation.
• Avoid abrupt discontinuation of therapy. (Withdrawal symptoms, including rebound anxiety and sleeplessness, are possible with abrupt discontinuation after long-term use.)	• Instruct the patient to take the drug exactly as prescribed and to not stop it abruptly.
• Assess home storage of medications and identify risks for corrective action. (Overdosage may occur if the patient takes additional doses when drowsy or disoriented from medication effects.)	• Instruct the patient that these drugs should not be kept at the bedside to avoid taking additional doses when drowsy.
• Assess prior methods of stress reduction or sleep hygiene. Reinforce previously used effective methods and teach new coping skills. (Drug therapy is used for the shortest amount of time possible. Developing other coping skills or improved sleep hygiene may lessen the need for drug therapy.)	• Teach the patient nonpharmacologic methods for stress relief and for improved sleep hygiene. Refer to appropriate healthcare providers or support groups as needed.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose, and scheduling; what adverse effects to observe for and when to report them; and the anticipated length of medication therapy.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., taking only the amount prescribed. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• The patient is able to discuss appropriate dosing and administration needs. • Teach patients to not open, chew, or crush extended release tablets (e.g., zolpidem [Ambien]); to swallow them whole with plenty of water. Sublingual forms of the drug (e.g., zolpidem [Edluar, Intermezzo]) should be allowed to dissolve under the tongue; water should not be taken.

Understanding Chapter 18

Key Concepts Summary

18.1 Proper diagnosis of anxiety disorders is important to identifying the most effective treatment option.

18.2 Anxiety disorders may be divided into five major categories.

18.3 Specific regions of the brain have been identified that are responsible for anxiety.

18.4 Sleep occurs in distinct stages.

18.5 Sleep disorders affect a large percentage of the population.

18.6 There is a link between insomnia and anxiety.

18.7 Management of anxiety and sleep disorders utilizes a combination of pharmacologic and nonpharmacologic therapies.

18.8 Benzodiazepines are preferred drugs for generalized anxiety disorder and the short-term therapy of insomnia.

18.9 Nonbenzodiazepine anxiolytics have become popular choices for treating anxiety and sleep disorders.

18.10 Antidepressants are widely prescribed for anxiety disorders.

18.11 Barbiturates are effective sedative–hypnotics but have potentially serious adverse effects that limit their use.

CASE STUDY: Making the Patient Connection

Remember the patient "Seraphina Alvarez" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within the chapter, respond to the critical thinking questions that follow.

Seraphina Alvarez, age 59, is an elementary school teacher who has planned on retiring at the end of this academic year. She is the married mother of seven adult children, six of whom live within a 15-mile radius and see her often. Her husband, Joe, has been retired for 3 years. He receives Social Security and a small pension from his former employment as a construction worker. Seraphina and Joe's oldest daughter's two children and two dogs came to live with them approximately 10 months ago because their daughter is unable to provide a home for them. The children, Joseph, age 15, and Mariah, age 12, are good students who are active in school and church activities. They resent having to move from their long-time home and school and are acting out some.

Seraphina resents having to raise her grandchildren. It interferes with plans that she and her husband had made to travel after she retired. In fact, she may not be able to retire as planned because they need the extra income to meet the children's needs. She loves the children and tries very hard not to let her resentment show. She also has guilt feelings that she did not do all she could or should have done to raise her daughter to be a responsible parent. As a result, she is unable to sleep well and reports having anxiety. Seraphina first turned to herbal remedies common in her Latino culture and to prayer. Neither of these interventions has helped, but she is reluctant to discuss her problems with anyone else. She sees her parish priest on a regular basis. He is very supportive of her and understanding of her feelings of resentment but does not realize that she is experiencing anxiety and insomnia.

Seraphina, whose health has always been good, has begun having some health issues, including hypertension, diarrhea, and weight loss. She finds herself becoming more anxious, and her family has noticed that she is decreasing time spent with family and friends and does not leave her home other than to go to work and to go to church. She has lost 16 kg (35 lb) in 2 months and appears to have lost her "zest" for living. Her diet consists of black coffee and fresh fruit. Joe frequently finds her sitting in a rocking chair on their front porch during the night, rather than being in bed. She also has begun missing work, saying "I just don't feel up to facing the kids today."

Critical Thinking Questions

1. What current factors in Seraphina's life may be interfering with her ability to get a good night's sleep?
2. What medications may Seraphina's healthcare provider order on a short-term or longer term basis?
3. What role may herbal remedies play in anxiety control and sleep induction? What specific herbs might Seraphina be using?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Craig Edwards is a 46-year-old sales representative working at a respected car dealership in the community. With the economy, his income has dropped significantly because it is partially based on commission and he is worried that he is not able to provide for his family. He begins to experience insomnia, difficulty concentrating, and other symptoms related to his anxiety. His healthcare provider prescribes a short-term course of lorazepam (Ativan) to help him through this difficult period.

1. What adverse effects are associated with this drug therapy?
2. What information should Craig receive about this medication?
3. What nonpharmacologic measures can the nurse recommend to Craig to assist him in feeling better about his current situation?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A nurse should advise a patient who is receiving lorazepam (Ativan) about the adverse effects of this medication, which include:
   1. Tachypnea.
   2. Astigmatism.
   3. Ataxia.
   4. Euphoria.

2. The patient with insomnia is being treated with temazepam (Restoril). The nurse monitors for therapeutic effectiveness by noting which of the following?
   1. Sleeping in 3-hour intervals, awaking for a short time, and then returning to sleep
   2. Feeling less anxiety during activities of daily living
   3. Having fewer episodes of panic attacks when stressed
   4. Sleeping 7 hours without awakening

3. Which of these statements, if made by a patient, would indicate that further instruction is needed about alprazolam (Xanax)?
   1. "I will stop smoking by undergoing hypnosis."
   2. "I will not drive immediately after I take this medication."
   3. "I will stop the medicine when I feel less anxious."
   4. "I will take my medication with food if my stomach feels upset."

4. The nurse should question a healthcare provider's order of phenobarbital for the patient with which condition?
   1. Seizure disorder
   2. Panic disorder
   3. Prior to a bronchoscopy
   4. Prior to receiving a general anesthetic

5. The nurse is caring for a patient receiving a sedative–hypnotic. Which adverse effect associated with this drug therapy is the highest priority for the nurse?
   1. Urinary incontinence
   2. Activity intolerance
   3. Fall risk
   4. Poor nutritional intake

6. The patient, who is receiving benzodiazepines, is a two-pack-per-day cigarette smoker. The nurse expects to administer a/an _____ dose of this medication.
   1. Larger
   2. Smaller
   3. Extra
   4. Half

See Answers to Chapter Review in Appendix A.

"For the past 4 to 5 weeks my wife, Adelphia, has been having problems. She doesn't get up to see that the children are off to school, dinner is not started when I get home from work at 6:00 p.m., no housework or laundry has been done, she is frequently still in pajamas with her hair uncombed, and obviously has not showered or brushed her teeth. Her friends say that Adelphia has not returned their calls in weeks."

"Charlie Williams," Adelphia's husband

Chapter 19
Pharmacotherapy of Mood Disorders

Chapter Outline

- Categories of Mood Disorders
- Major Depressive Disorder
- Pathophysiology of Depression
- Assessment of Depression
- Nonpharmacologic Therapies for Depression
- Pharmacotherapy of Depression

  Selective Serotonin Reuptake Inhibitors

  PROTOTYPE *Fluoxetine (Prozac), p. 261*

  Atypical Antidepressants

  PROTOTYPE *Venlafaxine (Effexor), p. 264*

  Tricyclic Antidepressants

  PROTOTYPE *Imipramine (Tofranil), p. 268*

  Monoamine Oxidase Inhibitors

  PROTOTYPE *Phenelzine (Nardil), p. 270*
- Bipolar Disorder
- Drugs for Bipolar Disorder

  PROTOTYPE *Lithium Carbonate (Eskalith, Lithobid), p. 274*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the major categories of mood disorders and their symptoms.
2. Explain the pathophysiology of major depression and bipolar disorder.
3. Discuss the nurse's role in the assessment of patients with mood disorders.
4. Identify the relationship between suicide and depression.
5. Describe the nurse's role in the pharmacologic and nonpharmacologic management of mood disorders.
6. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy for mood disorders.

Key Terms

antidepressants, 258
atypical antidepressants, 263
bipolar disorder, 273
depression, 254
electroconvulsive therapy (ECT), 258
hypomania, 274
major depressive disorder, 255
mania, 273
monoamine oxidase inhibitors (MAOIs), 269
mood disorder, 254
mood stabilizers, 274
phototherapy, 258
postpartum depression, 255
seasonal affective disorder, 255
serotonin, 259
serotonin syndrome (SES), 261
suicide, 257
tricyclic antidepressants (TCAs), 267
tyramine, 269

Inappropriate or unusually intense emotions are among the leading mental health disorders. Although mood changes are a normal part of life, when they become prolonged and severe and impair functioning within the family, work environment, or interpersonal relationships, a patient may be diagnosed as having a mood disorder. The purpose of this chapter is to explain the role of pharmacotherapy in treating the two primary categories of mood disorders: major depression and bipolar disorder.

PharmFACT

Over 7% of the United States population ages 12 or older reported experiencing depression in the previous 2 weeks. Those living below the poverty level were 2.5 times more likely to experience depression (Centers for Disease Control and Prevention [CDC], 2014).

Categories of Mood Disorders

19.1 The two primary categories of mood disorders are depression and bipolar disorder.

A **mood disorder** can be broadly defined as a persistent disturbance in mood that impairs an individual's ability to effectively deal with normal activities of daily living (ADLs). Mood disorders affect people of all cultures and ages, from children to older adults. Mood disorders are a major cause of disability and can significantly strain social relationships. They are a leading cause of absenteeism and diminished productivity in the workplace.

The diagnosis of mood disorders is often challenging; the line between normal emotion and a mood disorder is sometimes unclear. Because healthcare providers see patients for such brief periods, they must rely on patient self-reports or caregiver information, both of which are often quite subjective.

Mood disorders can present with a wide range of symptoms, which has resulted in classification of the disorder into the following categories:

- **Major depressive disorder.** When people use the word *depression*, they are most often referring to major depressive disorder. This is sometimes called clinical depression.
- **Dysthymic disorder.** This is mild, chronic depression that persists for at least 2 continuous years.
- **Bipolar disorder.** Formerly called manic depression, the patient alternates between intense excitement (mania) and major depressive disorder.
- **Manic and hypomanic episodes.** Include mania symptoms that last for at least 1 week and significantly impact social functioning. Hypomania is less intense, lasting only 4 days and has less impact on social or work functioning.
- **Cyclothymic disorder.** A mild form of bipolar disorder in which the patient alternates between hypomania and mild depression. Largely undiagnosed, 33% of these patients will eventually develop bipolar disorder.

Mood disorders often coexist with other conditions. For example, about 50% of patients diagnosed with major depression also meet the criteria for an anxiety disorder (see Chapter 18). Of those patients with mood disorder 25% to 40% have a comorbid substance abuse condition. Those with chronic medical conditions such as hypertension (HTN) or arthritis have a higher incidence of depression. The most serious of the comorbid conditions is completed or attempted suicide.

Major Depressive Disorder

19.2 Major depressive disorder is characterized by a depressed mood, with accompanying symptoms, that lasts at least 2 weeks.

Depression is a disorder characterized by a sad or despondent mood that becomes out of proportion to actual life events. Depression can manifest as an extremely diverse set of symptoms, including lack of energy, sleep disturbances, abnormal eating patterns, or feelings of despair, guilt, and hopelessness. Depression is the most common mental health disorder, affecting approximately 10% to 20% of the population. Although

Table 19.1 Symptoms of Depression

CNS Symptoms	Behavioral Symptoms	General Symptoms
Feelings of despair, lack of self-worth, guilt, and misery Obsessed with death; expresses desire to die or to commit suicide Delusions or hallucinations	Staying in bed most of the day and night Neglecting usual household chores Not going to work, or unable to function effectively at work Abnormal eating patterns (eating too much or not enough) Lack of interest in personal appearance or sex Avoiding psychosocial and interpersonal interactions	Extremely tired; without energy Vague physical symptoms (GI pain, joint or muscle pain, or headaches) Physiologic depression (constipation, sleep disorders, or decreased heart rate)

women between the ages of 25 and 45 are more likely to have a depressive disorder than any other group, depression in men more frequently results in suicide. Many people who are depressed never seek or receive care for their condition.

Major depressive disorder is diagnosed when the patient has a depressed mood that lasts for a minimum of 2 weeks and which is present for most of the day, every day, or almost every day. In addition, at least five of the symptoms shown in Table 19.1 must be present. Depressed moods caused by general medical conditions or by substances such as alcohol or other central nervous system (CNS) depressants do not warrant a diagnosis of major depressive disorder. For the purposes of this text, the terms *depression* and *major depressive disorder* are considered interchangeable unless otherwise specified.

Once a diagnosis of a mood disorder is made, additional details about the condition may be provided by the healthcare provider in the form of "specifiers." The use of specifiers gives mental health professionals additional information about the disorder and its treatment. Specifiers are best thought of as subcategories of major depressive disorder and bipolar disorder. Some of the specifiers used with depression include with or without psychotic features, single episode or recurrent, melancholic features, atypical features, and catatonic features. Two additional important specifiers are postpartum onset and seasonal onset.

Up to 80% of new mothers experience brief "baby blues" or **postpartum depression** during the first 2 weeks after the birth of a baby. About 10% to 15% of these women will experience major depression within the first 6 months postdelivery, which is likely related to the dramatic hormonal shifts that occur during that period. Along with the hormonal changes, additional situational stresses such as changing responsibilities at work and at home, single parenthood, and caring for children and for aging parents may contribute to the onset of symptoms. Because of the potentially serious consequences of postpartum-onset depression, some states mandate that all new mothers receive information about these mood disorders prior to their discharge after giving birth. All levels of healthcare providers treating new mothers are encouraged to conduct routine screening for symptoms of perinatal mood disorders.

During the dark winter months, some patients experience a type of depression known as **seasonal affective disorder**. Seasonal affective disorder is more common in areas such as Alaska, where the days are very short during the winter months and there is little natural sunlight. This type of depression is associated with a reduced release of the hormone melatonin from the pineal gland. The condition is generally self-limiting and resolves when spring arrives. Exposing patients on a regular basis to specific wavelengths of light may relieve this type of depression and prevent future episodes.

PharmFACT

Approximately 3 million adolescents (ages 12–17) experience at least one major depressive episode each year. This includes about 19.5% of the total number of female adolescents and 5.8% of all male adolescents (National Institute of Mental Health, 2016).

Pathophysiology of Depression

19.3 The pathophysiology of depression has biological, genetic, and environmental components.

Depression is one of the oldest known mental health conditions and one of the most frequently diagnosed. Despite this, the etiology of depression is not well understood. Several theories have been proposed to explain the causes of depression and why some people are predisposed to developing the disease. The etiology and pathogenesis are likely influenced by multiple, complex variables.

Research attempting to identify the biological causes of depression has focused on the levels and function of neurotransmitters in the limbic system of the brain. The limbic system is the region that regulates emotions (see Chapters 17 and 18). Major depression has been associated

with abnormally low levels of neurotransmitters such as norepinephrine, serotonin, and dopamine in this region. Although it is well known that some of the antidepressant medications act by increasing the levels of these neurotransmitters, scientists have yet to discover what role each specific neurotransmitter plays in the development of major depressive disorder. Does having depression deplete the brain of these neurotransmitters, or does a loss of neurotransmitters cause depression? The answers remain elusive.

Certain hormonal abnormalities are associated with depression, suggesting that the endocrine system also plays an important role in the pathogenesis of the disease. About half of those who are depressed have abnormally high serum cortisol levels. Cortisol mobilizes the body for stress situations and is thought to reduce serotonin levels in the brain, bringing about symptoms of depression. Recall from Chapter 18, that high cortisol levels are also associated with anxiety. Hypothyroidism is associated with depression. In some patients, therapy with thyroid hormone (T_3) results in a marked improvement in mood.

Depression clearly has a genetic component. Major depression is 1.5 to 3 times more common in individuals who have a first-degree relative (parent or sibling) with depression compared to the general population. In identical twins, when one twin is diagnosed with depression, the other twin has a 50% probability of acquiring the disorder. This relationship holds true whether the twins were raised together or separately. Even fraternal twins have a 19% chance of developing depression when the other twin is diagnosed, which is a percentage higher than that of the general population.

Environmental causes of depression include prolonged stress at work or at home, loss of a loved one, and other traumatic life events. Various childhood events have been associated with an increased risk of adult depression, including sexual or physical abuse, and death of, separation from, or mental illness of a parent.

CONNECTION Checkpoint 19.1

From what you learned in Chapter 17, what are the connections between the limbic system, the hypothalamus, and the cerebrum, and how can these connections be used to explain symptoms of depression? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Assessment of Depression

19.4 Assessment and diagnosis of depression are a collaborative effort among healthcare providers.

For proper diagnosis and treatment to occur, the recognition of depression must be a collaborative effort among healthcare providers. Because people who are depressed are present in multiple settings and in all areas of practice, every nurse should be proficient in the assessment and nursing care of patients who have this disorder.

The first step in implementing appropriate treatment for depression is a complete medical examination, because the diagnosis of depression begins by ruling out other medical conditions. Certain medications such as corticosteroids, beta blockers, levodopa, antipsychotic drugs, oral contraceptives, and CNS depressants can cause symptoms of clinical depression. Depression may be mimicked by a variety of medical and neurologic disorders, ranging from B-vitamin deficiencies to thyroid gland malfunction to early Alzheimer's disease. If medical causes for the depression are discovered, proper treatment of the underlying disorder may be sufficient to resolve symptoms of depression. If causes for the depression cannot be identified, a psychiatrist or psychologist may be consulted to perform a comprehensive psychologic evaluation to confirm the diagnosis.

Because they are comorbid with depression in a significant number of patients, inquiries should be made about alcohol and drug use and any thoughts about suicide. The initial examination should also include questions about any family history of depressive illness. The manifestation of depression that is most obvious to those surrounding someone who is depressed is a change in attitude toward usual daily activities. The patient loses interest in work, school, or other hobbies or activities that he or she previously enjoyed.

Severe depressive illness, particularly that which is recurrent, will require both medication and psychotherapy to achieve optimal outcomes. Daily outpatient visits to a treatment facility may be necessary when beginning treatment, then tapered to a less frequent schedule as improvement is noted. Some patients, especially those at high risk for suicide, will require an initial period of hospitalization where continuous monitoring is provided.

Depression remains greatly underdiagnosed among older adults despite the fact that as many as 6 million Americans over the age of 65 have this disorder. Of this group, only about 10% receive treatment. Older patients may be reluctant to admit to depression, seeing this as a sign of weakness or an inability to continue to care for themselves. Depression in the older adult may be manifested as difficulty making decisions and as a growing reluctance to leave the home. Feelings of despair, lack of self-worth, and guilt are common.

Factors that contribute to depression in the older adult include loss of spouse or children; the need to move from a long-term residence to a smaller home or in with other family or to assisted living; loss of friends and other support systems; being unmarried; living alone; having multiple health challenges; the expense of polypharmacy; decreased finances; and worry about end-of-life issues.

CONNECTIONS: Using Research in Practice

Vitamin D Deficiency as a Cause for Depression in Older Adults

Whereas depression and suicide risk are often viewed as health issues affecting the adolescent or young adult populations, the highest rate of suicide has been noted in older adults ages 45 to 64, with the second highest rate among adults over age 85 (American Foundation for Suicide Prevention, 2016; Curtin, Warner, & Hedegaard, 2016).

Recent research has suggested that low 25(OH)D (25-hydroxyvitamin D, vitamin D) concentrations may predict depression in otherwise healthy older adults. Williams et al. (2015) studied whether low vitamin D levels were a risk factor for depression. More than 3000 participants were followed over a 1-year period, with follow-up assessment at 1, 2, and 4 years. A depression scale was used at each screening, and fasting 25(OH)D levels were drawn. At baseline and 1-year screenings, no statistically significant changes in depression or 25(OH)D levels were noted. As the participants aged, a significant association was noted between 25(OH)D level and depression scores, with participants having levels of less than 20 ng/mL demonstrating a greater risk for depression than those with over 30 ng/mL.

Because vitamin D is easily obtained through sunlight, food sources, and supplementation, providers should consider 25(OH)D screening as part of an annual assessment in the older adult who exhibits depressive symptoms to rule out a deficiency as a potential cause for depression.

19.5 The majority of patients who attempt suicide have major depression.

Suicide is defined as the intentional act of ending one's life. Suicide is the 10th leading cause of death in the United States; over 44,000 people take their own lives every year (Xu, Murphy, Kochanek, & Arias, 2016). No age group, income level, educational level, race, religion, or other demographic group is exempt from it. Comorbid conditions include mood disorders, psychoses, personality disorder, anxiety disorders, severe insomnia, chronic alcohol or substance use, chronic disabling or painful disease, and family history, especially in the same-sex parent.

The majority of people who commit suicide have been diagnosed with major depression. Unfortunately, depending on the drug and the individual patient's response, 3 or more weeks of antidepressant pharmacotherapy may be required before the patient's mood begins to improve. Suicide may occur early in treatment, when a patient is being stabilized on the antidepressant. Some theories have proposed that antidepressant medications actually increase the risk of suicide. This prompted the U.S. Food and Drug Administration (FDA, 2004) to issue a black box warning indicating that antidepressant medications are associated with an increased risk of suicidal thinking and behavior in children and adolescents. This black box warning was later expanded to include young adults 18 to 25 years of age.

Researchers have continued to monitor the proposed link between antidepressant medications and suicide rate. Subsequent studies have been unable to confirm that antidepressant use increases overall suicide attempts and deaths due to suicide. Some have called for a reevaluation of the black box warning because it may lead to healthcare providers undertreating depression in young people (Isacsson & Rich, 2014). The relationship between antidepressants and suicide will likely be a continuing topic of research.

So what interventions can the healthcare provider implement to reduce the potential for suicidal behavior during antidepressant therapy? Careful monitoring of the patient is the simplest yet most important intervention. Weekly and even daily patient (or caregiver) contact may be necessary until the medication begins to effectively elevate mood, which could be as long as 12 weeks. A patient who has had a previous suicide attempt is at higher risk and must be more carefully monitored. Any patient who verbalizes about committing suicide must be taken seriously. The nurse must judiciously monitor all prescribed drugs because suicidal patients often take overdoses of their medications (including those prescribed to treat the depression!). Therapy with multiple CNS depressants such as for pain, anxiety, insomnia, and depression is strongly discouraged because these drugs produce additive sedation. Worsening symptoms of depression must be reported immediately because these may indicate that the drug is not working or that the patient is not compliant with pharmacotherapy. Switching to a different antidepressant or even hospitalization may be necessary.

Nonpharmacologic Therapies for Depression

19.6 Depression is sometimes treated with nonpharmacologic therapies.

Although pharmacotherapy is the standard treatment for patients with major depression, other therapies may be beneficial for patients with mild to moderate depression or for those whose condition is refractory to conventional treatment. Indeed, psychotherapy may be the treatment of choice if the patient is willing to participate and the depressive state is mild to moderate in intensity. Other nonpharmacologic therapies for depression are shown in Table 19.2.

Older nonpharmacologic treatments include cognitive–behavioral therapies to help patients change negative styles of thought and behavior that are often associated with their depression. These therapies focus on resolving the patients' internal conflicts by looking at the influence of past

Table 19.2 Nonpharmacologic Therapies for Major Depression

Type	Definition
Cognitive–behavioral therapy	Therapy that helps patients change the negative styles of thought and behavior that are often associated with their depression.
Electroconvulsive therapy (ECT)	The induction of a brief convulsion by passing an electric current through the brain as therapy for affective disorders, especially in patients who have not responded to pharmacotherapy.
Interpersonal therapy	Therapy focusing on the patient's disturbed personal relationships that both cause and exacerbate the depression.
Light therapy or phototherapy	Therapy that uses artificial lighting that is 5–20 times brighter than usual indoor lighting; it is used to simulate natural sunlight in areas where there is little natural sunlight for several months of the year, such as Alaska and other areas near the North Pole.
Psychodynamic therapy	Therapy focusing on resolving a patient's internal conflicts.
Repetitive transcranial magnetic stimulation (rTMS) therapy	An effective somatic therapy, experimental in the United States, that involves a device that administers a train of multiple stimuli per second. The device is a metal coil that is placed on or near the patient's head, allowing the magnetic field to pass through the skull and into specific targeted areas of the brain.
Vagus nerve stimulation (VNS)	Somatic therapy that involves placing a small generator into the patient's chest; it is attached to an electrode with ends wrapped around the left vagus nerve on the patient's neck; the generator is programmed for frequency and intensity of stimulus. The electrical current stimulates the vagus nerve.

experiences on current behavior and how behavior is influenced by emotional factors. These therapies are sometimes postponed until the acute depressive symptoms have improved. Light therapy or **phototherapy** is another type of therapy especially useful for people with seasonal affective disorder, using artificial lighting approximately 5 to 20 times brighter than normal indoor lighting. Normal activities can be pursued during the treatment, which can be conducted in the patient's home.

In patients with serious and life-threatening mood disorders that are unresponsive to pharmacotherapy and psychotherapy, **electroconvulsive therapy (ECT)** continues to be a useful treatment. ECT induces a brief convulsion (grand mal seizure) by passing an electric current into the brain through electrodes applied to one or both temples while the patient is anesthetized. A muscle relaxant is given prior to the treatment and the patient is unaware of the treatment or convulsion. Typically, 6 to 12 treatments are needed to relieve depression. In severe, refractory cases ECT may be continued for several years.

Transcranial magnetic stimulation (TMS) is an emerging therapy for major depression. TMS is a noninvasive procedure that passes a high electric current through a wire stimulation coil placed on or close to a specific area of the head. Treatments are generally administered daily; the length of treatment varies according to patient response. TMS has minimal effects on memory, does not require general anesthesia, and produces its effects without a generalized seizure.

Another somatic therapy is vagus nerve stimulation (VNS). VNS involves the surgical implantation of a 3- to 4-inch battery-powered device into the patient's chest. An electrode is threaded through the subcutaneous tissue from the device to the vagus nerve on the left side of the neck. The left vagus connects to the brainstem and deep brain structures thought to be involved in epilepsy and some psychiatric disorders. Stimulating these fibers affects the concentration of the neurotransmitter gamma aminobutyric acid (GABA) and other neurotransmitters in that area. VNS is approved in the United States for treating epilepsy and bipolar disorder, and for the adjunctive treatment of chronic depression that is unresponsive to antidepressant medications.

PharmFACT

Approximately 16% of the students in grades 9 through 12 seriously consider suicide each year. Over 8% state that they actually attempted suicide. Although girls most often report attempting suicide, 81% of the suicide deaths from ages 10 to 24 are males (CDC, 2015).

Pharmacotherapy of Depression

19.7 The mechanism of action of antidepressants involves modulation of neurotransmitter levels in the brain.

Antidepressants are drugs used to enhance, elevate, or stabilize mood. In the treatment of depression they are used to treat all symptoms of major depressive disorder as well as the depressive phases of bipolar disorder. They are ineffective against the manic phases of bipolar disorder, and other drugs must be used to control those symptoms (see Section 19.12).

The antidepressants act by restoring normal neurotransmitter balances in specific regions of the brain. Depending on the medication, the primary neurotransmitters affected are norepinephrine, serotonin, and, to a lesser degree, dopamine. The two basic mechanisms of action are blocking the enzymatic breakdown of norepinephrine and slowing the reuptake of serotonin into neurons. Although antidepressants may not completely restore chemical balance, they help to manage depressive symptoms while the patient develops effective strategies for coping.

In addition to elevating mood, changing the neurotransmitter balance has a number of other effects on

the brain. Some of the antidepressants have become major drugs in the treatment of anxiety disorders such as phobia, obsessive-compulsive behavior, panic disorder, and generalized anxiety disorder, as presented in Chapter 18. Certain antidepressants are also beneficial as adjuvant analgesics in the pharmacotherapy of pain (see Chapter 25). Antidepressants are beneficial in treating depression that is often associated with painful, chronic conditions such as fibromyalgia or muscle spasticity (see Chapter 23).

Once patients begin to feel better they sometimes want to discontinue drug therapy due to the expense of the medication or because they are experiencing uncomfortable adverse effects. Nurses must be aware that many patients taking antidepressants stop taking their medication without notifying their healthcare provider. Unfortunately, about half of these patients will relapse within 6 months of discontinuing antidepressant therapy; the percentage increases to 85% after 3 years. It is important to teach patients that daily antidepressant dosing is required and that adherence to the healthcare provider's instructions is essential for the long-term maintenance of mental health.

When administered at therapeutic doses, all antidepressants have similar effectiveness; therefore, the choice of drug is not usually based on this factor. The treatment of depression, however, is highly individualized and patients who are unresponsive to one class of medications may respond favorably to drugs from a different class. In fact, patients may respond differently to drugs within the *same* class. Furthermore, the spectrum of adverse effects differs among the classes, and patients may find that drugs from one class are more tolerable than another. Overall, about 65% of patients will respond favorably to antidepressant pharmacotherapy. Success rates improve to 85% when psychotherapy or alternative or adjunctive medicine is used along with antidepressant medications. The four primary classes of antidepressants, shown in Table 19.3, are as follows:

- Selective serotonin reuptake inhibitors (SSRIs)
- Atypical antidepressants
- Tricyclic antidepressants (TCAs)
- Monoamine oxidase inhibitors (MAOIs)

Therapy with antidepressants is generally begun with low doses of a drug from the SSRI class. If no improvement in mood is noted after 2 to 4 weeks, the dose of the drug is increased. Continued lack of response may indicate that the patient is not taking the medication as prescribed, or that a drug from a different class should be used, such as a TCA or an atypical antidepressant. It is important for patients to understand that antidepressant therapy may extend for many years. In general, antidepressant therapy should continue for a minimum of 6 months after the depressive symptoms resolve to prevent uncomfortable withdrawal symptoms and the potential for rebound depression.

Selective Serotonin Reuptake Inhibitors

19.8 Selective serotonin reuptake inhibitors are the preferred drugs for treating depression due to their low incidence of serious adverse effects.

Serotonin is a neurotransmitter in the CNS that is found in high concentrations in certain neurons in the hypothalamus, limbic system, medulla, and spinal cord. It is essential for several body activities, including the cycling between non–rapid eye movement (NREM) and rapid eye movement (REM) sleep, pain perception, and emotions. Lack of adequate serotonin in the limbic regions of the CNS can lead to depression. The actions of serotonin are terminated when it is metabolized to a less active substance by the enzyme monoamine oxidase (MAO). This process is illustrated in Figure 19.1. In the scientific literature, serotonin is commonly referred to by its chemical name, 5-hydroxytryptamine (5-HT).

In the 1970s, it became increasingly clear that serotonin had a more substantial role in depression than initially thought. Although TCAs and MAOIs had been in use for decades, clinicians did not understand how serotonin levels relieved symptoms of depression. Ongoing efforts to find drugs with fewer adverse effects than the existing antidepressants led to the development of the selective serotonin reuptake inhibitors (SSRIs), which were first introduced in 1987. Whereas the TCAs inhibit the reuptake of both norepinephrine and serotonin into presynaptic nerve terminals, the SSRIs *selectively* target serotonin. Increased levels of serotonin in the synaptic spaces induce complex neurotransmitter changes in presynaptic and postsynaptic neurons in the brain. Essentially, presynaptic receptors become less sensitive, and postsynaptic receptors become more sensitive.

SSRIs are as effective in treating depression as the TCAs but exhibit fewer significant adverse effects. Sympathomimetic effects (increased heart rate and HTN) and anticholinergic effects (dry mouth, blurred vision, urinary retention, and constipation) are less common with this drug class. Sedation occurs less frequently, and cardiotoxicity is not observed. The greater safety profile of the SSRIs has led to their current status as first-line drugs for depression.

One of the most common adverse effects of SSRIs relates to sexual dysfunction. Up to 70% of both men and women can experience decreased libido and inability to reach orgasm. In men, delayed ejaculation and impotence may occur. For patients who are sexually active, these adverse effects may be serious enough to cause nonadherence with pharmacotherapy, and a different antidepressant may be

Table 19.3 Antidepressant Drugs

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Selective Serotonin Reuptake Inhibitors (SSRIs)		
citalopram (Celexa)	PO: Start at 20 mg once daily; may increase to 40 mg after 1 wk (max: 40 mg/day)	*Nausea, vomiting, dry mouth, insomnia, somnolence, headache, nervousness, anxiety, diarrhea, dizziness, anorexia, fatigue, sexual dysfunction, weight changes* Stevens–Johnson syndrome (SJS), serotonin syndrome, suicidal ideation in children and young adults
escitalopram (Lexapro)	PO: 10–20 mg once daily (max: 20 mg/day)	
fluoxetine (Prozac)	PO: 20 mg/day (max: 80 mg/day); when stable may switch to 90-mg sustained release capsule once weekly (max: 90 mg/wk)	
fluvoxamine (Luvox)	PO (extended release): 100 mg once daily at bedtime (max: 300 mg/day)	
paroxetine (Paxil, Pexeva)	PO (immediate release): 20–50 mg once daily (max: 50 mg/day)	
	PO (controlled release): 25–62.5 mg daily (max: 62.5 mg/day)	
sertraline (Zoloft)	PO: Start with 50 mg once daily and increase at weekly intervals as needed (max: 200 mg/day)	
vortioxetine (Trintellix)	PO: 5–20 mg once daily (max: 20 mg/day)	
Atypical Antidepressants		
amoxapine	PO: Start with 50 mg bid–tid and increase to 100 mg bid–tid by the end of the first wk (max: 400 mg/day)	*Insomnia, nausea, dry mouth, constipation, increased blood pressure and heart rate, dizziness, sweating, agitation, blurred vision, headache, tremor, vomiting, drowsiness, somnolence, increased appetite, orthostatic hypotension* SJS, seizures, vaginal, uterine, or anal hemorrhage, suicidal ideation, priapism, neuroleptic malignant syndrome (amoxapine), parkinsonism (amoxapine), elevated hepatic enzymes (mirtazapine), bone marrow suppression (mirtazapine), liver failure (nefazodone)
bupropion (Wellbutrin, Zyban, others)	PO: 100 mg tid (immediate release) or 150 mg bid (sustained release) or 300 mg once daily (extended release) (max: 450 mg/day)	
mirtazapine (Remeron)	PO: 15 mg/day in a single dose at bedtime (max: 45 mg/day)	
nefazodone	PO: 50–100 mg bid (max: 600 mg/day)	
trazodone	PO: 150 mg/day (max: 600 mg/day)	
vilazodone (Viibryd)	PO: Start with 10 mg once daily and gradually increase to 40 mg once daily	
Atypical Antidepressants: Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)		
desvenlafaxine (Pristiq)	PO: 50 mg once daily (max: 100 mg/day)	*Nausea, dry mouth, constipation, sweating, agitation, somnolence, decreased appetite, changes in weight (loss or gain), increased blood glucose level (duloxetine), elevated blood pressure and heart rate (levomilnacipran)* Serotonin syndrome, suicidal ideation, hepatotoxicity, syncope, neuroleptic malignant syndrome, abnormal bleeding, HTN (desvenlafaxine, venlafaxine), seizures
duloxetine (Cymbalta)	PO: 30–60 mg/day in 1–2 divided doses (max: 60–120 mg/day)	
levomilnacipran (Fetzima)	PO: 40–120 mg daily (max:120 mg/day)	
venlafaxine (Effexor)	PO: Start with 75 mg/day and increase slowly at 4- to 7-day intervals as needed (max: 375 mg/day for regular release; 225 mg/day for extended release)	
Tricyclic Antidepressants (TCAs)		
amitriptyline (Elavil)	PO: 75–100 mg/day (max: 300 mg/day)	*Drowsiness, sedation, dizziness, orthostatic hypotension, dry mouth, constipation, urinary retention, blurred vision, mydriasis, tachycardia* Bone marrow depression, seizures, dysrhythmias, heart block, MI, hepatitis, acute renal failure
clomipramine (Anafranil)	PO: 25 mg once daily (max: 250 mg/day)	
desipramine (Norpramin)	PO: 75–100 mg/day; may increase to 150–300 mg/day	
doxepin (Silenor)	PO (generic for depression or anxiety): 25–150 mg/day in divided doses (max: 300 mg/day)	
	PO (Silenor for insomnia): 3–6 mg at bedtime	
imipramine (Tofranil)	PO: 75–150 mg/day (max: 300 mg/day)	
	IM: 50–100 mg/day in divided doses	
maprotiline	PO: 75–150 mg/day in divided doses (max: 225 mg/day)	
nortriptyline (Pamelor)	PO: 25 mg tid or qid (max: 150 mg/day)	
protriptyline (Vivactil)	PO: 15–40 mg/day in divided doses (max: 60 mg/day)	
trimipramine (Surmontil)	PO: 50–100 mg/day in divided doses (max: 300 mg/day)	
MAO Inhibitors (MAOIs)		
isocarboxazid (Marplan)	PO: 10–30 mg/day (max: 30 mg/day)	*Drowsiness, insomnia, orthostatic hypotension, blurred vision, nausea, constipation, anorexia, dry mouth, urinary retention, sexual dysfunction, overactivity* Hypertensive crisis, circulatory collapse, dysrhythmias
phenelzine (Nardil)	PO: Start with 15 mg tid; rapidly increase to at least 60 mg/day tid or qid (max: 90 mg/day)	
selegiline (Emsam)	Transdermal: one patch (6 mg/day)	
tranylcypromine (Parnate)	PO: 30 mg/day; may increase by 10 mg/day at 3-wk intervals (max: 60 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

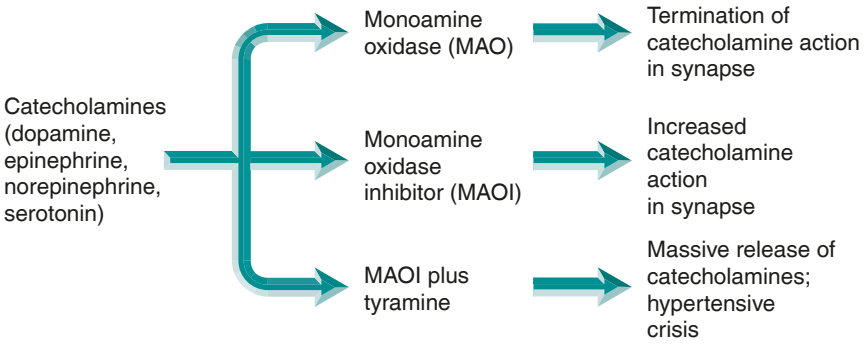

Figure 19.1 Catecholamines and monoamine oxidase.

indicated. The SSRIs can cause weight gain, which may also lead to discontinuation. Other common adverse effects include nausea, headache, nervousness, and insomnia.

All drugs in the SSRI class have equal effectiveness and similar adverse effects. In general, SSRIs elevate mood more quickly than TCAs, which is a major advantage when treating serious depression disorders. The SSRIs are used for a wide variety of other mental health disorders, including obsessive-compulsive disorder (OCD), social anxiety disorder, panic disorder, generalized anxiety disorder, post-traumatic stress disorder (PTSD), and premenstrual dysphoric disorder. They are one of the most widely prescribed drug classes in the United States.

Serotonin syndrome (SES) is a serious medical condition that can occur when a patient is taking multiple medications that affect the metabolism, synthesis, or reuptake of serotonin, causing this neurotransmitter to accumulate in neurons in the CNS. These drugs include SSRIs, MAOIs, TCAs, lithium, St. John's wort, opioids, and triptans. SES sometimes occurs as a result of illicit drug use because amphetamines, cocaine, MDMA (ecstasy), and opioids also affect serotonin levels. Symptoms of SES include mental status changes (confusion, anxiety, restlessness, agitation), HTN, tremors or muscle rigidity, sweating, hyperpyrexia, and ataxia. Symptoms may begin as early as 2 hours after taking the first dose or be delayed for several weeks. Conservative treatment is to discontinue all serotonergic drugs and provide supportive care that stabilizes vital signs; the condition usually resolves in 24 hours. In severe cases, mechanical ventilation and administration of muscle relaxants such as benzodiazepines may be necessary. Agitated patients may require sedation and in severe cases serotonin antagonists such as cyproheptadine, risperidone (Risperdal) or olanzapine (Zyprexa) may be administered.

PROTOTYPE DRUG Fluoxetine (Prozac)

Classification **Therapeutic:** Antidepressant, antianxiety drug
Pharmacologic: Selective serotonin reuptake inhibitor (SSRI)

Therapeutic Effects and Uses: Approved in 1987, fluoxetine was the first SSRI marketed to treat major depressive disorder in the United States. Fluoxetine was subsequently approved as the first medication to treat bulimia nervosa. It was also the first SSRI approved for the treatment of pediatric depression. It is approved for the treatment of OCD in both adults and children, panic disorder, and premenstrual dysphoric disorder.

Fluoxetine is available as tablets, capsules, oral solution, and delayed release capsules. Sarafem is a formulation of fluoxetine specifically marketed for premenstrual dysphoric disorder in a pulvule—a gelatin-based capsule. It is taken daily or for just the 2 weeks prior to an expected menses. Prozac Weekly is a capsule containing enteric-coated granules that allows for only one dose each week. Patients who have stabilized on daily fluoxetine can be switched to Prozac Weekly, which offers the convenience of once-a-week dosing. Symbyax is a fixed-dose combination of fluoxetine and olanzapine that is indicated for bipolar disorder. Olanzapine, an antipsychotic drug, is marketed by itself as Zyprexa for schizophrenia and the manic phase of bipolar disorder.

Fluoxetine is used off-label to treat many other disorders involving multiple body systems. Off-label indications include anorexia nervosa, obesity, alcohol dependence in patients with alcoholism, fibromyalgia, autism, refractory orthostatic hypotension, premature ejaculation, and menopausal hot flashes. Although patients gradually begin to feel less depressed after about 2 weeks of therapy, optimal response may take 8 weeks or longer.

Fluoxetine is extensively metabolized in the liver to norfluoxetine, which has about the same pharmacologic activity as the parent drug. Fluoxetine and norfluoxetine have long half-lives; it takes 30 to 60 days after discontinuing the drug for them to be eliminated by the body. This duration is even more prolonged in patients with liver disease.

Mechanism of Action: As with other serotonin reuptake inhibitors, fluoxetine blocks the uptake of the neurotransmitter serotonin (but not norepinephrine) at the neuronal presynaptic membrane. This increases the amount of neurotransmitter available at the postsynaptic receptor sites, thus enhancing the actions of serotonin.

Pharmacokinetics:

Route	PO
Absorption	Readily absorbed
Distribution	Widely distributed, including the cerebrospinal fluid; likely crosses the placenta; secreted in breast milk; 94% bound to plasma protein

Primary metabolism	Metabolized in the liver to norfluoxetine, an active metabolite
Primary excretion	Renal, small amounts in feces
Onset of action	Peak plasma level: 6–8 h
Duration of action	Half-life: 2–3 days

Adverse Effects: The most common adverse effects of fluoxetine are headache, nausea, and vomiting, which diminish as therapy progresses. Other common gastrointestinal (GI) effects include diarrhea, anorexia, cramping, and flatulence. Fluoxetine does not cause sedation; in fact, insomnia may occur in as many as 25% of patients receiving the drug. Fluoxetine also does not cause the serious cardiotoxicity, orthostatic hypotension, or anticholinergic effects seen with the TCAs. Fluctuations in weight are common. Significant anorexia and weight loss occur in 10% to 15% of patients, whereas others experience a weight gain of as much as 9 kg (20 lb) or more. Patients may experience various types of sexual dysfunction, including delayed ejaculation, impotence, anorgasmia, decreased libido, and priapism. The drug may induce seizures in patients with preexisting seizure disorders or during overdoses. Other adverse effects include cramping, constipation, poor concentration, diarrhea, hot flashes, palpitations, and nervousness. Serotonin syndrome can occur. Pediatric patients may experience personality disorders or hyperkinesia.

Abrupt withdrawal of fluoxetine or other SSRIs can result in a withdrawal syndrome; the patient may experience dizziness, headache, tremor, anxiety, dysphoria, and sensory disturbances. These symptoms usually begin 1 to 7 days after the last dose and may continue for 1 to 3 weeks. Because fluoxetine has an extended half-life and serum levels diminish gradually, withdrawal symptoms are generally less serious than those of the shorter acting SSRIs. Tapering the dose over 2 weeks or longer can prevent withdrawal symptoms. **Black Box Warning:** Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Patients of all ages should be monitored and observed closely during therapy for clinical worsening, suicidal ideation, or unusual changes in behavior.

Contraindications/Precautions: Hypersensitivity to fluoxetine is a contraindication to using the drug. The drug should not be administered to patients with bipolar disorder because it may precipitate a manic episode. It must be used cautiously in patients with cardiac dysfunction (including prolonged QT interval), diabetes, or seizure disorders. Children or young adults with a history of attempted suicide should not receive fluoxetine. There are no known age-related precautions for use in older adults, but children may experience more behavioral adverse effects such as restlessness and insomnia.

Caution must be used when fluoxetine is administered late in pregnancy. The neonate may exhibit symptoms of withdrawal, including irritability, respiratory distress, tremors, abnormal crying, and, possibly, seizures. With supportive care, symptoms of withdrawal in the neonate will disappear in a few days. In most cases, the benefits of treating pregnant women who have major depression with fluoxetine are greater than the potential risks to the neonate.

Drug Interactions: Because fluoxetine inhibits multiple CYP450 isozymes, it has the potential to interact with many other drugs and herbal products. Medications that are metabolized by CYP450 may build to toxic levels due to their impaired metabolism. Some drugs affected by diminished metabolism include TCAs, phenothiazines, most atypical antipsychotics, certain antidysrhythmics, and benzodiazepines. Excessive sedation may occur if fluoxetine is given concurrently with other CNS depressants, including opioids, sedative–hypnotics, or alcohol. Taken concurrently with or within 14 days of MAOIs can result in serotonin syndrome or neuroleptic malignant syndrome (NMS). Concurrent use with warfarin, aspirin, or other nonsteroidal anti-inflammatory drugs (NSAIDs) may increase the risk of bleeding. Fluoxetine may cause an increased risk of toxicity to phenytoin, digoxin, or carbamazepine. Concurrent use with certain antipsychotics may lead to increased extrapyramidal symptoms such as akathisia, dystonia, tardive dyskinesia, and pseudoparkinsonism. Fluoxetine can increase the half-life of diazepam. Caution must also be used if the patient is taking lithium because fluoxetine may increase plasma levels of the drug. **Herbal/Food:** Increased CNS effects may occur if fluoxetine is given concurrently with lavender, kava, or hops. There is an increased risk of serotonin syndrome with the concurrent use of St. John's wort. Increased anticholinergic effects may result from the use of jimsonweed or corkwood. Because grapefruit juice may cause elevated serum levels of fluoxetine, it should be avoided during therapy.

Pregnancy: Category C.

Treatment of Overdose: Overdose can result in seizures, tachycardia, somnolence, and, rarely, death. Supportive treatment is indicated, including gastric lavage and activated charcoal. With intentional overdose, the possibility of multiple drug involvement should always be considered.

Nursing Responsibilities: Key nursing implications for patients receiving fluoxetine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antidepressants.

Drugs Similar to Fluoxetine (Prozac)

Other SSRIs include citalopram, escitalopram, fluvoxamine, paroxetine, sertraline, and vortioxetine.

Citalopram (Celexa): Citalopram was approved by the FDA in 1998 for the treatment of major depressive disorder in adults. Off-label uses include all five major antianxiety categories: generalized anxiety disorder, social anxiety disorder, OCD, panic disorder, and PTSD. Other off-label uses include schizophrenia, premenstrual dysphoric disorder, and menopausal hot flashes. Citalopram is available as regular tablets, as oral disintegrating tablets, or as an oral solution. It is almost identical structurally to escitalopram but is very different from other SSRIs. Older adults are more susceptible to the anticholinergic effects of citalopram than to other SSRIs. It causes fewer drug interactions than does fluoxetine. All other actions and adverse effects are the same as those of fluoxetine and escitalopram. This drug is pregnancy category C.

Escitalopram (Lexapro): Since its approval in 2002, escitalopram has become one of the most frequently prescribed drugs in the United States. Approved indications include major depressive disorder in adults and in adolescents ages 12 to 17 years, and generalized anxiety disorder. It is used off-label to treat social anxiety disorder and panic attacks. It is nearly identical structurally to citalopram although it is more potent; 20 mg of escitalopram is bioequivalent to 40 mg of citalopram. It is available as a tablet or solution. Escitalopram has the same spectrum of adverse effects as fluoxetine and other SSRIs. It elevates mood relatively quickly, in 1 to 2 weeks. Its safety and effectiveness in children younger than 12 years have not been established. This drug is pregnancy category C.

Fluvoxamine (Luvox): Approved in 1994, fluvoxamine is an oral SSRI approved to treat OCD and social anxiety disorder. It is the only SSRI not FDA approved to treat major depression, although it is prescribed off-label for that indication. Other off-label uses include anxiety disorders in children, generalized anxiety disorder, PTSD, and panic disorder. It is available as regular release tablets and extended release capsules (Luvox CR). Adverse reactions are the same as with fluoxetine except that fluvoxamine causes sedation rather than CNS excitement. This drug is pregnancy category C.

Paroxetine (Paxil, Pexeva): Approved in 1992, paroxetine is available as oral tablets, oral suspension, or controlled release tablets (Paxil CR). It is approved to treat a large number of mental health conditions, including major depression, OCD, social anxiety disorder, panic disorder, generalized anxiety disorder, PTSD, and premenstrual dysphoric disorder. Off-label indications include hot flashes, fibromyalgia, bipolar disorder (with lithium), and premature ejaculation. Adverse effects are generally mild, dose dependent, and similar to those of other SSRIs. These effects usually diminish or disappear completely in time. A lower starting dosage is recommended for older adults. Precautions are similar to those for other SSRIs except that paroxetine is a pregnancy category D drug.

Sertraline (Zoloft): Approved in 1991, sertraline is one of the most frequently prescribed SSRIs. It is available as tablets or as an oral concentrate that must be diluted before use. Approved indications include major depressive disorder, OCD, PTSD, social anxiety disorder, and premenstrual dysphoric disorder. It may be used off-label to treat generalized anxiety disorder and eating disorders. Contraindications and precautions are the same as with escitalopram. The main difference between sertraline and fluoxetine is that sertraline blocks the uptake of dopamine in addition to blocking the uptake of serotonin. Adverse effects, uses, and drug interactions are the same as those of fluoxetine. The oral concentrate contains 12% alcohol, which is contraindicated in patients taking disulfiram (Antabuse). This drug is pregnancy category C.

Vortioxetine (Trintellix): The newest of the SSRIs, vortioxetine, was approved in 2013 for the treatment of major depression. In 2016, the trade name was changed from Brintellix to Trintellix to avoid confusion with a similar sounding medication. It has a complex mechanism that enhances serotonin activities in some regions of the brain, while inhibiting that neurotransmitter in other regions. It has the same spectrum of adverse effects as other drugs in this class and is pregnancy category C.

Atypical Antidepressants

19.9 Atypical antidepressants are alternatives to the selective serotonin reuptake inhibitors for depression and anxiety disorders.

Atypical antidepressants are a diverse class of newer drugs that act by mechanisms other than those of the SSRIs, TCAs, and MAOIs. In effect, this is a "miscellaneous" class of drugs because they have very little in common with each other except their ability to alleviate symptoms of depression. They act by preventing the reuptake of specific neurotransmitters in the CNS or by blocking neurotransmitter receptors. Mechanisms include the following:

- Serotonin–norepinephrine reuptake inhibitors (SNRIs): desvenlafaxine (Pristiq), levomilnacipran (Fetzima), venlafaxine (Effexor), and duloxetine (Cymbalta)
- Norepinephrine and dopamine reuptake inhibitors (NDRIs): bupropion (Wellbutrin)

- Norepinephrine reuptake inhibitors (NRIs): reboxetine (Edronax, Vestra)
- Combined reuptake inhibitor and receptor blocker: trazodone (Desyrel), nefazodone, and mirtazapine (Remeron).

As a group, the atypical antidepressants have similar pharmacologic actions to the SSRIs and exhibit fewer adverse effects than the TCAs and MAOIs. Each drug in the class has certain specific adverse effects, as described next. Some are widely used for indications other than depression, such as neuropathic pain, fibromyalgia, and anxiety disorders. The atypical antidepressants are considered to have equal efficacy to other well-established drugs for the treatment of depression.

PROTOTYPE DRUG Venlafaxine (Effexor)

Classification **Therapeutic:** Atypical antidepressant
Pharmacologic: Serotonin–norepinephrine reuptake inhibitor (SNRI)

Therapeutic Effects and Uses: Venlafaxine is an atypical antidepressant approved by the FDA in 1993 to treat major depression. Later, its approved indications were extended to include panic disorder, generalized anxiety disorder, and social anxiety disorder. It has been used off-label to treat a large number of other conditions, including neuropathic pain, premenstrual dysphoric disorder, menopausal hot flashes, migraines, OCD, and fibromyalgia. Venlafaxine XR is an extended release capsule that permits once-daily dosing. It is metabolized to an active metabolite in the liver. Venlafaxine has pharmacologic effects, drug interactions, and adverse effects very similar to those of the SSRIs.

Like other antidepressants, there is little potential for psychologic dependence with venlafaxine—it is not a drug of abuse. Abrupt discontinuation, however, can cause mild to moderate withdrawal symptoms such as nervousness, headache, agitation, fatigue, drowsiness, tremor, and sweating. Gradual tapering of the dose is a means of preventing withdrawal symptoms.

Mechanism of Action: Venlafaxine inhibits the presynaptic neuronal reuptake of both norepinephrine and serotonin in the CNS.

Pharmacokinetics:

Route(s)	PO
Absorption	92% absorbed from the GI tract
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 27% bound to plasma protein
Primary metabolism	Metabolized in the liver to desmethylvenlafaxine, an active metabolite; substantial first-pass effect
Primary excretion	Renal
Onset of action	Peak serum level: 5.5 h but the antidepressant action may take 2–3 weeks
Duration of action	Half-life: 5–7 h (9–11 h for the active metabolite)

Adverse Effects: The most common adverse effect of venlafaxine is nausea, which can occur in a large number of patients. Tolerance may develop to the nausea as therapy progresses. The nausea, combined with anorexia, sometimes leads to weight loss. Pediatric patients taking venlafaxine have been shown to have a decrease in overall height as well as weight. Venlafaxine has structural similarities to amphetamines and can cause CNS stimulation, nervousness, and insomnia. Other patients, however, exhibit sedative effects from the drug. Other CNS adverse effects include headache, emotional lability, dizziness, and asthenia. Sustained elevations, 10 to 15 mmHg, of blood pressure may occur. Types of sexual dysfunction seen with venlafaxine include impotence, abnormal ejaculation, and delayed or absent orgasm in women. Rare, life-threatening adverse reactions include rectal, vaginal, or uterine hemorrhage. **Black Box Warning:** Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Patients of all ages should be monitored and observed closely during therapy for clinical worsening, suicidality, or unusual changes in behavior.

Contraindications/Precautions: Venlafaxine is contraindicated if the patient has hypersensitivity to venlafaxine or an SSRI, if a MAOI is being used concurrently, or during lactation. Caution must be used when administered to patients with cardiac, hepatic, or renal impairment; recent myocardial infarction (MI); seizure disorder; anorexia; or suicidal ideation. Venlafaxine is not administered to patients with bipolar disorder or with a history of mania because it can trigger manic episodes. Safety in children under age 18 has not been established. Patients with hepatic impairment may require as much as a 50% reduction in dose.

Drug Interactions: Venlafaxine is primarily metabolized by the hepatic CYP2D6 isozyme; drugs that inhibit CYP2D6 may cause venlafaxine serum levels to rise. Serotonin syndrome may occur if venlafaxine is given concurrently with SSRIs, MAOIs, lithium, or other drugs that act by increasing serotonin levels. If switching from venlafaxine to a MAOI, venlafaxine must be withdrawn at least 7 days before beginning the MAOI. Alcohol, opioids,

sedatives, hypnotics, or antihistamines can cause additive CNS depression. Cimetidine, haloperidol, fluoxetine, sertraline, or phenothiazine can lead to increased toxicity. **Herbal/Food:** No food interactions have been reported, but there are several possible interactions with herbal products. St. John's wort and SAM-e may increase the risk of SES. CNS depression may occur with concurrent use of chamomile, kava, hops, lavender, valerian, or skullcap. Jimsonweed or corkwood may cause increased anticholinergic effects. Yohimbe may increase the risk for HTN.

Pregnancy: Category C.

Treatment of Overdose: Overdoses are generally not fatal but can cause serious symptoms such as CNS depression, seizures, altered level of consciousness, hypotension, and dysrhythmias. General measures include inducing emesis and administering activated charcoal and gastric lavage. The electrocardiogram (ECG) must be monitored and antiseizure drugs administered as necessary.

Nursing Responsibilities: Key nursing implications for patients receiving venlafaxine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antidepressants.

Drugs Similar to Venlafaxine (Effexor)

Other atypical antidepressants include amoxapine, bupropion, desvenlafaxine, duloxetine, levomilnacipran, mirtazapine, nefazodone, trazodone, and vilazodone.

Amoxapine: Approved in 1980, amoxapine is chemically related to older TCAs and phenothiazines. The drug exhibits potentially serious adverse effects, which limit its use to patients who have major depression accompanied by psychotic symptoms such as agitation. Adverse effects resemble those of TCAs (blood dyscrasias, orthostatic hypotension, sedation, anticholinergic effects, sexual dysfunction, cardiac toxicity) and phenothiazines (neuroleptic malignant syndrome, parkinsonism symptoms). There is cross hypersensitivity between amoxapine and TCAs. Amoxapine must be used cautiously in those with suicidal ideation. This drug is pregnancy category C.

Bupropion (Wellbutrin, Zyban, Others): Approved in 1985, bupropion has a chemical structure similar to that of amphetamine. It is approved to treat major depression as well as being the first approved therapy for persistent seasonal affective disorder. Bupropion is also marketed as Zyban and Buproban for the management of nicotine withdrawal during smoking cessation. Off-label uses include neuropathic pain and attention-deficit/hyperactivity disorder (ADHD).

The naming of bupropion has resulted in medication errors. It is available as immediate release tablets (100 mg, 3 times daily) and as extended release formulations, Wellbutrin SR (150 mg, twice daily) and Wellbutrin XL (300 mg, once daily). In pharmacology, the terms *sustained release* (SR) and *extended release* (XL or XR) are usually used interchangeably, but this is not the case for bupropion. Further confusing the naming is that the *U.S. Pharmacopeia* requires that all generic versions of prolonged release medications be labeled "extended release." In 2008 a new salt form, bupropion hydrobromide (Aplenzin), was approved as a once-daily tablet (348 mg, once daily) for depression. Caution must be used when dispensing bupropion to be certain the correct salt and dosing schedule are used.

Bupropion not only inhibits the reuptake of serotonin, but it may also affect the activity of norepinephrine and dopamine. Like amphetamine, bupropion has stimulant actions and suppresses the appetite. It does not cause weight gain or sexual dysfunction, which makes it appealing to women who are experiencing hypoactive sexual disorder. Indeed, it is sometimes used to counteract the sexual dysfunction that occurs in patients taking SSRIs. Antidepressant action begins in 1 to 3 weeks and is equal to that of the TCAs. Because bupropion has a greater potential for causing seizures than other antidepressants, it should be used with caution in patients with seizure disorders. The risk for seizures is dose dependent and increases for patients drinking alcohol or taking other drugs that lower the seizure threshold. Seizures have been reported in infants receiving breast milk from mothers taking bupropion. Common adverse reactions include CNS stimulation (agitation, insomnia, and restlessness), weight loss, headache, dry mouth, constipation, and GI upset. About 20% of patients taking this drug will develop tremors. Because of its potential adverse effects, bupropion is usually considered an alternative antidepressant for patients who do not respond to SSRIs. This drug is pregnancy category C.

Desvenlafaxine (Pristiq): Desvenlafaxine is an SNRI approved in 2008 for the treatment of major depressive disorder. It is available as an extended release tablet that is taken once daily. Common adverse effects include nausea, dizziness, excessive sweating, constipation, somnolence, anxiety, male function disorders, and decreased appetite. Because this drug can raise blood pressure, preexisting HTN should be corrected before starting therapy. Desvenlafaxine should be discontinued gradually to prevent the appearance of withdrawal symptoms. This drug is pregnancy category C.

Duloxetine (Cymbalta): Like venlafaxine, duloxetine is an atypical antidepressant that is classified as an SNRI. First approved for major depression in 2004, it has since received FDA approval to treat diabetic peripheral neuropathic pain, fibromyalgia, chronic musculoskeletal pain, and generalized anxiety disorder. Stress urinary incontinence is an off-label indication. Abnormal vision is the

most frequently reported adverse effect, and nausea is a common reason for discontinuation of therapy. Other adverse events include photosensitivity, bruising, anorexia, thrombophlebitis, constipation, diarrhea, dry mouth, insomnia, and anxiety. Postmarketing incidences of liver injury suggest that the drug should be used with great caution in patients with preexisting hepatic impairment or in people with alcoholism. Caution must be exercised when administered to individuals with mania, seizures, HTN, cardiac, renal or hepatic disease, older adults, children, or lactating women. When discontinuing therapy, the dose should be tapered slowly to prevent withdrawal symptoms. Patients may begin feeling the antidepressant effects of duloxetine within 2 weeks of beginning treatment. This drug is pregnancy category C.

Levomilnacipran (Fetzima): One of the newer SNRIs, levomilnacipran was approved in 2013 as an extended release capsule for the treatment of major depression in adults. It has very similar actions and side effects to other SNRIs such as venlafaxine. The most frequently observed side effects include nausea, vomiting, constipation, hyperhidrosis, heart rate increase, erectile dysfunction, and heart palpitations. Levomilnacipran is the isomer of milnacipran (Savella). Despite their close structural similarities, levomilnacipran is approved only for major depression, whereas milnacipran is approved only for fibromyalgia. Levomilnacipran is pregnancy category C.

Mirtazapine (Remeron): Classified as a tetracyclic compound, this drug was approved in 1996 for major depression in adults and may be used off-label to treat PTSD, hot flashes, or insomnia. It blocks presynaptic serotonin and norepinephrine receptors, thereby enhancing release of these neurotransmitters from nerve terminals. Unlike the TCAs, it has few anticholinergic actions. It does carry a higher risk of seizure activity in patients with a previous history of seizures, head injury, or alcoholism. Serious adverse reactions include worsening of psychosis in patients with bipolar disorder, bone fractures, agranulocytosis, serotonin syndrome, and suicidal ideation. Other adverse reactions include dizziness, orthostatic hypotension, QT prolongation, sedation, tachycardia, HTN, or extrapyramidal symptoms in older adults. Mirtazapine should not be used in patients with hypersensitivity to TCAs, seizure disorders, prostatic hypertrophy, serious hepatic impairment, chronic kidney disease, or those who are recovering from MI. Mirtazapine usually elevates mood within 2 to 4 weeks after the initiation of therapy. This drug is pregnancy category C.

Nefazodone: Chemically similar to trazodone, nefazodone causes minimal cardiovascular effects, fewer anticholinergic effects, less sedation, and less sexual dysfunction than some of the other antidepressants. The most common adverse effects are xerostomia, drowsiness, nausea, vomiting, dizziness, and constipation. Although FDA approved only for major depression, the medication is used off-label to treat anxiety, panic attacks, premenstrual dysphoric disorder, PTSD, and social anxiety disorder. Nefazodone acts by blocking serotonin receptors and inhibiting serotonin reuptake. It also has some blocking effect on norepinephrine reuptake. Originally approved in 1994, a trade name form of the drug, Serzone, was removed from the market in 2004 due to a possibility of liver damage; generic nefazodone is still available. A black box warning indicates that the drug should not be used in patients with acute liver impairment, and that hepatic laboratory values should be regularly monitored during therapy. The drug should be withdrawn if the patient develops signs of hepatic injury such as increased serum aspartate aminotransferase (AST) or serum alanine aminotransferase (ALT) levels greater than 3 times normal. This drug is pregnancy category C.

Trazodone: Approved in 1981, trazodone works by producing a moderate, selective blockade of serotonin reuptake. It is not very effective when used alone as an antidepressant, but its sedative properties are especially useful in patients who have antidepressant-induced insomnia. In fact, trazodone is most frequently used off-label as a sleep aid, rather than as an antidepressant. Other off-label indications include aggressive behavior, cocaine withdrawal, migraine prevention, and as an adjuvant to reduce cravings for alcohol in patients with alcohol dependency. It causes little cardiac toxicity and few anticholinergic effects so it may be useful for older adults and other individuals for whom either of these may be intolerable. Common adverse effects include orthostatic hypotension, nausea, sedation, and dry mouth. Reported sexual effects include priapism, anorgasmia, and ejaculation dysfunctions. Overdose with trazodone is considered to be safer than overdose from MAOIs or TCAs, and there have been no reports of death from trazodone use alone. However, death can occur from overdose when the patient combines trazodone with other CNS depressants. This drug is pregnancy category C.

Vilazodone (Viibryd): Approved in 2011, vilazodone acts by blocking serotonin reuptake and by demonstrating partial agonist action at serotonin receptors. It appears to have equivalent effectiveness to other drugs in this class. One advantage of vilazodone is that clinical improvement is noted after 7 days of therapy, compared to the 4 to 6 weeks required for some of the other antidepressants. In addition, the drug has only minor adverse effects, with GI-related symptoms being the most common. Like other antidepressants, the drug carries a black box warning about possible increased suicidality in adolescents and young adults. This drug is pregnancy category C.

CONNECTION Checkpoint 19.2

Atypical antidepressants are sometimes used to treat anxiety when drugs from other classes are not effective. From what you learned in Chapter 18, what class of drugs is the traditional choice for the short-term therapy of generalized anxiety disorder? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Tricyclic Antidepressants

19.10 Tricyclic antidepressants were once the mainstay for the treatment of depression but they have many adverse effects.

The **tricyclic antidepressants (TCAs)** have been available in the United States for more than 50 years. Although no longer the preferred drugs, the TCAs are still prescribed for many patients with major depressive disorder. This group of medications is named after its molecular structure, which has a three-ring core. Because this molecular arrangement is very similar to the structure of the phenothiazine antipsychotics, these two classes of drugs share similar adverse effects (see Chapter 20). Several of the TCAs are also prescribed to treat the depressive stage of bipolar disorder, chronic insomnia, OCD, neuropathic pain, and fibromyalgia.

The TCAs act by blocking the reuptake transport of norepinephrine and serotonin at synapses, as shown in Figure 19.2. This blockade results in a greater quantity of neurotransmitters being available in the synaptic space, leading to a more intensified action. Some TCAs such as desipramine, maprotiline, and protriptyline are specific to blocking the reuptake of norepinephrine, whereas the other drugs in this class affect both norepinephrine and serotonin. In general, all TCAs have similar effectiveness in treating depression and exhibit the same spectrum of adverse effects.

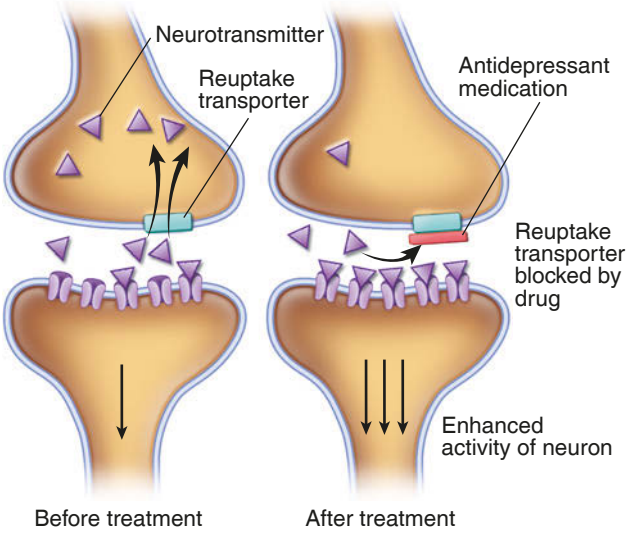

Figure 19.2 Mechanisms of action of antidepressants: (a) In adrenergic and serotonergic neurons the activity of the neurotransmitter is terminated by reuptake. (b) Tricyclic antidepressants and SSRIs produce their effects by inhibiting the reuptake of neurotransmitters. The neurotransmitter accumulates in the synaptic cleft and activates more receptors, thus causing an enhanced effect at the synapse.

The advantages of TCAs are that they are inexpensive and their effectiveness in treating depression has been well established for many decades. They are rapidly absorbed when given orally (PO) and widely distributed throughout the body. Relative to the SSRIs and atypical antidepressants, the TCAs have more frequent adverse effects, which has limited their use.

Blockade of muscarinic receptors by TCAs is responsible for causing a high incidence of anticholinergic adverse effects with symptoms such as dry mouth, blurred vision, constipation, urinary retention, and tachycardia. Orthostatic hypotension is common and may be serious enough to cause injury due to falls. Although rare, the most serious adverse effect is the ability of TCAs to cause life-threatening cardiac dysrhythmias, especially if the patient receives an overdose of the medication.

A few of the TCAs have central effects that cause sedation, which can be managed by taking the drugs at bedtime. Sedation is worsened by the concurrent use of other CNS depressants such as alcohol. Confusion, dizziness, and fatigue are other possible dose-limiting effects of TCAs. At high doses some cause seizures.

Compared to the SSRIs, TCAs exhibit a relatively high incidence of sexual dysfunction, including impotence and delayed ejaculation in men, and breast enlargement and impaired orgasm in women. Weight gain is possible. In addition, some patients quickly change mood from depression to hypomania or mania and may begin to display symptoms of bipolar disorder. These patients require a dosage adjustment or a change to a different antidepressant.

Tolerance and psychologic dependence are usually not major problems with TCAs. Once stabilized, therapy may often be conducted for years without requiring a dosage adjustment. Unlike many CNS depressants, the TCAs are not drugs of abuse. Patients on high doses for prolonged periods, however, may exhibit a mild withdrawal syndrome on discontinuation and experience symptoms such as irritability, nausea, sleep impairment, muscle aches, and fatigue. To avoid these symptoms, and to ensure that rebound depression does not occur, it is best that these drugs be withdrawn gradually.

CONNECTION Checkpoint 19.3

Anticholinergic effects are common with TCAs and some other antidepressants. From what you learned in Chapter 14, name the prototype anticholinergic drug. If anticholinergic effects become prominent in a patient, what class of drugs can be used to counteract the cardiovascular adverse effects? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Imipramine (Tofranil)

Classification **Therapeutic:** Tricyclic antidepressant
Pharmacologic: Norepinephrine reuptake inhibitor

Therapeutic Effects and Uses: Approved in 1959 as the first TCA, imipramine is effective in treating major depressive disorder. Like other TCAs, it is given PO and is well absorbed from the GI tract. A drawback to the use of imipramine is that it takes 2 weeks or longer to achieve full therapeutic effect. During the initial weeks of therapy, when blood levels of imipramine have not yet produced their full therapeutic effects, suicide risks may increase, especially in children, adolescents, and young adults. Although it is not a first-line therapy for the disorder, imipramine is one of only two drugs approved for nocturnal enuresis, or bedwetting, in children. The urge to urinate is diminished by the anticholinergic (urinary retention) effects of the drug.

Like other TCAs, imipramine has a number of off-label indications. These include the adjuvant treatment of cancer or neuropathic pain, overactive bladder, ADHD, insomnia, and bulimia nervosa. The use of TCAs in treating social anxiety disorder (social phobia) and panic disorder is presented in Chapter 18. The active metabolite of imipramine is desipramine, which is marketed separately as Norpramin.

Mechanism of Action: Imipramine blocks the reuptake of norepinephrine and serotonin into presynaptic nerve terminals. This results in an increased action of both neurotransmitters in neurons. Imipramine also blocks acetylcholine receptors, which is likely responsible for its effectiveness in treating enuresis.

Pharmacokinetics:

Route(s)	PO, IM (rare)
Absorption	Completely absorbed from the GI tract
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 85–95% bound to plasma protein
Primary metabolism	Hepatic; metabolized to the active metabolite desipramine
Primary excretion	Renal; small amounts in bile and feces
Onset of action	1–2 h for peak serum level; mood elevation requires 2–3 weeks
Duration of action	Not known

Adverse Effects: Frequent adverse reactions with imipramine include orthostatic hypotension (the most common adverse effect), dizziness, confusion, drowsiness, diarrhea, dry mouth, increased appetite, jaundice, urinary retention, rash, pruritus, and photosensitivity. Serious adverse reactions include seizures, hepatitis, acute renal failure, paralytic ileus, leukopenia, agranulocytosis, thrombocytopenia, or eosinophilia. Serious adverse reactions occur with acute doses when imipramine accumulates in cardiac tissue; dysrhythmias, heart failure, or MI can occur. **Black Box Warning:** Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Patients of all ages should be monitored and observed closely during therapy for clinical worsening, suicidality, or unusual changes in behavior.

Contraindications/Precautions: Imipramine should not be used by patients with seizure disorders because it lowers the seizure threshold. It must be used with caution in individuals with suicidal tendencies, urinary retention, prostatic hyperplasia, cardiac or hepatic disease, increased intraocular pressure, or hyperthyroidism. Use in patients with Parkinson's disease will induce or worsen parkinsonism symptoms. Patients with cardiac disease such as heart failure, QT prolongation, or history of MI should be carefully monitored during therapy; use in patients recovering from MI has resulted in sudden death. Imipramine should not be used during pregnancy or lactation.

Drug Interactions: Like other TCAs, imipramine is metabolized by hepatic CYP450 enzymes and is highly protein bound; thus there is a high potential for drug–drug interactions. Increased sedation can occur when imipramine is given concurrently with other CNS depressants, including alcohol. Drug interactions causing decreased effects of imipramine include oral contraceptives, clonidine, carbamazepine, and indirect-acting sympathomimetics. Concurrent use with thyroid hormone may induce dysrhythmias. Imipramine should not be given concurrently with other drugs that prolong the QT interval, such as the Class IA antidysrhythmics, because of the potential for serious cardiac toxicity. Phenothiazines and TCAs are structurally very similar and concurrent use will likely cause additive anticholinergic adverse effects. Concurrent use of MAOIs must be avoided because this combination may cause hypertensive crisis, seizures, or hyperpyretic crisis. SSRIs must not be used concurrently; this can cause increased toxicity of TCAs. **Herbal/Food:** Several commonly used herbal products may lead to increased imipramine effects, including kava, hops, lavender, valerian, skullcap, and chamomile. An increased anticholinergic effect can occur with the use of belladonna, jimsonweed, or henbane. Serotonin syndrome may occur with the use of St. John's wort.

Pregnancy: Category C.

Treatment of Overdose: Overdoses with TCAs may be life threatening with symptoms that include mixed mania and depression followed by coma. Medical management includes treating possible seizures, hypotension, and dysrhythmias.

Nursing Responsibilities: Key nursing implications for patients receiving imipramine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antidepressants.

Drugs Similar to Imipramine (Tofranil)

Other TCAs include amitriptyline, clomipramine, doxepin, maprotiline, protriptyline, and trimipramine. Desipramine is an active metabolite of imipramine, and the two drugs have the same actions and adverse effects, as previously described.

Amitriptyline (Elavil) and nortriptyline (Pamelor): Amitriptyline has been available by the PO route since 1961 for the therapy of major depression. It has been used for a large number of off-label indications, including neuropathic pain syndromes such as fibromyalgia, and for nocturnal enuresis, social anxiety disorder, ADHD, migraines, persistent hiccups, insomnia, and bulimia nervosa. It produces more sedation than most other TCAs and is thus taken at bedtime. It is metabolized in the liver to nortriptyline, which is marketed as a separate drug. Both amitriptyline and nortriptyline produce significant anticholinergic adverse effects. Like other TCAs, cardiac toxicity is a concern at high doses. These drugs are pregnancy category D.

Clomipramine (Anafranil): Approved in 1991, the only FDA-approved indication for clomipramine is OCD. Depression is an off-label indication. Other off-label uses are premature ejaculation and childhood autism. Because the drug produces significant anticholinergic effects and orthostatic hypotension, it is not a first-line drug for depression. This drug is pregnancy category C.

Doxepin (Silenor): Approved in 1969 to treat major depression, doxepin is also approved to treat insomnia and anxiety. Doses used to treat depression (25–150 mg/day) are much higher than those used for insomnia (3–6 mg). When given PO for depression or anxiety, the most common side effect is sedation. Other adverse effects include nausea and upper respiratory tract infection. A topical form of doxepin (Zonalon) is available for pruritus associated with atopic dermatitis. Because doxepin is absorbed through the skin, topical applications can cause systemic adverse effects. This drug is pregnancy category C.

Maprotiline: Maprotiline does not have a tricyclic chemical structure but it is included with the TCAs because it has very similar therapeutic and adverse effects. It was approved to treat major depression in 1980. Off-label indications include bulimia nervosa, neuropathic pain, panic attacks, and enuresis. It has the same adverse effects as other drugs in this class and offers no specific advantages over other TCAs. This drug is pregnancy category D.

Protriptyline (Vivactil): Protriptyline is an oral antidepressant that was approved in 1967. It has the same adverse effects as other TCAs except that it tends to produce CNS stimulation rather than sedation. It is the only TCA that has respiratory stimulant activity. These respiratory effects have led to its occasional off-label use for treating chronic obstructive pulmonary disease or sleep apnea. This drug is pregnancy category C.

Trimipramine (Surmontil): Trimipramine was approved in 1979 for major depression. Off-label indications include anxiety, schizophrenia, and rheumatoid arthritis. Drowsiness is a serious problem; however, the incidence of anticholinergic effects is one of the lowest of any drug in its class. It offers no major benefits over other TCAs. This drug is pregnancy category C.

Monoamine Oxidase Inhibitors

19.11 Monoamine oxidase inhibitors are effective antidepressants but are seldom used due to potentially serious adverse effects.

MAO is a key enzyme located in the liver, intestinal wall, and adrenergic neurons. It is responsible for inactivating monoamines: substances that contain one $-NH_2$ (amine) group. Not only does MAO inactivate natural monoamines such as norepinephrine, dopamine, and serotonin, but it also acts on those present in food and drugs. The **monoamine oxidase inhibitors (MAOIs)** are antidepressants that block the actions of MAO.

In adrenergic neurons, MAOIs slow the destruction of norepinephrine, dopamine, and serotonin. This creates higher levels of these neurotransmitters and enhances their activity in the brain. Through mechanisms incompletely understood, this increase in neurotransmitters creates an antidepressant action.

Although they are as effective in treating depression as the SSRIs or TCAs, serious adverse reactions limit their use. Because of their low safety margin, these drugs are reserved for patients with refractory depression that has not responded to TCAs, atypical antidepressants, or SSRIs. They are rarely used in clinical practice.

A serious adverse reaction with MAOIs is their ability to cause a hypertensive crisis if combined with foods that contain **tyramine**. Widely found in nature, tyramine is a type of monoamine that is formed by the metabolism

of tyrosine, an amino acid. When a patient is taking an MAOI, the drug blocks the breakdown of dietary tyramine, causing it to accumulate to high levels. In turn, tyramine causes the release of norepinephrine stored in adrenergic neurons. Rapid vasoconstriction occurs with a potential rise of blood pressure of 30 mmHg or more. Table 19.4 contains a list of tyramine-rich foods that must be avoided by patients taking MAOIs. Products containing tyramine are sometimes marketed as dietary supplements to increase fat loss from the body. There is no valid scientific evidence to support this claim, and these supplements must be strictly avoided by patients taking MAOIs.

PROTOTYPE DRUG **Phenelzine (Nardil)**

Classification **Therapeutic:** Antidepressant
Pharmacologic: Monoamine oxidase inhibitor

Therapeutic Effects and Uses: An older drug approved in 1959, phenelzine was once widely used to treat major depression. It has also been used off-label to treat OCD, panic disorder, and social anxiety disorder and for migraine prophylaxis. Although very effective in treating these disorders, phenelzine interacts with tyramine in foods and with many other drugs to produce potentially serious interactions.

Table 19.4 Foods High in Tyramine

Category of Food	Specific Foods
Meats	Beef or chicken liver, pate Hot dogs, bologna Pepperoni, salami, sausage
Dairy products	Aged cheese Sour cream Yogurt
Fruits	Avocados Bananas, in large amounts Canned figs Papaya products, including meat tenderizers Raisins
Vegetables	Pods of fava beans Fermented soybeans, soybean paste
Fish	Dried or cured fish Fermented, smoked, aged fish Pickled or kippered herring
Alcohol	Beer Wine, especially red wine
Miscellaneous	Protein dietary supplements Soups (may contain protein extract) Shrimp paste Soy sauce Yeast, brewer's or extracts

CONNECTIONS: Complementary and Alternative Therapies

St. John's Wort for Depression

Description

St. John's wort (*Hypericum perforatum*) is an herb found throughout Great Britain, Asia, Europe, and North America.

History and Claims

The herb gets its name from a legend that red spots once appeared on its leaves on the anniversary of St. John's beheading. The word *wort* is a British term for "plant." Use of the herb dates to ancient Greece, and Native Americans used it as an antiseptic or anti-inflammatory agent. Modern uses have focused on the antidepressant properties of the herb.

Standardization

The active substances in St. John's wort are believed to be hyperforin and hypericin. There is no standard dosage; however, some manufacturers are beginning to report dose by the percentage of hypericin in the extract. For example, one commonly used dose is 300 mg tid of St. John's wort standardized to 0.3% hypericin. Some studies use 5% hyperforin.

Evidence

Recent studies suggest that St. John's wort produces its effects by increasing the levels of glutamate, serotonin, norepinephrine, and dopamine in the brain (Vance, Ribnicky, Hermann, & Rogers, 2014). St. John's wort appears to be as effective as the SSRIs for treating minor to moderate depression, but has not been proven to treat major depression (Apaydin et al., 2016; Cui & Zheng, 2016).

St. John's wort induces hepatic CYP450 enzymes and interacts with many medications, including oral contraceptives, warfarin, digoxin, and cyclosporine. It should not be taken concurrently with antidepressant medications and patients should discuss the use of St. John's wort with their healthcare provider before taking the supplement. St John's wort has not been studied extensively in children or in pregnant women and should be avoided in those populations.

An active ingredient in St. John's wort is a photoactive compound that when exposed to light produces substances that can damage myelin. Patients have reported feeling stinging pain on the hands after sun exposure while taking the herbal remedy. Patients who take this herb should be advised to apply sunscreen or wear protective clothing when outdoors.

Like other antidepressants, phenelzine may take up to 4 to 8 weeks to produce a maximum antidepressant response. This drug is changed to active metabolites in the liver.

Mechanism of Action: Phenelzine produces its effects by binding irreversibly to MAO. This intensifies the actions of endogenous epinephrine, norepinephrine, serotonin, and dopamine in the CNS. Increased concentrations of these neurotransmitters result in elevated mood.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed
Distribution	Widely distributed; crosses the placenta
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Peak level: 2–4 h (antidepressant action takes 2–8 weeks)
Duration of action	Half-life: 11 h

Adverse Effects: The most serious adverse effect of phenelzine is hypertensive crisis precipitated by foods containing tyramine, which can induce fatal intracranial bleeding. Dizziness and orthostatic hypotension are common during therapy. Other frequent adverse reactions include drowsiness, sexual dysfunction, and anorexia. Life-threatening adverse reactions include dysrhythmias and a syndrome of inappropriate antidiuretic hormone-like symptoms. **Black Box Warning:** Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Patients of all ages should be monitored and observed closely during therapy for clinical worsening, suicidal ideation, or unusual changes in behavior.

Contraindications/Precautions: Patients with schizophrenia, cardiovascular or cerebrovascular disease, hepatic impairment or chronic kidney disease, or pheochromocytoma should not take phenelzine. Caution should be used when prescribing phenelzine to a patient with epilepsy, severe or frequent headaches, HTN, dysrhythmias, or suicidal tendencies.

Drug Interactions: Phenelzine interacts with many other drugs. The nurse should consult a current drug guide for a comprehensive list of drug–drug interactions. Other CNS depressants, including alcohol, may lead to additive CNS depression. Concurrent administration with buspirone may increase blood pressure. Use with opioid analgesics may lead to immediate excitation, severe HTN or hypotension, and, occasionally, severe respiratory distress, vascular collapse, seizures, coma, and death. CNS stimulants and sympathomimetics may increase the cardiac stimulant and vasopressor effects of phenelzine. SES may occur if phenelzine is administered with other drugs such as SSRIs, lithium, or dextromethorphan that potentiate the actions of serotonin. **Herbal/Food:** Patients who are taking phenelzine or any MAOI must avoid tyramine-containing foods (see Table 19.4) because these foods may precipitate a hypertensive crisis. Medications containing caffeine, including over-the-counter (OTC) products, should be avoided because they may increase the risk of HTN and dysrhythmias. An increased sympathomimetic effect may occur when phenelzine is combined with capsicum peppers or large amounts of green tea. Ginkgo, nutmeg, and yohimbe use can result in increased effects. Ginseng use can lead to irritability, hallucinations, mania, and increased tension headaches. Decreased effects can occur with the use of valerian. Serotonin syndrome may occur with the use of St. John's wort.

Pregnancy: Category C.

Treatment of Overdose: Overdosage with phenelzine is serious and can result in death if untreated. Symptoms may include either CNS stimulation (seizures) or depression (coma). Induction of gastric lavage with activated charcoal may be beneficial. Electrolytes and vital signs must be monitored and the appropriate intervention administered to keep values within normal ranges.

Nursing Responsibilities: Key nursing implications for patients receiving phenelzine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antidepressants.

Drugs Similar to Phenelzine (Nardil)

The other MAOIs that are available include isocarboxazid, selegiline, and tranylcypromine.

Isocarboxazid (Marplan): Like phenelzine, isocarboxazid was initially approved by the FDA for depression in the 1950s. Off-label indications include refractory panic disorder and social anxiety disorder. It is only used when other therapies have failed to produce satisfactory outcomes. The drug has the same precautions and potential interactions as phenelzine, including the possibility of a hypertensive crisis occurring when taken with tyramine-containing products. This drug is pregnancy category C.

Selegiline (Emsam): Approved in 2006 for major depression, selegiline is a transdermal patch that delivers a controlled amount of the MAOI over 24 hours. Absorption across the skin bypasses MAO located in intestinal cells; thus there is less risk of a hypertensive crisis when eating foods containing tyramine. The drug is also indicated for the treatment of Parkinson's disease by capsule (Eldepryl) or orally disintegrating tablets (Zelapar). The various forms of this drug should not be administered

concurrently due to the risk of hypertensive crisis caused by drug overdose. Common adverse effects include skin irritation at the site of the patch application, headache, sleep disorders, diarrhea, and dry mouth. This drug is pregnancy category C.

Tranylcypromine (Parnate): Tranylcypromine was approved in 1961 for the therapy of depression. Off-label indications include refractory panic disorder and social anxiety disorder. The drug binds reversibly to MAO. This results in a more rapid onset of antidepressant action than phenelzine or isocarboxazid and a more rapid return to normal MAO levels after the drug is discontinued. However, it has the same precautions and potential interactions as phenelzine and is rarely used due to its adverse effects. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antidepressants

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, urologic, cardiovascular, or neurologic disease, current mental status, closed-angle glaucoma status, and pregnancy or breastfeeding status. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a history of depression or mood disorder, including a family history of same and severity. Use objective screening tools when possible (e.g., Beck Depression Inventory or Geriatric Depression Scale).
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, hepatic and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased mood, lessening depression, increased activity level, return to normal ADLs, appetite, and sleep patterns).
- Continue periodic monitoring of CBC, electrolytes, glucose, and hepatic and renal function studies.
- Assess vital signs and weight periodically or as symptoms warrant.
- Assess for and promptly report adverse effects: dizziness or lightheadedness, drowsiness, confusion, agitation, suicidal ideations, palpitations, tachycardia, blurred or double vision, skin rashes, bruising or bleeding, abdominal pain, jaundice, change in color of stool, flank pain, or hematuria.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Drugs used for depression may take 2–8 weeks before full effects are realized. Use objective measures, e.g., PHQ-9, when possible to help quantify therapeutic results. For outpatient therapy, prescriptions may be limited to a 7-day supply of medication. Have patient sign "No Harm/No Suicide" contract as appropriate.)	• Teach the patient that full effects may not occur for a prolonged period, but that some improvement should be noticeable after beginning therapy. • Encourage the patient to keep all appointments with the therapist and to discuss ongoing symptoms of depression, reporting any suicidal ideations immediately.
Minimizing adverse effects: • Continue to monitor vital signs, mental status, coordination, and balance periodically. Ensure patient safety; monitor ambulation until the effects of the drug are known. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for falls. (Antidepressant drugs may cause drowsiness and dizziness, hypotension, or impaired mental and physical abilities, increasing the risk of falls.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to monitor CBC, electrolytes, and renal and hepatic function. (Some antidepressant drugs may cause hepatotoxicity as an adverse effect. **Diverse Patients:** SSRIs are metabolized through the CYP450 system and may result in less than optimal therapeutic results based on differences in enzymes. Monitor ethnically diverse patients more frequently in the early stages of drug therapy.)	• Instruct the patient on the need to return periodically for laboratory work. • Teach the patient to promptly report any abdominal pain, particularly in the upper quadrants, changes in stool color, yellowing of sclera or skin, or darkened urine. • **Diverse Patients:** Teach ethnically diverse patients to observe for less than optimal therapeutic effects and report promptly. • Teach the patient to wear or carry medical identification stating the type of drug therapy used, especially if MAOIs are given.
• Assess for changes in level of consciousness, disorientation or confusion, or agitation. (Neurologic changes may indicate under- or overmedication, exacerbation of other psychiatric illness, or adverse drug effects.)	• Instruct the patient or caregivers to report increasing lethargy, disorientation, confusion, changes in behavior or mood, agitation or aggression, slurred speech, or ataxia immediately.
• Assess for changes in visual acuity, blurred vision, loss of peripheral vision, seeing rainbow halos around lights, or acute eye pain, especially if accompanied by nausea and vomiting, and report immediately. (Increased intraocular pressure in patients with closed-angle glaucoma may occur in patients taking TCAs.)	• Instruct the patient to report any visual changes or eye pain immediately.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Monitor cardiovascular status. (Early signs of SES include rapid increases in blood pressure and pulse. Headache, palpitations, fever, and neck stiffness may signal a life-threatening hypertensive crisis in a patient taking MAOIs.)	• Instruct the patient to immediately report severe headache, dizziness, paresthesia, palpitations, tachycardia, chest pain, nausea, vomiting, diaphoresis, or fever.
• Assess for bruising, bleeding, or signs of infection. (TCAs may cause blood dyscrasias and increased chances of bleeding or infection.)	• Teach the patient to report any signs of increased bruising, bleeding, or infections (e.g., sore throat, fever, or skin rash) promptly.
• Assess for dry mouth, blurred vision, urinary retention, constipation, and sexual dysfunction. (Anticholinergic-like effects and sexual dysfunction, including loss of libido and impotence, are common antidepressant adverse effects. **Lifespan:** Be aware that the older adult man with an enlarged prostate is at higher risk for mechanical obstruction. Tolerance to anticholinergic effects usually develops in 2–4 weeks.)	• Teach the patient to use ice chips, frequent sips of water, chewing gum, or hard candy to alleviate dry mouth, and to avoid alcohol-based mouthwashes, which may increase dryness. • Use of "dry eye" drops and resting the eyes periodically may help decrease dry eye feeling. Teach the patient to report any feelings of scratchiness or eye pain immediately. • Instruct the patient to report difficulty with urination, hesitancy, or dysuria promptly. • Encourage the patient to discuss concerns about sexual functioning and refer to the healthcare provider if concerns affect medication adherence.
• Continue weekly weights and report gain or loss above 2 kg (5 lb). (Weight gain may be a reason for nonadherence with drug therapy. Adolescents and older adults may be at risk for anorexia and weight loss.)	• Have the patient weigh self weekly and report significant weight gain or loss to the provider.
• Avoid abrupt discontinuation of therapy. (Profound depression, seizures, or withdrawal symptoms may occur with abrupt discontinuation.)	• Instruct the patient to take the drug exactly as prescribed and to not discontinue it abruptly.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug, appropriate dose, scheduling, and what adverse effects to observe for and when to report them. • Patients taking MAOIs should be given explicit instructions, written as well as verbal, on foods and beverages that must be avoided while taking the medication.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug as prescribed and do not substitute brands. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication:
	  • Exactly as ordered and the same manufacturer's brand each time the prescription is filled. (Switching brands may result in differing pharmacokinetics and alterations in therapeutic effect.)
	  • Take a missed dose as soon as it is noticed but do not take double or extra doses to "catch up."
	  • Take with food to decrease GI upset.
	  • If the medication causes drowsiness, take at bedtime. If the medication causes insomnia, take the last dose before 4 p.m.
	  • Do not abruptly discontinue the medication.
	  • Do not take other drugs, including OTC, herbal products, grapefruit juice, or dietary supplements, while taking the antidepressant.

Bipolar Disorder

19.12 Bipolar disorder is a serious psychiatric disorder characterized by extreme mood swings from depression to euphoria.

Bipolar disorder, once known as manic depression, is a relatively common and serious psychiatric disorder. Suicide risk is high and many patients stop taking their medication during the course of pharmacotherapy. The etiology of the disorder is unknown, and symptoms may persist throughout the patient's lifespan.

Mania is characterized by symptoms that are generally the opposite of depressive symptoms. The excessive CNS stimulation that is characteristic of mania can be recognized by the following symptoms:

- Inflated self-esteem or grandiosity; the belief that one's ideas are far superior to anyone else's
- Decreased need for sleep or food
- Distractibility; racing thoughts with attention too easily drawn to irrelevant external stimuli
- Increased psychomotor or goal-directed activity (either socially, at work or school, or sexually)
- Excessive pursuit of pleasurable activities without consideration of the negative consequences, such as shopping sprees, sexual indiscretions, or unsound business investments

- Increased talkativeness or pressure to keep talking
- With severe disease, delusions, paranoia, hallucinations, and bizarre behavior.

To be diagnosed with bipolar disorder, these symptoms must persist for at least 1 week and evidence of impaired functioning must be present. Suicide is a major risk in patients who have bipolar disorder; up to 50% of these patients attempt suicide, and 10% to 20% succeed in taking their lives. **Hypomania** is characterized by the same symptoms, but they are less severe and do not cause impaired functioning. In some cases, patients may experience a mixed episode where depression and mania are experienced simultaneously.

Although the pathophysiology of bipolar disorder is incompletely understood, mania and hypomania likely result from abnormal functioning of neurotransmitters in the brain. Mania may involve an excess of excitatory neurotransmitters (such as glutamate or norepinephrine) or a deficiency of inhibitory neurotransmitters (such as GABA). It is important to distinguish bipolar disorder from drug abuse, severe anxiety disorders, schizophrenia, dementia, or electrolyte disturbances, which can all produce symptoms similar to those of bipolar disorder.

Nonpharmacologic interventions play important roles in the treatment of patients with bipolar disorder. Lack of sleep, excessive stress, and poor nutrition are triggers for manic episodes and should be addressed in the plan of care. Support groups and psychotherapy are helpful for many patients. ECT is very effective at treating acute manic and depressive episodes.

Pharmacotherapy of bipolar disorder is highly individualized and dependent on the severity of the condition and whether depression or mania is the predominant symptom. For patients with mild symptoms that cause only slight functional disruption, monotherapy with low doses of a mood stabilizer is indicated. More severely affected patients usually require combination therapy with a mood stabilizer plus an atypical antipsychotic. If the patient is on antidepressant medications, these are usually tapered or discontinued because they can worsen mania or hypomania. Caution must be used in female patients of childbearing potential because some drugs used for bipolar disorder cause fetal malformations.

Like the treatment of major depression, nonadherence with drug therapy is a serious problem in patients with bipolar disorder. As many as 50% of patients discontinue their medication during the first year of therapy. Lack of awareness is the single most common reason for nonadherence; mania is simply not viewed as abnormal by the individual experiencing it. In fact, people with mania are often able to work tirelessly on projects and accomplish many work- and home-related tasks. Surprisingly, the second most common reason for nonadherence is the presence of a comorbid substance abuse disorder, usually alcoholism. Psychotherapy and family support may be necessary to achieve proper adherence.

Drugs for Bipolar Disorder

19.13 Lithium is the conventional therapy for the treatment of bipolar disorder.

Drugs for bipolar disorder are called **mood stabilizers**, because they have the ability to moderate extreme shifts in emotion and relieve symptoms of mania and depression during acute episodes. The selection of drug(s) depends on the predominant symptoms in the individual patient. Some of the drugs are better at managing mania, aggression, or agitation, whereas others are more effective at treating the depressive stage.

The traditional medication for bipolar disorder is lithium carbonate (Eskalith, Lithobid), a mood stabilizer prescribed as monotherapy or in combination with other drugs. In recent years, valproic acid/divalproex (Depakene) has begun to replace lithium as the first-line therapy for bipolar disorder due to its improved safety profile. Valproic acid and other miscellaneous drugs for bipolar disorder are discussed in Section 19.14. Drugs used to treat bipolar disorder are shown in Table 19.5.

PROTOTYPE DRUG **Lithium Carbonate (Eskalith, Lithobid)**

Classification **Therapeutic:** Antimanic, drug for bipolar disorder
Pharmacologic: Alkali metal ion salt

Therapeutic Effects and Uses: Lithium was approved for use in 1970. Its benefit in treating bipolar disorder has been established since the 1950s, but its therapeutic safety has not been proved. Lithium is a simple inorganic element that is found in the same group as sodium and potassium. It is available for PO administration as tablets, syrup, and controlled release and slow release tablets. Onset of action may take 1 to 3 weeks. Dosing is highly individualized and is based on serum drug levels and clinical response. Lithium has a short half-life and must be taken in multiple doses each day.

Lithium is an effective drug for controlling acute manic episodes and for preventing the recurrence of mania or depression. In the patient with mania, lithium decreases euphoria, hyperactivity, and other symptoms without causing sedation. Previously lithium was used for all patients with mania; at the present time it is used primarily for those patients with classic euphoric mania. Lithium, rather than valproic acid, appears to be more effective in reducing suicide risk in people diagnosed with bipolar

Table 19.5 Drugs for Bipolar Disorder

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
lithium carbonate (Eskalith, Lithobid)	PO: Initially 600 mg tid or 900 mg sustained release bid or 30 mL (48 mEq) of solution tid Maintenance: 300 mg tid or qid or 15–20 mL (24–32 mEq) in two to four divided doses (max: 2.4 g/day)	*Headache, lethargy, fatigue, recent memory loss, nausea, vomiting, anorexia, abdominal pain, diarrhea, dry mouth, muscle weakness, nephrogenic diabetes insipidus, fine hand tremors, reversible leukocytosis* Peripheral circulatory collapse, neurotoxicity, seizures, coma
Antiseizure Drugs		
carbamazepine (Tegretol)	PO: 200 mg bid, gradually increased to 800–1200 mg/day in three to four divided doses	*Dizziness, ataxia, somnolence, headache, nausea, diplopia, blurred vision, sedation, drowsiness, vomiting, prolonged bleeding time, transient leukopenia* Heart block, aplastic anemia, agranulocytosis, respiratory depression, exfoliative dermatitis, SJS, toxic epidermal necrolysis, deep coma, death (with overdose), liver failure, pancreatitis, bone marrow depression
lamotrigine (Lamictal)	PO: 50 mg/day for 2 wk, then 50 mg bid for 2 wk; may increase gradually up to 300–500 mg/day in two divided doses (max: 700 mg/day)	
valproic acid/divalproex (Depakene)	PO: 250–750 mg/day in divided doses (max: 60 mg/kg/day)	
Atypical Antipsychotic Drugs		
aripiprazole (Abilify)	PO: 30 mg daily; may decrease to 15 mg (max: 30 mg daily)	*Tachycardia, sedation, dizziness, headache, lightheadedness, somnolence, anxiety, nervousness, agitation, hostility, insomnia, nausea, vomiting, transient fever, constipation, akathisia, parkinsonism, gynecomastia (risperidone)* Agranulocytosis, neuroleptic malignant syndrome (risperidone, rare), risk of stroke in older adults with dementia-related psychosis (aripiprazole)
asenapine (Saphris)	SL: 5–10 mg bid (max: 20 mg/day)	
olanzapine (Zyprexa)	PO: Start with 10 mg once daily; may increase or decrease in 5 mg/day increments	
quetiapine (Seroquel)	PO: Start with 25 mg bid and increase by 25–50 mg bid to tid to target dose of 300–400 mg/day divided bid or tid (max: 800 mg/day)	
risperidone (Risperdal)	PO: Start with 2–3 mg daily, may increase dose at intervals of 1 mg/day (max: 6 mg/day)	
ziprasidone (Geodon)	PO: 40 mg bid with food, may increase every 2 days up to 80 mg bid	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

disorder. Lithium may also be used for off-label indications, including alcoholism, bulimia, neutropenia, schizophrenia, prevention of vascular headaches, and hyperthyroidism.

Mechanism of Action: The precise mechanism of action of lithium is not known. It likely acts by changing neurotransmitter balance in specific brain regions. Lithium increases the synthesis of serotonin.

Pharmacokinetics:

Route(s)	PO
Absorption	Completely absorbed
Distribution	Distributed to all tissues and body fluids; crosses the blood–brain barrier and placenta; secreted in breast milk; not bound to plasma protein
Primary metabolism	Not metabolized
Primary excretion	Renal
Onset of action	Peak levels: 4–12 h (tablets) or 15–60 min (solutions)
Duration of action	Unknown

Adverse Effects: Many possible adverse effects are associated with the use of lithium. These are sometimes divided into those that occur at the initiation of therapy and those that occur with long-term therapy. Initial adverse effects are muscle weakness, lethargy, nausea, vomiting, polyuria, nocturia, headache, dizziness, drowsiness, tremors, and confusion. Many of the initial adverse effects are transient or may be easily managed. Long-term therapy can produce serious toxicity, including kidney impairment (proteinuria, albuminuria, or glycosuria), dysrhythmias, circulatory collapse, and leukocytosis. Lithium interferes with the synthesis of thyroid hormone and can cause hypothyroidism and goiter. **Black Box Warning:** Toxicity from lithium is closely related to serum concentrations and may occur at doses close to therapeutic levels. Facilities should be available to provide prompt and accurate serum concentration data. Serum lithium levels are monitored regularly during therapy and should be maintained within the narrow range of 0.8 to 1.4 mEq/L at the start of therapy and 0.4 to 1 mEq/L during maintenance therapy.

Contraindications/Precautions: Contraindications to the use of lithium include serious cardiovascular impairment, chronic kidney disease, and severe dehydration

or sodium depletion. Older adults and debilitated patients must be carefully monitored. Caution must be used when the drug is given to patients with cardiovascular disease, thyroid disease, history of a seizure disorder, diabetes, urinary retention, or a systemic infection. Lithium produces an increased incidence of congenital defects, especially those involving the heart, and is normally not used during pregnancy. Its use should be discouraged during lactation.

Drug Interactions: There are many potential drug interactions, some of which can be serious. Diuretics can increase the risk of lithium toxicity by promoting sodium loss; the body replaces lost sodium with lithium, which is also a salt. NSAIDs and thiazide diuretics can increase lithium levels by increasing the renal reabsorption of lithium. Lithium may cause an increased hypothyroid effect of antithyroid drugs or drugs containing iodine. Concurrent administration with haloperidol may cause increased neurotoxicity. SES may result if lithium is administered with other drugs, such as SSRIs or dextromethorphan, or MAOIs that potentiate the actions of serotonin. **Herbal/Food:** An increased lithium effect may occur with the use of dandelion, goldenrod, juniper, parsley, nettle, or horsetail. Black or green tea, cola nut, or plantain may lead to a decreased lithium effect. Significant changes in sodium intake from foods will alter lithium excretion.

Pregnancy: Category D.

Treatment of Overdose: Overdose of lithium is treated with supportive measures such as emesis or lavage, maintaining airway and respiratory function, and dialysis, if lithium intoxication is severe.

Nursing Responsibilities:

- Obtain a complete health history and history of depression and mania symptoms. Obtain a medication history, particularly other medications used for depression or bipolar disorder.
- Assess baseline vital signs, weight, and laboratory studies, especially serum sodium, CBC, hepatic, and renal values. Monitor drug levels, weight, CBC, electrolytes, and urinalysis for protein, albumin, and glucose periodically during therapy.
- Report thirst, dizziness, lethargy or confusion, muscle weakness, or polyuria to the provider immediately after the early period of therapy as possible toxic effects.

Lifespan and Diversity Considerations:

- Carefully assess the older adult for signs of sodium imbalance or dehydration and for therapeutic and adverse effects. Monitor the older adult frequently because lithium toxicity may occur at lower therapeutic levels than in a younger patient.
- Monitor ethnically diverse patients closely for signs of lithium toxicity. Evaluate normal diet routines for high-sodium content foods or beverages that may affect the therapeutic range of the drug.

Patient and Family Education:

- The full therapeutic effects of lithium may take 2 to 3 weeks or more to appear. Monitor the patient more closely during the early stages of therapy.
- Return regularly for laboratory work. Weigh self weekly and report a gain or loss of 1 kg (2 lb) in a day or 2 kg (5 lb) in a week.
- Maintain a normal-sodium diet and fluid intake without unusual or dramatic increases or decreases, which can affect drug level. Be cautious with exercising or on hot days because excessive sweating will lead to water and sodium loss. Avoid caffeine and alcohol.
- Report excessive thirst, urination, dizziness, muscle weakness, tachycardia, palpitations, or confusion promptly to the healthcare provider.
- Do not abruptly discontinue the drug. If discontinuation of the drug is desired, it should be discussed with the healthcare provider and alternative therapy considered.

Drugs Similar to Lithium Carbonate (Eskalith, Lithobid)

There are no drugs similar to lithium carbonate.

19.14 Antiseizure and atypical antipsychotic drugs are used to control symptoms of bipolar disorder.

Although lithium is well established as an effective treatment for bipolar disorder, pharmacologists have found several safe alternatives. Some of these have received FDA approval and others are prescribed off-label for bipolar disorder. All of these medications have additional primary indications and are presented in other chapters of this textbook. The other classes include antiseizure drugs, atypical antipsychotics, and antidepressants.

Antiseizure drugs: The antiseizure drugs for bipolar disorder are classified as mood stabilizers. These medications have pharmacologic actions similar to lithium: relieving symptoms and preventing the recurrence of mania and depression.

Valproic acid (Depakene) and divalproex sodium (Depakote ER) are FDA approved for mood stabilization and mania suppression. Valproic acid has replaced lithium as a preferred drug for many patients because it has far fewer adverse effects, a higher therapeutic index, and a more rapid onset of action. The only area in which it does not compare as favorably with lithium is in the ability to

prevent suicide. Valproic acid is well tolerated in most patients but can occasionally cause serious toxicity. Rare cases of thrombocytopenia, pancreatitis, and liver failure have occurred and signs of any of these adverse events require immediate withdrawal of the drug. As with lithium, valproic acid is teratogenic and should not be used during pregnancy. It is secreted in breast milk and therefore should not be used during lactation. A prototype feature for this drug is included in Chapter 22.

Carbamazepine (Tegretol) was one of the initial drugs studied as a lithium alternative, but it was not until 2005 that it was approved for that indication. It reduces the symptoms of both manic and depressive phases of bipolar disorder and can reduce recurrence of the condition. It is preferred over lithium for patients who have mixed mania or rapid-cycling bipolar disorder. Neurologic adverse effects such as vertigo, headache, unsteadiness, and ataxia are common during early therapy but usually subside with continued use. Oral contraceptives may be less effective, and pregnant women should not take carbamazepine because this drug is pregnancy category D. Increased CNS toxicity can result if carbamazepine is used concurrently with lithium. Carbamazepine is one of the most frequently prescribed antiseizure drugs, and a prototype feature is included in Chapter 22.

The antiseizure drug lamotrigine (Lamictal) is indicated for long-term maintenance therapy to prevent or delay relapses. It may be used alone or in combination with other mood stabilizers. The drug is well tolerated by most patients, with the most common adverse events being drowsiness, dizziness, ataxia, headache, diplopia, blurred vision, nausea, vomiting, and rash. Because rare cases of Stevens–Johnson syndrome (SJS) have been documented, any appearance of rash calls for discontinuation of the drug. To minimize the risk of serious skin rashes, the dose of lamotrigine is increased gradually. Lamotrigine is a pregnancy category C drug and should be used cautiously in lactating women.

Other antiseizure drugs have been used off-label for bipolar disorder but they do not appear to be more effective than existing medications. These include oxcarbazepine (Trileptal), gabapentin (Neurontin), and topiramate (Topamax). Clonazepam (Klonopin) and lorazepam (Ativan) are benzodiazepines used for seizures that have been used off-label for bipolar disorder in combination with other drugs.

Atypical antipsychotics: The primary use of antipsychotic drugs is to manage symptoms of severe psychosis, such as those found in patients with schizophrenia (see Chapter 20). Some of the antipsychotic medications are also effective in controlling acute symptoms of mania and as long-term mood stabilizers in bipolar disorder. These drugs are usually used in combination with lithium or valproic acid, but they are also effective as monotherapy. The atypical antipsychotics are preferred over the conventional antipsychotics such as chlorpromazine because of a much lower incidence of extrapyramidal adverse effects. Atypical antipsychotics approved for use in treating bipolar disorder include aripiprazole (Abilify), asenapine (Saphris), olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), and ziprasidone (Geodon). All of these drugs are effective in treating manic episodes, but only olanzapine is approved for long-term maintenance therapy. For specific information on typical and atypical antipsychotics, refer to Chapter 20.

Antidepressants: Antidepressants may be used to treat the depression stage of bipolar disorder. These medications must be used with caution because they have a tendency to cause hypomania or mania in depressed patients with bipolar disorder. Furthermore, studies suggest they may cause more rapid cycling between the manic and depressive stages of the disorder. Because of these potentially serious adverse effects, antidepressants are administered concurrently with a mood stabilizer. Frequently used antidepressants for treating bipolar disorder are the SSRIs, venlafaxine (Effexor), and bupropion (Wellbutrin). The antidepressant medications are discussed earlier in this chapter.

Understanding Chapter 19

Key Concepts Summary

19.1 The two primary categories of mood disorders are depression and bipolar disorder.

19.2 Major depressive disorder is characterized by a depressed mood, with accompanying symptoms, that lasts at least 2 weeks.

19.3 The pathophysiology of depression has biological, genetic, and environmental components.

19.4 Assessment and diagnosis of depression are a collaborative effort among healthcare providers.

19.5 The majority of patients who attempt suicide have major depression.

19.6 Depression is sometimes treated with nonpharmacologic therapies.

19.7 The mechanism of action of antidepressants involves modulation of neurotransmitter levels in the brain.

19.8 Selective serotonin reuptake inhibitors are the preferred drugs for treating depression due to their low incidence of serious adverse effects.

19.9 Atypical antidepressants are alternatives to the selective serotonin reuptake inhibitors for depression and anxiety disorders.

19.10 Tricyclic antidepressants were once the mainstay for the treatment of depression but they have many adverse effects.

19.11 Monoamine oxidase inhibitors are effective antidepressants but are seldom used due to potentially serious adverse effects.

19.12 Bipolar disorder is a serious psychiatric disorder characterized by extreme mood swings from depression to euphoria.

19.13 Lithium is the conventional therapy for the treatment of bipolar disorder.

19.14 Antiseizure and atypical antipsychotic drugs are used to control symptoms of bipolar disorder.

CASE STUDY: Making the Patient Connection

Remember the patient "Adelphia Williams" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Adelphia is a 34-year-old mother of three young children. Before the children were born, she was employed as a corporate attorney, but she and her husband decided prior to the birth of their first child that she would stay at home until the children completed high school. They are financially stable. Adelphia has been a soccer coach, Boy Scout leader, president of the ladies' group at her church, and involved in various other community organizations. Within the past month, she has not participated in any of her previous activities and she has not explained why. Adelphia is in good physical health and had her annual physical examination the previous month. Other than a recent weight gain of 14 kg (31 lb), there has been no change since her last health visit. She takes no routine medications or herbal supplements.

Critical Thinking Questions

1. What first step must Charlie take to aid his wife with her depression?
2. When Adelphia is evaluated by a mental health professional, they begin talking about how antidepressant drug therapy works. Provide a brief explanation of antidepressant therapy.
3. How can a nurse determine if a therapeutic effect from the antidepressant medication is being achieved with Adelphia?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Andrew Phillips, age 17, was diagnosed with bipolar illness with acute mania at age 15. He was stabilized with lithium for the manic periods and is also taking valproic acid. This fall, he played football and is looking forward to playing baseball this spring and summer. Although they have a close relationship, his parents have concerns about his dietary habits and post-game festivities, especially now that he is driving and they are not available to monitor the situation.

1. Considering Andrew's activities and eating habits, what risks are possible and what assessments would the nurse make to ensure Andrew's lithium dosage remains effective and within a therapeutic range?
2. What suggestions could the nurse make that would help Andrew participate fully in his sports interests and post-game festivities?
3. What strategies might the nurse suggest for helping Andrew's parents participate in his activities and care?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A healthcare provider has ordered imipramine (Tofranil) for four patients. A nurse would question the order for the patient with:
   1. Seizure disorders.
   2. Depression.
   3. Enuresis.
   4. Neuropathic pain.

2. The nurse determines that the patient understands an important principle in self-administration of fluoxetine (Prozac) when the patient makes which statement?
   1. "I should not decrease my sodium or water intake."
   2. "This drug can be taken concurrently with a monoamine oxidase inhibitor."
   3. "It may take up to 1 month to reach full therapeutic effects."
   4. "There are no problems associated with concurrent use of other central nervous system depressants."

3. The nurse is monitoring the patient for early lithium carbonate (Eskalith) toxicity. Which symptoms, if manifested by the patient, would indicate that toxicity may be developing? (Select all that apply.)
   1. Persistent gastrointestinal upset
   2. Confusion
   3. Polyuria
   4. Convulsions
   5. Ataxia

4. Which statement made by the patient who is taking lithium carbonate (Eskalith) indicates that further teaching is necessary?
   1. "I will be sure to remain on a low-sodium diet."
   2. "I will have blood levels drawn every 2 to 3 months, even when I have no symptoms."
   3. "Lithium has a narrow margin of safety, so toxicity is a very real concern."
   4. "I will not be able to breastfeed my baby."

5. The patient who has been taking venlafaxine (Effexor) for 2 weeks calls the nurse to report that there is no improvement in the depression. The nurse's best response is:
   1. "Call your healthcare provider and see if he or she will change the order to a different medication."
   2. "Are you sure that you are taking it as ordered? Perhaps you should consider increasing the dosage gradually."
   3. "The medication may take up to 3 weeks or longer to be effective. Continue taking the medication as ordered."
   4. "Add an over-the-counter antianxiety agent to your daily medications."

6. A 17-year-old patient is started on fluoxetine (Prozac) for treatment of depression. When teaching the patient and his family, what would the nurse include? (Select all that apply.)
   1. Report any sedation to the provider and exercise caution with activities requiring mental alertness.
   2. Fluctuations in weight may be managed with a healthy diet and adequate amounts of exercise.
   3. Report any thoughts of suicide to the provider immediately, especially during early initiation of the drug.
   4. The drug may be safely stopped if unpleasant side effects occur and reported to the provider at the next scheduled visit.
   5. The drug may cause excessive thirst but dramatic increase in fluid intake should be avoided.

Chapter 20
Pharmacotherapy of Psychoses

Chapter Outline

- Characteristics of Psychoses
- Symptoms of Schizophrenia
- Etiology of Schizophrenia
- Management of Psychoses
- Antipsychotic Drugs

  First-Generation Antipsychotics

  PROTOTYPE *Chlorpromazine, p. 290*

  PROTOTYPE *Haloperidol (Haldol), p. 291*

  Second-Generation (Atypical) Antipsychotics

  PROTOTYPE *Risperidone (Risperdal), p. 293*

  Dopamine System Stabilizers (DSSs)

  PROTOTYPE *Aripiprazole (Abilify), p. 297*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Describe the general symptoms of psychosis.
2. Compare and contrast the positive and negative symptoms of schizophrenia.
3. Explain theories for the etiology of schizophrenia.
4. Describe the initial treatment and maintenance pharmacotherapy of schizophrenia.
5. Explain the importance of patient drug adherence in the pharmacotherapy of psychoses.
6. Explain how antipsychotic drugs are classified.
7. Discuss the rationale for selecting a specific antipsychotic drug for the treatment of schizophrenia.
8. Identify the extrapyramidal adverse effects of antipsychotic drugs.
9. Describe the nurse's role in the pharmacologic management of schizophrenia.
10. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
11. Apply the nursing process to care for patients receiving pharmacotherapy for psychosis.

Severe mental illness can be incapacitating for the patient and intensely frustrating for caregivers and healthcare providers. Prior to the 1950s, patients with severe mental illness were institutionalized as soon as symptoms appeared, and often remained that way for their entire lives, with little or no hope of ever improving to the point of being able to function in society. The introduction of chlorpromazine (Thorazine) in the 1950s, and the subsequent development of newer drugs, revolutionized the treatment of mental illness. Many people with schizophrenia and other mental illnesses can now lead productive lives as functioning members of society, as long as their healthcare provider is able to successfully manage their condition. This chapter examines the nature and pharmacotherapy of psychotic illness.

Characteristics of Psychoses

20.1 Psychoses are severe mental disorders characterized by the inability to recognize reality.

Psychosis is a general term used in medicine to describe a loss of contact with reality. A psychosis is a symptom of a mental illness and is not considered a disease in itself. Characteristics of psychosis are relatively easy to recognize and include the following:

- **Delusions. Delusions** are firm ideas and beliefs that are false and not founded in reality. Delusions sometimes are religious in nature, with the individual believing he is a higher power or a messenger of a higher power. Delusions may be grandiose, with the individual believing he is a king or great leader. Some patients with psychosis exhibit paranoid delusions, an extreme suspicion that they are being followed and that others are trying to harm them.
- **Hallucinations. Hallucinations** involve seeing, hearing, or feeling something that is not really there. Hallucinations most often are auditory; patients may hear voices telling them to harm themselves or others, that they are worthless or ugly, or that their behavior is unacceptable. Some patients may have visual hallucinations, seeing people or objects that are not present.
- **Lack of insight and judgment.** Patients are often unaware of their bizarre behavior and truly believe that the voices they hear and the delusions they experience are real.
- **Mood and affect.** During psychotic episodes, the patient's mood and affect may vary widely and be socially inappropriate. The patient may laugh at sad events or show no emotion at all. The patient may rapidly shift between happy and sad moods for no apparent reason.

Psychotic behavior ranges from total inactivity to extreme agitation and combativeness. Because patients are unable to distinguish what is real from what is illusion, they are often labeled as insane.

Psychoses are classified as acute or chronic. Acute psychotic episodes occur over hours or days, whereas chronic psychoses develop over months or years. Sometimes a specific cause may be attributed to the psychosis, such as brain tumors, overdoses of certain medications, extreme depression, electrolyte disorders, chronic alcoholism, or psychoactive drugs. Treating the underlying disorder may cause the psychosis to disappear.

Unfortunately, the vast majority of psychoses have no identifiable cause. These include psychoses associated with schizophrenia, bipolar disorder, and severe clinical depression.

PharmFACT

Approximately 3.5 million Americans have schizophrenia, and about 50% of those diagnosed have received no treatment (Schizophrenia and Related Disorders Alliance of America, n.d.).

To function in society, people with chronic psychoses require long-term pharmacotherapy. Patients must see their healthcare provider at regular intervals, and medication must be taken for life. Family members and social support groups are important sources of help for patients who cannot function normally in society without continuous drug therapy. One major difficulty is that family relationships may be fractured secondary to the symptoms of psychosis,

Table 20.1 Common Symptoms of Schizophrenia

Mental Symptoms	Behavioral Symptoms	Interpersonal Symptoms
Delusions	Irrational distrust of others	Difficulty maintaining relationships because they believe friends or partners are unfaithful or persecuting them
Hallucinations	Strange behavior, such as communicating in rambling statements or made-up words	Marked withdrawal from social interactions and interpersonal relationships
Illusions	Strange or irrational actions; deterioration of personal hygiene and job or academic performance	Stopping attendance at work or school
Indifference or detachment toward life activities	Not appearing to care if someone else (or self) is in danger; not moving to help in a crisis situation; not moving self out of harm's way	Showing a complete lack of concern for self or another's well-being or even safety
Paranoia	Constant hypervigilance, worry, and vocalizations that everyone is "out to get me"	Obvious lack of trust in anyone, even those people with whom the patient has a positive relationship when disease is under control

the length of time symptoms have been evident, and the tendency for the patients to become nonadherent to drug therapy. If these patients stop taking the antipsychotic medications, then symptoms of psychosis will most assuredly promptly reappear.

Symptoms of Schizophrenia

20.2 Schizophrenia, the most common psychosis, has both positive and negative symptoms.

Schizophrenia is the most common psychotic disorder. Symptoms generally begin to appear in early adulthood, with a peak incidence in men 15 to 24 years of age and women 25 to 34 years of age. It is present in all cultures and ethnic groups.

Patients with schizophrenia experience a variety of diverse symptoms that may change over time. The disorder is characterized by abnormal thoughts and thought processes, disordered communication, withdrawal from people and the outside environment, an inability to independently perform activities of daily living (ADLs), and a high risk for suicide. Patients have a marked impairment in their ability to work or attend school. Many people with schizophrenia demonstrate all of these symptoms at some time during their illness, whereas others exhibit only one or two. Several subtypes of schizophrenia have been identified based on clinical presentation. Table 20.1 gives examples of symptoms frequently observed in patients with schizophrenia.

Symptoms of schizophrenia are classified as either positive or negative. **Positive symptoms** are those associated with a distortion in *excess* of normal function. These include hallucinations, delusions, disorganized thought or speech pattern, and movement disorders. **Negative symptoms** are those associated with a *loss* of normal functioning. These symptoms include a lack of interest in social activities, reduced or repetitious speech, loss of desire to perform personal hygiene measures, lack of emotion, unresponsiveness, or lack of pleasure in daily activities. Negative symptoms are characteristic of the indifferent personality exhibited by many patients with schizophrenia. Negative symptoms are harder to associate with schizophrenia and may be mistaken for depression or even laziness. Table 20.2 lists the different categories of schizophrenia symptoms.

Proper diagnosis of positive and negative symptoms is important for selection of the appropriate antipsychotic drug. Positive symptoms are easily recognized and more likely to motivate the patient or caregiver to seek treatment. Indeed, the positive symptoms respond more favorably to pharmacotherapy with antipsychotic drugs. The negative symptoms, however, often prevent a patient with schizophrenia from living independently, holding down a

Table 20.2 Categories of Symptoms of Schizophrenia

Positive Symptoms	Negative Symptoms	Cognitive Symptoms
Agitation, anxiety	Poor judgment	Difficulty following the thread of a conversation
Aggressiveness, combativeness	Little or no functional speech	Inability to focus attention
Delusions	Withdrawal from other people and the social environment	Difficulty in identifying the steps needed to complete a task and placing them in the proper sequence
Disorganized thoughts and speech	Lack of awareness or insight	Deficits in long-term memory
Hallucinations	Apathy	Diminished "working memory": an inability to remember recently learned information and use it right away
Illusions	Lack of ability to perform ADLs	Difficulty following instructions
Paranoia	Diminished or missing affect	

job, and enjoying life. When selecting outcomes for pharmacotherapy, the healthcare provider must address both positive and negative symptoms.

A third and more recently recognized category of symptoms exhibited during schizophrenia is called cognitive symptoms. These include thinking difficulties, decreased attentiveness or ability to concentrate, and significant learning and memory problems. A retrospective look at the patient diagnosed with schizophrenia will usually reveal that these cognitive symptoms were present for some time but were not recognized as part of schizophrenia until the more obvious positive and negative symptoms appeared.

Schizoaffective disorder is a condition in which the patient exhibits symptoms of both schizophrenia and mood disorder. An acute schizoaffective reaction may include distorted perceptions, hallucinations, and delusions, followed by extreme depression. Over time both positive and negative psychotic symptoms usually appear.

Many conditions can cause bizarre behavior, and these should be distinguished from schizophrenia. Chronic use of amphetamines or cocaine can create a paranoid syndrome. Certain complex partial seizures can cause unusual symptoms that are sometimes mistaken for psychosis. Brain neoplasms, infections, or hemorrhage can also cause bizarre, psychotic-like symptoms.

Etiology of Schizophrenia

20.3 The precise etiology of schizophrenia remains unknown.

The etiology and pathogenesis of schizophrenia are complex and likely involve multiple factors. Schizophrenia is best understood as a cluster of distinct disorders, each having a different etiology, rather than as a single disease.

Early theories of the etiology of schizophrenia focused on specific disturbances in child rearing, such as poor communication between parents and offspring with schizophrenia. This view has been rejected in favor of biological theories. It should be understood, however, that environmental factors such as family dynamics can affect coping skills, which may influence the onset of psychosis, drug response, and adherence to treatment.

There is a definite genetic component to schizophrenia. People have a 5 to 10 times greater risk of getting schizophrenia if they have a first-degree relative with the disorder. In identical twins, if one twin has schizophrenia, the other has nearly a 50% risk of having the disorder. If both parents have schizophrenia, there is a 40% risk that their offspring will have the disorder.

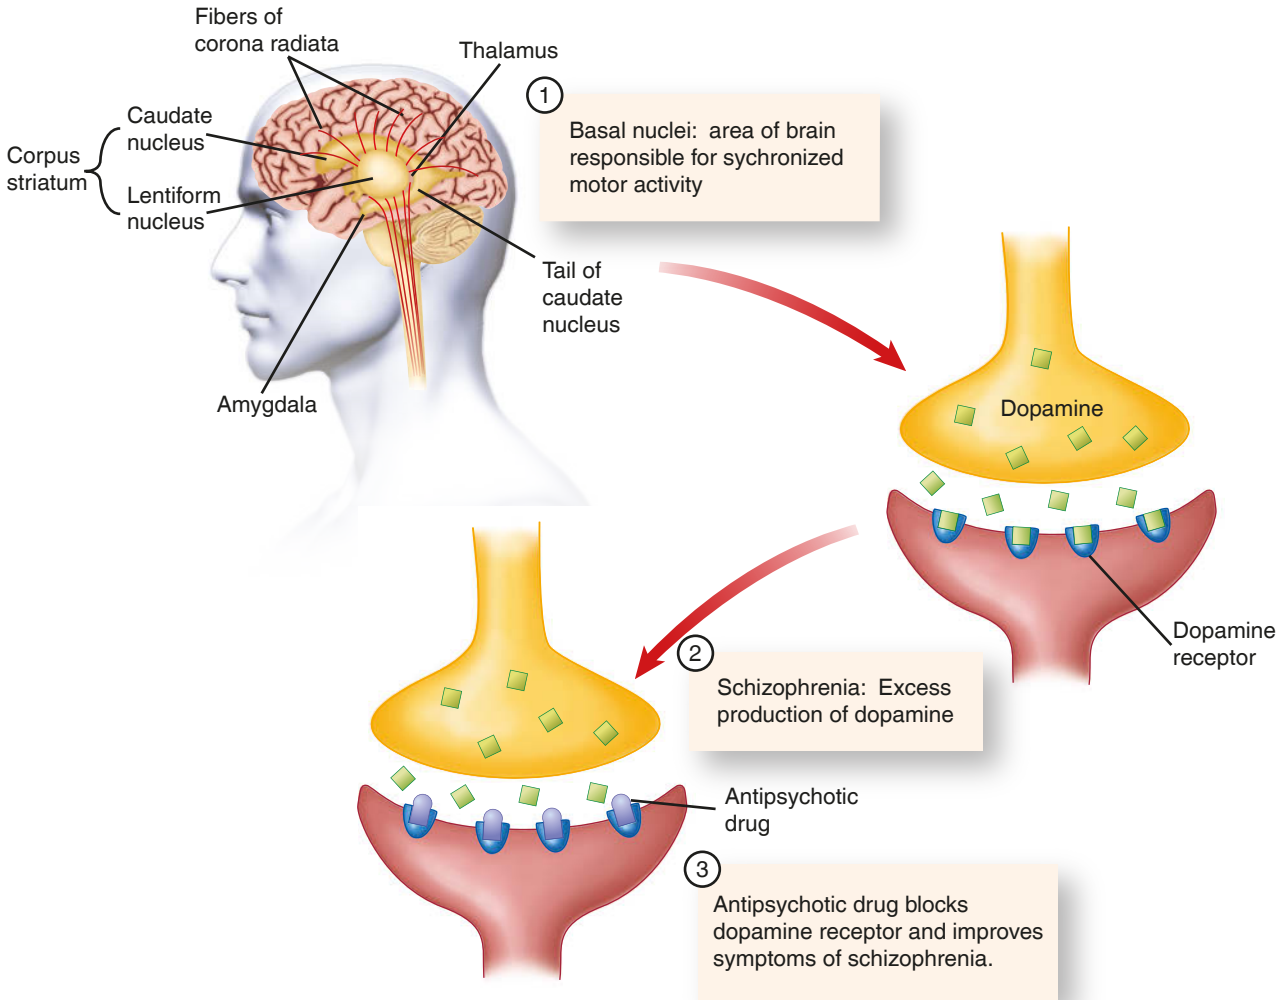
Whether caused by genetics or the environment, schizophrenia is likely the result of neurotransmitter imbalances in specific areas of the brain. This theory suggests the possibility of overactive dopaminergic pathways in the basal nuclei (basal ganglia), an area of the brain responsible for starting and stopping synchronized motor activity such as leg and arm motions during walking. Symptoms of schizophrenia seem to be associated with **dopamine type 2 (D_2) receptors**. The basal nuclei are particularly rich in D_2 receptors, whereas the cerebrum contains very few. Most antipsychotic drugs act by entering dopaminergic synapses and competing with dopamine for receptors. By blocking D_2 receptors, antipsychotic drugs reduce the symptoms of schizophrenia. Pharmacotherapy Illustrated 20.1 shows antipsychotic drug action at the dopaminergic receptor.

PharmFACT

Childhood schizophrenia (younger than age 13) is rare but carries a worse prognosis than adult-onset schizophrenia. The majority of these children present with mental health disorders such as anxiety, depression, bipolar disorder, or attention-deficit/hyperactivity disorder 2 years prior to the onset of psychotic symptoms (Loth, 2014).

Management of Psychoses

20.4 Medical management of psychosis is challenging because patients often lack insight into their disease and believe their behavior is normal.



The medical management of severe mental illness is extremely challenging. Many people do not view their behavior as abnormal and have difficulty understanding the need for drug therapy. When a medication produces undesirable adverse effects, such as severe muscle twitching or sexual dysfunction, patients stop taking it and relapse to experience their former symptoms. Agitation, distrust, and extreme frustration are common because patients cannot comprehend why others are unable to think as they do or see the same things that they see.

The primary goal in treating psychosis is to manage symptoms such that the patient can function independently and accomplish ADLs with minimum assistance. This includes obtaining and holding employment and maintaining satisfactory interpersonal relationships. This level of success in treatment requires setting many small, realistic benchmarks that the patient, caregiver, and healthcare provider can achieve. These subgoals nearly always involve pharmacotherapy as well as establishing effective psychologic and social support.

Initial treatment: The first psychotic episode may occur suddenly or it may be preceded by a long period of subacute symptoms such as depression or withdrawal from normal activities. If the patient is exhibiting agitation or aggressiveness or presenting a physical danger to others, the first doses of the antipsychotic drug may be higher than normal. High doses produce sedation, which is

Pharmacotherapy Illustrated 20.1

Mechanism of Action of Antipsychotic Drugs

normally viewed as an adverse effect but which is therapeutic in combative patients. Although most antipsychotics are given orally (PO), a few are available by the intramuscular (IM) route if the patient is uncooperative or if it is suspected that the patient is "cheeking" the medicine—hiding it in the mouth until the nurse leaves the room. Benzodiazepines such as lorazepam (Ativan) may be administered IM during the initial treatment period to relax or provide sedation for agitated patients. Lorazepam produces fewer serious adverse effects than antipsychotics and allows the dose of the antipsychotic drug to be reduced. Acute symptoms of psychosis usually resolve in 3 to 7 days, at which time the patient is switched to maintenance therapy.

Maintenance treatment: The pharmacotherapy of chronic psychosis is a long-term process, with symptoms resolving gradually. Some symptoms resolve faster than others, depending on the patient and specific drug used. A patient or caregiver may notice improvement in acute symptoms after less than a week of therapy. After 2 to 4 weeks, mood, socialization, and the ability to provide self-care usually improve. By 6 to 8 weeks, definite improvement should be noted in most symptoms. Patients who have experienced untreated schizophrenia for many years are slower to respond than those experiencing their first episode. As long as symptoms continue to gradually improve, the patient is maintained on a stable dosage.

If substantial improvement is not observed after 8 to 12 weeks of therapy, the healthcare provider must explore reasons for the lack of response. For example, the patient may not be taking the medication, or the original diagnosis may have been incorrect. If the patient has been taking the medication at average doses or higher, the healthcare

provider will generally not increase the dose because doing so increases the potential for serious adverse effects. Instead of increasing the dosage, a different antipsychotic drug may be substituted. The nurse, patient, and caregivers must understand that drug therapy is not a cure; in some cases, medications simply are not able to eliminate all psychotic symptoms.

How long does drug maintenance therapy continue? The answer to this is highly individualized, but the most common answer is for the lifetime of the patient. In patients experiencing their first acute episode, healthcare providers may slowly taper the dose after a year of successful therapy. Abrupt cessation of some antipsychotics can cause serious withdrawal symptoms, including nightmares, nausea, vomiting, salivation, sweating, and nervousness. When discontinuation is attempted, the patient should be monitored carefully and the drug restarted at the first sign of relapse. Approximately 15% to 25% of patients with psychoses can successfully stop drug therapy without returning to their former symptoms. Discontinuation is not usually attempted in patients with long-standing chronic psychosis.

Nonadherence: Patients with serious mental illness have a very high nonadherence rate. Unless they are deemed overtly dangerous to themselves or other people, patients cannot be held for long periods of hospitalization against their wishes. Once the patient returns to the community, he or she may discontinue taking the drug and not return for follow-up appointments.

Reasons for nonadherence are many. Lack of insight into their illness causes patients with psychosis to view their behavior as normal. Patients with paranoia may feel that drug therapy is a plot by others to poison them and keep them from thinking clearly. Adverse effects are common and sometimes serious. Even motivated patients who understand the need for continuous drug therapy may have difficulty tolerating the adverse effects. The nurse member of the treatment team must be diligent in teaching caregivers about means of maximizing adherence to the pharmacotherapeutic regimen and how to recognize signs of nonadherence.

Another factor causing nonadherence with medications for schizophrenia is the desire to drink alcohol. Excessive alcohol use is considered a comorbid condition with schizophrenia. Some patients use alcohol in an attempt to elevate their mood or to decrease symptoms of schizophrenia. However, alcohol can interact with some antipsychotic medications and cause a suboptimal response. Because studies have confirmed that alcohol worsens psychotic symptoms, patients should be instructed to avoid alcohol use.

Nonpharmacologic therapies: Psychotherapy is an essential component of the total care of the patient with psychosis. In addition to individual supportive therapy, occupational therapy is initiated to give patients the requisite technical, social, and behavioral skills to enable them to return to the workforce. Some patients need skills in performing ADLs such as cooking, cleaning, and dressing. Family and caregiver training are included in the plan of care for the treatment of patients with schizophrenia whenever feasible.

Prognosis: Although there is no cure, schizophrenia can be successfully managed in a significant number of patients. Strong family and caregiver support, combined with pharmacotherapy, can decrease hospitalization and relapse rates and increase the potential for recovery. According to the World Fellowship for Schizophrenia and Allied Disorders (n.d.) the prognosis for schizophrenia after 10 years of the disease is as follows:

- 25% completely recovered
- 25% much improved, relatively independent
- 25% improved, but require extensive support network
- 15% hospitalized, unimproved
- 10% deceased (mostly suicide).

Antipsychotic Drugs

20.5 Selection of an antipsychotic drug depends on its spectrum of adverse effects and the experience of the healthcare provider.

The pharmacotherapy of psychosis has undergone two major "generations." The first generation appeared in the early 1950s when the original drugs for treating severe mental illnesses were discovered. These drugs include conventional antipsychotics such as chlorpromazine. This essentially ended the era of placing all patients in insane asylums for their lifetimes. Unfortunately, first-generation drugs came with adverse effects that were sometimes as serious as the symptoms of the patient's original disorder.

The second-generation or *atypical* antipsychotic drugs were discovered in the 1970s and 1980s. "Atypical" refers to several characteristics of these drugs compared to the conventional drugs:

- Significantly fewer adverse effects related to the extrapyramidal system
- Better patient adherence due to reduced adverse effects and less cognitive impairment
- More effective at resolving negative psychotic symptoms.

Two older terms are occasionally used to describe antipsychotic drugs. *Major tranquilizer* was the term used following the introduction of the first-generation drugs because sedation is a prominent action of them. *Neuroleptic* is a term used to denote drugs that have effects on the nervous system, especially those that have Parkinson's-like

adverse effects on posture and body movement. Although the student will still encounter reference sources that refer to these drugs as tranquilizers or neuroleptics, *antipsychotic* is more accurate and is the preferred term.

Classification of antipsychotics: There are two means of classifying antipsychotic medications. The older system uses the conventional versus atypical distinction. The conventional group is further subdivided by chemical classes into phenothiazines and nonphenothiazines. This older classification scheme has flaws because there is not always a clear distinction between a drug that is "conventional" and one that is "atypical." Furthermore, some antipsychotics have an adverse effect profile that appears as if it is atypical at low doses but becomes conventional at high doses.

In recent years, a new system for classification has emerged. This system divides these medications by potency levels: low potency (drugs that require higher doses), moderate potency (drugs that require middle range dosing), and high potency (drugs able to control symptoms of schizophrenia with low doses). This categorization was made based on the amount of medication necessary to produce an equivalent effect as compared to other drugs in the same category. As an example, 100 mg of chlorpromazine is approximately equivalent to 2 mg of haloperidol (Haldol). According to the categories, haloperidol is a high-potency drug, whereas chlorpromazine is a low-potency drug (although both are conventional antipsychotics). The nurse must not confuse potency with efficacy or effectiveness. *Potency* refers to a quantity, whereas *efficacy* refers to therapeutic response. Unfortunately, the potency classification method does not give any indication of a drug's effectiveness, mechanism of action, or chemical class.

So for the antipsychotic drugs, which classification should the student learn and use? Because the conventional/atypical and potency methods of drug classification are used in clinical practice, the student must be aware of both schemes.

Drug selection: In terms of effectiveness, there is no single preferred drug for the long-term therapy of schizophrenia. Selection is based on clinician experience, the occurrence of adverse effects, and the therapeutic response of each individual patient. For example, patients with both psychosis and Parkinson's disease need an antipsychotic with minimal extrapyramidal symptoms. Those who operate machinery need a drug that does not cause sedation. Men who are sexually active may adhere better to a regimen with a drug that does not cause sexual dysfunction.

Clearly, the second-generation atypical antipsychotics result in a lower incidence of serious adverse effects and have become preferred drugs for psychosis. The experience and skills of the healthcare provider and mental health nurse are particularly valuable in achieving successful psychiatric pharmacotherapy.

Several long-acting IM depot preparations are available for patients who exhibit chronic nonadherence to the therapeutic regimen. For example, risperidone (Risperdal Consta), paliperidone (Invega Sustenna), and fluphenazine decanoate last 2 to 6 weeks, depending on the dose and patient response.

CONNECTION Checkpoint 20.1

From what you learned in Chapter 4, explain why it is more important to receive an antipsychotic drug that has greater effectiveness versus one that has higher potency. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Managing adverse effects: Although antipsychotic drug therapy clearly results in significant improvement in clinical symptoms, adverse effects are common and often serious. An important component of successful antipsychotic pharmacotherapy is managing these adverse effects.

Extrapyramidal symptoms (EPS) are a particularly serious set of adverse reactions to antipsychotic drugs. The term *extrapyramidal* refers to locations in the central nervous system (CNS) outside the cerebrospinal pyramidal tracts of the brain. Whereas the pyramidal system controls visible, voluntary movements, the extrapyramidal system is associated with postural and automatic movements that are not usually noticeable. EPS include the following:

- **Acute dystonia** occurs early in the course of pharmacotherapy with antipsychotics and involves severe muscle spasms, particularly of the back, neck, tongue, and face. In rare cases, acute dystonia can be so severe as to dislocate joints and impair respiration due to laryngospasm. The risk of acute dystonia is greater with high-potency antipsychotics. Administration of drugs with anticholinergic properties such as diphenhydramine (Benadryl) or benztropine (Cogentin) can reverse acute dystonia symptoms within minutes when administered parenterally. For dystonia refractory to anticholinergic drugs, diazepam (Valium) may be administered.
- **Akathisia**, the most common EPS, is an inability to rest or relax. The patient paces, has trouble sitting or remaining still, and has difficulty sleeping. Repetitive movements such as rocking while standing or sitting and crossing and uncrossing legs may be evident. Akathisia can even be mistaken for anxiety and agitation, possibly resulting in an increase in antipsychotic dose, which will exacerbate these adverse effects. In some cases, akathisia may require symptom management with beta-adrenergic blockers, anticholinergics, or benzodiazepines.
- **Parkinsonism** is induced by antipsychotic drugs and may include tremor, loss of fine motor skills, muscle rigidity, stooped posture, and a shuffling gait. The

treatment of antipsychotic drug-induced parkinsonism includes anticholinergic drugs and amantadine (Symmetrel) (see Chapter 21).

- **Tardive dyskinesia (TD)** is characterized by involuntary, unusual tongue and face movements such as lip smacking, rapid eye blinking, and wormlike motions of the tongue. They generally occur during long-term therapy, and symptoms may persist for months or years after the drug is discontinued. Symptoms of TD may worsen or even become permanent when the antipsychotic drug is withdrawn. In 2017 the first drug for treating TD was approved by the U.S. Food and Drug Administration (FDA). Valbenazine (Ingressa) improves the involuntary movements that are characteristic of TD. This drug may cause serious side effects such as drowsiness and QT prolongation.

When EPS are reported early, the drug is usually withdrawn or the dosage reduced so that the symptoms can be eliminated. If allowed to continue for prolonged periods, EPS may become permanent. The nurse must be vigilant in observing and reporting EPS, because prevention is the best treatment. Table 20.3 contains further information on the EPS of antipsychotic medications.

A potentially fatal adverse reaction to antipsychotic medications is **neuroleptic malignant syndrome (NMS)**. Symptoms include high fever, diaphoresis, muscle rigidity, tachycardia, and blood pressure fluctuations. Although rare, quick, aggressive treatment is necessary because the condition can rapidly deteriorate to stupor or coma. The most immediate intervention is to discontinue all antipsychotics. Supportive treatment includes antipyretics, electrolytes, and muscle relaxants.

Adverse effects on the reproductive system are a major cause of nonadherence to the drug regimen in some patients. Up to 50% to 60% of men taking antipsychotics may experience ejaculation disorders and erectile dysfunction. In women, decreased libido and inability to achieve orgasm may occur. Many antipsychotics increase serum levels of the hormone prolactin, which can cause secretion of breast milk (galactorrhea) and breast enlargement (gynecomastia). These events may occur in both men and women. Most women will also experience menstrual dysfunction due to the high prolactin levels.

Unlike many CNS drugs, antipsychotic medications do not cause physical or psychologic dependence. They also have a wide safety margin between a therapeutic and a lethal dose; deaths due to overdoses of antipsychotic drugs are uncommon. They should be gradually discontinued, however, to avoid withdrawal symptoms.

First-Generation Antipsychotics

20.6 The phenothiazines are effective at treating schizophrenia symptoms but exhibit a high incidence of adverse effects.

The first-generation or conventional antipsychotics form two subclasses: the phenothiazines and nonphenothiazines. *Phenothiazine* is a chemical term that refers to compounds with three rings that are joined together by nitrogen and sulfur atoms. Originally developed as a yellow dye in the 1800s, phenothiazine became the starting molecule for a series of drugs, which are recognized by the "-zine" suffix. The student will encounter the term *phenothiazine* in other chapters because several drug classes produce "phenothiazine-like" adverse effects. The phenothiazines are listed in Table 20.4.

At equivalent doses, all phenothiazines have the same effectiveness in treating psychoses, and all produce a

Table 20.3 Extrapyramidal Symptoms of Antipsychotic Medications

Type of Symptom	Time of Onset	Manifestations	Treatment
Acute dystonia	Several hours to 5 days	Severe spasms of the muscles of the tongue, face, neck, or back; involuntary upward deviation of the eyes; arching forward of the trunk while the head and legs are thrust backward	Immediately administer an anticholinergic such as diphenhydramine or benztropine IV or IM. Symptoms usually resolve within 5–20 min.
Akathisia	Within first 2 months of treatment	Pacing, squirming, inability to sit still, uncontrollable need to be moving	Anticholinergics (diphenhydramine, etc.), benzodiazepines (diazepam, alprazolam, etc.), or beta blockers (atenolol, labetalol, etc.).
Antipsychotic-induced parkinsonism	5–30 days	Tremor, rigidity, shuffling gait, masklike facies, drooling, cogwheeling (a jerky or clicking sensation when a limb is moved), stooped posture, bradykinesia. Symptoms cannot be distinguished from true Parkinson's disease.	Anticholinergics (benztropine, diphenhydramine, etc.), amantadine. Treatment should not need to be continued for more than a few months, because symptoms should resolve.
Tardive dyskinesia	During long-term therapy	Involuntary, unusual movements of the tongue and face and lip-smacking movements; may include involuntary movements of the arms and legs, fingers, toes, and trunk. Incidence is very high in older patients.	For some patients, decreased doses of antipsychotics, administration of benzodiazepines, or gradual withdrawal of anticholinergics may help. Some patients may benefit from switching to an atypical antipsychotic.

Table 20.4 First-Generation Antipsychotic Drugs

Drug	Route(s) and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Phenothiazines		
chlorpromazine (Thorazine)	PO: 10–25 mg tid initially, with dose gradually increased until response is obtained (max: 1000 mg/day) IM/IV: 25–50 mg (max: 600 mg q4–6h)	*Sedation, drowsiness, dizziness, EPS, constipation, photosensitivity, orthostatic hypotension, anticholinergic effects, seizures* Agranulocytosis, pancytopenia, anaphylaxis, TD, NMS, hypothermia, adynamic ileus, sudden unexplained death
fluphenazine	PO: 1–10 mg/day in 1–4 divided doses (max: 40 mg/day) Subcutaneous/IM: Decanoate 12.5–25 mg every 2–4 wk	
perphenazine	PO: 8–16 mg bid–qid (max: 64 mg/day)	
prochlorperazine	PO: 5–10 mg tid or qid (max: 150 mg/day for psychosis, 40 mg/day for nausea or vomiting) IM: 10–20 mg, may repeat q1–4h	
thioridazine	PO: 50–100 mg tid (max: 800 mg/day)	
trifluoperazine	PO: 1–2 mg bid (max: 20 mg/day)	
Nonphenothiazines		
haloperidol (Haldol)	PO (immediate release): 0.2–5 mg bid or tid IM (depot): 50–100 mg each month	*Akathisia, sedation, transient drowsiness, EPS, tremor, orthostatic hypotension, weight changes, anticholinergic effects* TD, NMS, acute kidney failure, respiratory depression, laryngospasm, hepatotoxicity, sudden unexplained death, agranulocytosis
loxapine (Loxitane)	PO: Start with 20 mg/day and increase to 60–100 mg/day in divided doses (max: 250 mg/day)	
pimozide (Orap)	PO: 1–2 mg/day (max: 10 mg/day)	
thiothixene (Navane)	PO: 2 mg tid (max: 60 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

similar spectrum of adverse effects. Selection of a specific phenothiazine is determined by the severity and extent of expected adverse effects. For example, if EPS are a major concern, thioridazine may be selected because it gives the lowest incidence of EPS in the class. If the patient is driving or working, fluphenazine may be selected because it produces less sedation and fewer anticholinergic effects than other phenothiazines.

It should be clearly understood at the outset of conventional antipsychotic therapy that it is not always possible to control the disabling symptoms of schizophrenia without producing some degree of EPS or anticholinergic adverse effects. Adjunct drug therapy may be warranted to treat expected adverse effects. For example, concurrent pharmacotherapy with an anticholinergic drug may prevent some of the EPS. For acute dystonias, benztropine (Cogentin) may be given parenterally. Levodopa (Dopar, Larodopa) is usually avoided because its ability to increase dopamine function antagonizes the mechanism of action of the phenothiazines. Beta-adrenergic blockers and benzodiazepines are sometimes given to reduce signs of akathisia.

Some phenothiazines have indications beyond psychiatry. These indications include:

- **Nausea and vomiting.** The phenothiazines reduce nausea and vomiting by blocking dopamine receptors in the chemoreceptor trigger zone in the medulla. Although effective, the use of phenothiazines in treating nausea and vomiting has declined due to the discovery of serotonin antagonists such as ondansetron (Zofran).
- **Cold and allergy symptoms.** Promethazine has antihistamine properties that are of benefit for treating serious cough and symptoms of the common cold. For this indication, promethazine is combined with other medications such as codeine or dextromethorphan.
- **Tourette's syndrome.** This condition is characterized by tics: sudden, loud vocalizations, often cursing, and muscle movements such as twitches, kicking, or hitting. The patient feels a premonitory urge, a type of warning, that a tic is forthcoming, and the tics may be consciously suppressed for limited periods. Drugs from a large number of classes have been used to suppress tics, including phenothiazines such as fluphenazine. There is no cure for Tourette's syndrome but the symptoms can be managed in many patients.
- **Organic brain syndrome (OBS).** *Organic brain syndrome* is a general term that refers to decreased mental function due to physical disorders rather than psychiatric illness. OBS can cause symptoms similar to those of schizophrenia, including delirium, amnesia, and agitation. OBS is a common diagnosis in older adults and is associated with a large number of conditions, including head trauma, brain tumors, stroke, shock, drug interactions, adverse effects, and kidney or hepatic failure. Chronic OBS is known as dementia. Historically, the

phenothiazines were the preferred drugs for treating symptoms of OBS; however, atypical antipsychotics such as risperidone (Risperdal) are now more commonly prescribed for this condition.

PROTOTYPE DRUG Chlorpromazine

Classification **Therapeutic:** Antipsychotic (first generation)
Pharmacologic: Phenothiazine, dopamine (D_2) receptor antagonist

Therapeutic Effects and Uses: Approved in 1954, chlorpromazine is a low-potency antipsychotic that blocks several types of receptors within and outside the CNS, including dopamine, histamine, norepinephrine, and acetylcholine receptors. The therapeutic effects in a patient with schizophrenia appear to be due to the blocking of dopamine receptors. Peak antipsychotic effects may take as long as 6 weeks to several months. IM dosing is available for acutely agitated patients. Thorazine was once a popular trade name for this drug, but chlorpromazine is now only available in generic form. The major use of chlorpromazine is to treat the symptoms of schizophrenia and other psychotic disorders. The drug can effectively suppress symptoms of acute psychotic episodes and can greatly decrease the incidence of relapse if it is used consistently. Although once widely prescribed for psychosis, chlorpromazine is rarely used today because of the potential for serious adverse effects. Other approved uses for chlorpromazine include treating schizoaffective disorder, the manic phase of bipolar disorder, as an antiemetic, as an adjunct in the treatment of tetanus, and for intractable hiccups. It is important to understand that chlorpromazine, and the other phenothiazines, do not change the underlying pathology of psychotic disease, but rather deal only with the symptoms.

Mechanism of Action: Chlorpromazine acts by blocking postsynaptic dopamine receptors. Decreases in the function of this neurotransmitter are associated with diminished psychotic symptoms. Decreased dopamine in the chemoreceptor trigger zone in the medulla results in an antiemetic effect.

Pharmacokinetics:

Route(s)	PO, rectal, IM, IV (only for severe conditions)
Absorption	20% absorbed PO; well absorbed IM
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; 92–97% bound to plasma protein
Primary metabolism	Hepatic; some active metabolites
Primary excretion	Renal
Onset of action	1/2–12 h, depending on route; optimal results will take several months
Duration of action	Half-life: 30 h

Adverse Effects: Common adverse effects of chlorpromazine include headache, anticholinergic symptoms (dry mouth, anorexia, nausea, vomiting, constipation), weight gain, anemia, phototoxicity, blurred vision, dry eyes, and glaucoma. Of all the antipsychotics, phenothiazines are the most likely to produce EPS. Serious or life-threatening adverse effects include tachycardia, cardiac arrest, laryngospasm, respiratory depression, seizures, agranulocytosis, leukopenia, leukocytosis, and NMS. Abrupt withdrawal can induce symptoms such as nausea, vomiting, and tremors. **Black Box Warning:** This drug is not indicated for the treatment of dementia-related psychosis. Older adults with dementia-related psychosis treated with antipsychotic drugs are at increased risk of death compared to placebo.

Contraindications/Precautions: There are many contraindications to the use of chlorpromazine; these are coronary artery disease, severe hypertension or hypotension, blood dyscrasias, coma, brain damage, bone marrow depression, alcohol or barbiturate withdrawal, glaucoma, hepatic dysfunction, and children under age 6 months. The drug should be used with caution in patients with cardiovascular disease because it may cause orthostatic hypotension (especially in older adults), increase the heart rate, and prolong the QT interval on the electrocardiogram (ECG). Patients with severe hepatic impairment may experience excessive CNS depression. The drug decreases the seizure threshold; thus patients with preexisting epilepsy must be carefully monitored. Chlorpromazine may produce drowsiness and lethargy in breastfeeding newborns; thus use is not recommended during lactation. Older adults are very sensitive to the EPS effects of phenothiazines; thus the drug must be used with caution in this population. Patients with benign prostatic hyperplasia (BPH) should use this drug with caution because it may cause urinary retention.

Drug Interactions: Many drug interactions are possible with chlorpromazine. Use with other CNS depressants, including alcohol, will cause additive sedation. Use with tricyclic antidepressants or anticholinergic drugs will result in additive anticholinergic adverse effects. Decreased absorption and thus lower serum levels of chlorpromazine will occur if used with antacids, barbiturates, or lithium. Increased serum levels and possible hypotension may occur if administered concurrently with epinephrine. Use with warfarin can lead to decreased anticoagulant effects. Phenothiazines inhibit the therapeutic effects of levodopa and may cause excessive sedation if used concurrently.

Herbal/Food: Increased action of chlorpromazine may occur with nutmeg, hops, nettle, and cola tree. Increased anticholinergic effects can occur with henbane leaf, kava, and betel palm.

Pregnancy: Category C.

Treatment of Overdose: Overdose will cause profound CNS depression, seizures, hypotension, and EPS. Treatment is supportive and may include vasopressors and antiseizure drugs. Airway and gastric lavage are provided if taken PO. Epinephrine should not be administered and vomiting should not be induced.

Nursing Responsibilities: Key nursing implications for patients receiving chlorpromazine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antipsychotics.

Drugs Similar to Chlorpromazine

Similar drugs include fluphenazine, perphenazine, prochlorperazine, thioridazine, and trifluoperazine. Promethazine (Phenergan) is chemically classified as a phenothiazine but the drug has no antipsychotic action and its primary use is as an antihistamine (see Chapter 45). All first-generation phenothiazines carry black box warnings that they are not to be used to treat dementia-related psychosis.

Fluphenazine: Approved in 1959, fluphenazine is a high-potency phenothiazine approved to treat psychotic disorders, including schizophrenia. The drug is most often given as fluphenazine decanoate, a long-acting depot formulation that is given either subcutaneously or IM. Administered at 1- to 4-week intervals, fluphenazine decanoate is advantageous for those patients who are not adherent to taking their PO medications daily. Oral and injectable preparations (fluphenazine hydrochloride) are also available. A stable dose of PO fluphenazine is generally achieved before placing the patient on the depot preparation. The injectable preparations are not recommended for children under age 12. Fluphenazine produces less sedation and fewer anticholinergic effects than chlorpromazine, but EPS are a major concern. This drug is pregnancy category C.

Perphenazine: Approved in 1959, perphenazine is a medium-potency drug used to treat schizophrenia, nausea, and vomiting. EPS are prominent. The drug has the same actions and adverse effects as chlorpromazine. This drug is pregnancy category C.

Prochlorperazine: Approved in 1956, prochlorperazine is a phenothiazine rarely used as an antipsychotic. Its primary use is for the management of severe nausea and vomiting (see Chapter 60). For this purpose, it may be administered PO, rectally, IM, or IV. When used as an antiemetic, doses are low and phenothiazine-like adverse effects are rare. This drug is pregnancy category C.

Thioridazine: Thioridazine, a low-potency phenothiazine, is approved to treat psychotic disorders, including schizophrenia, behavioral problems in children, major depression, anxiety, and OBS, or as an adjunct in the treatment of alcohol withdrawal. Because of the possibility of fatal dysrhythmias (black box warning), thioridazine should be used only to treat conditions that have not responded to safer drugs. Approved in 1959, thioridazine is available PO and has one of the lowest incidences of EPS of the phenothiazines. This drug is pregnancy category C.

Trifluoperazine: Trifluoperazine is a high-potency phenothiazine approved to treat psychotic disorders. Approved in 1958, it is available in PO form. Trifluoperazine causes less sedation than chlorpromazine but EPS is prominent. All other information is the same as with chlorpromazine, except that it cannot be used in children under age 6. Trifluoperazine was formerly available as Stelazine, but this trade name is no longer marketed. This drug is pregnancy category C.

20.7 The nonphenothiazine first-generation antipsychotics have the same therapeutic applications and similar adverse effects as the phenothiazines.

The nonphenothiazine conventional antipsychotic class consists of drugs whose chemical structures are dissimilar to the phenothiazines. Introduced shortly after the phenothiazines, the nonphenothiazines were initially expected to produce fewer serious adverse events. Unfortunately, this is not the case. The spectrum of adverse effects for the nonphenothiazines is identical to that for the phenothiazines, although the degree to which a particular effect occurs depends on the drug utilized.

In general, the nonphenothiazine drugs cause less sedation and fewer anticholinergic adverse effects than chlorpromazine but exhibit an equal or greater incidence of EPS. Concurrent therapy with other CNS depressants must be carefully monitored because of potential additive sedation.

Drugs in the nonphenothiazine class have the same therapeutic effects and efficacy as the phenothiazines. They are also believed to act by the same mechanism as the phenothiazines; that is, by blocking postsynaptic D_2 dopamine receptors. As a class, they offer no significant advantages over phenothiazines in the treatment of schizophrenia and have largely been replaced by the second-generation, atypical antipsychotics. Doses of the nonphenothiazine antipsychotics are shown in Table 20.4.

PROTOTYPE DRUG **Haloperidol (Haldol)**

Classification
Therapeutic: Antipsychotic (first generation)
Pharmacologic: Nonphenothiazine, dopamine (D_2) receptor antagonist

Therapeutic Effects and Uses: Haloperidol, a high-potency antipsychotic approved in 1967, is effective in treating both acute and chronic psychotic disorders. It may also be used off-label to treat Tourette's syndrome, persistent hiccups, autism, children with severe behavioral problems (short term) and OBS with psychotic features, and for the emergency sedation of patients who are severely agitated or delirious. It may be administered PO or IM but should not be given IV due to the potential for dysrhythmias.Haloperidol decanoate (Haldol LA) is a long-acting IM formulation that is administered once a month. This is an excellent formulation for patients who cannot be independent in their drug regimen, who may become nonadherent to the drug regimen, or who have no family members to assist them in taking their medication on a regular basis. The medication can be administered either in a clinic setting or by a home health nurse.

Mechanism of Action: Haloperidol depresses the cerebral cortex, hypothalamus, and limbic system, which are parts of the brain that control activity and aggression. It blocks neurotransmission at postsynaptic dopamine D_2 receptors and exhibits alpha$_1$-adrenergic blocking and anticholinergic effects.

Pharmacokinetics:

Route(s)	PO, IM
Absorption	Variable PO; well absorbed IM
Distribution	Widely distributed; may cross the placenta; secreted in breast milk; 92% bound to plasma protein
Primary metabolism	Hepatic; significant first-pass metabolism
Primary excretion	Renal; small amounts biliary with extensive enterohepatic recycling
Onset of action	Erratic if given PO; 15–30 min IM; decanoate form reaches peak plasma level in 7 days
Duration of action	Half-life: 24 h (PO); 21 h (IM); 3 wk (decanoate)

Adverse Effects: Haloperidol exhibits an adverse effect profile similar to that of other first-generation antipsychotics. Common adverse effects include drowsiness and EPS. Life-threatening adverse effects include TD, NMS, agranulocytosis, respiratory depression, and laryngospasm. Like chlorpromazine, thioridazine, and pimozide, haloperidol increases the QT interval and can pose a risk for dysrhythmias. **Black Box Warning:** This drug is not indicated for the treatment of dementia-related psychosis. Older adults with dementia-related psychosis treated with antipsychotic drugs are at increased risk of death compared to placebo.

Contraindications/Precautions: Contraindications for use of haloperidol include Parkinson's disease, seizure disorders, coma, alcoholism, severe mental depression, CNS depression, or lactation. Patients who are older or debilitated or those with urinary retention, glaucoma, or severe cardiovascular disorders must be given haloperidol cautiously. The drug lowers the seizure threshold; thus patients with preexisting epilepsy must be carefully monitored.

Drug Interactions: Haloperidol is metabolized by hepatic CYP450 enzymes and can inhibit some isozymes (CYP2D6). Thus interactions are possible with other drugs affecting these enzymes. For example, carbamazepine, an inducer of CYP450 enzymes, can reduce the serum level of haloperidol by up to 50%. Increased CNS depression can occur if given concurrently with other CNS depressants, including alcohol, tricyclic antidepressants, or opioids. Anticholinergics that are given concurrently may increase intraocular pressure. Use with methyldopa may precipitate dementia. Haloperidol may increase the QT interval and should be used with caution with other drugs that increase this interval due to the potential for additive cardiotoxicity. A few patients who were taking haloperidol and lithium concurrently experienced irreversible brain damage; thus the two drugs should not be combined. Haloperidol inhibits the therapeutic effects of levodopa and may cause excessive sedation if used concurrently. **Herbal/Food:** Increased action of haloperidol may occur if chamomile, hops, kava, nutmeg, skullcap, or valerian is used concurrently. An antagonist action may occur with the use of scopolia or jimsonweed. Increased EPS may occur if betel palm or kava is used concurrently.

Pregnancy: Category C.

Treatment of Overdose: Overdose will result in sedation, respiratory depression, coma, hypotension, and severe EPS. Treatment is supportive. Antidysrhythmic and vasopressor drugs may be necessary to maintain cardiovascular function.

Nursing Responsibilities: The phenothiazine and nonphenothiazine drug classes are both first-generation antipsychotics with very similar pharmacologic actions and adverse effects. Key nursing implications for patients receiving these drugs are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antipsychotics.

Drugs Similar to Haloperidol (Haldol)

Similar drugs include loxapine, pimozide, and thiothixene. All first-generation nonphenothiazines carry black box warnings that they are not to be used to treat dementia-related psychosis.

Loxapine (Loxitane): Approved in 1975, loxapine is a medium-potency antipsychotic given by the PO route. It is approved to treat schizophrenia, psychotic depression, and other psychotic disorders, and it is used off-label to treat severe behavioral disturbances associated with Parkinson's and Alzheimer's diseases. Use of loxapine is restricted to treating mental illness refractory to treatment from safer drugs. The adverse effect profile of loxapine is the same as that of haloperidol, and EPS frequently occur during therapy. An active metabolite of loxapine is amoxapine, a drug marketed separately as an antidepressant. This drug is pregnancy category C.

Pimozide (Orap): Approved in 1984, pimozide is a PO, high-potency medication used for treating motor and vocal tics associated with Tourette's syndrome. Although not a true antipsychotic medication, it may be used off-label to treat schizophrenia. The drug has little sedative action and should not be used to control acute psychosis characterized by agitation or hyperexcitability. EPS occur frequently with pimozide. Although effective, the drug exhibits a higher degree of cardiotoxicity than others in its class and is thus only used when other therapies fail to achieve their designated outcomes. This drug is pregnancy category C.

Thiothixene (Navane): Thiothixene, a high-potency antipsychotic, is approved to treat psychotic disorders, including schizophrenia, and acute agitation. Approved in 1967, it is available as a PO preparation and has adverse effects that are characteristic of those of other first-generation antipsychotics. It is not a first-line drug for psychosis. This drug is pregnancy category C.

Second-Generation (Atypical) Antipsychotics

20.8 Second-generation antipsychotics have become preferred drugs for the treatment of schizophrenia.

Available since the early 1990s, the second-generation, or atypical, antipsychotics have become preferred drugs for the pharmacotherapy of severe mental illness. The members of this group are diverse and have little in common with each other, except that they all improve negative psychosis symptoms and produce a lower incidence of adverse effects (especially EPS) than the first-generation drugs.

The exact mechanisms of action of the various second-generation antipsychotics are mostly unknown. It is known that atypical antipsychotics bind less tightly to dopamine (D_2) receptors than the first-generation drugs, which may explain the relatively low incidence of EPS with these drugs. Some inhibit different subtypes of dopamine receptors, D_1 and D_4, which are especially prominent in the limbic system of the brain. Some also inhibit serotonin (5-HT) receptors in the CNS. Like the first-generation drugs, some atypical antipsychotics have prominent anticholinergic adverse effects. Doses of the second-generation antipsychotics are listed in Table 20.5.

CONNECTIONS: Lifespan Considerations

Early Diagnosis and Treatment of Psychosis in Children

As in adults, the earlier a serious mental disorder such as schizophrenia is diagnosed in children, the earlier treatment can begin. Symptoms of psychosis may have an acute or insidious onset, and other conditions may also be present, such as bipolar disorder or neurologic conditions, which may cause similar symptoms.

Recent research suggests that prior to the development of psychosis, children may exhibit abnormal, involuntary motor movements (Kindler et al., 2016). Involuntary repetitive movements are most common in the facial area, limbs, and respiratory muscles and appear to be related to changes in the brain's subcortical areas. These movements appear to be related to changes in the brain's subcortical areas (Dean & Mittal, 2015). Although many other conditions, including seizure disorders and neuromuscular diseases, may cause involuntary movements in drug-naïve patients, these findings may lead to earlier diagnosis and treatment of children, especially those at high risk for developing psychosis based on a strong family history of the disorder.

PROTOTYPE DRUG **Risperidone (Risperdal)**

Classification **Therapeutic:** Antipsychotic (second-generation, atypical), antimanic drug
Pharmacologic: Dopamine (D_2) receptor antagonist

Therapeutic Effects and Uses: Risperidone is an atypical antipsychotic available for PO or IM use that has become one of the most frequently prescribed drugs for psychosis. It was initially approved in 1993 to treat negative psychotic symptoms in individuals with schizophrenia and related psychoses. In subsequent years, approved indications were extended to include acute mania associated with bipolar disorder. Risperidone was the first drug approved to treat irritability associated with autism in children ages 5 to 16. Off-label uses include the pharmacotherapy of Tourette's syndrome, attention-deficit/hyperactivity disorder, severely disruptive behavior in children with developmental disabilities, dementia, and psychotic depression. The IM depot form of Risperdal (Risperdal Consta)

Table 20.5 Second-Generation (Atypical) Antipsychotics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
aripiprazole (Abilify)	PO: 10–15 mg/day (max: 30 mg/day) IM (Abilify Maintena): 300–400 mg once monthly	*Sedation, headache, akathisia, confusion, insomnia, depression, tachycardia, dizziness, lightheadedness, anxiety, nervousness, hostility, nausea, vomiting, constipation, somnolence, EPS, asthenia, dry mouth, weight gain, tremor, restlessness, sleep disorders* Agranulocytosis (clozapine), NMS, bone marrow suppression, seizures, suicidal tendencies, TD, diabetes mellitus, ischemia, prolonged QT interval, hypotension, acute dystonia (risperidone)
asenapine (Saphris)	Sublingual: 5–10 mg bid	
brexpiprazole (Rexulti)	PO: 0.5–4 mg once daily (max: 4 mg/day)	
cariprazine (Vraylar)	PO: 1.5–6 mg once daily (max: 6 mg/day)	
clozapine (Clozaril, FazaClo)	PO: Start with 12.5–25 mg/day and gradually increase to 300–450 mg/day (max: 900 mg/day)	
iloperidone (Fanapt)	PO: Initial dose 1 mg bid then increased gradually over 1 wk to 12 mg/day (max: 24 mg/day)	
lurasidone (Latuda)	PO: 40 mg once daily (max: 80 mg/day)	
olanzapine (Zyprexa)	PO: Start with 5–10 mg/day and gradually increase to 10–20 mg/day (max: 20 mg/day) IM (extended release): 150–405 mg q2–4wk	
paliperidone (Invega, Invega Sustenna, Invega Trinza)	PO (immediate release): 6 mg/day (max: 12 mg/day) IM: 39–234 mg monthly (Invega Sustenna) or 272–819 mg every 3 months (Invega Trinza)	
pimavanserin (Nuplazid)	PO: 34 mg once daily	
quetiapine (Seroquel)	PO (immediate release): Start with 25 mg bid; increase gradually to 300–400 mg/day (max: 800 mg/day) PO (extended release): 300–450 mg/day (max: 800 mg/day)	
risperidone (Risperdal, Risperdal Consta)	PO: Start with 1–2 mg/day then increase by 0.5–1 mg/day q3–7days (max: 8 mg/day) IM: 12.5–50 mg once q2wk (max 50 mg)	
ziprasidone (Geodon)	PO: 20 mg bid (max: 80 mg bid) IM: 10 mg q2h or 20 mg q4h (max: 40 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

requires 3 weeks to produce a therapeutic response; the patient is usually placed on PO antipsychotics during this 3-week period. Subsequent IM injections are administered every 2 weeks. Risperidone is also available as orally disintegrating tablets (Risperdal M-TAB), which are especially beneficial when treating patients suspected of "cheeking" the drug.

Mechanism of Action: The precise mechanism for risperidone is unknown. It is believed that the drug acts by blocking the binding of dopamine to its receptors in various brain regions. It has highest affinity for type D_2 and has less effect on D_1 receptors. It also blocks 5-HT receptors, $alpha_1$-adrenergic receptors, and histaminergic receptors.

Pharmacokinetics:

Route(s)	PO, IM
Absorption	70% absorbed PO; slowly absorbed IM
Distribution	Widely distributed; crosses both the blood–brain and placental barriers; secreted in breast milk; 90% bound to plasma protein
Primary metabolism	Extensive hepatic metabolism by CYP2D6; changed to the active metabolite 9-hydroxyrisperidone
Primary excretion	Renal, with small amounts in feces
Onset of action	Peak action: 1–3 h (optimal antipsychotic effects may take several months)
Duration of action	Half-life: 20 h

Adverse Effects: The adverse effects of risperidone therapy are similar to those of other atypical antipsychotics. Gastrointestinal (GI) effects such as drowsiness, nausea, vomiting, constipation, and increased salivation are common. Symptoms of parkinsonism may occur in 5% to 10% of patients. The incidence of anticholinergic adverse effects is low, and agranulocytosis is very rare. Risperidone elevates serum prolactin levels, which can result in galactorrhea, impotence, gynecomastia, and menstrual irregularities. Hyperglycemia, including some rare cases of diabetic ketoacidosis, has been reported in patients taking this drug. Orthostatic hypotension is common at the initiation of therapy. Excessive weight

gain occurs in children taking risperidone. Adverse effects for the PO and IM depot formulations are the same, except the parenteral form may cause pain and local injection-site reactions. **Black Box Warning:** This drug is not indicated for the treatment of dementia-related psychosis. Older adults with dementia-related psychosis treated with atypical antipsychotics are at increased risk of death compared to placebo.

Contraindications/Precautions: Hypersensitivity to risperidone is a contraindication. The drug should be used with caution in patients with severe CNS depression, seizures, dysrhythmias, hypotension, diabetic ketoacidosis, and suicidal ideation. Patients with chronic kidney disease should be treated with caution. Use during lactation is contraindicated because the drug and its active metabolite are secreted in breast milk.

Drug Interactions: Risperidone is a substrate for hepatic CYP2D6 enzymes; thus it may interact with drugs that inhibit or induce these enzymes. For example, many of the selective serotonin reuptake inhibitors (SSRIs) inhibit CYP2D6, which reduces the metabolism of risperidone and raises serum drug levels. Concurrent use with alcohol, benzodiazepines, or other CNS depressants can cause severe CNS depression. Antihypertensives and nitrates may potentiate hypotension. Decreased risperidone levels may occur with the use of phenobarbital, rifampin, omeprazole, or carbamazepine. Increased risperidone levels may occur with the use of verapamil, azole antifungals, and lamotrigine. Risperidone antagonizes the actions of levodopa and dopamine agonists. Risperidone should be used with caution with drugs known to prolong the QT interval, such as amiodarone, droperidol, and pimozide. **Herbal/Food:** Increased CNS depression may occur if used with St. John's wort or valerian. Food does not affect the absorption of risperidone.

Pregnancy: Category C.

Treatment of Overdose: Symptoms of overdose include confusion, sedation, hypotension, and dysrhythmias. Treatment is supportive and includes gastric lavage and maintenance of cardiovascular function.

Nursing Responsibilities: Key nursing implications for patients receiving risperidone are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antipsychotics.

Drugs Similar to Risperidone (Risperdal) Other drugs classified as atypical antipsychotics include asenapine, clozapine, iloperidone, lurasidone, olanzapine, paliperidone, pimavanserin, quetiapine, and ziprasidone. Aripiprazole (Abilify) is an atypical antipsychotic that is a prototype for a different pharmacologic class (see Section 20.9). All the atypical antipsychotics carry a black box warning that they should not be used in older patients with dementia-related psychosis because they may increase mortality in those patients.

Asenapine (Saphris): One of the newer atypical antipsychotics, asenapine is a dopamine antagonist that blocks 5-HT receptors. One unique feature of asenapine is that it is approved to treat both schizophrenia and manic or mixed episodes associated with bipolar disorder, including in pediatric patients ages 10 to 17. A second advantage is that it is administered by the sublingual route, which bypasses hepatic first-pass metabolism. The types and incidences of adverse effects are similar to those of other drugs in this class. The most common adverse effects include akathisia, oral hypoesthesia, somnolence, dizziness, weight gain, and EPS. This drug is pregnancy category C.

Clozapine (Clozaril, FazaClo): In 1989, clozapine was the first atypical antipsychotic approved for use in the United States. Clozapine is approved for the management of schizophrenia in patients resistant to standard therapies and to reduce the risk of recurrent suicidal behavior in patients with schizophrenia. Off-label indications include treatment of bipolar disorder, severe obsessive-compulsive disorder, and dementia-related behavioral disorders. Clozapine is available as regular tablets or as orally disintegrating tablets (FazaClo).

Because of potentially severe adverse effects, it is generally reserved for schizophrenia symptoms that have not responded favorably to other drugs. The most serious and limiting adverse effect of clozapine is agranulocytosis, a white blood cell (WBC) count below 500/mm^3. Although it occurs in less than 1% of patients taking the drug, agranulocytosis can be fatal. To avoid toxicity, clozapine therapy requires special monitoring and surveillance requirements. WBC and absolute neutrophil counts (ANCs) are performed weekly for the first 6 months of treatment and reduced in frequency to every 2 weeks for the next 6 months. CNS effects such as sedation, dizziness, confusion, fatigue, and headache are common at the initiation of therapy but may diminish with continued therapy. Clozapine lowers the seizure threshold and can precipitate seizures in 5% of patients taking high doses. Although the incidence of EPS is less than with first-generation drugs, akathisia, tremor, and agitation can still occur. Orthostatic hypotension is common at the initiation of therapy and during dosage changes. Other warnings on the drug label include an increased risk of hyperglycemia leading to diabetic ketoacidosis and increased risk of fatal myocarditis. This drug is pregnancy category B.

Iloperidone (Fanapt): Approved to treat acute schizophrenia in 2009, iloperidone is a dopamine antagonist that also blocks 5-HT receptors. Iloperidone is considered a second-line drug because it prolongs the QT interval, which is associated with dysrhythmia and sudden death. The drug should be administered with caution when used in combination with other medications that prolong the QT interval. Another disadvantage is that iloperidone requires a week of gradually increasing the dose before the target drug level is reached. This is because the drug can cause orthostatic hypotension and possible syncope with the first few doses. Other common adverse effects include dry mouth, dizziness, fatigue, nasal congestion, somnolence, tachycardia, and weight gain. This drug is pregnancy category C.

Lurasidone (Latuda): Approved in 2010, lurasidone is an atypical antipsychotic approved to treat patients with schizophrenia. Lurasidone blocks dopamine receptors and its effectiveness is similar to that of other atypical antipsychotics. Common adverse effects are typical of other drugs in this class: somnolence, akathisia, nausea, agitation, and parkinsonism. Significant hypotension may occur early in treatment. This drug is pregnancy category B.

Olanzapine (Zyprexa): Approved in 1996, olanzapine is a second-generation antipsychotic available as regular tablets, orally disintegrating tablets, and IM (both immediate release and extended release forms). It is used to treat both the positive and negative symptoms of schizophrenia, and it is also approved to treat acute agitation and mania associated with bipolar disorder (see Chapter 19). A single IM dose can usually calm patients presenting with acute agitation in about 15 minutes. Off-label, it is used to treat severe behavioral symptoms associated with the dementia of Alzheimer's disease. It is also being used experimentally to treat nausea and vomiting in patients with cancer.

Like other second-generation antipsychotics, the incidence of EPS with olanzapine is low, with drowsiness being the most frequent adverse effect. Weight gain has been reported in up to 25% of patients and is a frequent cause of discontinuation of the drug. Other common adverse effects include dizziness, nervousness, insomnia, headache, and hostility. Use with other CNS depressants may cause additive CNS depression. The risk of patients developing type 2 diabetes mellitus is greater with the use of olanzapine than with other atypical antipsychotics. A major advantage of olanzapine is that it rarely causes neutropenia or agranulocytosis, which are major drawbacks to clozapine therapy. Safety and effectiveness in children under age 18 has not been established. This drug is pregnancy category C.

Paliperidone (Invega): Approved in 2006, paliperidone is approved for the acute and maintenance therapy of schizophrenia and for schizoaffective disorder. Paliperidone can improve both the positive and negative symptoms of schizophrenia. It is available as an immediate release tablet, as a monthly IM depot injection (Invega Sustenna), and as a quarterly IM depot injection (Invega Trinza). Invega Trinza is approved only after patients have stabilized on Invega Sustenna for 4 months. Paliperidone is the principal active metabolite of risperidone, which is the prototype antipsychotic for this class.

The incidence of serious adverse events with paliperidone is low. The drug is not extensively metabolized in the liver; thus it has less potential for drug–drug interactions than many other antipsychotics. The most common reported adverse effects include restlessness, akathisia, tachycardia, orthostatic hypotension, syncope, increased sensitivity to environmental heat, and insomnia. The IM form of the drug can cause injection-site reactions. NMS or TD may occur with the use of paliperidone. Like olanzapine, increased appetite and weight gain are possible. It does not cause neutropenia or agranulocytosis and does not appear to lower the seizure threshold. This drug is pregnancy category C.

Pimavanserin (Nuplazid): Approved in 2016, pimavanserin was the first atypical antipsychotic indicated for hallucinations and delusions specifically associated with Parkinson's disease. The drug is well tolerated, with peripheral edema and confusion being the most common adverse effects. It does not have adverse effects on motor function. Pimavanserin is metabolized by CYP3A4; therefore, caution must be used when this medication is given concurrently with strong inducers or inhibitors of this enzyme. This drug is not pregnancy rated.

Quetiapine (Seroquel): Approved to treat both positive and negative symptoms of schizophrenia in 1997, indications were later extended to include the short-term therapy of acute mania associated with bipolar disorder (in combination with lithium or valproic acid). The drug is also approved to treat major depressive disorder and depression associated with bipolar disorder. It is sometimes used off-label to treat obsessive-compulsive disorder that is unresponsive to other therapies. Quetiapine is available only in tablet form. An extended release formulation (Seroquel XR) is available.

Like other atypical antipsychotics, the incidence of EPS and other serious adverse effects with quetiapine is low. Unlike clozapine, agranulocytosis has not been reported. Sedation is commonly experienced during the initial stages of therapy. Cautious use is recommended in patients who have a history of cardiovascular disease or seizures, individuals with Alzheimer's disease, those who are taking other CNS depressants, and those who are older or debilitated. Lens changes have occurred during quetiapine use; thus baseline and 6-month eye examinations

are recommended. Other common adverse reactions include weight gain, constipation, postural hypotension, dyspepsia, and xerostomia. Like other antidepressants, quetiapine carries a black box warning that it may increase the risk of suicidal thinking in younger patients. This drug is pregnancy category C.

Ziprasidone (Geodon): Approved in 2001, ziprasidone is available in PO or IM formulations to treat schizophrenia and acute mania associated with bipolar disorder. The IM formulation is used to treat acute episodes of agitation or psychosis because it can reduce major symptoms in 15 minutes. Ziprasidone may be used off-label to treat Tourette's syndrome. Ziprasidone causes fewer EPS than most other antipsychotics but has the possibility of prolonging the QT interval and thereby increasing the risk for dysrhythmias; it should not be administered concurrently with other medications that increase the QT interval. It must also be used cautiously in patients with seizure history, Alzheimer's disease, cardiovascular or hepatic disease, or who are being treated with antihypertensives. Additive CNS depression may occur if used concurrently with antianxiety drugs, sedative–hypnotics, alcohol, or opiate preparations. Ziprasidone causes less weight gain than other atypical antipsychotics and does not cause agranulocytosis. This drug is pregnancy category C.

CONNECTION Checkpoint 20.2

When atypical antipsychotic drugs are used to treat bipolar disorder, they are usually combined with drugs from other classes. From what you learned in Chapter 19, what two drugs are usually combined with the atypical antipsychotics? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

20.9 Dopamine system stabilizers are a newer class of atypical antipsychotics.

Dopamine system stabilizers (DSSs) are medications that bind to the D_2 receptor. Unlike the conventional antipsychotics, however, they do not totally block the actions of dopamine. Instead DSSs act as if a weaker form of dopamine was occupying the receptor, causing a stabilizing, milder effect. In essence, DSSs are partial agonists. They reduce the hyperactivity of dopamine in certain regions of the brain (to produce therapeutic effects), while at the same time restoring normal dopamine activity in other regions (to lower the incidence of adverse effects observed with other antipsychotics). The balance between these two activities appears to account for the decrease in observed EPS, relative to other antipsychotics. The DSSs also affect serotonin ($5\text{-}HT_3$) receptors, which may explain some of their clinical effects.

The first DSS, aripiprazole, was approved in 2002. Two newer drugs in this class, brexpiprazole (Rexulti) and cariprazine (Vraylar) were approved in 2015.

PROTOTYPE DRUG **Aripiprazole (Abilify)**

Classification **Therapeutic:** Atypical antipsychotic
Pharmacologic: Dopamine system stabilizer (DSS)

Therapeutic Effects and Uses: Aripiprazole controls both the positive and negative symptoms of schizophrenia and improves cognition with minimal risk of EPS. In addition to tablet form, the drug is available as an orally disintegrating tablet (Abilify DISCMELT) and a parenteral, extended release form (Abilify Maintena, Aristada) that permits once-monthly dosing.

CONNECTIONS: Using Research in Practice

Weight Gain in Children and Adolescents Prescribed Antipsychotic Drugs

Weight gain is a potential adverse effect of both antipsychotic and antidepressant drugs in adult patients. It may be significant enough that some patients stop taking their medication in order to avoid gaining too much weight. Do the drugs used to treat behavioral health and serious mental illness cause weight gain for children and adolescents as well? With the increase in significant behavioral health disorders in children and adolescents, and the rise in type 2 diabetes in these populations, this is an important question.

Reekie et al. (2015) conducted a review of studies in which SSRIs, serotonin–norepinephrine reuptake inhibitors (SNRIs), and antipsychotics such as risperidone were used to treat children and adolescents. It was noted that in short-term use, these drug classifications, when used alone or with other antipsychotics, did not cause a significant weight gain. However, similar to studies of adults, long-term use of drug therapy, even SSRIs and SNRIs, led to weight gain, potentially due to the increase in appetite when serotonin-enhancing drugs were used. Risperidone, olanzapine, and clozapine were noted to have the highest risk for significant weight gain.

For patients who were already experiencing obesity, adding drugs such as metformin or topiramate appeared to have some beneficial effects against additional weight gain (Reekie et al., 2015). And because drugs for behavioral health disorders or serious mental illness are often required long term, short-term benefits on weight will be lost in the long term. If significant weight gain occurs, or if the patient is already experiencing obesity, additional drug therapy, such as with metformin, may be considered.

Aripiprazole appears to have the same level of effectiveness as other atypical antipsychotics but with a lower incidence of adverse effects. An advantage over other atypical drugs is that there is little or no weight gain, hypotension, dysrhythmias, anticholinergic effects, or prolactin release with aripiprazole. It does not appear to lower the seizure threshold.

Since its initial approval, a number of other indications have been added. An IM formulation is approved for the treatment of schizophrenia and for manic or mixed episodes associated with bipolar disorder. Aripiprazole is approved as an add-on for major depressive disorder in patients whose symptoms are not relieved by antidepressants alone. In addition, the drug is approved to treat Tourette's disorder, and irritability associated with autistic disorder in children. The drug is approved for pediatric patients ages 13 to 17 for schizophrenia, ages 10 to 17 for bipolar disorder, and ages 6 to 17 for autism.

Mechanism of Action: Aripiprazole is thought to act through a combination of partial agonist activity at dopamine type 2 (D_2 and D_3) and serotonin type 2 ($5\text{-}HT_{1A}$) receptors and antagonist activity at $5\text{-}HT_{2A}$ receptors.

Pharmacokinetics:

Route(s)	PO, IM
Absorption	Well absorbed PO and IM
Distribution	Widely distributed; unknown if crosses the placenta or is secreted in breast milk
Primary metabolism	Hepatic; metabolized to active metabolite
Primary excretion	Feces, some in urine
Onset of action	Peak effect: 3–5 h (PO); 1–3 h (IM)
Duration of action	Half-life: 75–146 h

Adverse Effects: Frequently reported adverse effects include drowsiness, insomnia, agitation, hyper- or hypotension, lightheadedness, anxiety, headache, restlessness, EPS, akathisia, nausea, vomiting, and constipation. Weight gain may occur in a significant number of patients. Serious adverse effects include seizures, NMS, and blood dyscrasias. About 5% of patients will develop EPS. **Black Box Warning:** This drug is not indicated for the treatment of dementia-related psychosis. Older adults with dementia-related psychosis treated with atypical antipsychotics are at increased risk of death compared to placebo. Antidepressants increase the risk of suicidal thinking and behavior in children, adolescents, and young adults. Patients of all ages should be monitored and observed closely during therapy for clinical worsening, suicidality, or unusual changes in behavior.

Contraindications/Precautions: Lactation, seizure disorders, or hypersensitivity are contraindications to the use of aripiprazole. Precautions must be taken when administering aripiprazole to individuals with cardiovascular or cerebrovascular disease or any condition that predisposes them to hypotension.

Drug Interactions: Aripiprazole is a substrate for several hepatic CYP450 enzymes and induces others; thus it may interact with drugs that undergo hepatic metabolism. For example, many of the SSRIs inhibit CYP2D6, which can cause reduced metabolism of aripiprazole, raised serum levels, and possible toxicity. Concurrent use of other antipsychotics or lithium may increase the incidence of EPS. Alcohol and other CNS depressants will cause increased CNS depression. Decreased excretion of aripiprazole may occur with the use of drugs such as fluoxetine or paroxetine. **Herbal/Food:** Grapefruit juice may increase the serum levels of aripiprazole and cause toxicity.

Pregnancy: Category C.

Treatment of Overdose: Overdose can cause vomiting, tremor, and drowsiness, but fatalities have not been reported. There is no specific treatment for overdose.

Nursing Responsibilities: Key nursing implications for patients receiving aripiprazole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Antipsychotics.

Drugs Similar to Aripiprazole (Abilify)

Drugs similar to aripiprazole include brexpiprazole and cariprazine.

Brexpiprazole (Rexulti): Brexpiprazole is believed to have a mechanism similar to that of aripiprazole. In addition to schizophrenia, it is approved as adjunctive therapy in the treatment of major depressive disorder. It carries the same black box warnings as other antipsychotics (not to be used for dementia-related psychosis) and the antidepressants (possible suicidal risk). It shows similar adverse effects to aripiprazole: About 5% of patients will exhibit symptoms of EPS. The most frequent adverse effects are akathisia and weight gain.

Cariprazine (Vraylar): Cariprazine is believed to have a mechanism similar to that of aripiprazole. In addition to schizophrenia, it is approved for the treatment of manic or mixed episode bipolar disorder. It carries the same black box warnings as other antipsychotics (not to be used for dementia-related psychosis). It shows similar adverse effects to aripiprazole.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Antipsychotics

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, urologic, cardiovascular, respiratory, or neurologic disease (especially Parkinson's disease or seizures), current mental status, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, alcohol use, smoking, and herbal preparations. Be alert to possible drug interactions.
- Obtain a history of depression or mental disorders, including a family history of same and severity.
- Assess for disturbances in thought processes, perception, verbal communication, affect, behavior, interpersonal relationships, and self-care. Use objective screening tools of the healthcare agency.
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], electrolytes, glucose, hepatic and renal function studies, drug screening).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., normalizing thought processes, lessening delusions, lessening hallucinations, improvement in positive or negative symptoms, ability to return to normal ADLs and appetite and sleep patterns; if used for other conditions, e.g., severe hiccups, assess for appropriate therapeutic effects).
- Continue periodic monitoring of CBC, electrolytes, glucose, hepatic and renal function studies, lipid levels, therapeutic drug levels.
- Assess vital signs, especially orthostatic blood pressure, and weigh periodically.
- Assess for and promptly report adverse effects: dizziness or lightheadedness, confusion, agitation, suicidal ideations, hypotension, tachycardia, increase in temperature, blurred or double vision, skin rashes, bruising or bleeding, abdominal pain, jaundice, change in color of stool, flank pain, or hematuria.
- Assess for and promptly report EPS including parkinsonism, acute dystonia, akathisia, and TD.
- Immediately report signs and symptoms of NMS: unstable blood pressure, elevated temperature, diaphoresis, dyspnea, or muscle rigidity.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Drugs used for psychoses and schizophrenia do not cure the underlying disorder but improve positive and negative symptoms of the disorder. Gradual improvement over several weeks to months should be noted.)	• Teach the patient, family, or caregivers that full effects may not occur immediately, but that some improvement should be noticeable after beginning therapy. • Supportive, inpatient care may be required during the acute, early period of therapy.
• Monitor patient adherence to the drug regimen. (Presence of severe mental disorders may result in nonadherence to prescribed medications. Regular, consistent dosing is essential to correcting the underlying disorder. Because the drugs do not cure the underlying disorder, if regular administration is disrupted, symptoms may return abruptly. Alternative drug forms such as PO disintegrating tablets or IM depot injections may need to be considered if chronic nonadherence continues.)	• Involve the family or caregiver in ensuring that the patient remains on regular medication routines. • Ensure that the patient takes the medication as prescribed. Never leave medications at the bedside. • Question the possibility of nonadherence if original symptoms or adverse effects suddenly increase in frequency or severity.
Minimizing adverse effects: • Continue to monitor vital signs periodically, especially orthostatic blood pressure, and for tachycardia. Ensure patient safety; monitor ambulation until the effects of the drug are known. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for falls. (Antipsychotic drugs may cause hypotension, increasing the risk of falls and injury.)	• Have the patient rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes. • Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone. For patients who are taking the medications at home or at an outpatient clinic, avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to monitor motor activity, coordination, and balance, and for EPS symptoms. • Ensure adequate nutrition and fluid intake if TDs are present. (Severe choreoathetoid tongue movement may significantly hinder or prevent adequate nutrition.) • Ensure patient safety if parkinsonism affects gait or if akathisia is present. Acute dystonias may require treatment with other medications to halt spasms. (Bradykinesia, slow to start ambulation, and slow, shuffling gait, may predispose the patient to falls. Akathisia with pacing may significantly impair the patient's ability to rest and sleep; additional medications may be required to treat it. Anticholinergics or other drugs may be required to stop spasms.)	• Instruct the patient, family, or caregiver to immediately report EPS symptoms for additional treatment. • Encourage the patient, family, or caregiver to obtain and record a weight weekly to ensure that dietary needs are being met if TDs are present.
• Monitor for and immediately report signs and symptoms of NMS: unstable blood pressure, elevated temperature, diaphoresis, muscle rigidity. (NMS is a rare but potentially fatal syndrome that must be recognized and treated immediately.)	• Instruct the patient, family, or caregiver to immediately report any changes in level of consciousness, elevated temperature, excessive sweating, severe muscle rigidity, increased respirations, shortness of breath, or incontinence.
• **Lifespan:** Monitor cardiovascular and respiratory function more frequently, particularly in the older adult with existing disease or dementia. (An increased risk of death from cardiovascular events [e.g., heart failure, sudden cardiac death], or from respiratory infection has been noted in some patients, particularly those taking atypical antipsychotic drugs.)	• Instruct the patient, family, or caregiver to immediately report dizziness, palpitations, tachycardia, chest pain, cough, chest congestion, fever, or breathing difficulties.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Continue to monitor CBC, electrolytes, glucose, renal and hepatic function, lipid levels, and therapeutic drug levels. (Antipsychotic drugs may cause bone marrow depression, hepatotoxicity, increased glucose levels, or hyperlipidemia as adverse effects. **Diverse Patients:** Most antipsychotic drugs are metabolized through the CYP450 system and may result in different effects based on differences in enzymes. Monitor ethnically diverse patients more frequently to ensure optimal therapeutic effects and minimal adverse effects, especially in early stages of drug therapy.)	• Instruct the patient on the need to return periodically for laboratory work. • Teach the patient, family, or caregiver to promptly report any abdominal pain, particularly in the upper quadrants, changes in stool color, yellowing of sclera or skin, darkened urine, skin rashes, low-grade fevers, general malaise or changes in behavior or activity level, or redness or swelling around sites of injury. • Teach the patient, family, or caregiver to promptly report excessive thirst, urination, hunger, unusual weight loss or gain, or other symptoms of diabetes. • **Diverse Patients:** Teach ethnically diverse patients to observe for appropriate effects, especially in early drug therapy, and promptly report less than optimal or adverse effects.
• Monitor for anticholinergic effects, including dry mouth, drowsiness, blurred vision, constipation, and urinary retention. Provide symptomatic treatment to ease effects. (Anticholinergic symptoms are common adverse effects of antipsychotic drugs. Tolerance to anticholinergic effects usually develops over time. **Lifespan:** Be aware that older men with enlarged prostates are at higher risk for mechanical obstruction.)	• Encourage sips of water, ice chips, hard candy, or chewing gum to ease mouth dryness. Avoid alcohol-based mouthwashes, which are drying to the mucosa and which the patient may drink. • Increase dietary fiber intake and adequate fluid intake. • Promptly report urinary frequency, hesitancy, or retention to the healthcare provider.
• Monitor for weight gain, gynecomastia (breast enlargement and tenderness in either sex), and changes in secondary sexual characteristics (e.g., amenorrhea, impotence). (Some antipsychotic drugs may cause weight gain and have pituitary effects. Impotence and weight gain may be significant reasons for nonadherence.)	• Teach the patient, family, or caregiver to weigh the patient daily and report a significant weight gain of 2 kg (5 lb) per week to the healthcare provider. • Encourage a healthy diet of increased fruits and vegetables, adequate protein intake, and increased exercise. • Address sexual concerns in a matter-of-fact manner and refer as appropriate to the healthcare provider.
• **Lifespan:** Monitor for the possibility of pregnancy in women of childbearing age. (Most antipsychotic drugs are pregnancy category C and the benefits of the use of any particular drug must be weighed against possible fetal effects.) • Monitor adolescents under age 24 and older adults for unusual symptoms or expressed thoughts of suicide. (Children and adolescents younger than 24, and the older adult, particularly with dementia, are at greater risk for suicide than other patients.)	• Encourage the patient, family, or caregiver to discuss family planning with the healthcare provider. • Teach the patient, family, or caregiver to promptly report a positive pregnancy test or suspicion of pregnancy to the provider. • Encourage the patient, family, or caregiver to keep all appointments with the healthcare provider and to promptly report overt symptoms of depression, suicidal ideations, or other unusual behaviors.
• Monitor for alcohol and illegal drug use. (Used concurrently, these cause an increased CNS depressant effect or an exacerbation in psychotic symptoms.)	• Instruct the patient to avoid alcohol and illegal drug use. Refer the patient to community support groups such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA) as appropriate.
• Monitor caffeine use. (Use of caffeine-containing substances may negate the effects of antipsychotics.)	• Teach the patient, family, or caregiver to avoid caffeine-containing beverages, foods, and OTC medications, and to read food labels when in doubt about whether a product contains caffeine.
• Monitor for smoking. (Heavy smoking may decrease metabolism of some antipsychotics such as haloperidol, leading to decreased efficacy.)	• Instruct the patient to stop or decrease smoking. Refer the patient to smoking cessation programs, if indicated.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. Use brief explanations during times of delusions or hallucinations. (Using time during nursing care helps to optimize and reinforce key teaching areas. Brief, consistent explanations assist to interrupt delusional periods.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, and what adverse effects to observe for and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient or caregivers in proper self-administration of the drug, e.g., take the drug as prescribed and do not substitute brands. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient, family, or caregiver to take the medication:
	  • Exactly as ordered and the same manufacturer's brand each time the prescription is filled. (Switching brands may result in differing pharmacokinetics and alterations in therapeutic effect.)
	  • Ensure that all medication is taken exactly when as ordered. Use of a calendar to track doses may be helpful.
	  • Unless otherwise directed, mix liquid drug solutions with water, milk, or non-grapefruit juices. Do not mix with cola, tea, or caffeine-containing beverages.
	  • Administer IM injections by deep gluteal injection using enclosed diluent and safety needle if provided by the manufacturer. Check the enclosed directions about refrigerating dosages.
	  • If medication causes drowsiness, take at bedtime. Tolerance to anticholinergic effects such as drowsiness usually develops over time.
	  • Do not abruptly discontinue the medication.

Understanding Chapter 20

Key Concepts Summary

20.1 Psychoses are severe mental disorders characterized by the inability to recognize reality.

20.2 Schizophrenia, the most common psychosis, has both positive and negative symptoms.

20.3 The precise etiology of schizophrenia remains unknown.

20.4 Medical management of psychosis is challenging because patients often lack insight into their disease and believe their behavior is normal.

20.5 Selection of an antipsychotic drug depends on its spectrum of adverse effects and the experience of the healthcare provider.

20.6 The phenothiazines are effective at treating schizophrenia symptoms but exhibit a high incidence of adverse effects.

20.7 The nonphenothiazine first-generation antipsychotics have the same therapeutic applications and similar adverse effects as the phenothiazines.

20.8 Second-generation antipsychotics have become preferred drugs for the treatment of schizophrenia.

20.9 Dopamine system stabilizers are a newer class of atypical antipsychotics.

CASE STUDY: Making the Patient Connection

Remember the patient "George Watkins" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

George Watkins is a 47-year-old African American man who was admitted to the psychiatric unit this morning. He was diagnosed with schizophrenia at age 20. He looks disheveled, with long, dirty, stringy hair. His clothes are mismatched and dirty. Although it is summer, he is wearing an overcoat and a winter hat pulled down over his ears. This is George's fourth hospitalization for out-of-control schizophrenia. The last severe episode occurred 4 years ago.

Sheri Watkins, George's wife, states that he quit his job as an assembly line supervisor about 2 weeks ago. He has also quit coaching softball and soccer games. Sheri and George have been married since they were both 18. Their marriage is basically strong but has had its difficult times, especially when George's schizophrenia is active. About 3 to 4 weeks before each hospitalization for psychosis, he stopped taking his antipsychotic medication. He has taken different antipsychotic medications over the course of his schizophrenia, but none has proved to be successful over a long period.

George and Sheri have two children: Toby, who is 14, and Felecia, who is 10. Both children do well in school, have many friends, and are active in several organizations and sports. As the children get older, they realize that "something is not quite right" with their father. They have never been told of their father's mental illness. The children worry that they will catch whatever it is that causes their father's erratic behavior. George's parents and four siblings live in the same town. George, his father, and his two brothers worked at the same manufacturing plant. His other two siblings are teachers in the local school system, as is Sheri.

Mr. and Mrs. Watkins, George's parents, tell you that their son had a normal childhood. He was active in sports, starred on the high school football team, was an honor student and a Boy Scout, and had many friends. They have always enjoyed many social occasions with their large extended family. George is always welcome at family gatherings, but relatives tend to avoid him when his behavior becomes bizarre. They all know he has schizophrenia but do not fully understand the implications of the diagnosis.

Critical Thinking Questions

1. What are the most likely reasons George gives for discontinuing his medication?
2. What clues do his family and friends have that would indicate that symptoms of his schizophrenia may be returning?
3. What can be done to prevent George's schizophrenia from returning in the future?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Suzette Anderson is a 19-year-old patient who has been admitted to the psychiatric unit with newly diagnosed schizophrenia. She is agitated and paces back and forth in the day room until she is called for dinner. She is heard muttering to herself, "I don't know why they put me here. They just don't want me to get my inheritance. Maybe it's because they know I'll leave them all when I get the money. I'll be real rich and can start a new life for myself." She demonstrates no overt threatening behavior toward any of the other patients or toward the staff. Her agitation escalates until she cannot calm herself down and will not listen to staff. She begins hitting her fist into the wall and shouting. There is an order for haloperidol (Haldol), 4 mg IM every 1 to 4 hours prn for agitation.

1. What is the main use of haloperidol (Haldol) in this situation?
2. As the nurse caring for Suzette, what adverse effects would you monitor for?
3. How long would you expect Suzette to remain hospitalized? Why?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient states that he has not taken his antipsychotic drug for the past 2 weeks because it was causing sexual dysfunction. The nurse is aware that the name *antipsychotic* indicates that continuing the medication as prescribed is important because:
   1. Hypertensive crisis may occur with abrupt withdrawal.
   2. Muscle twitching may occur with abrupt withdrawal.
   3. Parkinson-like symptoms will occur with withdrawal.
   4. Symptoms of psychosis are likely to return if the medication is withdrawn.

2. Prior to discharge, the nurse provides teaching related to adverse effects of aripiprazole (Abilify) to the patient and caregivers. Which of the following should be included?
   1. The patient may experience social withdrawal and slowed activity.
   2. Avoid grapefruit and grapefruit juice in the diet because it increases stomach acidity.
   3. Tardive dyskinesia is likely early in therapy.
   4. Additional drugs such as fluoxetine may be needed to prevent adverse effects.

3. The nurse expects that the patient experiencing extrapyramidal symptoms during therapy with phenothiazines will be prescribed:
   1. Benztropine (Cogentin).
   2. Diazepam (Valium).
   3. Haloperidol (Haldol).
   4. Lorazepam (Ativan).

4. Nursing implications of the administration of haloperidol (Haldol) to a patient exhibiting psychotic behavior include which of the following? (Select all that apply.)
   1. Take 1 hour before or 2 hours after antacids.
   2. The incidence of extrapyramidal symptoms is high.
   3. It is therapeutic if ordered on an as-needed basis.
   4. Haldol is contraindicated in Parkinson's disease, seizure disorders, alcoholism, and severe mental depression.
   5. Crush the sustained release form for easier swallowing.

5. Which statement made by the patient who is taking risperidone (Risperdal) indicates that further teaching is necessary?
   1. "I'll monitor my weight every month."
   2. "I can increase my intake of fluids and fiber if I have any gastrointestinal problems."
   3. "I'll have my blood pressure monitored regularly."
   4. "There is no problem if I want to drink alcohol on the weekends."

6. The development of which symptom(s) in a patient taking an antipsychotic must be reported immediately?
   1. Fever, tachycardia, stupor, and incontinence
   2. Suddenly occurring muscle spasms, especially in the neck and back
   3. Sexual dysfunction
   4. Leg pains, pacing, an inability to sit still

- Amyotrophic Lateral Sclerosis

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify the most common degenerative diseases of the central nervous system.
2. Distinguish between idiopathic Parkinson's disease and secondary Parkinson's disease.
3. Describe symptoms of Parkinson's disease.
4. Explain the neurochemical basis for Parkinson's disease, focusing on the roles of dopamine and acetylcholine in the brain.
5. Describe symptoms of Alzheimer's disease and explain theories about why these symptoms develop.
6. Describe the nurse's role in the pharmacologic management of Parkinson's disease and Alzheimer's disease.
7. Discuss the pharmacologic goals for the management of Parkinson's disease, Alzheimer's disease, and other neurodegenerative disorders.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients receiving pharmacotherapy for degenerative diseases of the central nervous system.

Key Terms

Alzheimer's disease (AD), 316
bradykinesia, 306
cholinesterase inhibitors, 317
COMT inhibitors, 313
dementia, 315
glutamate, 318
immunomodulator, 321
muscle rigidity, 306
neurodegenerative diseases, 305
neurofibrillary tangles, 316
on–off syndrome, 307
Parkinson's disease (PD), 306
pill rolling, 306
striatum, 307
substantia nigra, 307
wearing-off effect, 307

Degenerative diseases of the central nervous system (CNS) are difficult to treat pharmacologically. In nearly all cases, medications are unable to cure or reverse the progressive nature of these disorders, and the symptomatic relief provided by the drugs is only temporary. The focus of this chapter is on four debilitating and progressive conditions categorized as degenerative diseases of the CNS: Parkinson's disease, Alzheimer's disease, multiple sclerosis, and amyotrophic lateral sclerosis.

Degenerative Diseases of the Central Nervous System

21.1 Degenerative diseases of the central nervous system are characterized by irreversible and progressive loss of neuronal function.

Degenerative diseases of the CNS (**neurodegenerative diseases**) include a diverse set of disorders that differ in their causes and outcomes. Each involves a progressive and irreversible loss of neuron function in the brain or spinal cord, or both. Neuron loss is sometimes isolated to specific regions of the CNS, and symptoms will vary by the region(s) most affected by the disorder.

Alzheimer's disease and Parkinson's disease present major challenges for older adults as well as for the healthcare industry, which must provide services for the vast numbers of patients with these neurodegenerative disorders. Although less common, Huntington's disease, multiple sclerosis, and amyotrophic lateral sclerosis are equally devastating to patients and their families. These disorders are described in Table 21.1.

The etiology of most neurodegenerative diseases is unknown, although the loss of neurons appears to have both genetic and environmental components. Huntington's disease is clearly the result of an autosomal dominant genetic defect. Alzheimer's disease and Parkinson's disease also tend to occur more commonly within families but this does not account for the majority of cases. It is likely that exposure of neurons to various toxins, genetic predisposition, and normal aging processes all have important roles in the etiology of these disorders.

Most neurodegenerative diseases of the CNS progress from subtle signs and symptoms early in the course of the

Table 21.1 Major Degenerative Diseases of the Central Nervous System

Disease	Description
Alzheimer's disease	A chronic, progressive disease that profoundly diminishes memory, reasoning ability, and thinking skills and leaves the patient totally dependent on others for all aspects of care; usually affects people over age 60.
Amyotrophic lateral sclerosis (Lou Gehrig's disease)	A degenerative disease of the motor neurons characterized by weakness and atrophy of the muscles of the hands, forearms, and legs, spreading to involve most of the body and face; symptoms usually begin during the middle years, with death occurring within 2–5 years.
Huntington's disease (formerly called Huntington's chorea)	A rare hereditary condition characterized by progressive chorea and mental deterioration resulting in dementia; symptoms usually begin in the 30s–50s with death occurring within 15 years.
Multiple sclerosis	A chronic debilitating autoimmune disease characterized by fatigue, muscle weakness, difficulty with balance and walking, and vision, hearing, and speech abnormalities; symptomatic periods alternate with remissions; symptoms vary depending on which portion of the nervous system is experiencing inflammation.
Parkinson's disease	A debilitating disease characterized by resting tremor, muscle rigidity, hypokinesia, masklike faces, and a slow, shuffling gait. Symptoms usually appear in the 60s.

disease to profound neurologic and cognitive deficits. Because of this, neurodegenerative disorders are quite difficult to diagnose in their early stages. With some of them, diagnosis is made only after other neurologic, infectious, cardiovascular, or traumatic etiologies have been ruled out.

With the exception of Parkinson's disease, pharmacotherapy provides only minimal benefit to patients with neurodegenerative disease, especially in their more advanced stages. Currently, medications are unable to cure or significantly alter the clinical course of any of the degenerative diseases of the CNS.

PharmFACT

About 1 million Americans have Parkinson's disease. Approximately 60,000 new cases are diagnosed each year (Parkinson's Disease Foundation, n.d.).

Parkinson's Disease

21.2 Parkinson's disease is a progressive neurodegenerative disorder characterized by abnormal motor movement.

Named after British physician James Parkinson who identified the condition in 1817, **Parkinson's disease (PD)** is the second most common degenerative disease of the nervous system and the third most common neurologic disorder of older adults. The disease peaks between 58 and 62 years of age; however, even teenagers can develop the disorder. Men are affected 1.5 times more often than women. The disease is progressive, with the expression of full symptoms developing over many years.

The two etiologies of PD are called idiopathic and secondary. Idiopathic PD, the most common type, has no known cause and is characterized by a progressive destruction of neurons in specific regions of the brain. Some patients with idiopathic parkinsonism have a family history of the disorder, and a genetic link is highly probable.

Secondary parkinsonism is caused by medical conditions such as head trauma, brain infections, brain tumors, and exposure to neurotoxins. The most frequent cause of secondary parkinsonism is treatment with antipsychotic drugs (see Chapter 20). Once a patient on antipsychotic therapy shows signs of parkinsonism, the drug is normally discontinued. Symptoms of drug-induced PD are usually reversible but may become permanent if pharmacotherapy is prolonged.

PD begins with subtle symptoms. The patient reports feeling tired and seems to move more slowly, often demonstrating a slight tremor along with fatigue. There are no definitive tests for PD; diagnosis is based on clinical findings after the presence of other neurologic diseases has been ruled out. Once the disease progresses, the symptoms of PD are quite characteristic and can be easily recognized. The four cardinal signs of PD, or parkinsonism, are summarized as follows:

- **Tremor.** The hands and head develop a palsy-like, continuous motion or shaking when at rest. The tremors may be so pronounced that the individual cannot hold a glass or eating utensils and successfully bring them to his or her mouth. **Pill rolling** is a common behavior in progressive states, in which patients rub the thumb and forefinger together in a circular motion, resembling the motion of rolling a tablet between two fingers.
- **Muscle rigidity.** Resistance to passive movements of the arms and legs develops. The **muscle rigidity** or stiffness may resemble symptoms of arthritis. Patients often have difficulty bending over and moving limbs. Changes in facial expression, or a lack of facial expression, are due to rigidity of the facial muscles. This rigidity can lead to chewing and swallowing difficulties if the pharyngeal muscles are involved. Uncontrollable drooling may also be evident. A noticeable symptom of PD is a lack of arm swinging while walking; the patient walks with the arms close to the side. Muscle rigidity is present early in the disease process. Although the symptoms may be less noticeable at first, they progress and become obvious in later years.
- **Bradykinesia.** An involuntary slowness of voluntary movement and speech, **bradykinesia** is one of the most noticeable of all symptoms and is marked by difficulty chewing, swallowing, or speaking. Patients with PD have difficulties initiating movement and controlling fine muscle movements. Patients shuffle their feet without taking normal strides, making walking difficult.
- **Postural instability.** Patients may be stooped over and easily lose their balance. Stumbling results in frequent falls with associated injuries.

Although PD is a progressive neurologic disorder primarily affecting muscle movement, other health problems often develop in these patients, including anxiety, sleep disturbances, and disturbances of the autonomic nervous system such as constipation, difficulty urinating, and sexual dysfunction. Over half of these patients present with clinical depression. Many develop sensory and thought disturbances, and dementia may occur, especially in those over age 70. These associated health problems often require pharmacologic intervention, which increases the possibility of drug interactions and adverse effects in these patients.

21.3 Parkinson's disease is caused by a lack of sufficient amounts of dopamine produced by the substantia nigra.

Although the precise etiology of PD is incompletely understood, much is known about the effects of the disease on the CNS. Neurotransmitter deficiencies in specific regions of the brain are closely associated with the disease.

Involuntary muscle movements are controlled by the basal nuclei (also called basal ganglia), which are clusters of interconnected neurons in several distinct regions of the brain. The basal nuclei are responsible for regulating the flow of information from the cerebral cortex to the motor neurons in the spinal cord. This region helps to synchronize stopping and starting activity such as that which occurs during walking. Two portions of the basal nuclei that are important to the pathogenesis of PD are the substantia nigra and the striatum. The student should review the functions of the basal nuclei and associated structures in Chapter 17.

The **substantia nigra**, a dark band of gray matter in the midbrain, is a primary producer of the neurotransmitter dopamine. The dopamine travels through axons along the nigrostriatal pathway to the **striatum** (also called corpus striatum), where the neurotransmitter is released. In the striatum, dopamine encounters its receptors and produces multiple actions. One function that is important to the pathogenesis of PD is the planning and modulation of motor pathways responsible for unconscious muscle movement. Dopamine serves an inhibitory function, slowing the flow of impulses down spinal neurons.

When dopamine is present, the normal flow of motor impulses from the striatum helps to produce coordinated, unconscious muscle movement. Symptoms of parkinsonism develop when levels of dopamine fall because of the loss of dopamine-producing neurons in the substantia nigra. Remarkably, the body can function normally even when as many as 50% of the neurons stop producing dopamine. When 60% to 80% lose their function, however, symptoms of parkinsonism are observed.

A second neurotransmitter modulates the effects of neuronal outflow from the striatum. Acetylcholine (ACh) serves an excitatory function. Under normal conditions, the inhibitory effects of dopamine and the excitatory effects of ACh balance one another to produce smooth, coordinated muscle movement. If dopamine levels decline, ACh has a more dramatic stimulatory effect in this area and the abnormal muscular movements characteristic of PD are observed.

CONNECTION Checkpoint 21.1

Dopamine belongs to a class of natural hormones called catecholamines. From what you learned in Chapter 12, what are the other two major catecholamines found in the nervous system? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Parkinson's Disease

21.4 The drugs used for Parkinson's disease help to alleviate symptoms but do not cure the disease.

Antiparkinson medications are given to restore the balance between dopamine and ACh in specific regions of the brain. Maintaining a balance between the two neurotransmitters offers several means by which drug therapy may be used to manage the symptoms of PD:

- **Dopamine agonists.** These drugs increase the levels of dopamine in the striatum. This may be accomplished by directly replacing dopamine, decreasing the breakdown of dopamine, increasing the release of dopamine from neurons, or activating dopamine receptors.
- **Anticholinergic drugs.** These drugs block the excitatory actions of ACh in the striatum.

The goal of pharmacotherapy for PD is to increase the ability of the patient to perform normal activities of daily living (ADLs) such as eating, walking, dressing, and bathing, and decrease the chances of falls that could cause serious injury. Pharmacotherapy is an essential part of the management of PD; drugs decrease symptoms and allow the patient to provide at least some self-care, have a degree of self-worth, and improve his or her quality of life. Although pharmacotherapy does not cure this disorder, symptoms can be dramatically reduced in many patients.

Patients receiving prolonged antiparkinson pharmacotherapy may periodically experience a loss of drug effect. This **wearing-off effect** appears gradually near the end of a dosing interval. Symptoms worsen at this time because the concentration of the drug has fallen below the therapeutic level. Adjusting the dosing interval to provide for more frequent dosing may help to reduce this effect.

Another type of loss of drug effect occurs abruptly. The **on–off syndrome** occurs when the patient alternates between symptom-free periods (on) and times when the drugs stop working and symptoms abruptly reappear (off). The on–off time intervals range from just a few minutes to several hours. Off periods may occur even when the serum level of the drug is high. The on–off syndrome is difficult to control. Scheduling doses closer together or using a second, adjunct medication during the off period are strategies used to reduce the on–off syndrome in patients receiving levodopa and carbidopa.

Several classes of antipsychotic drugs can cause symptoms of parkinsonism as major adverse effects. These dyskinesias are referred to as extrapyramidal symptoms (EPS). The term *extrapyramidal* refers to locations in the CNS that contain neurons associated with postural and automatic movements. Recall from Chapter 20 that antipsychotic drugs act through a blockade of dopamine receptors. Thus, EPS develop for the same neurochemical reasons as PD: deficiency of dopamine in the striatum. Antiparkinson drugs may be used to treat these symptoms.

If drug therapy becomes ineffective, alternative treatments can be tried. Again, these treatments may help control symptoms, but they will not cure or prevent the disease from progressing. The four accepted nonpharmacologic treatments for PD are deep brain stimulation (DBS), fetal

Table 21.2 Nondrug Treatments for Parkinson's Disease

Name of Treatment	Type of Treatment	Procedure
Deep brain stimulation (DBS)	Electrical stimulation	An electrode is implanted in the thalamus or subthalamus. It is connected to a pacemaker-like device that delivers electric currents to interfere with cells that cause tremors. An implantable generator is inserted under the patient's skin in much the same way as a cardiac pacemaker. The patient can adjust the settings by using a special magnet placed over the implanted generator. DBS is used when medications are no longer controlling symptoms.
Fetal tissue transplantation	Surgical	Fetal tissue from either humans or pigs is transplanted into the caudate nucleus of the brain. The expected outcome is that the patient will show a substantial decrease of motor symptoms. This is very controversial and considered experimental at this time. No long-term results are available.
Pallidotomy	Surgical and electrical stimulation	The target area is identified with a computed tomography (CT) scan or magnetic resonance imaging (MRI). When the patient has been sedated, a burr hole is made into the target area and an electrode is inserted. A mild electrical current is passed through the electrode. The patient is closely observed for the desired effects of decreased tremor and rigidity. If the desired effect is not seen, or if untoward effects occur, the probe is repositioned until desired effects occur. A temporary lesion is made. If it is successful, a permanent lesion is made.
Thalamotomy	Surgical	Lesions, which are thought to decrease tremor and rigidity, are surgically produced within the thalamus. This is done only to benefit the side of the body that is most affected because surgical complications have resulted from bilateral thalamotomy.

tissue transplantation, pallidotomy, and thalamotomy. Table 21.2 describes each of these therapies.

21.5 Replacement therapy with levodopa is the most effective therapy for treating Parkinson's disease.

Drug therapy for PD attempts to restore the functional balance of dopamine and ACh in the striatum of the brain. Dopamine replacement drugs are used to directly increase dopamine levels in this region. Dopamine itself cannot be used for this purpose because it is unable to cross the blood–brain barrier after it is administered. Doses for these drugs are listed in Table 21.3.

Levodopa is a dopaminergic drug that has been prescribed more extensively than any other medication for this disorder. As shown in Pharmacotherapy Illustrated 21.1, levodopa is a precursor in the synthesis of dopamine. Unlike dopamine, however, levodopa easily crosses the blood–brain barrier to reach the affected region. Administration of levodopa directly leads to increased biosynthesis of dopamine within the nerve terminals. Carbidopa is nearly always administered with levodopa. Carbidopa increases the plasma levels and half-life of levodopa.

Two to three weeks of therapy are needed before improvement is observed, and many patients require several months of therapy to achieve optimal therapeutic outcomes. Dramatic improvement in symptoms is often noted early in therapy. As therapy progresses, however, the beneficial effects of the medication tend to diminish. In addition, the on–off syndrome tends to worsen with continued use of the drug.

PROTOTYPE DRUG **Levodopa and Carbidopa (Sinemet, Parcopa)**

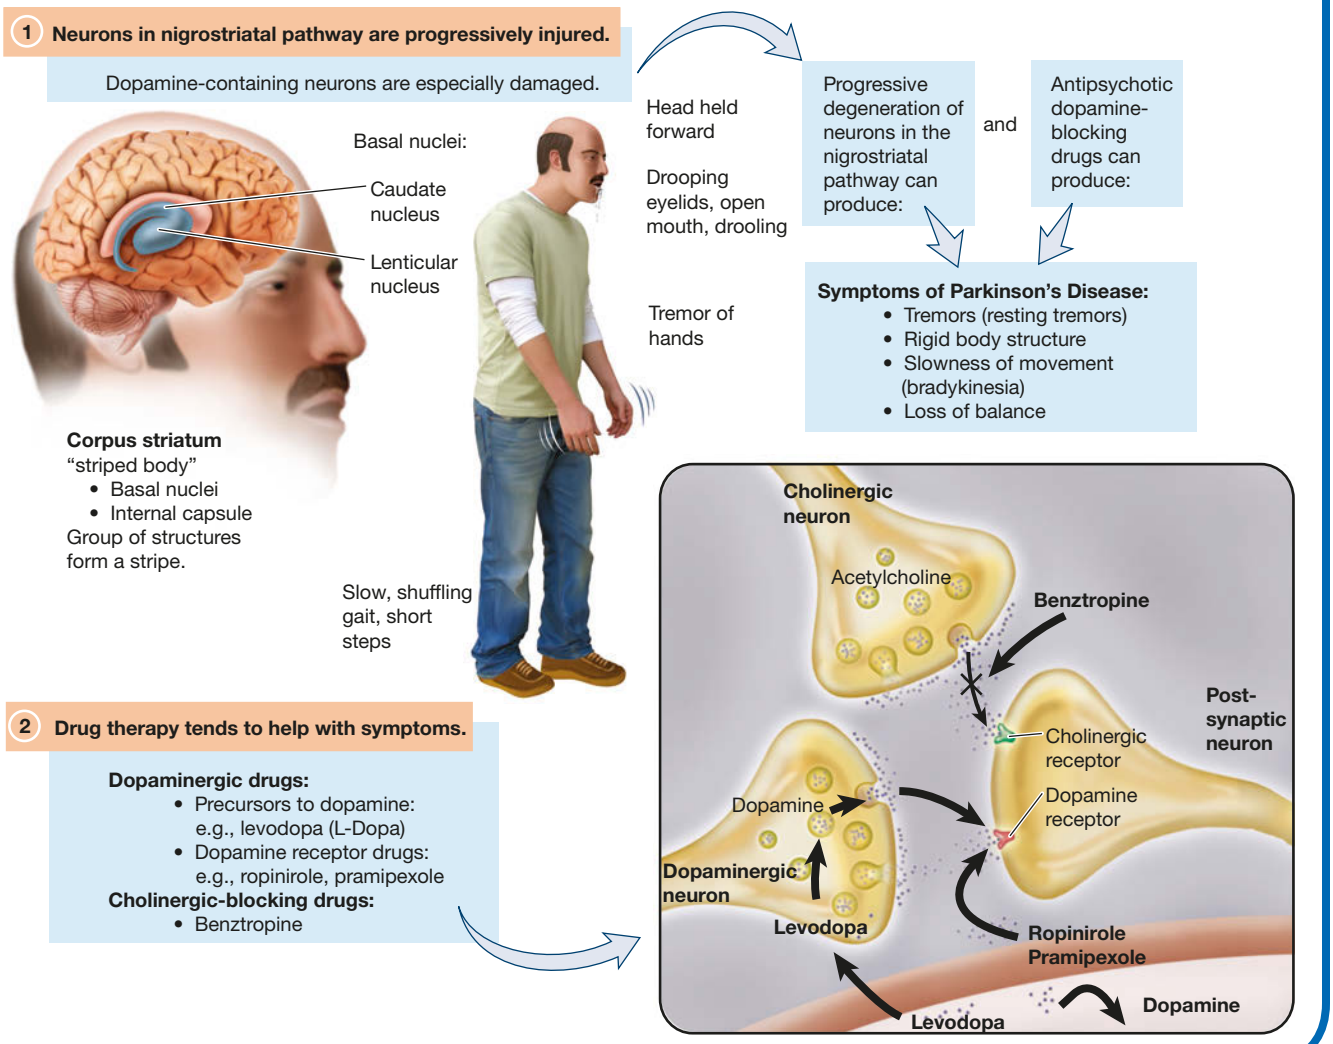
Classification **Therapeutic:** Antiparkinson drug
Pharmacologic: Dopamine replacement drug

Therapeutic Effects and Uses: Approved in 1970, levodopa is an oral (PO) drug indicated for the treatment of idiopathic and secondary PD. The drug restores normal dopamine levels in the striatum of the brain. Some symptoms of PD, such as tremor, bradykinesia, gait, and muscle rigidity, respond well to levodopa treatment. Others, such as imbalance, sensory problems, sexual dysfunction, and constipation, do not respond as well. Dosing is highly individualized to deliver the least amount of drug that will resolve the patient's symptoms.

The addition of carbidopa boosts the effectiveness of levodopa. Carbidopa itself has no therapeutic effects of its own because it cannot cross the blood–brain barrier. Instead, carbidopa inhibits the breakdown of levodopa in the intestine and peripheral tissues, which makes more levodopa available to reach the CNS. Without carbidopa, only 1% of the dose of levodopa reaches the CNS. The combination of the two drugs allows for much lower doses of levodopa to be prescribed than when levodopa is used alone; 25 mg of levodopa is used as a combination drug versus 125 mg of levodopa when delivered as monotherapy. Carbidopa also decreases dopamine production in peripheral tissues, leading to reduced nausea and vomiting as well as fewer cardiovascular responses to levodopa.

Table 21.3 Drugs for Parkinson's Disease

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Dopamine Replacement Drug		
levodopa/carbidopa (Parcopa, Sinemet)	PO (Sinemet CR): 50 mg carbidopa/200 mg levodopa or 25 mg carbidopa/100 mg levodopa with dosing based on individual response (max: 1600 mg levodopa/day)	*Involuntary movements (dyskinetic, dystonic, choreiform), orthostatic hypotension, sleep disturbances, anorexia, nausea, vomiting* Neuroleptic malignant syndrome, hallucinations, agranulocytosis, depression with suicidal ideation
Dopamine Agonists		
apomorphine (Apokyn)	Subcutaneous: 2–4 mg (max: 4 mg)	*Dyskinesias, injection site reactions, somnolence, yawning, orthostatic hypotension* Severe nausea and vomiting, syncope, hallucinations, sleep attacks
bromocriptine (Parlodel)	PO: 1.25–2.5 mg/day up to 100 mg/day in divided doses	*Nausea, hypotension, headaches, dizziness, orthostatic hypotension* Shock, acute myocardial infarction (MI), sleep attacks
pramipexole (Mirapex)	PO (immediate release): 0.125 mg tid for 1 wk and gradually increase to 1.5 mg tid PO (extended release): 0.375 mg/day and gradually increase as needed (max: 4.5 mg/day)	*Dizziness, somnolence, insomnia, dyskinesia, orthostatic hypotension, nausea, constipation* EPS, asthenia, sleep attacks, hallucinations
ropinirole (Requip)	PO (immediate release): 0.25 mg tid and gradually increase as needed (max: 24 mg/day) PO (extended release): 2 mg once daily and gradually increase as needed (max: dose of 24 mg/day)	*Fatigue, viral infection, dizziness, somnolence, nausea, vomiting, dyspepsia, orthostatic hypotension* Sleep attacks, syncope, hallucinations
rotigotine (Neupro)	Transdermal: 2–8 mg daily (one patch)	*Nausea, vomiting, somnolence, application-site reactions, dizziness, anorexia, hyperhidrosis, insomnia, peripheral edema, and dyskinesia* Hallucinations, hypertension, sleep attacks
COMT Inhibitors		
entacapone (Comtan)	PO: 200 mg administered with each dose of levodopa/carbidopa (max: 1600 mg/day)	*Urine discoloration, hyperkinesia, nausea, diarrhea, dystonia, orthostatic hypotension, sleep disorders*
tolcapone (Tasmar)	PO: 100 mg tid (max: 600 mg/day)	Dyskinesia, liver failure (tolcapone)
Monoamine Oxidase-B Inhibitors		
rasagiline (Azilect)	PO: 0.5–1 mg once daily	*Nausea, dizziness, confusion, depression, orthostatic hypotension, arthralgia* Dyskinesia, hallucinations, serotonin syndrome
safinamide (Xadago)	PO: 50–100 mg once daily as adjunct to levodopa/carbidopa therapy	
selegiline (Eldepryl, Zelapar)	PO: 5 mg bid (max: 10 mg/day)	
Miscellaneous Drug		
amantadine Gocovri	PO (regular release): 100 mg 1–2 times/day PO (extended release): 137–274 mg once daily at bedtime	*Dizziness, lightheadedness, difficulty concentrating, anxiety, headache, fatigue, nausea, vomiting, orthostatic hypotension* Falling asleep during activities of daily living, suicidal ideation, hallucinations



Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Sinemet and Rytary are extended release products containing levodopa and carbidopa. Parcopa is a preparation of levodopa and carbidopa that dissolves on the tongue and is swallowed with saliva, which is a distinct advantage for patients with swallowing difficulties. Duodopa is an enteral suspension of levodopa and carbidopa that is pumped directly into the small intestine continuously over 16 hours for patients in advanced stages of the disease. Stalevo is a combination of levodopa and carbidopa with entacapone, a COMT inhibitor (see Section 21.7). The addition of entacapone is believed to create a more consistent level of levodopa in the blood, which can minimize the extent and duration of the wearing-off effect.

Mechanism of Action: Levodopa is a metabolic precursor of dopamine. When metabolized through decarboxylation to dopamine, dopamine levels in the brain increase. If given alone, 99% of a dose is decarboxylated to dopamine before it ever enters the CNS.

Pharmacotherapy Illustrated 21.1

Antiparkinson Drugs Focus on Restoring Dopamine Function and Blocking Cholinergic Activity in the Nigrostriatal Pathway

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed from the gastrointestinal (GI) tract; absorption is decreased when given with meals
Distribution	Widely distributed throughout the body
Primary metabolism	Stomach, intestines, and liver (levodopa); carbidopa not extensively metabolized
Primary excretion	Renal
Onset of action	30 min (immediate release); 2 h (extended release)
Duration of action	Half-life: 1 h

Adverse Effects: The adverse effects of this combination of drugs are due to the levodopa component; carbidopa has no significant adverse effects. Common adverse effects include orthostatic hypotension, nausea, vomiting, anorexia, dysphagia, abdominal distress, fatigue, headache, anxiety, confusion, agitation, nightmares, and insomnia. Life-threatening adverse effects include agranulocytosis, leukopenia, and hemolytic anemia. Other potential adverse effects are related to the anticholinergic properties of levodopa, including urinary retention and dry mouth. Psychosis develops in up to 20% of patients taking levodopa, and drug therapy with an antipsychotic such as clozapine (Clozaril) or quetiapine (Seroquel) may be necessary to control hallucinations and paranoid feelings.

Although the dystonias characteristic of PD are treated with levodopa and carbidopa, this drug combination also

has the potential to cause dystonias. Some dystonias such as head bobbing or jaw clenching may be minor side effects of levodopa therapy, whereas others such as quick jerking movements may be serious. These dystonias may occur just as the optimal dosage level of levodopa is reached, which is extremely discouraging for patients and their caregivers. To reduce the severity of these dystonias, the dose of levodopa and carbidopa must be reduced. This, of course, causes the symptoms of PD to return.

Contraindications/Precautions: Levodopa and carbidopa is contraindicated in patients with hypersensitivity to the drug and those with closed-angle glaucoma, or within 2 weeks of use of a monoamine oxidase inhibitor (MAOI). Caution must be taken if administering levodopa to patients with cardiac, respiratory, endocrine, renal, or hepatic disease; myocardial infarction (MI) with dysrhythmias; seizure disorder; lactation; peptic ulcer; psychiatric disorders; or hypertension. This drug may cause patients to fall asleep during ADLs. The drug should not be abruptly discontinued due to the possibility of the development of neuroleptic malignant syndrome (NMS), such as tachycardia, muscular rigidity, fever, mental status changes, diaphoresis, and tachypnea.

Drug Interactions: Although antipsychotic drugs may be used to control psychosis associated with parkinsonism, conventional antipsychotic drugs block dopamine receptors in the brain and can decrease the therapeutic effects of levodopa. MAOIs can lead to a hypertensive crisis. Increased orthostatic hypotension may occur if used with tricyclic antidepressants. Concurrent use with antihypertensives may cause additive hypotension. Decreased levodopa effects can occur with use of anticholinergics, hydantoins, or pyridoxine. Antacids may increase the effects of levodopa. **Herbal/Food:** Food, especially high-protein foods and vitamin-fortified foods containing vitamin B_6, decreases the rate and extent of levodopa absorption; however, many people must take levodopa with food to decrease the nausea and vomiting that may occur. Kava may worsen symptoms of PD. Indian snakeroot will decrease levodopa action while increasing EPS.

Pregnancy: Category C.

Treatment of Overdose: No specific treatment.

Nursing Responsibilities: Key nursing implications for patients receiving levodopa and carbidopa are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Neurodegenerative Disorders.

Drugs Similar to Levodopa and Carbidopa

There are no other drugs similar to levodopa and carbidopa.

21.6 Dopamine agonists may be used as monotherapy for early symptoms of Parkinson's disease or as adjuncts to levodopa in patients with advanced disease.

Dopamine agonists (also called dopaminergic agonists) directly activate dopamine receptors in the CNS. They are less effective than levodopa at reducing symptoms of PD. They are used as monotherapy for patients with mild to moderate symptoms of PD and may be used in combination with levodopa in patients with advanced disease. Doses of these drugs are listed in Table 21.3.

Dopamine agonists have certain advantages over levodopa. The drugs do not have to be metabolized to be effective and they are not converted to potentially toxic metabolites. Dietary protein does not interfere with their absorption, so a low-protein diet is not necessary. They exhibit a lower incidence of the wearing-off effect and are less likely to cause dyskinesias in patients younger than age 60.

Certain adverse effects of dopamine agonists may be more serious than those of levodopa. These include orthostatic hypotension, unexpected sleep attacks, and hallucinations. This group of drugs is generally reserved for younger patients, who tend to tolerate adverse effects better than older adult patients.

The dopamine agonists are divided into two subclasses: ergot alkaloids and nonergot drugs. Bromocriptine (Parlodel) is an ergot alkaloid derived from the ergot fungus that grows on rye wheat. Another use of ergot alkaloids is in the treatment of migraines. The nonergot alkaloids include apomorphine (Apokyn), pramipexole (Mirapex), ropinirole (Requip), and rotigotine (Neupro).

PROTOTYPE DRUG **Pramipexole (Mirapex)**

Classification **Therapeutic:** Antiparkinson drug
Pharmacologic: Dopamine receptor agonist, nonergot

Therapeutic Effects and Uses: Pramipexole is an oral drug indicated for the treatment of idiopathic PD. It is used as monotherapy in early PD and in combination with levodopa in advanced stages of the disease. It can produce significant motor improvement in early PD and decreases fluctuations in motor performance in late disease. Many patients are able to lower their doses of levodopa when they take pramipexole concurrently. It is also approved at low doses for treating symptoms of restless leg syndrome. Several weeks of therapy are necessary for the patient to obtain maximum benefits from pramipexole. An extended duration form of the drug, Mirapex ER, permits a convenient once-daily dosing schedule.

Mechanism of Action: Pramipexole is a selective agonist of the D_2 subfamily of dopamine receptors at both

presynaptic and postsynaptic sites in the striatum. The binding helps to restore the balance of dopaminergic effects in the striatum. Binding at D_3 receptors also contributes to the antiparkinson effects.

Pharmacokinetics:

Route(s)	PO
Absorption	90% absorption
Distribution	Widely distributed, especially to red blood cells; 15% bound to plasma proteins
Primary metabolism	Hepatic (minimal)
Primary excretion	Renal, mostly unchanged
Onset of action	2 h
Duration of action	Half-life: 8 h; in the older adult, 12–14 h

Adverse Effects: Pramipexole has many possible adverse effects. The most common are hallucinations, dizziness, drowsiness, and nausea. The incidence of hallucinations increases with age and may cause discontinuation of therapy in older patients. Orthostatic hypotension occurs in over half the patients taking the drug and may contribute to injury due to falls. Life-threatening adverse effects include unexpected sleep attacks, hemolytic anemia, agranulocytosis, and leukopenia. Sleep attacks can occur without warning, regardless of current activity level, and cause unintentional injuries. Agitation, insomnia, hypotension, constipation, anorexia, and dyskinesias are other adverse effects. In 2012 the U.S. Food and Drug Administration (FDA) issued a safety alert that pramipexole is associated with new-onset heart failure.

Contraindications/Precautions: Pramipexole should not be used in an individual who has hypersensitivity to the drug. The drug should be used cautiously if the patient has renal, hepatic, or cardiac disease; is taking CNS depressants; or has psychosis, dyskinesia, or affective disorders.

Drug Interactions: Concurrent use with antipsychotic drugs will reduce the pharmacologic effects of pramipexole. Caution should be used if the drug is combined with other dopaminergic drugs such as levodopa or ropinirole. Drugs that may increase pramipexole levels include cimetidine, ranitidine, diltiazem, verapamil, and quinidine. Pramipexole may worsen dyskinesias when used concurrently with levodopa. **Herbal/Food:** Kava may decrease the effects of pramipexole.

Pregnancy: Category C.

Treatment of Overdose: No specific treatment is available for overdose. General supportive measures should be implemented.

Nursing Responsibilities: Key nursing implications for patients receiving pramipexole are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Neurodegenerative Disorders.

Drugs Similar to Pramipexole (Mirapex)

Other dopamine agonists used to treat PD include apomorphine, bromocriptine, ropinirole, and rotigotine.

Apomorphine (Apokyn): Apomorphine, available as a subcutaneous injection, is a nonergot dopamine agonist used as a single dose to treat severe off episodes in patients who have advanced PD. It is not intended for use as routine management of PD symptoms. Apomorphine is structurally related to morphine, but it does not bind to opioid receptors or cause morphine-like effects (see Chapter 25). Life-threatening adverse effects include sleep attacks or acute circulatory failure. Sleep attacks are more serious than the general drowsiness or sleepiness that occurs frequently with dopaminergic agonists. They can occur during any activity, including driving and other potentially dangerous activities. The drug causes significant nausea and vomiting, and the manufacturer recommends the administration of trimethobenzamide (Tigan), an antiemetic drug, 3 days prior to the apomorphine injection. The serotonin ($5\text{-}HT_3$) antagonist antiemetics such as ondansetron (Zofran) are contraindicated because they may result in severe hypotension and loss of consciousness. Common adverse effects are orthostatic hypotension, nausea, vomiting, and dyskinesias. This drug is pregnancy category C.

Bromocriptine (Parlodel): Approved in 1978, bromocriptine, available as a tablet, is an ergot alkaloid that has a variety of uses. In addition to being a dopamine agonist used for adjunctive treatment with levodopa for PD, it is approved for pituitary adenoma, acromegaly, type 2 diabetes (Cycloset), and for women with amenorrhea and infertility caused by excessive prolactin secretion. Off-label indications include alcoholism, cocaine withdrawal, mastalgia, NMS, and premenstrual syndrome.

When used concurrently, bromocriptine allows a significant dose reduction of levodopa. Life-threatening adverse reactions may include seizures, shock, or MI. The most common dose-limiting adverse effects are psychologic reactions, including confusion, agitation, hallucinations, paranoid delusions, or nightmares. Other adverse effects include orthostatic hypotension, headache, nausea, vomiting, anorexia, and rash on the face and arms. This drug is pregnancy category B.

Ropinirole (Requip): Approved for PD in 1997, ropinirole is an oral nonergot dopamine receptor agonist used as monotherapy for the treatment of early PD, or in combination with levodopa in more advanced disease. The

most common adverse effects are syncope, fatigue, drowsiness, nausea, vomiting, and viral infections. A major advantage of ropinirole is that it causes a lower rate of dyskinesias than levodopa. In addition, the patient taking ropinirole rarely experiences sleep attacks. Ropinirole was subsequently approved to treat restless leg syndrome. An extended release form (Requip XL) offers the convenience of once-daily dosing for PD. This drug is pregnancy category C.

Rotigotine (Neupro): Approved in 2007, rotigotine is a transdermal patch available for treating early and late-stage PD as well as restless leg syndrome. The patch provides for ease of use and is changed daily. Rotigotine can reduce the on–off periods experienced during levodopa therapy. Nausea, vomiting, and drowsiness are common during therapy. Care must be taken to prevent injuries due to unexpected sleep attacks. This drug is pregnancy category C.

21.7 Several miscellaneous dopaminergic drugs are used as adjuncts to levodopa therapy.

In addition to levodopa and dopaminergic agonists, several other drugs may be used to increase dopamine levels in the striatum. These drugs act on neurons by either increasing the release of dopamine or by reducing its destruction. Doses of these drugs are listed in Table 21.3.

Amantadine (Gocovri): Amantadine acts by increasing the release of dopamine from storage sites in the presynaptic neurons. It also blocks the reuptake of dopamine into the presynaptic neurons. Both of these mechanisms result in increased dopamine action. Given PO, the drug produces a rapid reduction in parkinsonism symptoms but its effects begin to diminish after several months of therapy. Adverse effects are primarily CNS related and include confusion, dizziness, irritability, and headache. Amantadine should be used with caution in patients with mental illness because it can exacerbate psychoses and cause hallucinations and suicidal ideation. Gocovri is an extended release form of the drug approved in 2017 specifically for treating dyskinesia in patients with PD. Amantadine is an antiviral drug used for the prophylactic and symptomatic treatment of influenza A virus infection. A prototype feature may be found in Chapter 54. This drug is pregnancy category C.

Catechol-O-methyltransferase inhibitors: Catechol-O-methyltransferase, or COMT, is the enzyme responsible for metabolizing levodopa to its inactive intermediate, 3-O-methyldopa. The **COMT inhibitors** are drugs that prevent the destruction of levodopa in peripheral tissues, thus increasing the amount of levodopa available to enter the brain. This results in a longer half-life and more consistent serum levels of levodopa. The COMT inhibitors have no therapeutic effects on their own; their beneficial effects are entirely the result of increased levodopa levels.

Two drugs in this category are available in the United States. Approved in 1999, entacapone (Comtan) is available as a tablet and is recommended as an adjunct to levodopa and carbidopa. Entacapone can significantly reduce the off time experienced during levodopa therapy. It is contraindicated for pregnant patients (pregnancy category D) and during lactation. Approved in 1998, tolcapone (Tasmar) is also available as a tablet as an adjunct to levodopa and carbidopa. Tolcapone has a longer duration of action than entacapone and acts on COMT both peripherally and centrally. Tolcapone is a pregnancy category C drug.

Most adverse effects observed during therapy with the COMT inhibitors are those of excessive amounts of levodopa: nausea, vomiting, dyskinesias, orthostatic hypotension, and psychiatric symptoms. Entacapone itself can cause nausea, diarrhea, abdominal pain, and urine discoloration. Tolcapone carries a black box warning regarding the possible development of liver failure, which may be fatal. Regular monitoring of hepatic status must be performed during tolcapone therapy. If improvement is not observed after 3 weeks of tolcapone therapy, the drug should be withdrawn.

Monoamine oxidase-B inhibitors: Monoamine oxidase (MAO) is an enzyme found in synaptic spaces that metabolizes catecholamines to inactive compounds. MAO-A acts on norepinephrine and serotonin, whereas MAO-B inactivates dopamine. Although MAOs are distributed throughout the body, most of the MAO located in the brain is type B. By inhibiting MAO-B these drugs increase the level of dopamine in the striatum, resulting in greater dopaminergic activity in this region.

Approved for PD in 1989, selegiline is available as a tablet or capsule (Eldepryl) and as an orally disintegrating tablet (Zelapar). A selegiline transdermal patch (Emsam) is approved for the treatment of major depression. Selegiline may be used off-label to treat Alzheimer's disease. A second MAO-B inhibitor, rasagiline (Azilect), was approved in 2006 and offers the convenience of once-daily dosing. The newest drug in this class, safinamide (Xadago), was approved in 2017. Selegiline and rasagiline may be prescribed either as monotherapy for PD or concurrently with levodopa and carbidopa. Safinamide is approved only as an adjunct to levodopa and carbidopa therapy to reduce the frequency of off periods.

The most frequent adverse effects during MAO-B therapy are those that are also associated with levodopa: nausea, vomiting, confusion, orthostatic hypotension, and dyskinesias. Minor adverse effects include insomnia, headache, arthralgia, and dyspepsia. With most MAOIs,

the patient must strictly avoid food containing tyramine and certain medications that could result in hypertensive crisis. Because these drugs selectively inhibit MAO-B, this is not a major concern. With high doses, however, they lose their selectivity for MAO-B, and begin to affect MAO-A, thus increasing the risk of a hypertensive crisis when high-tyramine foods are eaten. There is a risk of severe CNS toxicity (serotonin syndrome) if MAO-B inhibitors are used concurrently with antidepressants. The MAO-B inhibitors are contraindicated or should be used with extreme caution in patients taking other MAOIs, opioids, selective serotonin reuptake inhibitors, tricyclic antidepressants, methylphenidate, amphetamine, dextromethorphan, or St. John's wort. The three MAO-B inhibitors are pregnancy category C.

CONNECTION Checkpoint 21.2

From what you learned in Chapter 19, what is the other major indication for MAO inhibitors? What food nutrient must be strictly avoided in patients taking these drugs? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

21.8 Anticholinergic drugs are the oldest of the antiparkinson drugs and are effective at reducing tremor.

Anticholinergic drugs comprise the oldest category of drugs used to treat symptoms of PD, having been used for over 150 years. They help to restore the balance between ACh and dopamine by blocking ACh (muscarinic) receptors in the striatum of the brain. This inhibits the effects of ACh, allowing dopamine to have greater influence.

Anticholinergics are of most benefit to the patients whose primary symptom is tremor; they are less effective at reducing bradykinesia. Overall, they exhibit fewer serious adverse effects than levodopa but they are less effective. Anticholinergics are not recommended for older adults because this population often has difficulty with the CNS adverse effects, including confusion, delusion, and hallucinations. The anticholinergic drugs used most often to treat PD are benztropine (Cogentin), diphenhydramine (Benadryl), and trihexyphenidyl (Artane). The student should refer to Chapter 14 for a complete discussion on the indications, actions, and adverse effects of this class of medications. Doses of selected anticholinergics used to treat PD are listed in Table 21.4.

CONNECTIONS: Using Research in Practice

Anticholinergic Toxicity in Parkinson's Disease

Anticholinergic drugs are used in the treatment of PD to improve motor function and decrease cholinergic adverse effects, such as excessive salivation, resulting from the imbalance between dopamine and ACh. Anticholinergic toxicity may occur if too much drug or multiple drugs are given that have anticholinergic effects.

Lertxundi et al. (2015) studied anticholinergic toxicity related to drugs known to have anticholinergic action. Rather than one single drug causing anticholinergic toxicity, multiple drugs with anticholinergic activity used to treat non-PD conditions increased the risk of toxicity (Lertxundi et al., 2015). Drug groups with anticholinergic activity may be used to treat other concurrent conditions that the patient with PD may have. These drug groups include antidepressants (e.g., fluoxetine), antipsychotics (e.g., clozapine), antihistamines (e.g., dimenhydrinate), bronchodilators (e.g., ipratropium), and antiemetics (e.g., chlorpromazine).

Symptoms of anticholinergic toxicity include dry mouth, blurred vision, photophobia, visual changes, difficulty swallowing, agitation, and hallucinations (see Chapter 14). A thorough medication history, including all over-the-counter (OTC) drugs in use, is crucial to detect and prevent overlapping toxicities when multiple drugs with anticholinergic effects are used.

PROTOTYPE DRUG **Benztropine (Cogentin)**

Classification **Therapeutic:** Antiparkinson drug
Pharmacologic: Anticholinergic drug

Therapeutic Effects and Uses: Benztropine is used as combination therapy with trihexyphenidyl or levodopa and carbidopa in the management of PD

Table 21.4 Anticholinergic Drugs and Drugs with Anticholinergic Activity Used for Parkinsonism

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
benztropine (Cogentin)	PO: 0.5–1 mg/day; gradually increase as needed (max: 6 mg/day)	*Nausea, constipation, dry mouth, blurred vision, drowsiness, dizziness, tachycardia, hypotension, nervousness* Paralytic ileus, cardiovascular collapse, anaphylactic shock (diphenhydramine)
biperiden (Akineton)	PO: 2 mg 1–4 times/day	
diphenhydramine (Benadryl)	PO: 25–50 mg tid–qid (max: 300 mg/day)	
trihexyphenidyl (Artane)	PO: 1 mg on day 1; 2 mg on day 2; then increase by 2 mg q3–5days up to 6–10 mg/day (max: 15 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

symptoms. It is also used to treat drug-induced EPS. Although it suppresses tremor and rigidity, it is not effective at alleviating tardive dyskinesia. The patient may notice decreased symptoms after only 2 to 3 days of therapy with benztropine. It is an older medication approved in 1954 that is available by PO and parenteral routes. An off-label indication is to treat hypersalivation in patients who have developmental disabilities.

Mechanism of Action: Benztropine acts by reducing the excess cholinergic effect associated with dopamine deficiency and by restoring neurotransmitter balance in the striatum.

Pharmacokinetics:

Route(s)	PO, intramuscular (IM), intravenous (IV)
Absorption	Rapidly absorbed
Distribution	Wide distribution; 95% bound to plasma proteins
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	1–2 h PO; 15 min if given IM or IV
Duration of action	Half-life: 6–10 h

Adverse Effects: Common adverse reactions to benztropine are related to its anticholinergic effects and include sedation, constipation, blurred vision, dry mouth, decreased sweating, urinary retention, and confusion. Paralytic ileus is the only identified life-threatening adverse reaction.

Contraindications/Precautions: Contraindications to the use of benztropine include closed-angle glaucoma, myasthenia gravis, tardive dyskinesia, GI or urinary obstruction, prostatic hypertrophy, peptic ulcers, tachycardia, and children under age 3. Caution must be taken when benztropine is given to patients with psychiatric diagnoses because it may worsen these conditions.

Drug Interactions: Additive toxicity can occur when benztropine is taken with other drugs that exhibit anticholinergic effects, including antihistamines, tricyclic antidepressants, phenothiazines, MAOIs, or quinidine. Alcohol and other CNS depressants will have an additive sedative effect. Antidiarrheals will slow GI motility and decrease absorption of the medication. **Herbal/Food:** Kava will cause a decreased benztropine effect. Jimsonweed or butterbur may lead to increased benztropine effects.

Pregnancy: Category C.

Treatment of Overdose: Overdose can cause circulatory collapse, respiratory depression, shock, and coma. Physostigmine, 1 to 2 mg subcutaneous or IV, will reverse symptoms of anticholinergic intoxication. If needed, it may be repeated in 2 hours. Other treatment is supportive, according to symptoms being experienced.

Nursing Responsibilities: Key nursing implications for patients receiving benztropine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Neurodegenerative Disorders in this chapter and in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Cholinergic (Muscarinic) Antagonists in Chapter 14.

Drugs Similar to Benztropine (Cogentin)

The other anticholinergic widely used for PD is trihexyphenidyl . Biperiden has weak anticholinergic effects and exhibits the same basic actions and adverse effects as trihexyphenidyl. Diphenhydramine is most often prescribed for allergies and information on this drug can be found in Chapter 45.

Trihexyphenidyl (Artane): Approved in 1949, trihexyphenidyl is available in several PO formulations in both regular and extended release forms. It is indicated for both idiopathic and drug-induced PD and its actions and adverse effects are similar to those of benztropine. It is useful in decreasing involuntary movements and salivation, which are two problems experienced by patients with PD. The only life-threatening adverse effect is paralytic ileus. Other adverse effects include typical anticholinergic reactions such as constipation, dryness of the mouth, nausea, blurred vision, urinary retention, dizziness, and nervousness. In patients over age 60, the dose must be increased gradually to prevent serious side effects. It must not be given to patients with hypersensitivity to the drug, closed-angle glaucoma, severe cardiac impairment, myasthenia gravis, or GI or urinary obstruction. In addition, this drug should be used with caution in older men due to the potential for developing prostatic hyperplasia. This drug is pregnancy category C.

Alzheimer's Disease

21.9 Alzheimer's disease, the most common dementia, leads to a progressive loss of cognitive function.

Dementia is a chronic, degenerative disorder characterized by progressive memory loss, confusion, and inability to think or communicate effectively. It is usually associated with cerebral atrophy or other degenerative structural changes within the brain. Loss of short-term memory is an early sign. Patients have difficulty finding their way

around familiar places and forget where they leave items. Mood swings and changes in behavior or personality eventually develop as patients become angry and frustrated with their condition. They forget how to perform normal ADLs such as bathing, cooking, or toileting and may not comprehend instructions. They often have an altered sense of time and place. Psychosis occurs in about 10% of patients and 15% to 20% develop major depression as comorbid conditions. Late changes include the inability to walk or feed themselves, incontinence, and inability to swallow.

PharmFACT

More than 5 million Americans have Alzheimer's disease. Every 66 seconds, someone in the United States develops the disease (Alzheimer's Association, 2016).

The etiology of most dementia is unknown. Known causes of dementia include multiple small cerebral infarcts (vascular dementia), toxins (lead), severe infections, metabolic disorders (hypothyroidism and vitamin B_{12} deficiency), and brain tumors. Infection with the human immunodeficiency virus (HIV) causes dementia late in the progress of the disease. Approximately 60% to 80% of the patients with dementia are diagnosed as having Alzheimer's disease.

It should be clearly understood that dementia is not a normal consequence of aging. Although cognitive changes such as memory impairment and a decline in the speed of information recall do occur with aging, these rarely interfere with ADLs and are not considered dementia.

Alzheimer's disease (AD) is a neurodegenerative disease that involves a chronic, progressive loss of cognitive function. The disorder generally begins after age 60 and affects as many as 50% of the population over age 85. AD is the sixth leading cause of death. A summary of the major symptoms of AD is shown in Table 21.5.

AD leads to loss of productivity and wages (both for the patient and the caregivers), and often the patient must be placed in a long-term care facility. It is the third most expensive disease in the United States. In addition to the economics of caring for an individual with AD, there are the psychologic and emotional costs to families and caregivers. Pharmacotherapy has limited success in improving the cognitive function of patients with AD.

Despite many attempts at identifying the etiology of AD, the causes remain largely unknown. Although the cause has been elusive, structural damage in the brains of patients with AD has been well documented. Beta-amyloid protein and **neurofibrillary tangles** are found at autopsy in the brains of nearly all patients with AD. The neurofibrillary tangles are composed of insoluble proteins, and their abundance is proportional to the amount of cognitive impairment observed in the patient. It is suspected that these structural changes are caused by chronic inflammatory or oxidative cellular damage to the surrounding neurons. Environmental, immunologic, and nutritional factors, as well as viruses, are considered possible sources of brain damage. There are losses in both the numbers and functions of neurons.

In addition to structural changes, there are abnormalities in the balance of neurotransmitters in the brains of patients with AD. The best documented change is a deficiency of ACh, which is likely caused by brain atrophy and destruction of neurons. This loss of cholinergic activity is thought to be responsible for decreased cognition, loss of recent memory, and the inability to retain new information. Deficiencies in other brain neurotransmitters are also likely to contribute to the complex symptoms of AD.

Genetic factors likely contribute to the development of AD. Early-onset AD (ages 30–60) has been associated with mutations on chromosomes 1, 14, and 21 that are believed to lead to the development of the neurofibrillary tangles. The contribution of genetics to late-onset AD (after age 65)

Table 21.5 Symptoms of Alzheimer's Disease

Early (2–4 Years Duration)	Middle (2–12 Years Duration)	Late (2–4 Years Duration and Longer)
Depression	Lack of ability to recall names of acquaintances	Lack of ability to recognize family members
Loss of ability to concentrate	Recent memory loss	Loss of ambulation ability
Increased anxiety and agitation	Loss of orientation to time, person, or place	Loss of ability to perform any ADLs
Irritability	Changes in personal habits (may become loud, use profane language, have delusions, or show repetitive behavior)	Loss of sphincter control
Weight loss	Increasing difficulty with self-care	Loss of ability to recognize self (e.g., does not recognize self in the mirror)
Forgetting the location of common items (car keys, home); blaming others for moving or stealing items	Unable to recall their address, day of the week or year	Sundowning syndrome (worsening of symptoms in the evening)
Forgetting important dates (family birthdays, healthcare provider appointments)		
Not paying bills		

is less clear but is believed to result from a mutation on chromosome 19, combined with environmental and lifestyle factors.

It is important to assess the degree of cognitive impairment in patients with dementia. Various assessment tools are used to determine a baseline degree of cognition to make decisions on whether pharmacotherapy should be implemented. During pharmacotherapy, these tools are used to determine the progression of dementia and to gauge the effectiveness (or ineffectiveness) of therapy. Tools for assessing the progress of AD include periodic MRI and cognitive tests for memory, problem solving, attention, and language.

Pharmacotherapy of Alzheimer's Disease

21.10 Pharmacotherapy of Alzheimer's disease produces only modest results and is ineffective at stopping the progression of the disorder.

Drugs are used to slow memory loss and other progressive symptoms of dementia. In most cases, the pharmacologic treatment of dementia is the same regardless of its cause. In addition, pharmacotherapy is often required to treat common comorbid conditions such as depression, anxiety, or psychosis.

The FDA has approved only a few drugs for AD. These medications, listed in Table 21.6, do not cure or prevent AD; at best, they may slow progression of memory loss. The pharmacotherapy of AD is shown in Pharmacotherapy Illustrated 21.2.

The reversible **cholinesterase inhibitors** are the most widely prescribed drug class for treating AD. Donepezil (Aricept), a popular first-line therapy because it can be taken once daily, is well tolerated by most patients and is effective at all stages of the disease. Higher doses for severe disease produce GI adverse effects that can limit drug therapy.

ACh is naturally degraded in the synaptic cleft by the enzyme cholinesterase. When cholinesterase is inhibited, ACh levels become elevated and produce a more profound effect on ACh receptors. They are similar to the peripheral cholinesterase inhibitors such as neostigmine but demonstrate greater CNS activity.

The goal of pharmacotherapy with reversible cholinesterase inhibitors is to improve function in three domains: ADLs, behavior, and cognition. Although the cholinesterase inhibitors improve all three domains, their effectiveness is modest at best. Therapy is begun as soon as the diagnosis of AD is established. These medications are less effective in treating the severe stages of this disorder, probably because too many neurons have died; increasing the level of ACh is effective only if functioning neurons are present. As the disease progresses and fewer neurons are present, drug effects diminish and the cholinesterase inhibitors are discontinued; their therapeutic benefit may not outweigh their expense or the risks of adverse effects.

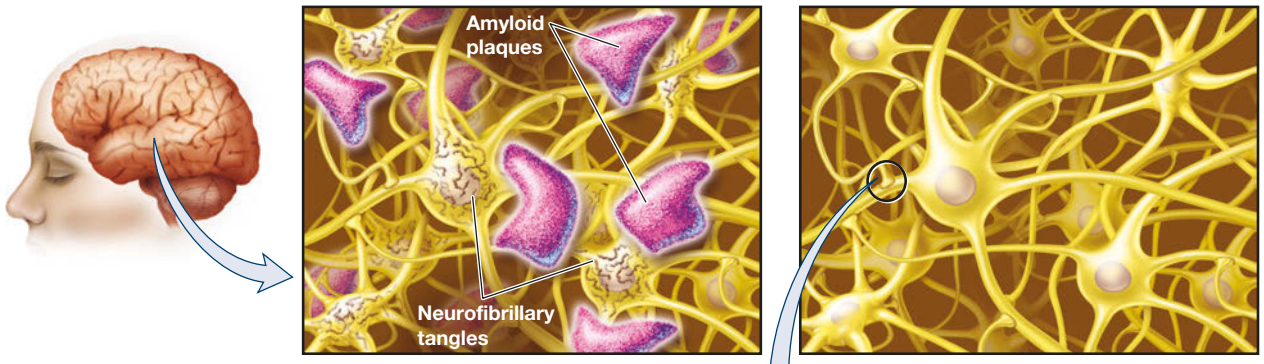
All cholinesterase inhibitors used to treat AD have similar efficacy. Adverse effects are those expected of drugs that enhance the parasympathetic nervous system (see Chapter 13). The GI system is most often affected, with nausea, vomiting, and diarrhea being frequent adverse events. Rivastigmine (Exelon) is associated with weight loss, which is a potentially serious adverse effect in some older adults. When therapy is discontinued, doses of the cholinesterase inhibitors should be tapered gradually.

CONNECTION Checkpoint 21.3

The cholinesterase inhibitors for Alzheimer's disease are used for their central actions. From what you learned in Chapter 13, what are the indications for cholinesterase inhibitors that act peripherally? What drug is the prototype peripheral cholinesterase inhibitor? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Table 21.6 Drugs to Treat Alzheimer's Disease

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
memantine (Namenda XR)	PO: 7–28 mg once daily	*Headache, confusion, dizziness, cough, hypertension* No serious adverse effects
Cholinesterase Inhibitors		
donepezil (Aricept)	PO: 5–10 mg at bedtime	*Nausea and vomiting, anorexia, diarrhea, abdominal pain, dizziness, headache, weight loss, muscle cramps* Hallucinations, depression, confusion, hepatotoxicity, increased mortality in patients with mild cognitive impairment (galantamine)
galantamine (Razadyne ER)	PO: 8–24 mg once daily	
rivastigmine (Exelon)	PO: 1.5–6 mg bid (max: 12 mg bid) Transdermal: 4.6 mg (one patch) daily and gradually increase to one 9.5-mg patch and then one 13.3-mg patch daily	



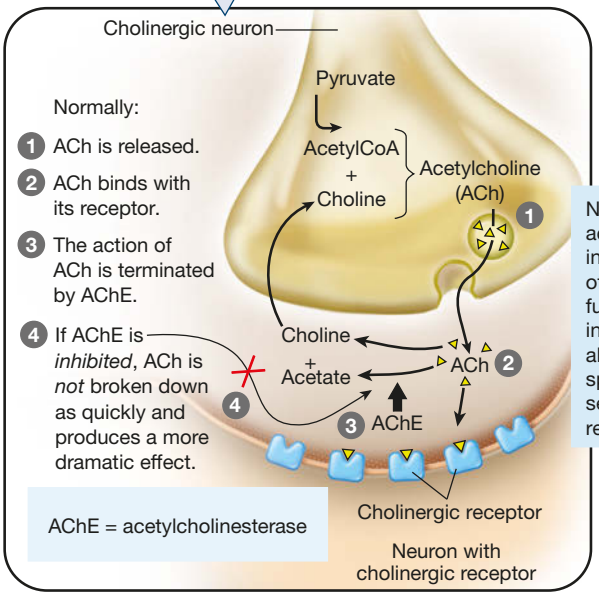
Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Pharmacotherapy Illustrated 21.2

Alzheimer's Drugs Work by Intensifying the Effect of Acetylcholine at the Receptor

1 Alzheimer's disease

Characterized by abnormal structures in the brain:
- Neurons die
- The brain shrinks
- Memory is lost



2 Drug therapy focuses on restoring or enhancing acetylcholine's role in the brain

- Cholinesterase inhibitors
  e.g., donepezil

3 Factors responsible for brain cell death include excessive transmission of glutamate

Drug therapy:
- N-methyl-D-aspartate (NMDA) receptor drugs
  e.g., memantine

Combination drug therapy:
- Donepezil and memantine

Normal role of acetylcholine in a vast array of brain functions, including the ability to speak, move, see, think, and remember.

Memantine (Namenda) was approved in 2003 for the treatment of patients with moderate to severe AD. It acts by a different mechanism than the centrally acting cholinesterase inhibitors. Memantine reduces abnormally high levels of **glutamate**, which is the major excitatory neurotransmitter of the CNS. Chronic, high levels of brain glutamate have been associated with the progression of AD and cell death. Glutamate exerts its neural effects through interaction with the N-methyl-D-aspartate (NMDA) receptor. Memantine binds to the NMDA receptor, preventing glutamate from causing its excitatory actions and, theoretically, slowing nerve damage.

Caution is indicated when memantine is given to older adults or those with chronic kidney disease or seizure disorder. No life-threatening adverse effects have been identified. Occasional adverse effects have been reported, including dizziness, confusion, vomiting, headache, cough, and hypertension. Because memantine and cholinesterase inhibitors act by different mechanisms, they may be taken in combination. When taken together, these drugs do not interfere with each other's absorption, distribution, metabolism, or elimination. An extended release form (Namenda XR) offers the convenience of once-daily dosing. Namzaric, a fixed-dose combination of

memantine and donepezil, was approved in 2015 to treat moderate to severe AD.

Other medication classes frequently prescribed for symptoms associated with AD include antipsychotics, antidepressants, and antianxiety drugs. Agitation occurs in the majority of patients with AD, which may be accompanied by delusions, paranoia, hallucinations, or other psychotic symptoms. Atypical antipsychotics such as risperidone (Risperdal) and olanzapine (Zyprexa) may be used to control these episodes. Conventional antipsychotics such as haloperidol (Haldol) are occasionally prescribed, although EPS often limit their use. The antipsychotic medications are presented in Chapter 20.

Although not as common as agitation, anxiety and depression occur in many patients with AD. Anxiolytics such as buspirone (BuSpar) or benzodiazepines are used to control anxiety. Mood stabilizers such as sertraline (Zoloft), citalopram (Celexa), or fluoxetine (Prozac) are given when major depression interferes with daily activities. The student should refer to Chapters 18 and 19 for information on these drugs.

PROTOTYPE DRUG **Donepezil (Aricept)**

Classification **Therapeutic:** Anti-Alzheimer's drug
Pharmacologic: Reversible cholinesterase inhibitor

Therapeutic Effects and Uses: Donepezil was approved to treat symptoms of AD in 1996. The drug is available in tablet, PO solution, and PO disintegrating tablet (Aricept ODT) forms. It has an extended duration of action that allows for once-daily dosing. Donepezil is the most frequent drug prescribed for AD.

There is no evidence that donepezil stops the destruction of neurons or that it alters the course of the underlying dementia. It may, however, prolong the time between diagnosis and the institutionalization of the patient. A caregiver must be present to assist the patient in adhering to the medication regimen.

Mechanism of Action: Donepezil raises ACh concentrations in the brain. Because the drug is moderately selective for cholinesterase in the CNS, it produces fewer peripheral adverse effects than other drugs in this class.

Pharmacokinetics:

Route(s)	PO
Absorption	Completely absorbed
Distribution	Well distributed; crosses the blood–brain barrier; 96% bound to plasma proteins
Primary metabolism	Hepatic; metabolized to active metabolites
Primary excretion	Primarily renal; some feces
Onset of action	3–4 h
Duration of action	Half-life: 10 h, if single dose; 70 h if multiple dose

Adverse Effects: Common adverse effects of donepezil that cause discontinuation of therapy are diarrhea,

CONNECTIONS: Complementary and Alternative Therapies

Ginkgo Biloba for Treatment of Dementia

Description

Ginkgo biloba is one of the oldest species of trees in the world, with fossils of the tree dating back to the dinosaurs. Ginkgo seeds and leaves have been used in traditional Chinese medicine for thousands of years. The tree is now planted throughout the world, including the United States.

History and Claims

In Chinese medicine, ginkgo was used to treat asthma, tinnitus, hypertonia, and angina. In Western medicine, the focus has been on treating depression and memory loss. In Germany, an extract of ginkgo biloba is approved for the treatment of dementia.

Standardization

Ginkgo biloba extract is often standardized to contain 24% ginkgo flavonoids and 6% terpenoids. A typical dose is 120–240 mg/day.

Evidence

In U.S. studies, 240 mg of ginkgo taken daily has been shown to improve mental functioning and stabilize AD in patients with mild cognitive impairment and dementia (Solfrizzi & Panza, 2015). Some studies have suggested that ginkgo may provide additional positive effects in patients already taking AD drugs (Canevelli et al., 2014). The mechanism of action seems to be related to neuroprotective effects on brain cells (University of Maryland Medical Center, 2015). Ginkgo has also been studied for the treatment of intermittent claudication, age-related macular degeneration (AMD), glaucoma, Raynaud's phenomenon, anxiety, and premenstrual syndrome, although results from these studies are mixed.

Patients should consult with their healthcare provider before taking this herb. Although most people can take ginkgo without problems, those who are also taking anticoagulants, aspirin, or NSAIDs may have an increased risk for bleeding. Because the FDA does not approve herbal products, ginkgo and other herbs have not undergone the same scrutiny given to newly developed medications.

nausea, and vomiting. Donepezil exhibits typical cholinergic effects such as diaphoresis, bradycardia, salivation, and muscle weakness. Other possible adverse effects are anorexia, muscle cramps, fatigue, arthralgia, abnormal dreams, and headache. Many of these adverse events will diminish with continued therapy or by using a lower dose of the drug. Potential life-threatening adverse effects include atrial fibrillation, sinus bradycardia, and seizures. Abrupt discontinuation of the drug results in a sudden decline of cognitive function and an increase in behavioral disturbances.

Contraindications/Precautions: The only contraindication to the use of donepezil is hypersensitivity to the drug. There is a risk of GI bleeding, especially in patients with a history of peptic ulcers or chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs). It should be used with caution in patients with hyperthyroidism or hepatic dysfunction, or those who are lactating. Increased numbers of seizures have been recorded in patients taking donepezil, especially in those patients with a history of seizures.

Drug Interactions: Donepezil is metabolized by CYP450 enzymes (CYP2D6 and CYP3A4), and drugs that enhance or inhibit these enzymes have the potential to interact with donepezil. Decreased effects of donepezil will occur with concurrent administration of phenytoin, phenobarbital, rifampin, dexamethasone, and carbamazepine. Concurrent use of NSAIDs may lead to GI ulceration and bleeding. Synergistic effects will occur with cholinergic agonists, cholinesterase inhibitors, and succinylcholine. Because it is a cholinergic agonist, donepezil will decrease the effects of anticholinergic drugs. Metabolism of donepezil may be inhibited by quinidine and ketoconazole. **Herbal/Food:** None known.

Pregnancy: Category C.

Treatment of Overdose: Overdosage will result in signs of cholinergic crisis, such as nausea, vomiting, bradycardia, respiratory depression, hypotension, and seizures. Anticholinergic drugs such as 1 to 2 mg IV atropine may be administered to reverse some of the overdose symptoms.

Nursing Responsibilities: Key nursing implications for patients receiving donepezil are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Neurodegenerative Disorders.

Drugs Similar to Donepezil (Aricept)

Other cholinesterase inhibitors used to treat the symptoms of AD are galantamine and rivastigmine.

Galantamine (Razadyne): Galantamine is an oral cholinesterase inhibitor that has the same uses and actions as donepezil. Approved in 2001, it is indicated for mild to moderate symptoms of dementia. Like other AD medications, it does not alter the progression of the disease. It is available in immediate and extended release (ER) forms. This drug was originally named Reminyl, but to avoid prescribing errors with the drug Amaryl (an antidiabetic drug), the FDA ordered the name changed to Razadyne.

The most frequent adverse effects are nausea and vomiting. The drug may be administered with food or with an antiemetic to reduce these effects. Other adverse reactions include diarrhea, bradycardia, chest pain, fatigue, anemia, syncope, vertigo, headache, insomnia, or tremor. Anorexia and weight loss are possible and may be serious effects in patients who are debilitated. In addition, it is not recommended for use in individuals with severe hepatic or renal dysfunction or in children or a lactating woman. It must be used cautiously in individuals with respiratory disease, bradycardia, cardiac conduction disorders, seizure history, history of GI bleeding, peptic ulcer disease, or asthma. It is a pregnancy category C drug.

Rivastigmine (Exelon): Like other drugs in this class, rivastigmine inhibits brain cholinesterase more than heart or skeletal muscle cholinesterase. Approved in 2000, it is used to treat mild to moderate symptoms of dementia associated with AD and PD. It has similar effectiveness to donepezil. Rivastigmine is given PO with food to prevent nausea and vomiting, which frequently occur with this medication. Liquid preparations should be mixed only with water, soda, or juice. A once-daily transdermal patch of rivastigmine is available for both PD and AD.

Rivastigmine is contraindicated in patients with hypersensitivity to rivastigmine or carbamate. Nausea, vomiting, anorexia, and diarrhea occur in a significant number of patients. The transdermal patch form of the drug causes a lower incidence of GI adverse effects. Other common adverse effects include headache, vertigo, abdominal pain, and confusion. Cautious use is indicated when given to patients with a hypersensitivity to cholinesterase inhibitors; cardiac, pulmonary, renal, or hepatic disease; diabetes; GI disorders; concurrent use of other cholinergic or anticholinergic drugs; PD; seizure history; or concurrent use of NSAIDs. No potential life-threatening adverse effects have been identified. It is a pregnancy category B drug.

Multiple Sclerosis

21.11 Multiple sclerosis is a chronic, neurodegenerative disease that is treated with immunomodulator drugs.

Multiple sclerosis (MS) is a neurodegenerative disease characterized by demyelination, the destruction or removal of the myelin sheath from a nerve or nerve fiber.

The destruction is secondary to an inflammatory response that leads to random areas of demyelination, known as plaques, in the white matter of the CNS. The exact cause of MS is unknown. It is believed that a pathogen, such as a latent virus, may trigger an abnormal autoimmune response in patients who are genetically susceptible. MS is a leading cause of neurologic disability in the 20- to 40-year-old age group, although it may affect individuals of any age (Figure 21.1).

MS has a typical pattern of progression that is characterized by periods of symptom exacerbation alternating with periods of remission during which symptoms completely disappear. Remissions may last several months or even years. Less commonly, progression may be continuous without any clear remission periods.

Diagnosis of MS is often difficult because its symptoms mimic those of other neurologic disorders. The early symptoms are frequently vague and nonspecific and include weakness, visual disturbances, paresthesias, mild affective disturbances, and difficulty with bladder control. Cognitive impairment is common. It should be determined if the symptoms are worsening or are intermittent. Also of note is whether the activity level of the patient has decreased, along with worsening fatigue, things that aggravate the symptoms (e.g., hot showers or baths, overexertion, stress), and any changes in personality or behavior. A diagnosis is made after other neurologic disorders have been ruled out. Imaging studies such as MRI are useful in identifying the areas of demyelination in the brain.

Like other neurodegenerative disorders, there are no drugs available that can cure MS or reverse the progressive demyelination of nerves. Existing drugs for MS are only partially effective and some have serious adverse effects. In general, pharmacotherapy has the following three goals:

- Modify the progression of the disease.
- Treat acute exacerbations.
- Manage symptoms.

Drugs for modifying the progression of MS: Although the exact etiology of MS remains unknown, it is considered an autoimmune disease. The body has mounted an immune attack against its own tissues, in this case, the myelin surrounding nerves. Strategies for slowing the progression of MS have therefore focused on modifying the abnormal immune response of these patients through the application of immunomodulators. **Immunomodulator** is a general term that refers to drugs that affect body defenses. There are two basic types of immunomodulators: those that stimulate or *boost* the immune response and those that *suppress* some aspect of immune function. Both types are used in MS pharmacotherapy. For detailed information on the immunomodulators, refer to Chapter 42.

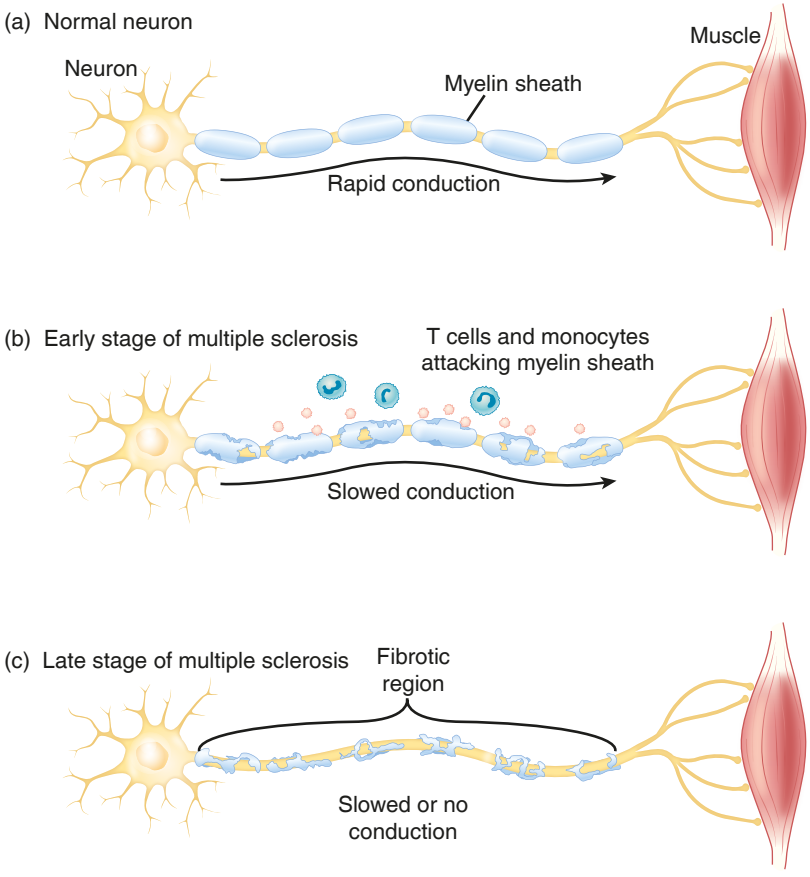


Figure 21.1 Multiple sclerosis.

The immunomodulators are used to prevent exacerbations in patients with MS. Immunomodulators are initiated soon after the diagnosis of MS is confirmed because early control of disease activity has been demonstrated to delay the progressive phase of MS and prolong the ability of patients to remain actively involved in daily activities. Treatment should continue indefinitely and only be changed or stopped if toxicity develops or there is no apparent benefit. Doses of these drugs are listed in Table 21.7.

The immunomodulators have equal efficacy in treating MS. Selection is frequently based on the clinical experiences of the healthcare provider and patient tolerance. They all are expensive, with monthly costs exceeding $4000. Interferon beta-1a (Avonex, Rebif), peginterferon beta-1a (Plegridy), interferon beta-1b (Betaseron, Extavia), glatiramer (Copaxone, Glatopa), and ocrelizumab (Ocrevus) are immunomodulators used as first-line therapy to modify the progression of MS. With the exception of ocrelizumab, these drugs require frequent self-administration, which increases the risk for injection-site reactions or

Table 21.7 Drugs for Modifying the Progression of Multiple Sclerosis

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
alemtuzumab (Lemtrada)	IV (two infusions, 12 months apart): first course 12 mg/day for 5 days; second course 12 mg/day for 3 days	*Infections, rash, headache, pyrexia, nasopharyngitis, fatigue* Cytopenias, infusion reactions, serious infections, increased risk of malignancies, serious autoimmune conditions
daclizumab (Zinbryta)	Subcutaneous: 150 mg once monthly	*Skin infections, nasopharyngitis, upper respiratory tract infection, rash* Hypersensitivity reactions, immune-mediated disorders, severe hepatotoxicity, serious infections, depression, suicide ideation
dimethyl fumarate (Tecfidera)	PO: 120 mg bid for 7 days, then 240 mg bid	*Flushing, abdominal pain, diarrhea, and nausea* Lymphopenia
fingolimod (Gilenya)	PO: 0.5 mg once daily	*Headache, back pain, diarrhea, elevated liver transaminase* Macular edema, bradycardia and other dysrhythmias
glatiramer (Copaxone, Glatopa)	Subcutaneous: 20 mg daily or 40 mg 3 times/wk	*Local reactions, arthralgia, back pain, flulike symptoms, infection, anxiety, vasodilation, chest pain, palpitations, rash, pruritus, diarrhea, nausea, dyspnea, rhinitis* Asthenia, lymphadenopathy
interferon beta-1a (Avonex, Rebif) and peginterferon beta-1a (Plegridy)	IM: 30 mcg/wk Subcutaneous (Rebif): 4.4–44 mcg 3 times/wk Subcutaneous (Plegridy): 63 mg once on day 1; 94 mcg on day 15; 125 mcg on day 29 and thereafter q2wk	*Myalgia, upper respiratory tract infection, flulike symptoms, injection-site reactions, headache, fever, nausea, chills* Hepatotoxicity, leukopenia, myelosuppression, severe depression (suicide risk), seizures, anaphylaxis
interferon beta-1b (Betaseron, Extavia)	Subcutaneous: 0.0625–0.25 mg every other day	
mitoxantrone (Novantrone)	IV: 12 mg/m^2 every 3 months (max: lifetime dose 140 mg/m^2)	*Nausea, vomiting, diarrhea, cough, headache, abdominal pain, fever, alopecia* Myelosuppression, renal failure, hepatotoxicity, cardiotoxicity (heart failure, MI, fetal harm)
natalizumab (Tysabri)	IV: 300 mg infused over 1 h every month	*Headache, depression, fatigue, menstrual dysfunction* Anaphylaxis (rare), infections
ocrelizumab (Ocrevus)	IV: 300 mg followed by 300 mg 2 wk later; subsequent dosing is 600 mg every 6 months	*Respiratory and skin infections* Infusion reaction, possible malignancies and teratogenicity
teriflunomide (Aubagio)	PO: 7–14 mg once daily	*Alopecia, diarrhea, influenza, nausea, paresthesia* Severe hepatotoxicity, teratogenicity, leukopenia, severe skin reactions

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

abscess formation. The recent development of oral drugs for MS will likely lead to additional first-line drugs that slow the progression of the disease.

PROTOTYPE DRUG Interferon Beta-1b (Betaseron, Extavia)

Classification **Therapeutic:** Drug for relapsing forms of multiple sclerosis
Pharmacologic: Immunomodulator

Therapeutic Effects and Uses: Approved in 1993, interferon (IFN) beta-1b is produced by recombinant DNA technology and is very similar to natural IFN. It was one of the first drugs developed that was found to slow the progression of MS. Patients taking IFN beta-1b experience fewer relapses and a reduction in brain lesions characteristic of MS. This drug is available by subcutaneous injection for the treatment of patients with relapsing MS.

Mechanism of Action: The mechanism of action by which IFN beta-1b produces improvements in the symptoms of MS is unknown. It is believed to act by suppressing the activity of T cells and reducing the inflammatory actions of cytokines, which are substances secreted by activated T cells.

Pharmacokinetics:

Route(s)	Subcutaneous
Absorption	50% absorbed
Distribution	Crosses the blood–brain barrier poorly; crosses placenta and enters breast milk
Primary metabolism	Rapidly metabolized in body tissues
Primary excretion	Unknown
Onset of action	6–12 h
Duration of action	Half-life: 8 min–4 h

Adverse Effects: Adverse effects are very common with IFN beta-1b. Most patients taking interferon beta-1b will experience transient flulike symptoms: Analgesics and antipyretics may be premedicated on injection days to reduce these symptoms. Injection-site reactions also occur in the majority of patients. Patients should be monitored closely for depression and suicidal ideation. Injection-site inflammation occurs in most patients and may progress to necrosis. Other common adverse effects include leukopenia, headache, insomnia, asthenia, increased liver enzymes, rash, peripheral edema, and malaise.

Contraindications/Precautions: The only contraindication is history of hypersensitivity to interferon beta, albumin, or mannitol.

Drug Interactions: Zidovudine (AZT) levels may increase to toxic levels during therapy. **Herbal/Food:** None known.

Pregnancy: Category C.

Treatment of Overdose: Treatment for overdose of this drug has not been documented.

Nursing Responsibilities: Key nursing implications for patients receiving interferon beta-1b are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Neurodegenerative Disorders.

Drugs Similar to Interferon Beta-1b (Betaseron, Extavia)

Other drugs used to treat the relapsing symptoms of MS are alemtuzumab, daclizumab, dimethyl fumarate, fingolimod, glatiramer, IFN beta-1a, mitoxantrone, natalizumab, and teriflunomide.

Alemtuzumab (Lemtrada): Alemtuzumab is a monoclonal antibody against CD52 approved in 2014 for relapsing forms of MS. Because of the potential for serious adverse effects, it is used for patients who have had an inadequate response to at least two other MS medications. It is given by two IV infusions, 12 months apart. Because nearly all patients experience infusion reactions, premedication with a high-dose corticosteroid just prior to alemtuzumab dosing is necessary. This drug comes with several black box warnings including an increased risk for cytopenias (including fatal pancytopenia), infusion reactions (some of which have been fatal), serious infections (including *Pneumocystis jiroveci*), and malignancies (including thyroid cancer, melanoma, and lymphoproliferative disorders). This medication is pregnancy category C.

Daclizumab (Zinbryta): Approved in 2016, daclizumab is a monoclonal antibody that blocks the interleukin-2 receptor called CD25. Because of the potential for serious adverse effects, it is reserved for patients who have had an inadequate response to at least two other MS medications. The medication carries black box warnings regarding an increased risk for hepatic injury and immune-related disorders. Its use is contraindicated in patients with preexisting hepatic impairment or a history of autoimmune disorders. Prescribers must complete special training and pharmacies must be certified to dispense daclizumab. The drug has not been assigned a pregnancy category.

Dimethyl fumarate (Tecfidera): Approved in 2013, dimethyl fumarate is used for treating relapsing forms of MS. Given PO, its mechanism of action is unknown. Adverse effects include mild to moderate flushing, abdominal pain, diarrhea, and nausea. Lymphocyte counts should be monitored during therapy because dimethyl fumarate can cause significant lymphopenia. This drug is pregnancy category C.

Fingolimod (Gilenya): Approved in 2010, fingolimod has a unique mechanism of action in that it blocks the capacity of lymphocytes to exit lymph nodes. Because they remain in the nodes, there are fewer lymphocytes in peripheral tissues, including the CNS. The drug can reduce lymphocyte counts to 60% of baseline values within 4 to 6 hours after a single dose. Fingolimod is approved for the treatment of patients with relapsing forms of MS. A major advantage is that the drug is given PO with once-daily dosing. Unfortunately the drug has the potential to cause serious dysrhythmias: Patients must be carefully monitored for bradycardia and other cardiac rhythm abnormalities during therapy. Due to the diminished lymphocyte count, patients are at risk for infections. Macular edema is an adverse effect that is especially troublesome in patients with a history of uveitis or diabetes. The most common adverse effects are headache, influenza, diarrhea, back pain, cough, and elevated liver transaminase levels. Fingolimod is pregnancy category C.

Glatiramer (Copaxone, Glatopa): Approved in 1996, glatiramer is one of several first-line drugs in the treatment of relapsing MS, including patients who have experienced their initial clinical episode of the disease. The drug reduces the annual relapse rate for MS and the generation of new lesions in the brain. It is believed to dampen the immune response by activating suppressor T cells. It is administered daily by the subcutaneous route. The most common adverse effects are injection-site reactions, vasodilation, weakness, dyspnea, and chest pain, which are usually transient. The drug is pregnancy category B.

IFN beta-1a (Avonex, Rebif) and PEG IFN beta-1a (Plegridy): Approved in 1996, IFN beta-1a is structurally identical to the natural IFN produced by the body. IFN beta-1a decreases the frequency of clinical exacerbations and slows the progression to physical disability. The drug acts

by inhibiting the release of proinflammatory cytokines that initiate the autoimmune reaction leading to MS. IFN beta-1a also changes the blood–brain barrier and reduces T-lymphocyte migration into the brain, thereby reducing inflammation. It is available by the subcutaneous (Rebif) and IM (Avonex) routes. Peginterferon beta-1a (Plegridy) has the same actions but has a longer duration of action that allows for dosing once every 2 weeks. Adverse effects are similar to those of other IFNs, with flulike symptoms being observed in the majority of patients. Patients should be monitored for depression and suicidal ideation. Decreased peripheral blood counts, including thrombocytopenia and leukopenia, have been reported. Rare cases of severe hepatotoxicity, including some cases requiring liver transplantation, have been reported in patients taking IFN beta-1a. In 2014 the long-acting form of the drug, Plegridy, was approved. This drug is pregnancy category C.

Mitoxantrone (Novantrone): Mitoxantrone is an immunomodulator that is approved to treat acute myelogenous leukemia, prostate cancer, and chronic, progressive relapsing forms of MS. In treating MS, mitoxantrone acts by suppressing B and T lymphocytes and macrophages. Fatigue and GI-related adverse effects are common. The most serious toxicities are myelosuppression and cardiotoxicity. The drug carries a black box warning that it may result in potentially fatal heart failure as long as several years after therapy is discontinued. It is only administered by IV infusion. This drug is pregnancy category D.

Natalizumab (Tysabri): Natalizumab is a monoclonal antibody that acts by preventing white blood cells from migrating to the CNS. This inhibition reduces the inflammation and demyelination of nerves in the brain. It is administered by IV infusion. Although effective for treating MS, its use is severely restricted due to a small risk of progressive multifocal leukoencephalopathy (PML), a rare and sometimes fatal demyelinating disease of the CNS. Restrictions limit the prescribers to those who have special training in PML. In addition, only certain pharmacies can distribute the drug. The drug carries a black box warning for its risk of producing PML. Additional details on the monoclonal antibody class of drugs may be found in Chapter 42. Natalizumab is pregnancy category C.

Ocrelizumab (Ocrevus): Approved in 2017, ocrelizumab is a monoclonal antibody that binds to the CD20 receptor on B lymphocytes. The binding results in the immune destruction of these cells. It is the only drug approved to treat primary progressive MS, a form of the disease that steadily worsens, without relapses. The most common adverse effects include infusion reactions, respiratory infections, and skin infections. An increased risk of malignancies has been reported. The drug is not pregnancy rated but animal data suggests it may cause fetal harm.

Teriflunomide (Aubagio): Approved in 2012, teriflunomide is an oral drug for treating relapsing forms of MS. It is an active metabolite of leflunomide (Arava), a drug for treating rheumatoid arthritis. Teriflunomide acts by suppressing the division of B and T cells. Teriflunomide is generally well tolerated; however, some serious toxicities are associated with the drug. It carries a black box warning that severe, and sometimes fatal, liver injury may occur. In addition, the drug may cause birth defects and is pregnancy category X. This drug is eliminated very slowly and may take 8 to 24 months to be completely excreted from the body.

Drugs for treating acute exacerbations of MS: Acute exacerbations of the disease are treated with high-dose corticosteroid therapy with prednisone or methylprednisolone. The recommended length of treatment is no longer than 3 weeks and no more than 3 times a year. Although very high doses are administered, the short-term use of corticosteroids does not usually cause significant adverse effects (see Chapter 68). Another drug that can be used to treat an acute exacerbation is IV gamma globulin. This has proven to be a successful treatment for patients who are unresponsive or unable to tolerate corticosteroids.

Drugs for managing symptoms of MS: Many classes of medications may be ordered to manage symptoms of MS including antianxiety drugs, antidepressants, antipsychotics, or sedative–hypnotics. These symptomatic medications are used to treat other conditions and are discussed in other chapters of this text. The patient may experience physical symptoms such as muscle spasticity or bladder or bowel dysfunction. Depression is common; it may be the emotional response to a diagnosis of a chronic, progressive, potentially debilitating disease, or it may be secondary to damage to mood-regulating neurons as the disease progresses. Chronic pain may require the use of analgesics. Approved in 2010, dalfampridine (Ampyra) is specifically indicated to improve walking in patients with MS.

Pain is experienced in up to 86% of patients with MS but it is not always well classified. Research is ongoing to develop a classification system (Truini, Barbanti, Pozzilli, & Cruccu, 2013). Determining the cause of pain leads to more effective treatment strategies. For example, neuropathic pain caused by plaques in the spinal cord may respond to drugs such as amitriptyline or carbamazepine. Pain due to muscle spasms related to MS may be treated with baclofen and gabapentin. Because many patients with MS have mixed types of pain, thorough assessment is needed in order to determine the most effective therapy.

PharmFACT

Although it most commonly occurs in adults, it is estimated that 8,000 to 10,000 children have MS in the United States. Children have symptoms similar to those of adults but present with a higher incidence of seizures and mental status changes (National Multiple Sclerosis Society, n.d.).

Amyotrophic Lateral Sclerosis

21.12 The pharmacotherapy of amyotrophic lateral sclerosis is limited to a few drugs.

Amyotrophic lateral sclerosis (ALS), commonly known as Lou Gehrig's disease, is the most common degenerative disease of the motor neurons. Its symptoms include weakness and atrophy of the muscles of the legs, hands, and forearms that spread to all muscles of the body. Sensory and cognitive functions are not affected. It usually occurs in middle age and progresses rapidly to death in 2 or 3 years due to respiratory failure or pneumonia. There is no known cause or curative treatment for the disease. About 10% of cases have a familial history of the disorder.

Few drugs have FDA approval for treating patients with ALS, and none of them is able to cure the disease. Approved in 1995, riluzole (Rilutek) has been shown to extend survival by reducing the degeneration of neurons. It is estimated that survival is prolonged by only 3 months. Riluzole is a tablet that is given every 12 hours on an empty stomach. Seizures are the only life-threatening adverse effect. Common adverse effects include headache, dizziness, poor concentration, confusion, anxiety, hypotension, and edema.

Approved in 2017, edaravone (Radicava) has been shown to slow the progression of ALS and help individuals to preserve function for a longer period of time. Administered by IV infusion, edaravone is administered for 14 consecutive days, followed by a 2-week drug-free period. All cycles thereafter are infused for 10 days, followed by a 2-week drug-free period. The most common adverse effects include bruising, difficulty walking, and headache. This drug is not pregnancy rated but it may cause fetal harm based on animal data.

The patient with ALS experiences painful muscle spasticity. Treatment with muscle relaxants such as baclofen (Lioresal) may bring some relief (see Chapter 23). Anticholinergic drugs such as trihexyphenidyl or benztropine may be administered to decrease saliva production. RimabotulinumtoxinB (Myobloc) may be used off-label to reduce saliva secretion for up to 3 months. Opioids may be necessary to treat severe pain late in the progress of the disease.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Neurodegenerative Disorders

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, musculoskeletal diseases, or glaucoma. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a history of the current disease and symptoms, exacerbating conditions, and ability to carry out ADLs, particularly mobility and eating. Consider safety concerns and whether alternative care environments are needed.
- Evaluate appropriate laboratory findings such as hepatic or renal function studies.
- Obtain baseline vital signs, bowel sounds, urinary output, muscle strength, and mental status as appropriate.
- Assess for disturbances in thought processes, perception, verbal communication, affect, behavior, interpersonal relationships, and self-care. Use objective screening tools such as the Movement Disorder Society Unified Parkinson's Disease Rating Scale (MDS-UPDRS), the Mini-Mental State Examination (MMSE), or as per healthcare agency.
- Obtain a history of depression or sleep disorders and current treatments used.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased tremors, bradykinesia, or rigidity, decreased agitation, fearfulness, and maintenance of current functioning level).
- Continue periodic monitoring of vital signs, mental status, motor function, and the ability to carry out ADLs.
- Assess for and promptly report adverse effects: hypotension, increasing tremors, dizziness, salivation, anorexia, dysphagia, nausea, vomiting, diarrhea, changes in heart rate or rhythm, or changes in mental status, including agitation or confusion.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue frequent assessments as above for therapeutic effects. Drug therapy may take several weeks or months to have full effect. Support the patient in self-care activities as necessary until improvement is observed. (The ability to carry out ADLs gradually improves with consistent usage of drug therapy in PD. Continued tremors, rigidity, or other symptoms may require dosage adjustment. Symptoms help determine the stage of the disease in AD and whether the medication remains therapeutic.)	• Teach the patient, family, or caregivers that gradual improvement in PD symptoms may be noted. The patient should report continued or increasing symptoms similar to those noted before drug therapy was initiated. • In AD, teach the patient, family, or caregivers that these drugs delay the progression of symptoms but do not treat or cure the underlying disease process. Increasing symptoms or a decrease in the ability to perform self-care activities should be reported.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Ensure patient safety; monitor motor coordination and ambulation, eating, or other essential motor activities. **Lifespan:** Be particularly cautious with older adults who are at increased risk for falls. (Gradual improvement in symptoms may be noticed over time, but the drug does not cure the underlying disorder, and symptoms may wax and wane over the course of the drug regimen. Particular care with ambulation is required in PD because bradykinesia and rigidity may increase the risk of falls.)	• Instruct the patient with PD to call for assistance prior to getting out of bed or attempting to walk alone if bradykinesia, rigidity, or tremors are particularly severe. • Assess the ability of the patient, family, or caregivers to safely carry out ADLs at home, including previously safe activities such as cooking, walking alone, and living alone. Report changes that may require early intervention to the provider. Explore the need for additional healthcare referrals.
• Continue to monitor vital signs. Take blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be particularly cautious with older adults who are at increased risk for hypotension. Notify the healthcare provider if blood pressure decreases beyond established parameters or if hypotension is accompanied by reflex tachycardia. (Orthostatic hypotension is a common adverse effect and may increase the risk of falls or injury.)	• Teach the patient to rise from lying to sitting or standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes.
• Monitor for behavioral changes. (Drug therapy may increase the risk of agitation, confusion, depression, or suicidal thoughts, and may cause other mood disturbances such as aggressive behavior.)	• Teach the patient, family, or caregivers to watch for and report immediately any signs of changes in behavior or mood such as increased aggression or confusion. Provide additional healthcare referrals as required for a support group, counseling, or respite care.
• Carefully evaluate and report dose-related symptoms such as increased tremors and rigidity before the next dose is due or greatly increased symptoms unrelated to the timing of dose. (In PD, the return or gradual increase of symptoms as the next dose comes due may signal a wearing-off effect and the dose may need to be increased, the interval of dosage adjusted, or an adjunctive drug added. A significant and sudden increase in symptoms may signal an overdose or on–off syndrome where symptoms dramatically increase. If symptoms are significant, hospitalization may be required to assess for the reason behind the exacerbation.)	• Instruct the patient, family, or caregivers to be aware of newly occurring muscle twitching, including blepharospasm (in the muscles of the eyelids), greatly increasing tremors, rigidity, sweating, or other symptoms, and to report them immediately. • Encourage the patient, family, or caregivers to maintain a symptom diary if effects seem to diminish as the next dose is due. Review the diary with the patient on each healthcare visit.
• Evaluate nutritional intake. (Absorption of levodopa taken for PD decreases with high-protein meals or high consumption of foods or vitamins that contain vitamin B_6 [pyridoxine]. Symptoms may dramatically increase if absorption is impaired because the dose does not adequately absorb during the expected time. Patients with neurodegenerative disease may eventually experience difficulty in feeding themselves or with swallowing. Weigh the patient weekly to assess the effects of dietary intake.)	• Teach the patient to take medication for PD on an empty stomach or to avoid taking it with a high-protein meal. Avoid excessive consumption of vitamin B_6-rich foods such as bananas, wheat germ, fortified cereals, green vegetables, meat, and legumes, and avoid multivitamins that contain vitamin B_6. • Teach the family or caregivers to assist the patient with AD with eating and to offer fluids on a regular basis.
• Monitor hepatic and renal function laboratory values periodically. (A decrease in these functions may slow metabolism and excretion of the drug, possibly leading to overdose or toxicity.)	• Teach the patient, family, or caregivers about the importance of returning for follow-up laboratory studies.
• Monitor for other drug-related changes. (PD replacement drug therapy may cause darkening of urine and perspiration.)	• Advise the patient that urine or sweat may darken and that undershirts or dress shields may help to avoid staining of clothing.
• Evaluate the family or caregivers for signs of stress, fatigue, or other effects related to caring for the patient with a neurodegenerative disease. (Caring for a patient with neurodegenerative disease is challenging and difficult. Additional social and financial resources may be needed, including alternative care environments.)	• Encourage the family or caregivers to discuss concerns related to their own health, financial status, or other issues. • Provide additional healthcare referrals as required for a support group, counseling, or respite care.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregivers should be able to state the reason for the drug, appropriate dose and scheduling, and what adverse effects to observe for and when to report them.
Patient self-administration of drug therapy: • When administering the medications, instruct the patient, family, or caregiver in proper self-administration of the drugs and the need for regular, consistent dosing. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration guidelines. Encourage the patient, family, or caregivers to maintain a medication log, noting symptoms or adverse effects along with the dose and timing of medications. • Patients taking injectable drug forms for the treatment of MS (e.g., interferon beta-1b [Betaseron]) should report increasing redness, pain, or blackening of the injection site, which may indicate that tissue necrosis is occurring.

Understanding Chapter 21

Key Concepts Summary

21.1 Degenerative diseases of the central nervous system are characterized by irreversible and progressive loss of neuronal function.

21.2 Parkinson's disease is a progressive neurodegenerative disorder characterized by abnormal motor movement.

21.3 Parkinson's disease is caused by a lack of sufficient amounts of dopamine produced by the substantia nigra.

21.4 The drugs used for Parkinson's disease help to alleviate symptoms but do not cure the disease.

21.5 Replacement therapy with levodopa is the most effective therapy for treating Parkinson's disease.

21.6 Dopamine agonists may be used as monotherapy for early symptoms of Parkinson's disease or as adjuncts to levodopa in patients with advanced disease.

21.7 Several miscellaneous dopaminergic drugs are used as adjuncts to levodopa therapy.

21.8 Anticholinergic drugs are the oldest of the antiparkinson drugs and are effective at reducing tremor.

21.9 Alzheimer's disease, the most common dementia, leads to a progressive loss of cognitive function.

21.10 Pharmacotherapy of Alzheimer's disease produces only modest results and is ineffective at stopping the progression of the disorder.

21.11 Multiple sclerosis is a chronic, neurodegenerative disease that is treated with immunomodulator drugs.

21.12 The pharmacotherapy of amyotrophic lateral sclerosis is limited to a few drugs.

CASE STUDY: Making the Patient Connection

Remember the patient "Mary Lee" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Mary Lee is a 76-year-old retired high school principal with a PhD in educational administration. She has been married to Robert for almost 50 years, and they have three grown children who live within 25 miles of them. Mary's physical health has been good. She has mild hypertension and had colon cancer successfully removed 20 years ago. She has an annual physical examination and cancer screenings as recommended for her age. Robert makes an appointment with Mary's healthcare provider, because he has noticed signs of decreasing mental acuity over the past year. Mary's physical examination is negative, but the healthcare provider suspects that she is experiencing the early stage of AD. Mary is started on Aricept, 5 mg at bedtime.

Critical Thinking Questions

1. What information should be included in the initial assessment by the nurse and the provider in order to determine a diagnosis for Mary?
2. What recommendations will the healthcare provider most likely make to Mary and her husband?
3. What should Robert be alert for with regard to the donepezil?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Michael, at 45 years of age, could not believe his ears when the healthcare provider told him he had PD. "Isn't that an old person's disease?" he asked. However, he knew something had been very wrong for about 3 months. At first he felt more tired than usual, and he noticed a slight tremor, especially when he became fatigued. Michael's wife pointed out that his "hand shakes" were getting worse. Like many people first diagnosed with a degenerative

nervous system disease, Michael has many questions and concerns. Following are just a few of his questions. As his nurse, how would you respond?

1. What physiologic problem causes PD and what is the etiology of this disease? How could a nurse describe this etiology to Michael?
2. Eventually, Michael is prescribed levodopa and carbidopa (Sinemet) for his parkinsonism. How does this medication work? What is the advantage of combining the two medications?
3. What drug-related adverse effects would you discuss with Michael?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The patient is receiving levodopa and carbidopa for parkinsonism. Which drug would the nurse expect to be added to the patient's drug regimen to help control tremors?
   1. Amantadine (Gocovri)
   2. Benztropine (Cogentin)
   3. Haloperidol (Haldol)
   4. Donepezil (Aricept)

2. Which statement, if made by the patient, would alert the nurse that the antiparkinson medication is effective?
   1. "I'm sleeping a lot more, especially during the day."
   2. "My appetite has improved."
   3. "I'm able to shower by myself."
   4. "My skin doesn't itch anymore."

3. The nurse is counseling the caregivers of a patient with Alzheimer's disease. Which statement, if made by a caregiver, would indicate that the session had been effective?
   1. "I should give this medication as symptoms of Alzheimer's disease become noticeable."
   2. "If constipation occurs, I will notify the healthcare provider immediately."
   3. "The medication may improve symptoms but will not cure the disease."
   4. "I will take the patient's vital signs before every dose of the medication."

4. The nurse knows that the use of donepezil (Aricept) to treat the symptoms of early Alzheimer's disease has which of the following advantages? (Select all that apply.)
   1. It is not associated with hepatotoxicity.
   2. It is taken once per day.
   3. It may be used safely in patients with peptic ulcer disease.
   4. It may be used safely in patients with cardiac disease.
   5. It may increase the time between diagnosis and when memory care is needed.

5. The nurse knows an advantage to rivastigmine (Exelon) over other cholinesterase inhibitors is that it:
   1. Has no significant drug interactions.
   2. Does not cause cholinergic adverse effects.
   3. Is absorbed best on an empty stomach.
   4. Does not alter glucose control in patients with diabetes.

6. Interferon beta-1b (Betaseron) has been ordered for the patient with MS. The nurse will instruct the patient on possible adverse effects that may be managed symptomatically by the patient. These include (select all that apply):
   1. Flulike symptoms.
   2. Insomnia.
   3. Depression.
   4. Rashes.
   5. Pain at the injection site and blackening of the surrounding skin.

Chapter 22
Pharmacotherapy of Seizures

Chapter Outline

- Characteristics of Seizure Disorders
- Classification of Seizure Disorders
  - Generalized Seizures
  - Partial Seizures
- Antiepileptic Drugs
  - Barbiturates
  - Benzodiazepines
    - **PROTOTYPE** *Diazepam (Valium), p. 342*
  - Hydantoins
    - **PROTOTYPE** *Phenytoin (Dilantin, Phenytek), p. 344*
  - Dibenzazepines
    - **PROTOTYPE** *Carbamazepine (Carbatrol, Tegretol, Others), p. 346*
  - Succinimides
    - **PROTOTYPE** *Ethosuximide (Zarontin), p. 347*
  - Miscellaneous Antiepileptics
    - **PROTOTYPE** *Gabapentin (Neurontin), p. 348*
    - **PROTOTYPE** *Valproic Acid (Depacon, Depakene, Depakote), p. 349*
  - Other Miscellaneous Drugs

Learning Outcomes

After reading this chapter, the student should be able to:

1. Understand the causes of epilepsy.
2. Differentiate among the following terms: *epilepsy*, *seizures*, and *convulsions*.
3. Describe how the presentation and pharmacotherapy of epilepsy change throughout the lifespan.
4. Differentiate the signs, symptoms, and treatment of the different types of seizure disorders.
5. Compare and contrast the pharmacotherapy of generalized and partial seizures.
6. Identify factors that influence the selection of a specific antiepileptic drug by the healthcare provider.
7. Describe the nurse's role in the pharmacologic management of seizures.
8. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
9. Apply the nursing process to care for patients receiving pharmacotherapy for seizures.

Key Terms

absence seizures, 335
atonic seizures, 335
automatisms, 336
complex partial seizures, 336
convulsions, 332
eclampsia, 333
epilepsy, 331
febrile seizures, 336
generalized seizures, 334
infantile spasm, 336
Lennox–Gastaut syndrome, 336
myoclonic seizures, 335
partial (focal) seizures, 335
postictal state, 335
preeclampsia, 333
seizure, 331
simple partial seizures, 335
status epilepticus, 336
tonic–clonic seizures, 334

The word *epilepsy* is derived from the Greek word *epilepsia*, meaning "to take hold" or "seize." Epilepsy is a neurologic condition characterized by recurrent seizures that affects approximately 2 million Americans. Research in the past two decades has resulted in the development of new drugs to treat epilepsy and other seizure disorders. In this chapter the student will study the current medications for seizures and understand the nurse's role in the administration and patient education associated with the medication regimen.

Characteristics of Seizure Disorders

22.1 Epilepsy is characterized by recurrent seizures caused by disturbances in the electrical activity of the brain.

Epilepsy is a disruption of the activity of clusters of neurons in the brain that is characterized by two or more seizures. A **seizure** is a disturbance of the brain's electrical activity that may result in loss of consciousness, sensory malfunction, and an alteration in motor activity. The many diverse symptoms of seizure are caused by abnormal neuronal discharges within the different regions of the brain. Abnormal neuronal discharges can be measured as sharp spikes or waves on an electroencephalogram (EEG), which is a valuable tool in diagnosing seizure disorders.

When a patient presents with symptoms of a seizure, it is important to identify the cause of seizure activity so that an appropriate treatment plan can be implemented. Epileptic seizures are sometimes symptoms of an underlying disorder such as a brain tumor, head trauma, brain aneurysm, stroke, alcoholism, or infectious disease of the brain. The diagnosis of epilepsy always begins with a search for an underlying disorder that could explain the seizures. Table 22.1 lists common etiologies for seizure disorders. Successful treatment of the underlying condition often eliminates the seizure activity. If a brain abnormality remains after the acute seizure has resolved, recurrent seizures are likely.

In 50% to 70% of cases, the etiology of a seizure is idiopathic; no specific cause can be identified. These patients

Table 22.1 Etiology of Seizure Disorders

Etiology	Pathophysiology
Fever	Rapid increase in body temperature may result in febrile seizure. This is particularly noted in infants and toddlers.
Infectious disease	Meningitis and encephalitis, which are infections of the brain, result in brain inflammation and seizure development.
Metabolic disorders	Alteration in the fluid and electrolyte levels can result in seizure development. Hypoglycemia, hyponatremia, and water intoxication contribute to the alteration in electrical impulse transmission at the cellular level.
Miscellaneous causative agents	Medication used to treat mood disorders and psychotic episodes and local anesthetics produce increased levels of stimulatory neurotransmitters or toxicity. Drug abuse, such as cocaine addictions, alters the neurotransmitters in the brain and produces seizures. Alcohol and sedative–hypnotic drug withdrawal can result in seizure activity.
Neoplastic disorders	Both benign and malignant brain lesions, particularly those that grow rapidly, prevent adequate oxygenated blood supply to the brain tissue and contribute to increased intracranial pressure, which results in seizure development.
Trauma	Head injuries may result in increased intracranial pressure, which results in seizure development. Exposure to toxic fumes or substances, or ingestion of poisons, can result in trauma to brain tissue and resultant seizures.
Vascular disorders	Hypoxia of brain tissue disrupts the electrical transmission of impulses contributing to seizure development. Carbon monoxide poisoning reduces the oxygen-carrying ability of the blood and results in cerebral hypoxia. The related ischemia of brain tissue alters the electrical transmission of impulses and contributes to seizure development. Other vascular causes of seizures include hypotension, stroke, shock, and cardiac dysrhythmias.

may have a lower tolerance to environmental triggers, and seizures may occur when they are sleep deprived, are exposed to strobe or flickering lights, or have a fluid and electrolyte imbalance. Diagnostic tests such as complete blood count (CBC), serum lead levels, and blood glucose are important in excluding the systemic causes of seizures. Virtually anything that changes the homeostatic environment of neurons in the brain has the potential to cause seizures, thus complicating the diagnosis and treatment of epilepsy.

It is important to distinguish between the terms *convulsion* and *seizure*. Most often, patients associate epilepsy with **convulsions**, which are involuntary, violent spasms of the large skeletal muscles of the face, neck, arms, and legs. Convulsions are a characteristic sign of tonic–clonic seizures. Many forms of epilepsy, however, do not involve convulsions. For example, absence seizures do not involve any dramatic movement of the limbs and may be barely noticeable by those observing the affected individual. Thus, it may be stated that all convulsions are seizures, but not all seizures are convulsions. Because of this difference, drugs used to treat epilepsy are best described as antiepileptic drugs (AEDs) or antiseizure medications, rather than anticonvulsants.

PharmFACT

Adults with early Alzheimer's disease who have epilepsy present with cognitive decline almost 7 years earlier (age 64) than those who do not have epilepsy (age 71). The start of seizure activity coincides with the beginning of cognitive decline (Vossel et al., 2013).

Seizures have the potential to significantly impact one's quality of life. They may cause serious injury if they occur while someone is driving a vehicle or performing a potentially hazardous activity. Without pharmacotherapy, epilepsy can severely limit participation in school, employment, and social activities and affect self-esteem. Chronic depression may accompany poorly controlled seizures. Proper treatment, however, can reduce or completely eliminate seizures in many patients. Important considerations in nursing care include identifying patients at risk for seizures, documenting the pattern and type of seizure activity, and implementing safety precautions. In collaboration with the patient, healthcare provider, and pharmacist, the nurse is instrumental in achieving positive therapeutic outcomes during AED therapy. The nurse must educate patients that effective seizure control is usually achieved through a combination of pharmacotherapy and support from family and caregivers.

22.2 Seizure disorders differ throughout the lifespan.

Seizure disorders occur throughout the lifespan. Of those who experience seizures, about half will experience their first seizure before age 10. Because of this, epilepsy is considered a major disorder of childhood. Fortunately, many patients who have childhood epilepsy experience a reduction in symptoms as they age, and some will no longer require pharmacotherapy as adults. In addition to childhood, epilepsy manifests with higher frequency during pregnancy and in older adults. Treatment of epilepsy differs throughout the lifespan.

Women, pregnancy, and lactation: The pharmacotherapy of epilepsy in women with childbearing potential can be challenging. These patients require special education to prevent conception during AED pharmacotherapy or to safely prevent seizures during pregnancy.

Some AEDs interact with oral contraceptives, diminishing the effectiveness of birth control pills. AEDs that are inducers of hepatic CYP450 enzymes will increase the metabolism of contraceptive hormones, thus decreasing their effectiveness in preventing conception. Antiseizure drugs that induce CYP450 include phenobarbital, carbamazepine, oxcarbazepine, topiramate, and phenytoin. To prevent an unplanned pregnancy, the patient should receive a higher dose of oral contraceptive and be instructed to use a backup method of birth control such as condoms. Therapy with antiseizure drugs that do not induce CYP450 enzymes, such as valproic acid or gabapentin, may be an option for these women.

Pregnancy is a major concern for women with seizure disorders. Women with epilepsy have a higher risk for delivering a child with congenital abnormalities, and many of the AEDs have the potential to produce teratogenic effects. The risk of birth defects is further increased because some AEDs cause folic acid (folate) deficiency, a condition that has been associated with increased risk of neural tube defects in the embryo. Folic acid supplements (0.4–4 mg/day) should always be recommended for women who are considering pregnancy and those who become pregnant. The use of vitamin supplementation will also reduce the risk of developing cardiac abnormalities and cleft lip or palate. Single-drug therapy should be used whenever possible because therapy with multiple AEDs results in a higher risk of birth defects. Doses are reduced to the lowest possible level that effectively controls the seizures. AEDs such as lamotrigine, gabapentin, and zonisamide should be considered because they appear to have a lower risk of teratogenicity.

Women who have epilepsy have a reduced fertility rate. Epilepsy and AEDs can disrupt the hypothalamus–pituitary axis, causing menstrual irregularities. The length of the menstrual cycle in these patients may vary from 23 to 35 days, and 40% of women with epilepsy have polycystic ovaries. Many women who have epilepsy do not ovulate. Genital blood flow is diminished and libido is reduced, contributing to a reduction in the frequency of intercourse.

During pregnancy, some of the enzyme-inducing AEDs cross the placenta and induce hepatic enzyme metabolism in the fetal liver. This decreases the circulating vitamin K levels, posing an increased risk of hemorrhage in the newborn. It is recommended that prenatal vitamin K be prescribed to women who are taking AEDs during pregnancy to prevent hemorrhagic disease in the newborn; 10 to 20 mg of vitamin K should be administered daily during the last 4 months of pregnancy.

Gestational epilepsy is a rare condition in which the patient experiences her first seizure during pregnancy. Seizures in a pregnant patient who has never been diagnosed with epilepsy may indicate the development of preeclampsia or eclampsia. **Preeclampsia** usually begins after the 20th week of pregnancy and is diagnosed by blood pressure of 140/90 mmHg or higher on two separate occasions, and 300 mg of protein is found in the urine over a 24-hour period. The rate of preeclampsia in the United States is approximately 5% to 7% of all pregnancies, affecting about 1 in every 2000 to 3000 deliveries.

Eclampsia occurs when hypertension (HTN) continues to worsen during pregnancy. Eclampsia is associated with seizures and a high risk of cerebral edema, which can result in coma. If the baby is of proper gestational age, delivery is the treatment of choice for eclampsia. When the pregnant woman is diagnosed with preeclampsia or eclampsia and delivery is not imminent, intravenous (IV) magnesium sulfate may be administered to prevent or terminate seizures. Magnesium sulfate acts by decreasing the amount of acetylcholine liberated from the motor nerve terminals and produces a peripheral neuromuscular blockade. It also has the therapeutic effect of increasing uterine blood flow. Because seizures may extend beyond labor and delivery, magnesium sulfate therapy may continue for 24 hours postpartum or until the HTN resolves.

The issue of maternal AEDs during lactation has been addressed by a number of research studies. Many studies have confirmed the safety of AEDs taken during lactation, especially when considering the substantial benefits to the neonate derived from breastfeeding. It is likely that the amounts of AEDs secreted in breast milk are too low to cause ill effects in the baby. Follow-up studies performed 6 years after breastfeeding confirm that breastfeeding does not affect the cognitive development of children exposed to AEDs in breast milk (Haunt, 2016). The exception is valproate, which may have a higher risk than other AEDs.

CONNECTION Checkpoint 22.1

From what you learned in Chapter 8, how does each of the following affect the amount of drug that passes to the infant during lactation: lipid solubility of the drug, drug ionization, and drug half-life? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Childhood: Seizures in children are either idiopathic or acquired. Children with idiopathic seizures often have a

CONNECTIONS: Complementary and Alternative Therapies

The Ketogenic Diet

Description

The ketogenic diet is used when seizures cannot be controlled through pharmacotherapy or when the adverse effects of an AED medication are unacceptable. Before AEDs were developed, this diet was a primary treatment for epilepsy.

History and Claims

The ketogenic diet may be used for babies, children, or adults. With adults, however, it is harder to develop the ketones that are necessary for the diet.

Standardization

The ketogenic diet is a stringently calculated diet that is high in fat, moderate in protein, and low in carbohydrates. It limits water intake to avoid ketone dilution and carefully controls caloric intake. Each meal has the same ketogenic ratio of 4 g of fat to 1 g of protein and carbohydrate. Extra fat is usually given in the form of cream.

Evidence

Research suggests that the diet produces a success rate, in some cases, that is equivalent to that of modern antiepileptic drugs. The diet appears to be equally effective for every seizure type, although those with drop attacks (atonic seizures) may be the most rapid responders. It also helps children with Lennox–Gastaut syndrome and shows promise in babies with infantile spasms. Adverse effects include hyperlipidemia, constipation, vitamin deficiencies, kidney stones, acidosis, and, possibly, slower growth rates.

Not all patients respond to the diet. Several studies suggest that response within the first 3 to 6 months may indicate that the diet has positive results, whereas those patients who fail to respond in that time period are not likely to respond with continued diet therapy for longer periods (Lambrechts et al., 2015; Vehmeijer, van der Louw, Arts, Catsman-Berrevoets, & Neuteboom, 2015).

The parents of children who follow the diet may have conflicted feelings about feeding their children high-fat foods and the controlled nature of the diet. Encouraging parents to view the diet as medicine, planning ways that the family can have similar, ketogenic alternatives that make meals more inclusive, and recognizing that food can have significant meanings, both positive and negative, may make dietary treatment more successful (Webster & Gabe, 2016).

family history of epilepsy or have an associated serious neurologic abnormality, such as mental retardation or cerebral palsy. Febrile seizures are another form of idiopathic seizure that occurs in children under the age of 2 years. Seizures represent the most common serious neurologic problem affecting children, with an overall incidence of approximately 1% for idiopathic epilepsy.

Acquired seizure disorders may result from injury to the brain during the prenatal, antenatal, or postpartum periods. Infants whose mothers have been exposed to cytomegalovirus during pregnancy are at increased risk of developing an acquired seizure disorder. Other causes of acquired seizures include head trauma, metabolic imbalances, exposure to toxins, and infection.

Seizure treatment for infants and children is usually accomplished with pharmacotherapy. The most commonly prescribed pediatric AEDs include phenobarbital, valproic acid, phenytoin, carbamazepine, felbamate, lamotrigine, and topiramate. To maintain optimal seizure control, the dosage of AEDs should be increased during periods of rapid growth and development.

Nonpharmacologic treatments for epilepsy are available. One such alternative therapy is the ketogenic diet. The beneficial effects of this diet occur when ketones are eliminated from the body, thus decreasing seizure activity. Other forms of seizure treatment include surgical intervention with an excision of a circumscribed area of the brain affected by the seizure activity. The implantation of a vagal nerve stimulator in the brain is a type of therapy that delivers electrical signals to the vagus nerve to reduce the frequency of seizures.

Older adults: Seizure disorders in the older adult are often associated with an underlying comorbid condition. Stroke accounts for one third of new-onset cases and is the most common risk factor for the development of epilepsy after age 60. Other conditions associated with epilepsy in the aging patient include progressive Alzheimer's disease, subdural hematoma from a head injury due to falling, central nervous system (CNS) infection, and brain tumors.

Older adults often take multiple medications that can contribute to seizure activity. It is vital to regularly monitor the liver and kidney functions of the older patient when administering multiple medications because impairment may lead to toxic serum drug levels and possible seizures.

The nurse needs to assess the patient's therapeutic response to the AEDs and also monitor the serum drug level. The clinical response should be used to guide the needed dosage changes. When possible, only a single AED is prescribed because the use of multiple AEDs increases the risk of adverse drug events. In most patients, therapy with AEDs begins with low doses followed by careful monitoring for drug effectiveness. Gradual dosage changes are made based on clinical outcomes.

Older patients with memory deficits may have difficulty remembering to take their AEDs. The nurse should teach these patients and their caregivers that these medicines must be taken on a regular basis, at the same time each day, for the most effective seizure prevention. If a dose is forgotten, the nurse should teach these patients not to take a double dose of an AED because this could cause serious CNS toxicity. Furthermore, patients need to understand that waiting until the first sign of a seizure before taking their AED is ineffective at stopping the seizure because the drug will not be absorbed quickly enough.

Classification of Seizure Disorders

22.3 Most seizures are classified as generalized or partial.

Seizures begin with the firing of hyperexcitable neurons in the brain. The area where the abnormal electrical activity starts is known as an abnormal focus (plural = foci). As these neurons discharge impulses, the patient begins to exhibit the characteristic signs and symptoms of epilepsy. The specific symptoms depend on the nature of the discharge: the location of the abnormal focus in the brain and the extent of the discharge. Because symptoms vary widely from patient to patient, there are many ways to classify seizures. It is important to identify and classify the type of seizure experienced by the patient because this determines which drugs will be prescribed. There are two broad categories of seizure activity: generalized and partial. Preferred drugs for the management of seizures are shown in Table 22.2.

Generalized Seizures

In **generalized seizures**, multiple foci spread abnormal neuronal discharges across both hemispheres of the brain simultaneously. The patient often experiences loss of consciousness, and the seizure may occur with or without convulsions. The four primary types of generalized seizures are tonic–clonic seizures, absence seizures, atonic seizures, and myoclonic seizures.

Tonic–clonic seizures, also referred to as grand mal seizures, are the type of seizure most associated by the public with epilepsy. It is the most common type of seizure in every age group. The seizure may be preceded by an aura, a warning that a seizure is imminent, that some patients describe as a spiritual feeling, flash of light, or special noise. Neurologists consider the aura to be part of the actual seizure. Loss of consciousness and intense muscle contractions indicate the tonic phase. A hoarse cry may occur at the onset of the seizure due to air being forced out of the lungs, and patients may temporarily lose bladder or bowel control. Breathing may become shallow and even stop

Table 22.2 Drugs Used for the Management of Seizures

Type of Seizure	First-Line Drugs*	Alternative Drugs
Generalized Seizures		
Absence	ethosuximide, lamotrigine, valproic acid	clonazepam
Atonic	clonazepam, valproic acid	lamotrigine, levetiracetam, topiramate
Myoclonic	valproic acid	clonazepam, lamotrigine, phenobarbital, topiramate
Tonic–clonic	carbamazepine, lamotrigine, valproic acid	clonazepam, diazepam, levetiracetam, oxcarbazepine, phenobarbital, phenytoin, topiramate, zonisamide
Partial Seizures		
Complex partial	carbamazepine, lamotrigine, phenytoin	gabapentin, oxcarbazepine, phenobarbital, pregabalin, tiagabine, topiramate, zonisamide
Simple partial	carbamazepine, lamotrigine, phenytoin, valproic acid	brivaracetam, clorazepate, diazepam, felbamate, gabapentin, levetiracetam, oxcarbazepine, phenobarbital, pregabalin, tiagabine, topiramate, zonisamide
Other Seizures		
Alcohol withdrawal	lorazepam or diazepam	carbamazepine
Febrile	acetaminophen for prophylaxis	diazepam, phenytoin
Infantile spasms	adrenocorticotropic hormone (ACTH)	none
Lennox–Gastaut	benzodiazepines, valproic acid	felbamate, rufinamide
Status epilepticus	lorazepam	diazepam, phenobarbital, phenytoin, valproic acid

*Selection of first-line drugs varies according to patient age and comorbid conditions, prescriber experiences, institution, and geographic region.

momentarily. The clonic phase is characterized by alternating contraction and relaxation of muscles that are characteristic of convulsions. The seizure usually lasts 1 to 2 minutes, after which the patient becomes drowsy and disoriented and sleeps deeply. The period following the seizure is known as the **postictal state**.

Absence seizures, formerly known as petit mal seizures, most often occur in children and last only a few seconds. Approximately half of the patients with absence seizures may also experience at least one tonic–clonic seizure. Absence seizures involve a reduction of normal brain activity. Staring and transient loss of responsiveness are the most common signs, but there may be slight motor activity with eyelid fluttering or muscular jerking movements. These episodes are subtle and can be mistaken for daydreaming or inattention, such as is seen in attention-deficit/hyperactivity disorder (ADHD). Children with absence seizures may experience poor academic performance because these episodes can occur several times per day. Most children who experience absence seizures will "outgrow" the disorder and become seizure free in adulthood.

Atonic seizures are sometimes known as drop attacks, due to the fact that the patient will stumble and fall for no apparent reason. The episode is brief, lasting only a few seconds. The patient loses control of muscle function throughout the body. During the episode of weakness, the patient's head will droop forward or the trunk muscles will not support the patient, thus causing the drop attack. Although the seizure itself causes no serious harm, the patient is at risk of injury due to falls.

Myoclonic seizures are generalized seizures characterized by jerking body movements, usually involving the muscles of the neck, shoulders, and upper arms. Major muscle groups contract quickly, usually for only a few seconds, and patients appear unsteady and clumsy. These patients do not lose consciousness but may fall or drop whatever they might be holding. Most patients with myoclonic seizures also exhibit tonic–clonic or absence seizures, or both. Myoclonic seizures usually begin around puberty and comprise 5% to 10% of all epilepsies. Although these seizures continue for the life of the patient, they can be controlled with pharmacotherapy. Valproic acid has been the traditional preferred drug for myoclonic seizures but newer AEDs such as topiramate and lamotrigine are being increasingly prescribed.

Partial Seizures

Partial (focal) seizures involve a limited portion of the brain, with the abnormal neuronal discharges starting on one side and traveling only a short distance before they stop. Many partial seizures do not involve loss of consciousness or convulsions, although discharge may begin as a partial seizure and become a generalized seizure. Some symptoms are subtle and reflect the simple nature of neuronal misfiring in limited areas of the brain, whereas other symptoms may be more complex.

Simple partial seizures have an onset that begins at a small, regional focus. Patients with simple partial seizures experience a wide array of symptoms depending on the specific region of the brain affected. If the motor cortex is

affected, jerky, rhythmic contractions of a specific muscle group are noted. Seizures affecting the sensory cortex are less noticeable to an observer. Patients may feel for a brief moment that their precise location is vague, they may hear or see things that are not present, or they may have an upset stomach. Senses of hearing, taste, smell, or sensation may be affected. Other patients become emotional and experience a sense of joy, fear, or grief. Consciousness is retained during the seizure, although the patient may express amnesia about the event. Numerous AEDs are available to treat simple partial seizures.

Complex partial seizures (formerly known as psychomotor or temporal lobe seizures) originate from a single focus, usually in the temporal lobe of the brain. Patients exhibit sensory, motor, or autonomic symptoms with some degree of altered or impaired consciousness. Total loss of consciousness may not occur during a complex partial seizure, but a brief period of somnolence or confusion may follow the episode. Complex partial seizures are usually preceded by an aura that may be described as an unpleasant odor or taste, colored spots, unexplained fear, or tingling. Seizures may start with a blank stare and proceed to repetitive arm movements, leg movements, head rolling, chewing, lip-smacking, or swallowing. These repetitive movements are called **automatisms**. Most patients will be unresponsive to verbal commands and act as if they are having hallucinations. Complex partial seizures occur in about 35% of patients with epilepsy. Numerous AEDs are available to treat complex partial seizures.

22.4 Some types of seizures are called special epileptic seizures or are unclassified.

Not all seizure disorders can be classified neatly into the two broad categories of generalized and partial. These "other" types of seizures are referred to as special or unclassified epileptic seizures.

Febrile seizures are most likely to occur in the 3-month to 5-year age group. As many as 5% of children experience febrile seizures. These seizures are associated with high fever and are characterized by tonic–clonic motor activity lasting 1 to 2 minutes with rapid return of consciousness. They usually occur only once during any given illness. Febrile seizures may be generalized (occur once and quickly resolve) or complex partial (occur multiple times in 24 hours and are prolonged). Pharmacotherapy with AEDs is not necessary with most febrile seizures. Prevention of the onset of fever with acetaminophen is the best method for controlling this disorder.

Status epilepticus is a medical emergency that occurs when a seizure continues for more than 30 minutes or when two or more sequential seizures occur without full recovery of consciousness between them. Status epilepticus is sometimes classified as a generalized form of epilepsy because tonic–clonic symptoms are usually exhibited. However, some forms of this disorder do not involve convulsions and may resemble simple partial or complex partial seizures. When generalized tonic–clonic seizures are prolonged or continuous, the time in which breathing is affected by muscle contraction is lengthened and hypoxia may develop. The continuous muscle contraction also can lead to hypoglycemia, acidosis, and hypothermia due to increased metabolic needs, lactic acid production, and heat loss during contraction. If untreated, status epilepticus could lead to brain damage and death. Medical treatment involves administration of AEDs by the IV route. In the home setting, valproic acid or diazepam can be administered by the rectal route.

Infantile spasm, also called West syndrome, usually occurs in the first year of life and is characterized by a sudden bending forward, body stiffening, or arching of the torso. Infantile spasms may occur in clusters, often with several dozen separated by 5 to 30 seconds. Infants who experience infantile spasms often have some degree of mental and developmental delays. Adrenocorticotropic hormone (ACTH) and prednisone are preferred drugs for the treatment of infantile spasms.

Lennox–Gastaut syndrome is considered a mixed seizure that has characteristics of tonic–clonic, atonic, and atypical absence seizures. The cause of this syndrome is unknown. This seizure disorder has a mean age of onset of 26 to 28 months and is often associated with mental retardation and mood instability. In older children, this type of epilepsy is associated with personality disorders and psychotic episodes. The preferred drugs for Lennox–Gastaut syndrome include benzodiazepines and valproic acid, although newer AEDs such as rufinamide are being increasingly prescribed. Seizures associated with Lennox–Gastaut syndrome are often resistant to pharmacotherapy.

22.5 The selection of antiepileptic drug therapy is dependent on seizure type and characteristics.

The choice of AED medication is highly individualized for each patient and is dependent on many factors, including the type of seizure; the patient's medical history, including the characteristics and length of the seizure; the results of the EEG and other diagnostic laboratory studies; and the presence of comorbid medical conditions. To prevent adverse drug effects, the prescriber initially chooses the lowest, effective dose of an AED and increases it as necessary. Serum drug levels may be obtained to assist the healthcare provider in determining the most effective drug concentration. To prevent adverse effects and possible seizure onset, the discontinuation of an AED or significant dose reductions are extended over 6 to 12 weeks. Drugs for the different types of seizures are listed in Table 22.2.

In most cases, effective seizure management can be obtained by using a single AED. If seizure activity continues, the initial drug is gradually discontinued and replaced

by a medication from a different class. Some patients require multiple AEDs for effective seizure control. However, certain AED drug combinations have the potential to increase the incidence of seizures; thus it is important for the nurse to consult current literature for drug compatibility and administration guidelines. At the initiation of pharmacotherapy, the patient must be carefully assessed for adverse effects, particularly increased CNS depression, and advised not to drive or engage in hazardous activities until drug levels have stabilized.

Patients who remain symptom free for prolonged periods often believe that they have "outgrown" their seizures and therefore no longer require medication. Although this may indeed be the case, the nurse should teach patients to never stop taking AEDs without the guidance of their healthcare provider. In general, withdrawal of antiepileptic medications is attempted only after the patient has been seizure free for at least 3 years. The withdrawal of medications requires close monitoring by the patient's healthcare provider, and doses must be reduced slowly, one medication at a time, over a period of several months. If seizures recur during the withdrawal process, pharmacotherapy is resumed with the same medication previously prescribed. The nurse must educate the patient and family to maintain strict adherence to the pharmacotherapy regimen. Periodic serum drug levels can assist the nurse in assessing adherence: Low serum drug levels in a patient claiming to be taking his or her medication may indicate nonadherence to therapy.

Many patients with epilepsy attempt a nondrug treatment, with stress management techniques and prayer being the most common alternative therapies. Other therapies utilized to manage epilepsy include herbal supplements, chiropractic care, acupuncture, and yoga. The implementation of the ketogenic diet can produce positive effects in some patients by decreasing seizure activity. However, the use of alternative therapies alone for the management of epilepsy is not considered effective and should be discouraged by the nurse.

PharmFACT

Contrary to popular belief, it is impossible to swallow the tongue during a seizure, and one should never force an object into the mouth of someone who is having a seizure (Epilepsy Foundation of America, 2014).

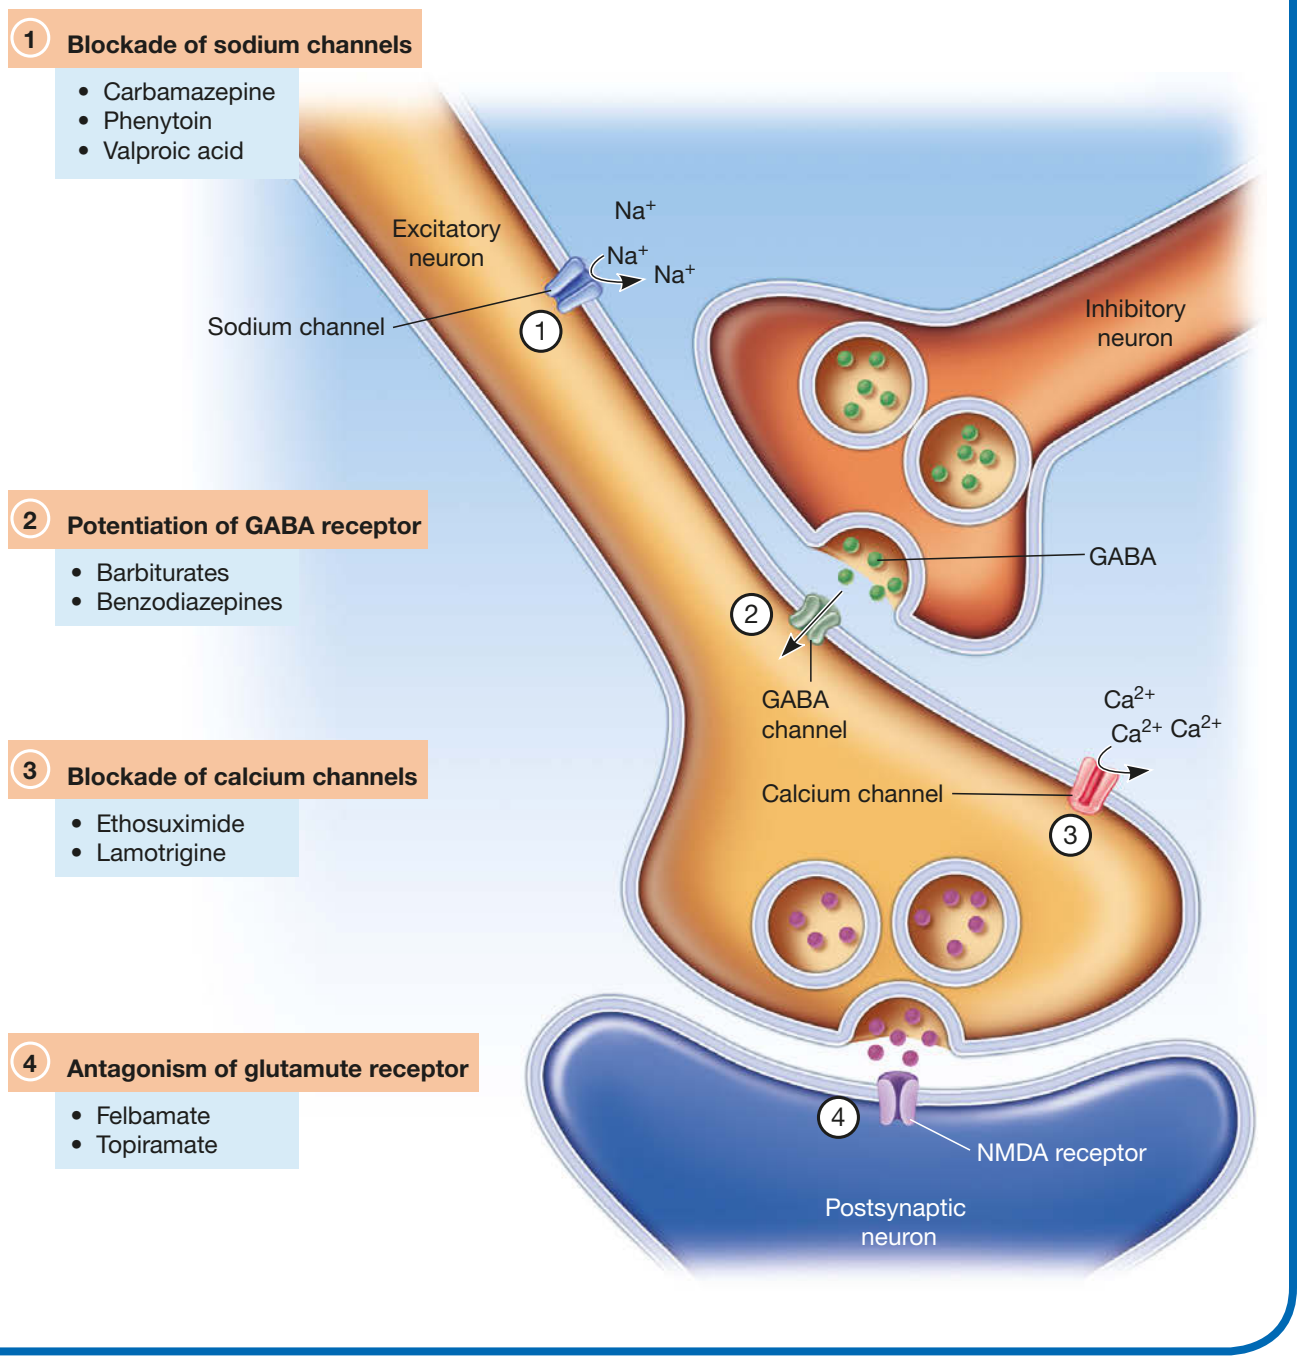
22.6 Antiepileptic drugs act by suppressing abnormal neuronal discharges.

All antiepileptic medications suppress neuron discharges, thus preventing the abnormal focus from forming or spreading across the cerebrum. AEDs suppress abnormal discharges by at least four mechanisms. The study of AEDs is complicated because some of these drugs act through multiple mechanisms, and a few have unknown mechanisms. These mechanisms are shown in Pharmacotherapy Illustrated 22.1. The basic mechanisms are:

- Electrolyte movement
  Inhibition of the influx of sodium into neurons
  Inhibition of the influx of calcium in neurons
- Neurotransmitter balance
  An increase in the activity of GABA in the brain
  Blocking of glutamate receptors in the brain.

Control of electrolyte movement: In their resting state, neurons are surrounded by a high extracellular concentration of sodium, calcium, and chloride ions. Potassium levels are higher inside the cell. An influx of sodium or calcium into the neuron enhances neuronal activity, whereas an influx of chloride ions has an inhibitory effect. This affords several mechanisms to dampen abnormal neuronal activity.

The primary target for many AEDs is the *sodium* channel. The sodium channel on the neuronal plasma membrane must open, allowing sodium to rush into the cell, for an action potential to be generated and propagated. Phenytoin, lamotrigine, and carbamazepine bind to the sodium channel, inactivating it and preventing the passage of sodium ion into the neuron. This slows the excitability of neurons, dampening the flow of abnormal, repetitive discharges.



Calcium channels are found at the synaptic terminals. When opened, calcium enters the presynaptic neuron, causing the release of stored neurotransmitter into the synaptic cleft. Blocking calcium channels prevents the release of the neurotransmitter and dampens impulse conduction. The AEDs believed to block calcium channels include ethosuximide, gabapentin, pregabalin, and lamotrigine.

Neurotransmitter balance: Drugs that enhance or inhibit neurotransmitter activity in the CNS will affect neuronal firing. The neurotransmitter most affected by AEDs is gamma aminobutyric acid (GABA), the primary *inhibitory* neurotransmitter in the brain. Increasing the activity of GABA in the CNS will decrease neuronal firing, thus suppressing seizure activity. AEDs accomplish this suppression by means of several mechanisms, as illustrated in Figure 22.1:

- **Increased synthesis or amount of GABA in the presynaptic nerve terminal.** Some drugs block the metabolic breakdown of GABA or enhance its formation. An example is valproic acid.
- **Activation of GABA receptors.** Some drugs mimic GABA and occupy its receptor on the postsynaptic membrane, causing the same inhibitory effect as GABA. This is achieved by stimulating an influx of chloride ion, which causes the neuron to have greater

Pharmacotherapy Illustrated 22.1

Mechanisms of Action of Antiepileptic Drugs

difficulty achieving an action potential. Examples include barbiturates, benzodiazepines, topiramate, and felbamate.

- **Blocked reuptake of GABA.** After GABA produces its action at the synapse, it is normally pumped back into the presynaptic neuron, which terminates its action. Drugs that block this reuptake will keep GABA on its receptors for a longer time, thus causing more neuronal inhibition. An example is tiagabine.

A second neurotransmitter affected by AEDs is glutamate, the primary *excitatory* neurotransmitter in the brain. By blocking glutamate receptors (known as N-methyl-D-aspartate [NMDA] receptors), these drugs serve as antagonists to glutamate and suppress neuronal firing. Examples include topiramate and felbamate.

Antiepileptic medications are difficult to classify. One method is by mechanism of action; however, many AEDs act by multiple means and a few have unknown

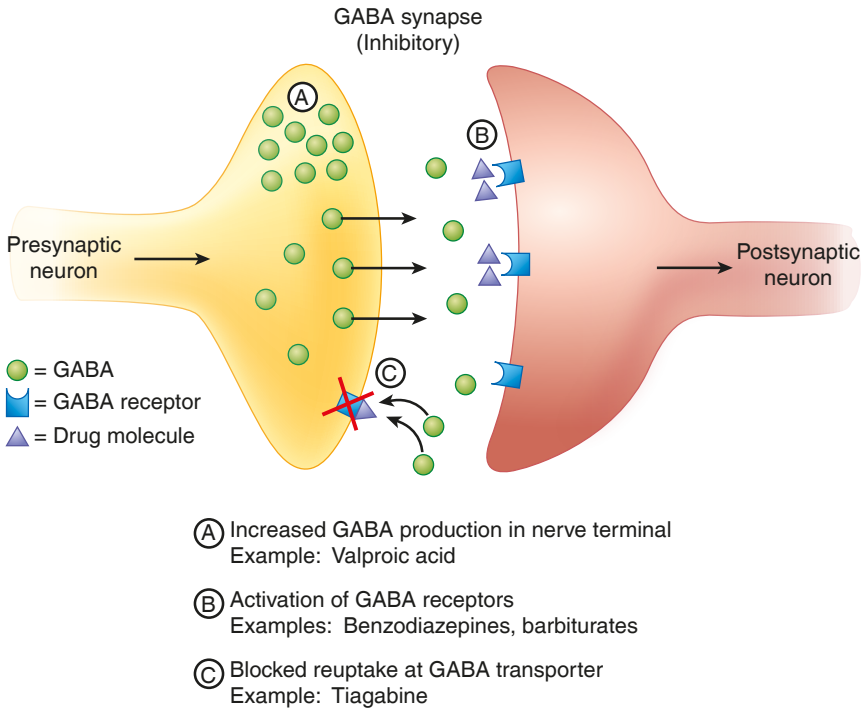


Figure 22.1 Mechanisms of action of antiepileptic drugs that affect GABA.

mechanisms. Another classification scheme groups these drugs into "newer" and "older" generations, but there is no clear distinction between the groups. Grouping by type of seizure is not possible because most of these medications are useful against more than one type. This text uses a combination of chemical classes and mechanisms of action. The student should be aware, however, that other classifications will be encountered in clinical practice. The AEDs are listed in Table 22.3.

Antiepileptic Drugs

22.7 Barbiturates are traditional drugs for tonic–clonic seizures that have been replaced by newer and safer medications.

The barbiturates have been used to treat seizures for almost 100 years. Barbiturates act biochemically in the brain by enhancing the inhibitory action of GABA, the neurotransmitter responsible for suppressing abnormal neuronal discharges.

Although barbiturates are still prescribed for epilepsy, newer drugs have largely replaced them as first-line drugs for this indication. Barbiturates have several major disadvantages. As a class, they have a low margin of safety and can cause profound CNS depression, including sedation, coma, and death. Barbiturates will yield significant sedation when combined with alcohol, antidepressants, and other CNS depressants. Children may exhibit hyperkinesis rather than sedation. Cardiovascular and respiratory adverse effects include respiratory depression, bradycardia, syncope, and hypotension. Patients with impaired hepatic, respiratory, renal, and cardiovascular function should not receive barbiturates, or the doses should be lowered to prevent toxicity. Barbiturates also possess a high potential for drug dependence, and the nurse must be certain that this fact is included as part of patient and caregiver teaching.

This section highlights only the antiseizure properties of barbiturates. These drugs are also classified as sedative–hypnotics, and a prototype feature for phenobarbital can be found in Chapter 18. Nursing responsibilities, lifespan and diversity considerations, and patient and family education for this drug class may also be found in Chapter 18. Mephobarbital was withdrawn from the United States market in 2012.

Phenobarbital: Phenobarbital is effective for long-term management of tonic–clonic seizures and partial seizures. It can be administered in patients with status epilepticus or febrile seizures or to treat eclampsia. It is relatively ineffective in treating absence seizures. Phenobarbital has largely been replaced by safer AEDs, although it is still considered an important drug for neonatal seizures.

Oral (PO) administration of phenobarbital may take several weeks for an optimal level of antiseizure activity to be achieved. The advantages of phenobarbital are that it is relatively inexpensive and long acting, and it can suppress seizures without causing major sedation with careful selection of dosage. The sedation effect of the drug is prominent at the initiation of therapy but often diminishes as treatment progresses.

Phenobarbital is a major inducer of hepatic CYP450 enzymes and will markedly increase the metabolism of other drugs metabolized by these enzymes. This results in a significant potential for drug interactions with other medications metabolized in the liver. Phenobarbital also increases its own metabolism, which leads to significant tolerance as therapy progresses. Phenobarbital is pregnancy category D. Women of childbearing potential who are taking barbiturates should use two methods of birth control.

Primidone (Mysoline): Primidone is a barbiturate that is metabolized in the liver to phenobarbital, which is responsible for many of its pharmacologic effects. It is effective for treating all types of seizures except absence seizures. It has no approved indications other than seizure. The actions and adverse effects of primidone are equivalent to those of phenobarbital. It is pregnancy category D.

Table 22.3 Drugs for Seizures

Drug	Route and Dose (Maximum Dose Where Indicated)	Adverse Effects
Barbiturates		
phenobarbital	Adult: PO: 50–100 mg bid–tid IV/IM: 200–600 mg (max: 20 mg/kg) Child: PO/IV: 3–8 mg/kg or 125 mg/m^2/day	*Drowsiness, dizziness, nausea, vomiting, sedation, confusion, unsteady gait, lethargy, paradoxical excitement, pain at the injection site, hypotension with IV administration* Agranulocytosis, angioedema, Stevens–Johnson syndrome (SJS), respiratory depression, bradycardia, CNS depression, coma
primidone (Mysoline)	Adult: PO: 100–250 mg bid–tid (max: 2 g/day) Child younger than age 8: PO: 50–250 mg tid (max: 2 g/day)	
Benzodiazepines		
clobazam (Onfi)	PO: 5–10 mg/day gradually increased to a target dose of 20–40 mg/day	*Sedation, headache, drowsiness, weakness, vertigo, ataxia, paradoxical excitement, short-term amnesia* Coma, respiratory depression, cardiac arrest, suicidal ideation, blood dyscrasias, physical dependence, cardiovascular collapse (diazepam), status epilepticus with abrupt withdrawal
clonazepam (Klonopin)	Adult: PO: 1.5 mg/day gradually increased until seizures are controlled (max: 20 mg/day) Child younger than age 10: PO: 0.01–0.03 mg/kg/day gradually increased until seizures are controlled (max: 0.2 mg/kg/day)	
clorazepate (Tranxene)	Adult: PO: 7.5 mg tid (max: 90 mg/day) Child ages 9–12: PO: 3.75–7.5 mg bid (max: 60 mg/day)	
diazepam (Valium)	Status epilepticus: Adult: IV/IM: 5–10 mg, repeat if needed at 10- to 15-min intervals up to 30 mg Child: IV/IM: 0.2–1 mg slowly q2–5min up to 5–10 mg	
lorazepam (Ativan)	Adult: IV: 4 mg injected slowly at 2 mg/min; may repeat dose once after 10 min (max: 8 mg during any 12-h period) Status epilepticus: Child: IV: 0.1 mg/kg slowly over 2–5 min; may repeat with 0.05 mg in 10–15 min (max: 4 mg/dose)	
Hydantoins		
fosphenytoin (Cerebyx)	Adult: IV loading dose: 10–20 mg phenytoin equivalents/kg administered at 100–150 mg phenytoin equivalents/min Maintenance IV dose: 4–6 mg PE/kg/day	*Hypotension, nystagmus, ataxia, lethargy, confusion, slurred speech, dizziness, nervousness, headache, nausea, vomiting, gingival hyperplasia, rash, somnolence* Seizures, dysrhythmias, blood dyscrasias, systemic lupus erythematosus, cardiac arrest, cardiovascular collapse, coma, toxic epidermal necrolysis, SJS, osteomalacia
phenytoin (Dilantin, Phenytek)	Adult: PO (extended release): 100 mg tid, then adjust for seizure control (max: 600 mg/day) IV: 10–15 mg/kg loading dose, then 100 mg tid Child: PO (extended release): 5 mg/kg/day	
Dibenzazepines		
carbamazepine (Carbatrol, Tegretol, others)	Adult: PO: 200 mg bid gradually increased to 800–1200 mg/day Child younger than age 6: PO: 10–20 mg/kg/day gradually increased weekly (max: 35 mg/kg/day) Child ages 6–12: PO: 100 mg, gradually increased to 400–800 mg	*Dizziness, headache, ataxia, fatigue, rash, pruritus, dry mouth, nausea, vomiting, diplopia, abnormal gait* SJS, aggravated absence seizures, hallucinations, aplastic anemia, agranulocytosis, heart block, respiratory depression, exfoliative dermatitis, suicidal ideation, status epilepticus (with abrupt withdrawal)
eslicarbazepine (Aptiom)	PO: 400 mg once daily gradually increased to 1200 mg once daily	
oxcarbazepine (Oxtellar XR, Trileptal)	Adult: PO: 300 mg bid (max: 2400 mg/day as monotherapy) Child ages 4–16: PO: 8–10 mg/kg/day (max: 600 mg/day)	
Succinimides		
ethosuximide (Zarontin)	Adult: PO: 250 mg bid (max: 1.5 g/day) Child ages 3–6: PO: maintenance dose 20 mg/kg/day	*Drowsiness, headache, diarrhea, nausea, vomiting* Anorexia, SJS, psychosis, blood dyscrasias, systemic lupus erythematosus, suicidal ideation
methsuximide (Celontin)	PO: 150–300 mg/day (max: 1.2 g/day)	
Miscellaneous Antiepileptic Drugs		
brivaracetam (Briviact)	PO, oral solution, and IV: 50 mg bid	*Drowsiness, dizziness, nervousness, nausea, vomiting, fatigue* Suicidal ideation, psychoses
ezogabine (Potiga)	Adult: PO: 100 mg tid gradually increased to 200–400 mg tid	*Dizziness, fatigue, blurred vision, diplopia, vertigo, tremor* Retinal abnormalities, confusion, memory impairment, urinary retention, psychosis, prolongation of QT interval

Table 22.3 Drugs for Seizures (*continued*)

Drug	Route and Dose (Maximum Dose Where Indicated)	Adverse Effects
felbamate (Felbatol)	Adult: PO: 1200 mg/day gradually increased to 3600 mg/day Child ages 2–14: PO: 15 mg/kg/day (max: 45 mg/kg/day)	*Headache, dizziness, blurred vision, nausea, vomiting, anorexia* Liver failure, aplastic anemia
gabapentin (Neurontin)	Adult: PO: 300 mg tid gradually increased to 1800–2400 mg/day Child ages 3–12: PO: 10–15 mg/kg/day gradually increased to 40 mg/kg/day	*Dizziness, drowsiness, fatigue, weight gain, ataxia, diplopia, nystagmus, tremor, impaired concentration, dry mouth, flulike syndrome* Increased frequency of partial seizures, blurred vision, unintentional injury, suicidal ideation
lacosamide (Vimpat)	Adult: PO: 50 mg bid gradually increased to 200–400 mg/day	*Dizziness, headache, diplopia, nausea* Suicidal ideation, prolongation of QT interval, syncope, hypersensitivity reactions
lamotrigine (Lamictal)	Adult: PO: 25–50 mg/day gradually increased to 150–500 mg/day (max: 700 mg/day without concurrent valproic acid, 200 mg/day with valproic acid) Child ages 2–16: PO: 0.2–1 mg/kg/day gradually increased to 1–5 mg/kg/day (max: 15 mg/kg/day without valproic acid; 5 mg/kg/day or 250 mg/day with concurrent valproic acid)	*Dizziness, headache, ataxia, drowsiness, insomnia, tremor, rash, diplopia, blurred vision, flulike symptoms, infection, nausea, vomiting, back pain* SJS, toxic epidermal necrolysis, emotional lability (children), suicidal ideation
levetiracetam (Keppra)	Adult (regular release): PO: 500 mg bid; gradually increased to 3 g/day Adult (extended release): PO: 1000–3000 mg once daily Child ages 4–16: PO: 20 mg/kg/day; gradually increased to 60 mg/kg/day	*Drowsiness, headache, dizziness, nervousness, flulike symptoms, vomiting, anorexia, asthenia* Emotional lability and personality disorder (children), unintentional injury, suicidal ideation, blood dyscrasias
pregabalin (Lyrica)	PO: 150 mg/day gradually increased to 600 mg/day	*Dizziness, confusion, drowsiness, fatigue, weight gain, ataxia, diplopia, nystagmus, tremor, impaired concentration, dry mouth* Increased frequency of partial seizures, blurred vision, unintentional injury, angioedema, suicidal ideation
rufinamide (Banzel)	Adult: PO: 400–800 mg/day gradually increased to 3200 mg/day Child ages 4 and older: PO: 10 mg/kg/day gradually increased to 45 mg/kg/day or 3200 mg/day, whichever is less	*Dizziness, headache, somnolence, nausea, fatigue* Suicidal ideation, shortening of QT interval, hypersensitivity reactions
tiagabine (Gabitril)	Adult: PO: 4 mg/day gradually increased to 56 mg/day Adolescent ages 12–18: PO: 4 mg/day gradually increased to 32 mg/day	*Dizziness, asthenia, tremor, somnolence, nervousness, difficulty concentrating* Vasodilation, HTN, palpitations, tachycardia, syncope, peripheral edema
topiramate (Topamax, Trokendi XR, Others)	PO: 50 mg/day gradually increased to 400 mg/day	*Paresthesia, anorexia, weight loss, fatigue, dizziness, somnolence, nervousness, psychomotor slowing, difficulty with memory or concentration, confusion* Acute myopia with closed-angle glaucoma, oligohidrosis and hyperthermia, suicidal ideation, hyperammonemia with encephalopathy
valproic acid (Depacon, Depakene, Depakote)	Adult/child: PO/IV: 10–15 mg/kg/day gradually increased to 60 mg/kg/day	*Nausea, vomiting, abdominal cramps, anorexia, dyspepsia, drowsiness, dizziness, asthenia, insomnia, weight gain* Deep coma, hallucinations, hyperammonemia, thrombocytopenia, blurred vision, hepatotoxicity, pancreatitis, bone marrow depression, prolonged bleeding time
vigabatrin (Sabril)	Adult: PO: 500 mg bid gradually increased to 1500 mg/day	*Fatigue, somnolence, nystagmus, tremor, vision changes, memory impairment, weight gain, arthralgia, abnormal coordination* Depression, psychosis, confusion, severe rash, anemia, suicidal ideation
zonisamide (Zonegran)	Adult: PO: 100 mg/day gradually increased to 200–400 mg/day	*Dizziness, ataxia, drowsiness, fatigue, anorexia, speech abnormalities and difficulty in concentrating or remembering, flulike symptoms, headache, abnormal gait, gingivitis, rhinitis* Severe rash including SJS, kidney stones, depression, psychosis

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PharmFACT

Twenty to thirty percent of patients with epilepsy also have psychiatric disturbances, the most common of which is mood or anxiety disorder. The risk of suicide in patients with epilepsy is about 13%, which is almost twice that of the general population (Algreeshah, 2016).

22.8 Benzodiazepines are important drugs in the treatment of status epilepticus.

Benzodiazepines are the first-line drugs for the treatment of certain anxiety disorders and are one of the most widely prescribed drug classes in the United States. Detailed information about the benzodiazepines used for anxiety and a prototype feature for lorazepam (Ativan) are included in Chapter 18. The remainder of this section focuses on the antiseizure properties of drugs in this class.

Benzodiazepines control seizures by acting in the limbic, thalamic, and hypothalamic regions of the CNS. All drugs in this class act by enhancing the inhibitory action of GABA. They accomplish this by increasing the affinity of GABA for its receptors.

The applications of benzodiazepines in the treatment of seizure disorders are limited. The parenteral benzodiazepines diazepam (Valium) and lorazepam are utilized in the treatment of status epilepticus. Clonazepam (Klonopin) and clorazepate (Tranxene) are used for specific types of seizures, usually when other drugs have proven ineffective.

When giving these medications by the IV route, the patient is administered oxygen, and resuscitation equipment should be readily available. IV administration of diazepam or lorazepam for status epilepticus should be given in a large vein and the drug should not be mixed with other drugs or IV fluid additives. These drugs have a tendency to precipitate from solution and are irritating to veins. Close monitoring of the respiratory and cardiovascular systems is necessary for the early recognition of adverse effects associated with respiratory depression or cardiovascular collapse. Benzodiazepines should never be discontinued abruptly because status epilepticus may result.

PROTOTYPE DRUG **Diazepam (Valium)**

Classification **Therapeutic:** Antiepileptic drug, antianxiety drug, skeletal muscle relaxant
Pharmacologic: Benzodiazepine, GABA receptor agonist

Therapeutic Effects and Uses: Diazepam was originally approved by the U.S. Food and Drug Administration (FDA) in 1963. In antiseizure therapy, the primary indication for diazepam is status epilepticus. It may also be used to prevent seizures in patients who have received toxic substances or during the acute phase of alcohol or benzodiazepine withdrawal. Oral diazepam may be combined with other AEDs in the treatment of refractory seizures. A newer indication for diazepam is the oral prophylaxis of febrile seizures in children ages 6 months to 5 years.

Diazepam has a large number of other indications. It was once widely prescribed for the management of anxiety disorders, although it has largely been replaced by other drugs such as alprazolam (Xanax). It is administered prior to procedures such as cardioversion or endoscopy to provide relaxation or sedation. Oral or parenteral diazepam may be administered for muscle relaxation in patients with acute inflammation, trauma, tetanus, or spasticity.

Mechanism of Action: Diazepam enhances the action of GABA in the brain, thus inhibiting the abnormal neuronal discharges characteristic of seizures.

Pharmacokinetics:

Route(s)	IV, IM, PO, rectal
Absorption	Rapidly absorbed by the GI tract; erratic absorption with IM administration
Distribution	Widely distributed; crosses the blood–brain barrier and the placenta; 99% bound to protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	IV: 1–5 min; IM: 15–30 min; PO: 30–60 min
Duration of action	Half-life: 20–50 h

Adverse Effects: The most serious adverse effect of diazepam is cardiovascular collapse. The nurse should assess for hypotension, tachycardia, and edema, which are precursors to cardiovascular collapse. CNS adverse effects include drowsiness, fatigue, ataxia, dizziness, and vertigo. Diazepam can cause urinary retention and menstrual irregularities. The major respiratory adverse effect is laryngeal spasm and cough. Benzodiazepines are Schedule IV drugs and possess a risk for substance abuse in susceptible individuals (see Chapter 27).

Contraindications/Precautions: Diazepam should not be administered to patients with depressed vital signs, those in shock, or those with acute alcohol intoxication. It is also contraindicated in the presence of closed-angle glaucoma because it can increase intraocular pressure. Diazepam should be used cautiously in patients with depression and myasthenia gravis, and a reduced dose should be administered in patients with impaired hepatic or renal function. Patients who have respiratory disorders such as chronic obstructive pulmonary disease (COPD) should be monitored closely due to the risk of respiratory depression.

After prolonged therapy, abrupt discontinuation of diazepam may precipitate withdrawal symptoms, including seizures in patients with epilepsy. The drug can cause birth defects and should not be administered to pregnant patients unless benefits clearly outweigh the potential risks. Diazepam is not recommended during lactation because the drug is secreted in breast milk and may cause CNS depression in the neonate.

Drug Interactions: Diazepam is metabolized by hepatic CYP450 enzymes and may interact with drugs that inhibit these enzymes. Other CNS depressants, including alcohol, will intensify the sedative effects of diazepam. Concurrent administration with cimetidine will increase the plasma levels of diazepam. Administration of diazepam with antiparkinsonism medications may worsen the severity of Parkinson's disease symptoms. Diazepam when administered with phenytoin will result in increased phenytoin levels and possible toxicity. Diazepam should never be administered within 14 days of a monoamine oxidase inhibitor (MAOI) due to the risk of hypertensive crisis. **Herbal/Food:** Kava and valerian administered with diazepam will result in additive sedative effects. Echinacea may lower the serum levels of diazepam. Grapefruit juice increases the peak serum concentrations of diazepam by as much as two times.

Pregnancy: Category D.

Treatment of Overdose: Flumazenil (Romazicon) is administered for overdosage of diazepam. This medication is a specific benzodiazepine receptor antagonist that reverses the CNS depression from diazepam.

Nursing Responsibilities: Key nursing implications for patients receiving diazepam are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures and in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders in Chapter 18.

Drugs Similar to Diazepam (Valium)

Clobazam, clonazepam, clorazepate, and lorazepam are benzodiazepine antiepileptic medications.

Clobazam (Onfi): Clobazam was approved for the U.S. market in 2013 and is available PO for one specific indication: seizures associated with Lennox–Gastaut syndrome in patients 2 years of age or older. The drug exhibits the adverse effects typical of benzodiazepines, especially sedation, which can be profound when the drug is used with alcohol or other CNS depressants. Stevens–Johnson syndrome (SJS) is a serious, though rare, adverse effect. Tolerance to the sedation effect, as well as the antiepileptic effect, occurs with continued therapy. Clobazam is pregnancy category C and a Schedule IV controlled substance.

Clonazepam (Klonopin): Approved in 1975, clonazepam is an oral benzodiazepine with strong antiseizure properties. It is approved for the prophylaxis of absence seizures, Lennox–Gastaut syndrome, akinetic and myoclonic seizures, and nocturnal myoclonus. Its primary use as an AED is to treat refractory myoclonic seizures. Clonazepam is also approved for the treatment of panic disorder, with or without agoraphobia. It is occasionally prescribed off-label for other anxiety disorders, insomnia, and restless leg syndrome.

Like other drugs in the class, the most common adverse effect is sedation. Hyperactivity, restlessness, irritability, and cardiovascular or respiratory depression are possible. If given for an extended period, the patient may require an increase in dose due to the development of tolerance. Tolerance also develops to the sedative side effects of the drug. Therapeutic serum levels are 20 to 80 mg/mL. Clonazepam is pregnancy category C and a Schedule IV controlled substance.

Clorazepate (Tranxene): Approved in 1972, clorazepate is approved for the pharmacotherapy of anxiety, partial seizures, and seizures associated with acute ethanol withdrawal. It may be used off-label to treat insomnia. Clorazepate is administered PO and has a long duration of action. The actions of clorazepate are the same as those of diazepam because the two drugs share the same active metabolite. It is not a first-line drug for epilepsy but it may be used as an adjunct to control partial seizures. Most adverse effects are CNS related and include mental depression, confusion, fatigue, tremor, and vertigo. Like diazepam, clorazepate is a Schedule IV drug and is pregnancy category D.

Lorazepam (Ativan): Approved in 1977, lorazepam is a first-line drug for treating status epilepticus because it persists in the cerebrospinal fluid (CSF) longer than diazepam. Whereas diazepam remains active in the brain for 30 to 60 minutes, lorazepam may prevent seizures for up to 12 hours. It is also used to prevent or treat seizures associated with acute ethanol withdrawal. When given orally, lorazepam is indicated for the short-term management of anxiety disorders or anxiety associated with depressive symptoms. It is the most potent of the benzodiazepines and has the ability to produce skeletal muscle relaxation, sedation, and a hypnotic state. Oral, IM, and IV forms are available. Lorazepam is pregnancy category D and a Schedule IV controlled substance. A prototype feature for lorazepam is presented in Chapter 18.

CONNECTION Checkpoint 22.2

In addition to epilepsy, what are other indications for benzodiazepines? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

22.9 Hydantoins are effective in the management of most types of seizures but have many adverse effects.

First used in 1938, phenytoin (Dilantin) became a preferred drug for many types of epilepsy because it provided effective seizure prevention without the serious CNS depression and abuse potential associated with barbiturates. Despite having many drawbacks, phenytoin remains an important drug in the pharmacotherapy of seizures.

Hydantoins act by delaying the influx of sodium ions across neuronal membranes in the brain. Sodium ion movement is the major factor determining the initiation and propagation of a neuron action potential. Hydantoin medications do not block the sodium channels but instead desensitize them. Total blockage of sodium channels would cause neuronal activity to cease as is seen with the administration of local anesthetics. At high doses, the hydantoins begin to exert excitatory CNS effects and can induce seizures.

PROTOTYPE DRUG **Phenytoin (Dilantin, Phenytek)**

Classification **Therapeutic:** Antiepileptic drug
Pharmacologic: Hydantoin, neuronal sodium channel modulator

Therapeutic Effects and Uses: Available since the 1930s phenytoin is approved for the prophylactic therapy of all types of seizures except absence seizures. Phenytoin has been used to prevent seizures that might occur during neurosurgery or eclampsia. The IV form of phenytoin is effective in treating generalized convulsions due to status epilepticus. The action of IV phenytoin is not immediate; therefore, an IV benzodiazepine should be administered prior to, or concurrently with, IV phenytoin to achieve faster seizure control. Phenytoin injections must always be performed slowly (not to exceed 50 mg/min in adults) to prevent cardiovascular collapse. Phenytoin (Phenytek) is an extended release form of the drug that allows once-daily dosing.

Patients taking phenytoin must be closely monitored and the dosage adjusted based on clinical response and laboratory results. The therapeutic serum range is narrow, 10 to 20 mcg/mL, and small increases in dose can produce large changes in the serum concentration. Thus, the patient should be educated on the importance of maintaining a strict schedule for administration of the medication and for keeping all laboratory appointments. The brand of phenytoin should not be changed without approval of the healthcare provider because differences in bioavailability among brands have been noted.

Phenytoin is a Class 1B antidysrhythmic and may be used to treat ventricular tachycardia (especially those induced by digoxin) or paroxysmal atrial tachycardia, although it is not approved for these indications (see Chapter 37). Other off-label indications for phenytoin include the treatment of migraines, diabetic neuropathy, and neuropathic pain.

Mechanism of Action: Phenytoin inhibits seizure activity by delaying the influx of sodium ions in neurons, thus slowing the propagation and spread of abnormal discharges. Unlike some AEDs, phenytoin does not elevate the seizure threshold.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Slowly but completely absorbed in the GI tract
Distribution	Enters the CSF; crosses the placenta; secreted in breast milk; 95% bound to protein
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	PO (with loading dose): 30–120 min
Duration of action	Half-life is highly variable, ranging from 7 to 42 h with an average of 24 h

Adverse Effects: Phenytoin can be a very toxic drug and patients must be monitored carefully during therapy. CNS adverse effects are relatively common and include lethargy, headache, drowsiness, and dizziness. High doses can cause nystagmus, confusion, ataxia, coma, and seizures. Cardiovascular adverse effects include bradycardia, ventricular fibrillation, hypotension, and phlebitis. Gastrointestinal (GI) adverse effects include gingival hyperplasia (swelling of the gums), weight loss, and liver necrosis. Hematologic adverse effects include agranulocytosis, leukopenia, thrombocytopenia, and aplastic anemia. Rashes and serious dermatologic conditions occur in 5% to 10% of patients taking the drug. Abrupt discontinuation of phenytoin can induce status epilepticus. **Black Box Warning:** When IV infusion rates exceed 50 mg/min in adults, the patient is at risk for hypotension and dysrhythmias. Careful cardiovascular monitoring is needed during and after IV administration.

Contraindications/Precautions: Patients who have developed a rash, sore throat, fever, oral ulcers, or other hypersensitivity reactions to a hydantoin should not receive phenytoin. This medication is contraindicated in patients who have experienced seizures caused by hypoglycemia. Phenytoin should be administered cautiously to patients with impaired liver or kidney function because these may increase the serum concentration of phenytoin to toxic levels. Patients with serious cardiovascular signs and symptoms such as dysrhythmias, bradycardia, and

heart failure must be monitored carefully during therapy. Patients with blood dyscrasias should not receive phenytoin because this drug can worsen these conditions. Phenytoin is a known teratogen and should not be administered to pregnant patients unless the seizures cannot be managed by safer drugs. The drug is secreted in breast milk, although it may be used during lactation, if necessary, to control serious seizures.

Drug Interactions: Because phenytoin strongly induces hepatic CYP3A4 enzymes, the metabolism of many other drugs may be affected, and drug–drug interactions are common. Phenytoin increases the metabolism of corticosteroids, warfarin, and oral contraceptives, thus rendering these drugs less effective. Chronic alcohol ingestion, carbamazepine, and barbiturates can increase the metabolism of phenytoin, thus decreasing the antiseizure effects of phenytoin. Amiodarone, chloramphenicol, diazepam, valproic acid, isoniazid, omeprazole, and ticlopidine will increase phenytoin levels when administered concurrently. **Herbal/Food:** The administration or consumption of foods that contain folic acid, calcium, and vitamin D will decrease the absorption of phenytoin. Ginkgo may decrease the antiseizure effectiveness of phenytoin.

Pregnancy: Category D.

Treatment of Overdose: Overdoses of phenytoin are treated with activated charcoal with gastric lavage.

Nursing Responsibilities: Key nursing implications for patients receiving phenytoin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures.

Drugs Similar to Phenytoin (Dilantin, Phenytek)

Fosphenytoin is the only other hydantoin.

Fosphenytoin (Cerebyx): Approved in 1996, fosphenytoin is a prodrug that is converted to phenytoin following metabolism. Given only by the parenteral route, it is considered functionally equivalent to phenytoin; their actions and adverse effects are the same. Doses on the label are indicated as phenytoin equivalents (PE). Indications for fosphenytoin include tonic–clonic seizures, status epilepticus, and seizure prophylaxis during neurosurgery. Because the drug is converted to phenytoin, therapeutic serum levels of phenytoin may be monitored during therapy. Advantages of fosphenytoin over phenytoin include more rapid IV administration (important during status epilepticus), ability to be administered by the IM route, and less pain and phlebitis at the injection site. The adverse effects are the same as IV phenytoin, except that fosphenytoin may cause intense burning, itching, and paresthesia (not at the site of injection) for several minutes to hours following the IV dose. Fosphenytoin carries the same black box warning as phenytoin. The drug is pregnancy category D.

22.10 Carbamazepine is a first-line drug for treating many tonic–clonic and partial seizures.

The dibenzazepines are a small class of drugs that have important applications to seizure management. These drugs have three rings in their structures, which makes them chemically related to the tricyclic antidepressants (see Chapter 19). The drugs in this class, carbamazepine (Carbatrol, Tegretol), eslicarbazepine (Aptiom), and oxcarbazepine (Oxtellar XR, Trileptal), have similar pharmacologic activity.

CONNECTIONS: Treating the Diverse Patient

Post-Traumatic Epilepsy in Veterans with Traumatic Brain Injury

Epilepsy can develop after any form of head trauma. For soldiers returning from war and conflict, seizures and epilepsy related to traumatic brain injury (TBI) can occur from both closed and open head wounds. As a result of recent military conflicts, TBI in veterans has increased. The risk for post-traumatic epilepsy (PTE) appears to be directly related to the severity of the TBI (Chen et al., 2014; Pugh et al., 2015).

Pugh et al. (2015) found that the risk for epilepsy following TBI was 18 times greater than for veterans without TBI. The authors also found statistically significant associations between epilepsy and headache, mental health conditions such as bipolar disorder and schizophrenia, and substance abuse disorder (p. 35). Epilepsy was also more common in younger veterans under the age of 50. Chen et al. (2014) found that psychogenic nonepileptic seizures may be occurring, rather than PTE, a finding not inconsistent with high levels of post-traumatic stress disorder (PTSD) in veterans.

PTE in the wounded veteran population significantly affects their ability to reenter civilian life as productive members of society. Depending on whether or not the PTE is controlled, normal life activities such as driving and employment using skills learned in the armed services, for example, automotive or aviation jobs, may be difficult or impossible to obtain or maintain. Nurses should be aware of the stigma of epilepsy in all patients, but especially for veterans returning from combat with head wounds. Reentry into society may be difficult for any veteran with wounds related to combat. However, when a closed head injury has resulted in PTE and negatively affects the ability to function normally in society, the veteran, who may look normal, has sustained a significant wound that cannot be seen. By providing teaching and care, and by working with veterans' support groups, nurses can help ease the transition for these veterans when they return home.

The mechanisms of action of the dibenzazepines are incompletely understood. Like phenytoin, they affect the sodium channels in cortical neurons, slowing the propagation and spread of repetitive action potentials. These drugs have other actions, however, that are unexplained by the sodium channel mechanism, including analgesic, anticholinergic, antidysrhythmic, antidepressant, and sedative effects. They also have muscle relaxant and neuromuscular-blocking properties. Doses for the dibenzazepines are listed in Table 22.3.

PROTOTYPE DRUG Carbamazepine (Carbatrol, Tegretol, Others)

Classification **Therapeutic:** Antiepileptic drug
Pharmacologic: Dibenzazepine, neuronal sodium channel modulator

Therapeutic Effects and Uses: Approved by the FDA in 1968, carbamazepine is one of the most widely prescribed AEDs in the world because of its effectiveness and relative safety. It is indicated for the management of generalized tonic–clonic seizures, partial seizures with complex symptomatology, and mixed seizure patterns. It is ineffective against absence seizures. Carbamazepine may be administered as monotherapy or in combination with other AEDs. Carbamazepine is also approved for the treatment of acute mania associated with bipolar disorder, either as monotherapy or in combination with lithium (see Chapter 19). Carbamazepine is available as an extended release form (Tegretol XR and Carbatrol CR), and as a multiphasic extended release form (Equetro). In 2016 an IV form (Carnexiv) was approved to treat generalized tonic–clonic seizures or partial seizures when oral administration is not feasible.

Prior to its use as an AED, carbamazepine was approved to treat pain associated with trigeminal neuralgia. It remains one of the most effective drugs for this condition. Off-label uses of carbamazepine include the treatment of neuropathic pain associated with diabetic neuropathy and post-herpetic pain. The drug is also used off-label to treat hiccups and for the management of severe symptoms of dementia such as aggression and agitation, which are seen in some patients with Alzheimer's disease.

Although carbamazepine is structurally similar to the tricyclic antidepressants, it does not produce the antidepressant effects of drugs in that class. The medication is metabolized in the liver to an active metabolite and is a potent inducer of CYP450 enzymes that will increase its own metabolism. Long-term administration of carbamazepine will result in the need to increase the dose because its half-life becomes shortened.

For all indications, therapy with carbamazepine must be monitored carefully and the dosage adjusted based on clinical outcomes and drug serum levels. The therapeutic serum concentrations usually range from 4 to 12 mcg/mL. Several weeks of therapy may be required before the optimal dose is determined and the effective plasma drug concentration achieved.

Mechanism of Action: Carbamazepine inhibits sodium channels, blocking the repetitive, sustained firing of neurons that is characteristic of epilepsy. Other mechanisms are likely but are incompletely understood.

Pharmacokinetics:

Route(s)	PO
Absorption	Slowly absorbed across the GI tract
Distribution	Widely distributed; enters the CSF; crosses the placenta; secreted in breast milk; 75–85% bound to proteins
Primary metabolism	Hepatic (induces CYP450 enzymes)
Primary excretion	Primarily renal with some in feces
Onset of action	Slow and variable
Duration of action	Half-life: 14–16 h; 35–40 h for extended release

Adverse Effects: Carbamazepine is well tolerated; adverse effects are usually transient and diminish as therapy progresses. The most frequently observed effects include drowsiness, dizziness, ataxia, and nausea and vomiting. Transient sedation is common at the onset of therapy or after dosage increases. Other CNS effects include confusion, blurred vision, lethargy, and visual disturbances, although the patient usually develops tolerance to these effects. Other possible adverse effects include myalgia, leg cramps, carbamazepine-induced systemic erythematosus, heart block, aplastic anemia, respiratory depression, phototoxicity, urticaria, and alopecia. Elevated hepatic enzymes occur during therapy, although the patient is usually asymptomatic for hepatic disease. A few rare cases of serious hepatic impairment have been documented. Some patients have reported urinary retention and frequency, and male patients may experience impotence. **Black Box Warning:** Aplastic anemia and agranulocytosis have been reported with this drug. Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrosis and SJS, have also occurred with carbamazepine. Patients testing positive for the HLA-B 1502 gene (usually found in people of Asian ancestry) are at higher risk for severe dermatologic reactions and should not receive this drug unless the benefit clearly outweighs the risk.

Contraindications/Precautions: Patients who are hypersensitive to tricyclic antidepressants should not take carbamazepine. Patients who have been diagnosed with increased intraocular pressure, systemic lupus erythematosus, cardiac disease, hepatic disease, and liver disease should not take carbamazepine. This medication is contraindicated with HTN. Older adults should be monitored closely if they possess a history of cardiac disease because a major adverse effect is heart block. Carbamazepine causes multiple birth defects in laboratory animals. If used during pregnancy, monotherapy is recommended because the use of two or more AEDs increases the risk of teratogenesis.

Drug Interactions: Carbamazepine induces the activity of several hepatic CYP450 enzymes, which can result in decreased serum concentrations of AEDs and other drugs metabolized by the liver. Increased carbamazepine levels have been noted when the drug is administered with verapamil, erythromycin, ketoconazole, or nefazodone. Patients who take carbamazepine with anticoagulants will experience decreased hypoprothrombinemic effects. Carbamazepine may decrease the effectiveness of oral contraceptives. **Herbal/Food:** Ginkgo may decrease the antiepileptic effectiveness of carbamazepine. Grapefruit juice and St. John's wort induce CYP450 enzymes and can decrease serum carbamazepine levels.

Pregnancy: Category D.

Treatment of Overdose: Activated charcoal and gastric lavage are administered with carbamazepine overdose.

Nursing Responsibilities: Key nursing implications for patients receiving carbamazepine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures.

Drugs Similar to Carbamazepine (Carbatrol, Tegretol, Others)

Other dibenzazepines include eslicarbazepine and oxcarbazepine.

Eslicarbazepine (Aptiom): One of the newer AEDs, eslicarbazepine was approved in 2013 for the treatment of partial-onset seizures. It is usually used as an add-on treatment to therapy with other drugs in this class. It has a long half-life that allows for once-daily dosing. Eslicarbazepine and oxcarbazepine have very similar actions and adverse effects because both are converted to the same active metabolite. Common adverse effects include dizziness, somnolence, nausea, headache, vomiting, blurred vision, and tremor. Serious adverse effects include suicidal ideation, agranulocytosis, hyponatremia, and severe dermatologic reactions. This drug is pregnancy category C.

Oxcarbazepine (Oxtellar XR, Trileptal): Although oxcarbazepine is similar to the tricyclic antidepressants, it does not possess antidepressant activity. Approved in 2000, oxcarbazepine can be administered as monotherapy or in combination with other medications in the treatment of partial seizures, with or without secondary generalization. Off-label uses include the treatment of neuropathic pain and bipolar disorder. A major advantage of oxcarbazepine over carbamazepine is that drug interactions appear less significant and monitoring of drug plasma levels and hematologic values is generally not necessary. Although it induces CYP450 enzymes, it is not as strong an inducer as carbamazepine and it does not induce its own metabolism. An extended release form of the drug (Oxtellar XR) is available for once-daily dosing.

For checking adherence with the drug regimen or in overdose situations, the therapeutic serum concentration of the drug is 12 to 30 mcg/mL. Adverse effects are similar to those of carbamazepine, with dizziness, drowsiness, headache, and ataxia being the most common effects. Serious adverse effects include suicidal ideation, agranulocytosis, hyponatremia, and severe dermatologic reactions. A serious and sometimes fatal adverse event called drug reaction with eosinophilia and systemic systems (DRESS) has been reported with oxcarbamazepine. Oxcarbamazepine is pregnancy category C, although caution should be used during pregnancy because this drug is closely related structurally to carbamazepine, which is category D.

22.11 Succinimides are the first-line drugs for the pharmacotherapy of absence seizures.

Succinimides form a small group of AEDs that suppress the influx of calcium into neurons during neuronal transmission. This is believed to increase the electrical threshold of the neuron, which reduces the likelihood of abnormal action potentials. Recent research has questioned this mechanism of action, and the actual mechanism of antiepileptic activity of this group remains largely unknown. Despite the small size of the class and their unknown mechanism of action, these drugs have important roles in the pharmacotherapy of absence seizures.

PROTOTYPE DRUG **Ethosuximide (Zarontin)**

Classification **Therapeutic:** Antiepileptic drug
Pharmacologic: Succinimide, neuronal calcium channel modulator

Therapeutic Effects and Uses: Ethosuximide is the only drug in this class that is commonly prescribed. Approved in 1960, it is a preferred drug for managing absence seizures. Because ethosuximide is ineffective in treating simple or complex partial seizures and tonic–clonic seizures, combination pharmacotherapy is needed to manage mixed seizures.

Ethosuximide is only administered by the oral route. Therapeutic serum concentrations range from 40 to 100 mcg/mL, although dosing is usually based on clinical response rather than serum levels. It may take 4 to 7 days before optimal therapeutic levels are attained.

Mechanism of Action: Ethosuximide depresses the motor cortex by delaying the calcium influx into the neuron.

Pharmacokinetics:

Route(s)	PO
Absorption	Readily and completely absorbed
Distribution	Widely distributed; very small amounts bound to proteins; crosses the placenta and is secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Primarily renal, with some in feces and bile
Onset of action	Peak: 4 h
Duration of action	Half-life: 30 h in children; 60 h in adults

Adverse Effects: The most common adverse effects of ethosuximide are GI related, including anorexia, nausea, vomiting, abdominal pain, and diarrhea. Adverse CNS events include drowsiness, dizziness, ataxia, confusion, and night terrors. Hematologic toxicity may include agranulocytosis, pancytopenia, and aplastic anemia. Dermatologic effects include rash, pruritus, and exfoliative dermatitis. Like many AEDs, this drug may increase the risk of suicidal ideation.

Contraindications/Precautions: Ethosuximide is contraindicated in patients who have a known sensitivity to succinimides. It should be administered with caution to patients with liver or kidney impairment. Administration of ethosuximide may increase the frequency of tonic–clonic seizures. Patients with blood dyscrasias or bone marrow suppression should not receive this drug because it can worsen these conditions. Safety has not been established for the administration of this medication during pregnancy. Although small amounts of the drug are secreted in breast milk, the drug is believed to be compatible with breastfeeding.

Drug Interactions: Ethosuximide can participate in many drug–drug interactions. When used in combination therapy with other AEDs, serum drug levels should be regularly monitored. CNS depressants and ethanol may cause additive sedation. Use of ethanol may also reduce the effectiveness of the antiseizure medication. Ethosuximide administered concurrently with phenobarbital, phenothiazines, or tricyclic antidepressants can increase seizure frequency. Isoniazid administered in combination with ethosuximide can result in increased serum ethosuximide levels. Carbamazepine will cause a decrease in ethosuximide serum levels. Concurrent use of valproic acid will inhibit the metabolism of ethosuximide, leading to possible toxicity. **Herbal/Food:** Unknown.

Pregnancy: Category C.

Treatment of Overdose: Activated charcoal and gastric lavage are administered with ethosuximide overdose.

Nursing Responsibilities: Key nursing implications for patients receiving ethosuximide are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures.

Drugs Similar to Ethosuximide (Zarontin)

Methsuximide is the only other drug in this class.

Methsuximide (Celontin): Like ethosuximide, methsuximide is indicated for the management of absence seizures. This drug is rarely used in clinical practice because it is less effective and more toxic than ethosuximide. It has the same indications and adverse effects as ethosuximide. This drug is pregnancy category C.

22.12 Several miscellaneous drugs are important in treating epilepsy.

As explained in Section 22.6, it is difficult to classify AEDs because many act by multiple mechanisms, whereas others are unique and are the only drug in a class. Several of these "miscellaneous" drugs are widely used. Following the discussion of the two prototypes, other miscellaneous drugs and their indications are described.

PROTOTYPE DRUG **Gabapentin (Neurontin)**

Classification **Therapeutic:** Antiepileptic drug
Pharmacologic: GABA analog

Therapeutic Effects and Uses: Gabapentin consists of a molecule of the neurotransmitter GABA with an attached side chain. The side chain makes the molecule lipid soluble so that it readily crosses the blood–brain barrier. Approved in 1993, gabapentin is used in combination with other AEDs to control partial seizures with or without secondary generalization. Doses are based on therapeutic response, making it unnecessary to measure serum drug levels during therapy. It is available as capsules, as tablets, and as an oral solution.

Therapy with gabapentin has been found to benefit a number of other conditions. Gabapentin (Gralise) is approved for the treatment of post-herpetic neuralgia and gabapentin (Horizant) for restless leg syndrome. Gabapentin is used off-label for other conditions with neuropathic

pain such as diabetic neuropathy. In fact, the drug is probably prescribed more often for the treatment of neuropathic pain than for epilepsy. Hot flashes are reduced in approximately 50% of the women taking the drug. It has been designated as an orphan drug for the treatment of amyotrophic lateral sclerosis (ALS). Some research has suggested that gabapentin is useful in treating trigeminal neuralgia, paresthesia, spasticity, and ocular ataxia in patients with multiple sclerosis.

Mechanism of Action: The exact mechanism of anticonvulsant action for gabapentin is unknown. Although closely related structurally to GABA, it does not appear to bind to GABA receptors or to prevent endogenous GABA from binding. It does not appear to affect the binding of other neurotransmitters such as serotonin, dopamine, glutamate, or histamine. It likely affects calcium channels but its exact mechanism has not been determined.

Pharmacokinetics:

Route(s)	PO
Absorption	50–60% is absorbed from the GI tract
Distribution	Crosses the blood–brain barrier and the placenta; readily passes into the CSF; secreted in breast milk; very small amounts bound to proteins
Primary metabolism	Not metabolized
Primary excretion	Excreted unchanged by the kidneys
Onset of action	1 h
Duration of action	Half-life: 5–6 h

Adverse Effects: Gabapentin is well tolerated, with CNS symptoms such as drowsiness, fatigue, nystagmus, and dizziness being the primary adverse effects. The administration of gabapentin can lead to increased frequency of viral infections, weight gain, and gastric upset. Behavioral problems such as hostility, emotional lability, impaired cognition, aggressiveness, and hyperkinesia have been reported in the pediatric population ages 3 to 12.

Contraindications/Precautions: Gabapentin should not be administered during pregnancy or lactation unless the benefits of pharmacotherapy outweigh the risks. It should not be administered in patients who have experienced a hypersensitivity reaction to GABA-related medications. It should be used cautiously with status epilepticus and with older adults. Gabapentin should be used with caution in patients with chronic kidney disease because the drug could accumulate to toxic levels. The drug should be discontinued gradually to prevent withdrawal-associated seizures.

Drug Interactions: A major advantage of gabapentin is that it does not induce CYP450 enzymes, and thus it exhibits fewer drug interactions than many other AEDs. No interactions with carbamazepine, phenobarbital, phenytoin, or valproic acid have been observed. Morphine and hydrocodone may cause additive CNS depression when administered with gabapentin. **Herbal/Food:** The administration of ginkgo with gabapentin may result in decreased anticonvulsant effects. The use of valerian is contraindicated due to the risk of additive sedation.

Pregnancy: Category C.

Treatment of Overdose: Overdose results in dyspnea, sedation, double vision, and slurred speech. Renal dialysis can be utilized to treat gabapentin overdose.

Nursing Responsibilities: Key nursing implications for patients receiving gabapentin are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures.

PROTOTYPE DRUG Valproic Acid (Depacon, Depakene, Depakote)

Classification **Therapeutic:** Antiepileptic drug, antimanic drug
Pharmacologic: GABA agonist

Therapeutic Effects and Uses: Approved in 1978, valproic acid has become a preferred drug for treating many types of epilepsy. This medication has several trade names and formulations, which can cause confusion when studying it.

- Valproic acid (Depakene) is the standard form of the drug given by the oral route.
- Valproate sodium (Depacon) is the sodium salt of valproic acid given orally or IV.
- Divalproex sodium (Depakote ER) is a sustained release combination of valproic acid and its sodium salt in a 1:1 mixture. It is given orally and is available in an enteric-coated form.

All three formulations of the drug form valproate after absorption or on entering the brain. The pharmacokinetics of each form varies, and they are not interchangeable. In this text, the name "valproic acid" is used to describe all forms of the drug, unless specifically stated otherwise.

Valproic acid is administered as monotherapy or in combination with other AEDs to treat absence seizures and complex partial seizures. Depakote ER is also approved for the prevention of migraines and mania associated with bipolar disorder. Off-label indications include severe behavioral disturbances such as agitation due to dementia, Alzheimer's disease, or explosive temper in patients with

ADHD; persistent hiccups; and status epilepticus refractory to IV diazepam. Dosage adjustments for valproic acid are usually based on patient response; normal serum drug levels for epilepsy are 50 to 100 mcg/mL. In 2007, the FDA approved Stavzor, a soft gelatin capsule of valproic acid. The capsule dissolves in the small intestine, rather than the stomach, thus reducing nausea and vomiting, which are common adverse effects of the drug.

Mechanism of Action: Valproic acid increases concentrations of the inhibitory neurotransmitter GABA in the brain. Abnormal neuron discharges are suppressed, leading to decreased seizure activity.

Pharmacokinetics:

Route(s)	IV, PO
Absorption	Rapidly absorbed in the GI tract
Distribution	Crosses the placenta and is secreted in breast milk; 80–90% bound to protein
Primary metabolism	Hepatic
Primary excretion	Renal and GI tract
Onset of action	15–30 min
Duration of action	Half-life: 5–20 h

Adverse Effects: Valproic acid is well tolerated in most patients and adverse effects rarely cause discontinuation of therapy. The most common adverse effects are GI related, such as nausea, vomiting, diarrhea, abdominal pain, and diminished appetite. An enteric-coated formulation of valproic acid can be used to reduce these uncomfortable effects. These effects are usually transient and not severe. CNS adverse effects such as headache, tremor, dizziness, and sedation occur in about 25% of patients. High doses of valproic acid cause diminished platelet aggregation, which can result in prolonged bleeding and clotting times. Bone marrow depression, photosensitivity, and pulmonary edema are rare potential adverse effects. Valproic acid may cause hyperammonemic encephalopathy, especially in combination with topiramate, which requires discontinuation of valproic acid therapy. **Black Box Warning:** Serious hepatotoxicity has been reported in infants younger than age 2 taking valproic acid. Life-threatening pancreatitis has occurred as a result of valproic acid administration. When given during pregnancy, valproic acid can produce neural tube defects and children exposed while in utero demonstrate lower cognitive scores.

Contraindications/Precautions: Patients with hypersensitivity to any formulation of valproic acid should not be administered this drug. Other contraindications include significant hepatic impairment, bleeding disorders, cirrhosis, congenital metabolic disorders, and autoimmune deficiency syndrome. Patients with known or suspected pancreatitis should not receive this drug because life-threatening pancreatitis has been reported. Valproic acid should be administered cautiously in patients with a low serum albumin or chronic kidney disease. Extreme caution should be used in treating patients under age 2 because fatal hepatotoxicity has been reported. The drug should not be administered to patients with known hepatic impairment. Abrupt discontinuation may cause status epilepticus. This drug is a known teratogen and should be used during pregnancy only when benefits of therapy clearly outweigh the risk of birth defects.

Drug Interactions: Valproic acid inhibits CYP450 enzymes, which can result in many drug–drug interactions. Valproic acid administered concurrently with alcohol and other CNS depressants may result in additive sedation. Patients taking enzyme-inducing AEDs such as carbamazepine, phenytoin, and phenobarbital will metabolize valproic acid more rapidly, and dosage adjustment will be necessary. Valproic acid may increase the serum levels of tricyclic antidepressants, requiring a reduction in antidepressant dosage. Aspirin increases the serum drug levels of valproic acid and should not be administered concurrently. Isoniazid will elevate serum valproic acid levels. Cholestyramine will decrease absorption of valproic acid. Cimetidine will increase valproic acid levels and will place the patient at risk for hepatotoxicity. Valproic acid should not be administered with topiramate due to an increased risk of hyperammonemic encephalopathy. **Herbal/Food:** Ginkgo may decrease the antiepileptic effects of valproic acid.

Pregnancy: Category D.

Treatment of Overdose: The effects from overdose of valproic acid may be serious and include sedation, heart block, deep coma, and death. Naloxone (Narcan) is utilized to reverse the CNS depression, and hemodialysis can lower drug serum levels. Caution must be used when administering naloxone because this drug may also reverse the antiseizure action of valproic acid.

Nursing Responsibilities: Key nursing implications for patients receiving valproic acid are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Seizures.

Other Miscellaneous Drugs

Brivaracetam (Briviact): Approved in 2016, brivaracetam is one of the newest drugs for treating partial-onset seizures. This drug acts by a similar mechanism of action to levetiracetam, although its dose is 10 times lower than the older medication. It is used as an add-on when other AEDs

are unable to successfully control seizures. The patient should be carefully monitored for sedation and suicidal ideation during therapy. Brivaracetam may be administered by either the PO or IV route. This drug is pregnancy category C.

Ezogabine (Potiga): Ezogabine was approved in 2011 for the adjunctive treatment of partial-onset seizures in adults. The drug acts by stabilizing potassium channels in the brain, which reduces brain excitability. The drug should be used with caution in patients with benign prostatic hyperplasia because it may cause urinary retention. Dizziness, somnolence, and fatigue are common side effects during therapy. Ezogabine carries a black box warning that the drug may cause retinal abnormalities and vision loss. All patients should receive baseline and periodic ophthalmic examinations while taking this drug. Ezogabine is a Schedule V drug and is pregnancy category C.

Felbamate (Felbatol): Approved in 1993, felbamate is an oral drug that is effective against most types of seizures. Serious adverse effects, however, limit its use to severe partial seizures and the treatment of partial and generalized seizures associated with Lennox–Gastaut syndrome in children who have not responded to other therapies. Although the incidence of these adverse effects is rare, they may be serious or fatal. More common adverse effects include nausea, vomiting, anorexia, drowsiness, dizziness, insomnia, and vision changes. This drug carries a black box warning that fatal aplastic anemia and fatal hepatic failure have been associated with felbamate use. Baseline and periodic hematologic and hepatic laboratory tests should be conducted. This drug is pregnancy category C.

Lacosamide (Vimpat): Lacosamide is a miscellaneous AED used in the management of partial-onset seizures in adults whose seizures are not well controlled by other medications. Approved in 2008, its most frequent adverse effects include diplopia, headache, dizziness, and nausea. Patients with cardiac conduction abnormalities should be carefully monitored during therapy. This drug is pregnancy category C.

Lamotrigine (Lamictal): Approved in 1994, lamotrigine is an oral drug indicated for the adjunctive therapy of partial seizures, Lennox–Gastaut syndrome, absence seizures, and tonic–clonic seizures in adults and pediatric patients 2 years of age or older. It is also used in the maintenance therapy of bipolar disorder. Lamotrigine inhibits the release of glutamate in neurons and inhibits flow through sodium ion channels, which stabilizes neuronal membranes. Lamotrigine is rapidly absorbed, 55% bound to plasma proteins, and almost entirely excreted by the kidneys.

Lamotrigine does not induce or inhibit hepatic metabolic enzymes. It is metabolized by CYP450 enzymes, however, and patients who are taking potent inducers of CYP450 enzymes (e.g., carbamazepine, phenytoin, and phenobarbital) will metabolize the drug more rapidly. Doses of lamotrigine will need to be increased in these patients to produce an optimal antiseizure response. On the other hand, valproic acid will reduce the elimination of lamotrigine, and the dose of lamotrigine should be reduced to prevent toxicity. Oral contraceptives reduce serum levels of lamotrigine, and the dosage of the AED will need to be adjusted when therapy with the hormones is initiated or discontinued and during the "pill-free" week of the month. Lamotrigine is one of the preferred drugs for managing epilepsy in pregnant women.

Lamotrigine is generally well tolerated by patients. The most common adverse effects are drowsiness, dizziness, ataxia, headache, diplopia, blurred vision, nausea, vomiting, and rash. Patients should be monitored for the development of suicidal ideation. Over 10% of patients taking this AED will develop a rash, which normally occurs during the first 2 to 8 weeks of therapy. This drug carries a black box warning that serious dermatologic toxicity, including SJS, has been reported, especially in children. Lamotrigine should be discontinued at the first sign of any type of rash. This drug is pregnancy category C.

Levetiracetam (Keppra): Levetiracetam is available for both PO and IV routes and is utilized in the therapy of the following seizures: adjunctive therapy for partial seizures in adults and children ages 4 years and older, adjunctive therapy for myoclonic seizures in adults and adolescents ages 12 years and older, and adjunctive therapy of primary generalized tonic–clonic seizures in adults and children ages 6 years and older. Approved in 1999, the mechanism of its antiseizure activity is unknown. Levetiracetam is excreted unchanged by the kidneys; thus dosage should be reduced in patients with chronic kidney disease (CKD). Few significant drug interactions have been recorded. In 2008, an extended release form of the drug (Keppra XR) was approved to treat partial-onset seizures.

Levetiracetam is well tolerated, with the most common adverse effects being drowsiness, dizziness, infections, headache, and asthenia. The nurse must teach the patient to exercise care in performing tasks because an increase in unintentional injuries is associated with levetiracetam use. Pediatric patients exhibit a relatively high incidence of behavioral effects, including agitation, nervousness, hyperkinesia, hostility, depression, and emotional lability. Levetiracetam is pregnancy category C.

Pregabalin (Lyrica): Approved in 2004, pregabalin is an oral AED that is very similar to gabapentin. Pregabalin is indicated for the adjunctive therapy of adult patients with partial-onset seizures. Like gabapentin, it is used more often for its other approved indications: the management of neuropathic pain associated with diabetic peripheral

neuropathy, post-herpetic neuralgia, and fibromyalgia. Off-label uses include the therapy of anxiety and social phobia. The safety of pregabalin in pediatric patients has not been established. Although its mechanism of action has not been clearly demonstrated, it is thought to act by increasing GABA levels by reducing the calcium channel function of neurons in the brain. This drug does not affect CYP450 enzymes; thus it has fewer drug–drug interactions than many other AEDs. Pregabalin is not bound to plasma proteins and is excreted in an unmetabolized form by the kidneys. Dose reduction in patients with CKD is necessary to avoid toxicity.

Pregabalin is well tolerated by most patients. Dizziness and drowsiness are the most common adverse effects and these may affect 20% to 40% of patients taking pregabalin, especially at high doses. Other common adverse effects of pregabalin are blurred vision, lethargy, dry mouth, peripheral edema, weight gain, and difficulty with concentration or attention. Concurrent administration with other CNS depressants can lead to increased sedation. Because pregabalin is a Schedule V controlled substance that may cause physical and psychologic dependence, it should be used with caution in patients with a known or suspected history of substance abuse. Pregabalin is pregnancy category C.

Rufinamide (Banzel): Rufinamide is an oral drug approved in 2008 for the adjunctive treatment of seizures associated with Lennox–Gastaut syndrome. It is well tolerated, with dizziness, headache, and fatigue being common adverse effects. The drug acts by regulating the activity of sodium channels in the brain. It is contraindicated in patients with familial short ST syndrome. Rufinamide is pregnancy category C.

Tiagabine (Gabitril): Tiagabine is given by the oral route for the adjunctive treatment of partial seizures in patients who have not responded to therapy with other AEDs. Safety in patients under age 12 has not been established. Approved in 1997, it acts by inhibiting GABA reuptake into the presynaptic neuron. Tiagabine is extensively metabolized by CYP3A enzymes. Patients who are taking potent inducers of CYP450 enzymes (e.g., carbamazepine, phenytoin, and phenobarbital) will metabolize tiagabine more rapidly. Doses of tiagabine will need to be increased in these patients to produce an optimal antiseizure response. Tiagabine itself does not induce CYP450 enzymes; thus it has fewer drug–drug interactions than many other AEDs. Tiagabine is 98% bound to plasma proteins and is eliminated in both the urine and feces.

Approximately 10% to 20% of patients taking tiagabine experience adverse effects that require discontinuation of therapy. The most common adverse effects are dizziness, lethargy, confusion, somnolence, nausea, irritability, tremor, asthenia, abdominal pain, and difficulty with concentration or attention. As with other AEDs the nurse should teach patients to avoid injury due to possible sedative effects. Although tiagabine suppresses seizures in patients with epilepsy, it has been found to increase new-onset seizures when given to patients without epilepsy (for off-label indications). Because of this, the FDA and the manufacturer have advised prescribers not to administer tiagabine for any indication other than partial seizures in patients 12 years and older. An additional FDA warning advises healthcare providers to monitor carefully for any increase in suicidal behavior or ideation. Tiagabine is pregnancy category C.

Topiramate (Topamax, Trokendi XR, Others): Approved in 1996, topiramate has become an important medication in treating a broad range of seizure types in adults and children. It may be used as monotherapy or in combination with other AEDs. The drug is usually well tolerated, with the most frequent adverse effects being dizziness, fatigue, paresthesia, anorexia, weight loss, and psychomotor slowing. Newer, extended release forms (Qudexy XR, Trokendi XR) offer the convenience of once-daily dosing. During therapy, patients should be monitored for visual changes, glaucoma, metabolic acidosis, cognitive dysfunction, and suicidal behavior. Adequate fluid intake should be encouraged to prevent kidney stone formation. Because this drug can decrease sweating, the patient may be susceptible to hyperthermia during hot weather. Topiramate is pregnancy category D and may increase the risk of oral clefts in children exposed to the drug while in utero.

Vigabatrin (Sabril): Available PO, vigabatrin was approved in 2009 for adjunctive therapy of refractory complex partial seizures in adults. Because of potential serious adverse effects, vigabatrin is available in a restricted distribution program and is only prescribed when patients have not responded adequately to other medications. This drug contains a black box warning that permanent vision loss can occur during therapy. Other serious adverse effects include anemia, confusion, and memory impairment. Vigabatrin is pregnancy category C.

Zonisamide (Zonegran): Approved in 2000, zonisamide is an oral sulfonamide that is effective in combination with other AEDs for partial seizures in adults. Safety in patients under age 16 has not been established although the drug is sometimes used off-label in children. It produces antiepileptic effects by inhibiting sodium and calcium channels in brain neurons. Zonisamide has a long half-life and 2 weeks may be required before optimal antiseizure activity is achieved.

Zonisamide is well tolerated by most patients. The most common adverse effects are dizziness, ataxia, drowsiness, fatigue, anorexia, speech abnormalities, and difficulty

in concentrating or remembering. Because many patients are allergic to sulfonamides, it is important to assess these patients for sulfonamide hypersensitivity prior to the administration of the medication. Sulfonamides can cause fatal skin reactions, including SJS. The medication should be administered cautiously in patients who are receiving drugs that inhibit or reduce CYP3A4 enzymes; phenytoin, carbamazepine, phenobarbital, and valproic acid will decrease the half-life of zonisamide. Doses of zonisamide will need to be increased in these patients to produce an optimal antiseizure response. Zonisamide itself does not induce CYP enzymes; thus it has fewer drug–drug interactions than many other AEDs. Zonisamide is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Seizures

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, cardiovascular, or neurologic disease, mental status, closed-angle glaucoma, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a seizure history (e.g., frequency, duration, physical symptoms, preseizure symptoms that occur, and length of postictal period).
- Obtain baseline vital signs, weight, and, in pediatric patients, height.
- Obtain a developmental history in pediatric patients (e.g., DDST-II level of growth and development, and school performance).
- Evaluate appropriate laboratory findings (e.g., CBC, electrolytes, hepatic or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished or absence of seizure activity).
- Continue periodic monitoring of CBC and liver and renal function studies.
- Assess vital signs and weight periodically or if symptoms warrant. Assess height and weight in all pediatric patients.
- Assess for and promptly report adverse effects: excessive dizziness, drowsiness, lightheadedness, confusion, agitation, palpitations, tachycardia, blurred or double vision, continuous seizure activity, skin rashes, bruising or bleeding, abdominal pain, jaundice, change in color of stool, flank pain, and hematuria.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Antiseizure drugs may not completely resolve symptoms but frequency and severity of seizures should be diminished.)	• Teach the patient, family, or caregiver to keep a seizure diary of frequency, type, length, preseizure symptoms, and postictal period.
Minimizing adverse effects: • Continue to monitor vital signs, mental status, coordination, and balance periodically. Ensure patient safety; monitor ambulation until effects of the drug are known. **Lifespan:** Be particularly cautious with the older adult who is at increased risk for falls. (Antiseizure drugs may cause drowsiness and dizziness, hypotension, or impaired mental and physical abilities, increasing the risk of falls and injury.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes. **Lifespan:** Teach the patient, family, or caregiver to be especially cautious with the older adult who is at greater risk for falls. • Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• **Lifespan:** Continue to monitor height, weight, and developmental level in pediatric patients. In the school-age child, assess school performance. (Adverse effects of antiseizure drugs or unresolved seizures may hinder normal growth and development.)	• Teach the patient's family or caregiver to keep regularly scheduled appointments with the healthcare provider and report any developmental lags or concerns.
• Continue to monitor drug levels, CBC, renal and hepatic function, and pancreatic enzymes. • **Diverse Patients:** Some antiseizure drugs induce or inhibit CYP450 enzymes and may interact with other drugs. Ethnically diverse populations may also experience less than optimal effects of the drug. (Antiseizure drugs require periodic evaluation of drug levels to correlate level with symptoms. Antiseizure drugs may cause hepatotoxicity and valproic acid may cause pancreatitis as an adverse effect.)	• Instruct the patient on the need to return periodically for laboratory work. • **Diverse Patients:** Teach all patients, but especially ethnically diverse patients, to observe for less than optimal effects and report promptly. • Instruct the patient to carry a wallet identification card or wear medical identification jewelry indicating a seizure disorder and antiseizure medication. • Teach the patient to promptly report abdominal pain, particularly in the upper quadrants, changes in stool color, yellowing of sclera or skin, or darkened urine.
• Assess for changes in level of consciousness, disorientation, confusion, or agitation. (Neurologic changes may indicate overmedication or adverse drug effects.)	• Instruct the patient, family, or caregiver to report increasing lethargy, disorientation, confusion, changes in behavior or mood, slurred speech, or ataxia immediately.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Assess for changes in visual acuity, blurred vision, loss of peripheral vision, seeing rainbow halos around lights, acute eye pain, accompanied by nausea and vomiting, and report immediately. (Increased intraoptic pressure in patients with closed-angle glaucoma may occur in patients taking benzodiazepines.)	• Instruct the patient to report any visual changes or eye pain immediately.
• Assess for bruising, bleeding, or signs of infection. (Antiseizure drugs may cause blood dyscrasias and increased chances of bleeding or infection.)	• Teach the patient to report any signs of increased bruising, bleeding, or infections (e.g., sore throat and fever, or skin rash) promptly.
• Monitor for dermatologic effects including red or purplish skin rash, blisters, and sunburn. Immediately report severe rashes, especially associated with blistering. (Carbamazepine may cause significant dermatologic effects including SJS.)	• Teach the patient to wear sunscreen and use protective clothing for sun exposure and to avoid tanning beds. Immediately report any sunburn or rashes.
• Monitor affect and emotional status. (Antiseizure drugs may increase the risk of mental depression and suicide. Concurrent use of alcohol or other CNS depressants increases the effects and the risk.)	• Instruct the patient, family, or caregiver to report significant mood changes, especially depression, and to avoid alcohol and other CNS depressants while taking the drug.
• Assess the condition of gums and oral hygiene measures. (Hydantoins and phenytoin-like drugs may cause gingival hyperplasia, increasing the risk of oral infections.)	• Instruct the patient to maintain excellent oral hygiene and keep regularly scheduled dental appointments.
• Encourage appropriate lifestyle and dietary changes: increased intake of foods that are rich in vitamins K, D, and B, and folic acid, lowered caffeine intake including OTC medications that contain caffeine, and limited or no alcohol intake. (Caffeine and nicotine may decrease the effectiveness of the benzodiazepines. Barbiturates, drugs with GABA action, and hydantoins and phenytoin-like drugs affect the absorption of vitamins K, D, and B, and folic acid. Alcohol and other CNS depressants may increase the adverse effects of antiseizure drugs.)	• Encourage the patient to decrease or abstain from caffeine, nicotine, and alcohol, and to increase the intake of foods that are rich in vitamins K, D, and B, and folic acid. • Advise the patient to discuss all OTC medications with the healthcare provider to ensure that caffeine or alcohol is not included in the formulation.
• **Lifespan:** Monitor children for paradoxical response to barbiturates. (Hyperactivity may occur.)	• Instruct the patient, family, or caregiver to notify the healthcare provider if the patient exhibits hyperactive behavior.
• **Lifespan:** Assess women of childbearing age for the possibility of pregnancy, and plans for pregnancy, breastfeeding, and contraceptive use. (Antiseizure medications are category D in pregnancy. AEDs are known to decrease the effectiveness of oral contraceptives and additional forms of contraception should be used.)	• Discuss pregnancy and family planning with women of childbearing age. Explain the effect of medications on pregnancy and breastfeeding and the need to discuss any pregnancy plans with the healthcare provider. Discuss the need for additional forms of contraception, including barrier methods.
• Avoid abrupt discontinuation of therapy. (Status epilepticus may occur with abrupt discontinuation.)	• Instruct the patient to take the drug exactly as prescribed and to not stop it abruptly.
• Provide emotional support and appropriate referrals as needed. (Treatment with antiseizure drugs may require using combinations of drugs, and seizure activity may diminish but may not be resolved. Social isolation and low self-esteem may occur with continued seizure disorder.)	• Teach the patient, family, and caregiver about support groups, and make appropriate referrals as needed.
• Closely monitor the IV infusion site when using IV antiseizure drugs. All IV drips should be given via infusion pump. (Benzodiazepines, hydantoins, and barbiturates are irritating to the vein. Blanching and pain at the IV site are an indicator of extravasation; the IV infusion should be immediately stopped and the provider contacted for further treatment orders. Infusion pumps will allow precise dosing of the medication.)	• Teach the patient to report pain or burning at the IV site or in the extremity with the IV immediately.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for and when to report them, and the anticipated length of medication therapy.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug as prescribed and do not substitute brands. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication:
	  • Exactly as ordered and the same manufacturer's brand each time the prescription is filled. (Switching brands may result in differing pharmacokinetics and alterations in seizure control.)
	  • Read label directions for how to take the medication. Some forms may not be opened or chewed; others require chewing thoroughly. When in doubt, consult a pharmacist or other healthcare provider.
	  • Take a missed dose as soon as it is noticed but do not take double or extra doses to "catch up."
	  • Take with food to decrease GI upset.
	  • Do not abruptly discontinue the medication.

Understanding Chapter 22

Key Concepts Summary

22.1 Epilepsy is characterized by recurrent seizures caused by disturbances in the electrical activity of the brain.

22.2 Seizure disorders differ throughout the lifespan.

22.3 Most seizures are classified as generalized or partial.

22.4 Some types of seizures are called special epileptic seizures or are unclassified.

22.5 The selection of antiepileptic drug therapy is dependent on seizure type and characteristics.

22.6 Antiepileptic drugs act by suppressing abnormal neuronal discharges.

22.7 Barbiturates are traditional drugs for tonic–clonic seizures that have been replaced by newer and safer medications.

22.8 Benzodiazepines are important drugs in the treatment of status epilepticus.

22.9 Hydantoins are effective in the management of most types of seizures but have many adverse effects.

22.10 Carbamazepine is a first-line drug for treating many tonic–clonic and partial seizures.

22.11 Succinimides are the first-line drugs for the pharmacotherapy of absence seizures.

22.12 Several miscellaneous drugs are important in treating epilepsy.

CASE STUDY: Making the Patient Connection

Remember the patient "Jorge Alvarez" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Jorge Alvarez is a 3-year-old boy who has been hospitalized following a seizure. Since being admitted 2 days ago, he has experienced three subsequent tonic–clonic seizures lasting 2 to 2.5 minutes each. Prior to having a seizure, Jorge notices a flash of light. He then loses consciousness, emits a hoarse cry, and has intense muscle contractions. During the clonic phase he is incontinent of bowel and bladder. His postictal phase is characterized by drowsiness, disorientation, and deep sleep.

On admission Jorge was scheduled for a sleep-and-awake EEG. His EEG revealed a high-voltage spike discharge, which is diagnostic of a tonic–clonic seizure. The laboratory studies performed on Jorge included a serum lead level to rule out lead intoxication and a serum glucose level to rule out hypoglycemia. Both the lead level and blood glucose were in the normal range.

Jorge has been started on the following medications to assist in controlling his tonic–clonic seizures: carbamazepine (Tegretol) 300 mg PO tid and phenytoin (Dilantin) 120 mg PO tid.

Critical Thinking Questions

1. Jorge's mother expresses concern about what to do if he has a seizure. Create a list of home safety tips that could be given to her.
2. What will you instruct Jorge's mother about with regard to his medication administration?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Matt has had epilepsy since childhood. It seems that his current medications are no longer keeping him seizure free. Valproic acid (Depakene) is being added to Matt's medication regimen. How would you respond to the following questions from Matt about this new medication?

1. How does valproic acid (Depakene) work to prevent seizures?
2. What adverse effects are associated with this drug?
3. Why should Matt inform his dentist that he is now on valproic acid?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A 10-year-old child has been evaluated for a learning disability and has been diagnosed with absence seizures. Ethosuximide (Zarontin) has been ordered and the nurse is teaching the patient and family about the drug. Because of the patient's age, it is important to include instructions to:
    1. Curtail after-school sports activities because the drug's metabolism may be increased with physical activity.
    2. Increase intake of calcium-rich foods and vitamin D to prevent bone loss.
    3. Monitor height and weight weekly to be sure GI side effects are not hindering nutrition and normal growth.
    4. Increase fluid intake to avoid dehydration caused by the drug.

2. The nurse is caring for a 42-year-old patient who was recently diagnosed with partial seizures and has been prescribed oxcarbazepine (Trileptal). Which laboratory study would the nurse expect to be ordered?
    1. CBC with differential
    2. Serum albumin and glucose levels
    3. Sedimentation rate and platelet count
    4. Serum sodium and renal function studies

3. An 80-year-old patient is prescribed carbamazepine (Tegretol) for a newly diagnosed seizure disorder. The nurse will implement safety measures because this patient is at an increased risk for which adverse effects with the administration of this drug?
    1. Dementia and confusion
    2. Insomnia and forgetfulness related to sleep deprivation
    3. Stroke and decreased motor function
    4. Sedation and falls

4. A 23-year-old patient has been taking gabapentin (Neurontin) for control of partial seizures. He is admitted to the emergency department with slurred speech, dyspnea, reports of double vision, and sedation. The admitting nurse suspects the patient has:
    1. Not taken his drug for several days.
    2. Taken an overdose of the drug, either unintentionally or deliberately.
    3. Taken the drug with grapefruit or grapefruit juice.
    4. Continued to smoke despite prior patient education that smoking interacts with the drug.

5. The nurse, who is monitoring a patient taking phenytoin (Dilantin), has noted symptoms of nystagmus, confusion, and ataxia. Considering these findings, the nurse would suspect that the dose of the drug should be:
    1. Reduced.
    2. Increased.
    3. Maintained.
    4. Discontinued.

6. Carbamazepine (Tegretol) has been prescribed for a 24-year-old patient for the control of partial seizures. The nurse will teach the patient to immediately report:
    1. Blurred vision.
    2. Leg cramps.
    3. Blister-like rash.
    4. Lethargy.

Chapter 23
Pharmacotherapy of Muscle Spasms and Spasticity

Chapter Outline

- Etiology and Pathophysiology of Muscle Spasms and Spasticity
- Nonpharmacologic Therapies for Muscle Spasms and Spasticity
- Pharmacotherapy of Muscle Spasms

  Centrally Acting Skeletal Muscle Relaxants

  PROTOTYPE *Cyclobenzaprine (Amrix), p. 363*
- Pharmacotherapy of Muscle Spasticity

  Direct-Acting Skeletal Muscle Relaxants

  PROTOTYPE *Dantrolene (Dantrium, Revonto), p. 366*
- Skeletal Muscle Relaxants as Surgical Adjuncts

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the etiology and pathophysiology of muscle spasm and muscle spasticity.
2. Describe the nonpharmacologic management of muscle spasms and muscle spasticity.
3. Identify drug classes used to treat muscle spasms and spasticity.
4. Compare and contrast the actions of the centrally acting and direct-acting skeletal muscle relaxants.
5. Explain the role of skeletal muscle relaxants as surgical adjuncts.
6. Describe the nurse's role in the pharmacologic management of muscle spasms and muscle spasticity.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving pharmacotherapy for muscle spasms and spasticity.

Key Terms

dystonia, 360 **muscle spasms, 359** **muscle spasticity, 359**
malignant hyperthermia, 367

The administration of drugs to relieve muscle spasms and musculoskeletal pain dates back to the early 19th century when scientists discovered curare, a substance used for hundreds of years by Amazon Indians as a poison on arrows. Although everyone experiences muscle aches and pains from time to time, these symptoms often resolve without pharmacotherapy. There are some conditions, however, where medications may be used to relieve painful muscle pain, spasm, or spasticity. This chapter examines how these drugs produce their actions and their applications to the pharmacotherapy of muscle conditions.

Etiology and Pathophysiology of Muscle Spasms and Spasticity

23.1 Whereas muscle spasms are often caused by overuse of skeletal muscle, muscle spasticity involves damage to motor nerves.

Intense skeletal muscle contractions can cause severe pain and disability. Abnormal contractions may be classified as spasms or spasticity. Although both may occur in the same patient, the etiology, pathogenesis, and treatment strategies differ for the two conditions.

Muscle spasms: **Muscle spasms** are involuntary contractions of skeletal muscles that are usually localized to a specific muscle group. As the affected muscles strongly contract and tighten, the spasm causes sudden, intense pain, which gradually diminishes after a few minutes. Patients may refer to the condition as a charley horse or cramp. In addition to causing intense pain, chronic or severe spasms can impair joint mobility.

When treating a patient with muscle spasms, it is important to identify their cause. The etiology of muscle spasms may involve many body systems, including the nervous, musculoskeletal, endocrine, and cardiorespiratory systems. The most common etiology of muscle spasm is overuse of a skeletal muscle. When subjected to trauma or overexertion, the muscle may spasm. If the history does not reveal muscle overuse or injury, the healthcare provider will need to assess for possible metabolic or electrolyte imbalances such as hypocalcemia, hypokalemia, or dehydration. Poor blood circulation to the legs, known as claudication, is a common cause of muscle cramping.

Some medications may cause muscle spasms, muscle weakness, and other types of myopathy as adverse effects, as shown in Table 23.1. Signs of drug-induced myopathy usually develop slowly after several months of drug therapy. The most important class causing this pathology is the statins, which are widely used to lower blood cholesterol levels. Statins can cause a severe form of myopathy called rhabdomyolysis that may cause significant disability and morbidity. Most drug-induced myopathies are reversible in their early stages. If a medication is suspected of causing myopathy, the dose is lowered or the drug is discontinued.

Table 23.1 Medications That May Cause Myopathy as an Adverse Effect

Drug Class	Example(s)
Alzheimer's drug	donepezil (Aricept)
Antifungals	fluconazole (Diflucan), ketoconazole (Nizoral)
Antihyperlipidemics	statins (Crestor, Lipitor, Zocor), niacin, red yeast rice
Antineoplastics	cisplatin (Platinol), imatinib (Gleevec), vincristine
Antiulcer drugs: proton pump inhibitors	esomeprazole (Nexium), omeprazole (Prilosec)
Asthma drugs	albuterol (Proventil, Ventolin), terbutaline (Brethine)
Calcium channel blockers	nifedipine (Procardia)
Diuretics	furosemide (Lasix), hydrochlorothiazide (Microzide)
Immunosuppressants	corticosteroids, leflunomide (Arava)

Muscle spasticity: Muscle spasticity has a different etiology than muscle spasm. **Muscle spasticity** is a condition caused by damage to upper motor neurons in the central nervous system (CNS), which causes certain muscle groups to remain in a continuous state of contraction. The patient may experience irritable deep tendon reflex activity, muscle spasms, involuntary jerking, and scissoring movements of the lower extremities. Patients with muscle spasticity are unable to voluntarily relax their limbs. Spasticity, also referred to as hypertonia, causes pain that is more intense than muscle spasm and produces greater impairment of mobility.

Whereas muscle spasms occur most often with overexertion, muscle spasticity is associated with neuromuscular diseases that are the result of damage to neurons in the region of the cerebral cortex that controls muscle movements. Conditions most commonly associated with muscular spasticity include severe head or spinal cord trauma,

multiple sclerosis (MS), stroke, cerebral palsy (CP), trauma, and amyotrophic lateral sclerosis (ALS).

Under normal conditions a muscle receives a balance of both excitatory and inhibitory signals from motor neurons. When a muscle needs to contract, an impulse is sent from the brain or spinal cord down an excitatory motor neuron. When a muscle needs to relax, the brain sends a signal to the muscle through an inhibitory motor neuron. As a simple example, consider flexion and extension of the elbow. Forearm flexion occurs when the biceps receives an excitatory impulse; at the same time its antagonist, the triceps, receives an inhibitory impulse. On extension, the opposite occurs: The biceps receives the inhibitory message while the triceps contracts after receiving the excitatory message. Proper contraction of skeletal muscle thus involves a balance of signals from the CNS through both excitatory and inhibitory motor neurons.

Muscle spasticity from a spinal cord injury occurs when there is an imbalance of excitatory and inhibitory signals. The area that is distal to the spinal cord injury or lesion becomes disassociated from the inhibitory area of the brain, and the excitatory impulses dominate at the affected muscles. The muscles may go into spastic paralysis; flexor muscles become tight, and the muscles can be extended only with great difficulty. Once extended, the muscles tend to immediately flex back. It is important to understand that although the obvious symptoms appear to be muscle related, the cause of the spasticity is actually neurologic injury.

In the advanced stages of MS, muscle spasticity is caused by destruction of the myelin sheath, which interrupts the main motor pathways from the spinal cord to the muscles. Spasticity results in a stiff, unbalanced gait and may eventually confine these patients to a wheelchair. Patients with MS are treated with a combination of medications including muscle relaxants, corticosteroids, and immunosuppressants (see Chapter 21).

Approximately 35% of patients experience spasticity following a stroke. If the brain area affected by the stroke is able to reestablish communication with the muscle, the spasticity may be reversible and voluntary movement may be restored. In many cases, however, the spasticity becomes permanent and can be recognized by a clenched fist, permanently flexed elbow, or pointed toes.

Cerebral palsy is a neurologic disorder that results in severe muscular spasticity, which can affect facial muscles, cause an unsteady, scissoring gait, and result in painful joint contractures and deformities. The primary cause of spasticity associated with CP is congenital trauma to the brain or spinal cord. Pharmacologic options for treating CP are limited. Intrathecal baclofen may be beneficial in reducing severe spasticity.

Muscle spasms, spasticity, and twitching are also characteristic of ALS, also known as Lou Gehrig's disease. ALS is caused by the degeneration and loss of lower and upper motor neurons in the CNS. The disorder is progressive and fatal. Muscle relaxants may bring some pain relief during periods of intense muscle spasticity.

Dystonia is a chronic neurologic disorder that is characterized by involuntary muscle contraction that forces body parts into abnormal, painful movements or postures. The condition may affect the entire body (generalized dystonia), or it may be localized to a single body region (focal dystonia) such as the arms, legs, trunk, neck, eyelids, face, or vocal cords. Dystonia may occur secondary to other neurologic disorders such as MS, stroke, or CP. The impairment in mobility and intense pain produced by muscle spasms and spasticity inhibits the patient's ability to perform activities of daily living (ADLs). Generalized dystonias are treated with high doses of anticholinergic drugs such as benztropine, benzodiazepines, and baclofen. Patients with focal dystonia may obtain some relief with botulinum toxin type A.

Dupuytren's contracture is a condition of the hand in which a thick cord of connective tissue forms in the palm, causing the fingers to curl inward. Although not usually painful, the curling is progressive and can restrict motion and use of the hand. This disorder is not caused by muscles; therefore, traditional muscle relaxants and antispasmodics are ineffective. For severe cases, surgical removal of the connective tissue cord is performed. Collagenase (Xiaflex) is an enzyme medication approved to treat this disorder. The enzyme is injected multiple times into the affected cord, over a 4-week interval. The most frequently reported adverse effects are swelling of the affected hand, contusion, injection-site reaction or hemorrhage, and localized pain.

Nonpharmacologic Therapies for Muscle Spasms and Spasticity

23.2 Nonpharmacologic interventions for treating muscle spasms and spasticity are limited.

The therapeutic goals for treating muscle spasms or spasticity are to decrease discomfort and enhance mobility so that the patient is better able to perform ADLs. Nonpharmacologic complementary and alternative therapies (CATs) are sometimes implemented to achieve these goals. When the spasms or spasticity are prolonged or disabling, pharmacotherapy is initiated. A combination of CATs and drug therapy is often the most effective treatment.

Nonpharmacologic interventions that sometimes benefit patients with muscle spasm or spasticity include the application of heat or cold, massage, traction, and manipulation. The application of heat or cold to the affected site will reduce or relieve the muscle spasm and pain. If the spasm has occurred due to overexertion, application of

heat to the area can reduce cramping and relieve localized pain. If the spasms persist after 3 to 5 days, the application of cold packs to the site may be used to slow the transmission of pain impulses. The application of touch, massage, and gentle pressure are sometimes effective at promoting musculoskeletal relaxation. Other nonpharmacologic techniques that may be useful include acupuncture, sensory nerve stimulation, and ankle splints for leg pain.

The implementation of physical therapy is sometimes effective for treating muscle spasticity. Routine and consistent physical therapy exercises provide the patient with increased muscle movement and decreased severity of symptoms. Effective physical therapy exercises include muscle stretching, which assists in the prevention of contractures (permanent shortening of muscles). The implementation of muscle group strengthening and repetitive motion exercises may allow for safer ambulation. In extreme cases, surgery may be necessary to release tendons or to sever the nerve–muscle pathway.

Herbal remedies are occasionally used to treat patients with muscle spasms. Black cohosh, first used for neuralgia and muscular pain in the 1840s, may be applied topically to produce relaxation of muscles. Castor oil packs can be applied to the site of pain and muscle spasm. The castor oil should be warmed, soaked into a flannel, wool, or cotton cloth, and then applied to the tonic muscle. Capsaicin, derived from cayenne pepper, is applied topically as a cream four times per day to increase mobility and reduce pain. It is important to instruct the patient to wear gloves while applying capsaicin cream to prevent irritation of the skin on the hands and to avoid introducing the capsaicin to the eyes or other parts of the body not under treatment. A high-potency prescription drug containing 8% capsaicin (Qutenza) is approved to treat neuropathic pain associated with post-herpetic neuralgia.

A final nonpharmacologic therapy for muscle spasm is treatment with B complex vitamins, specifically pyridoxine (B_6). In some patients, the B complex vitamins can reduce both the intensity and duration of leg cramps.

Pharmacotherapy of Muscle Spasms

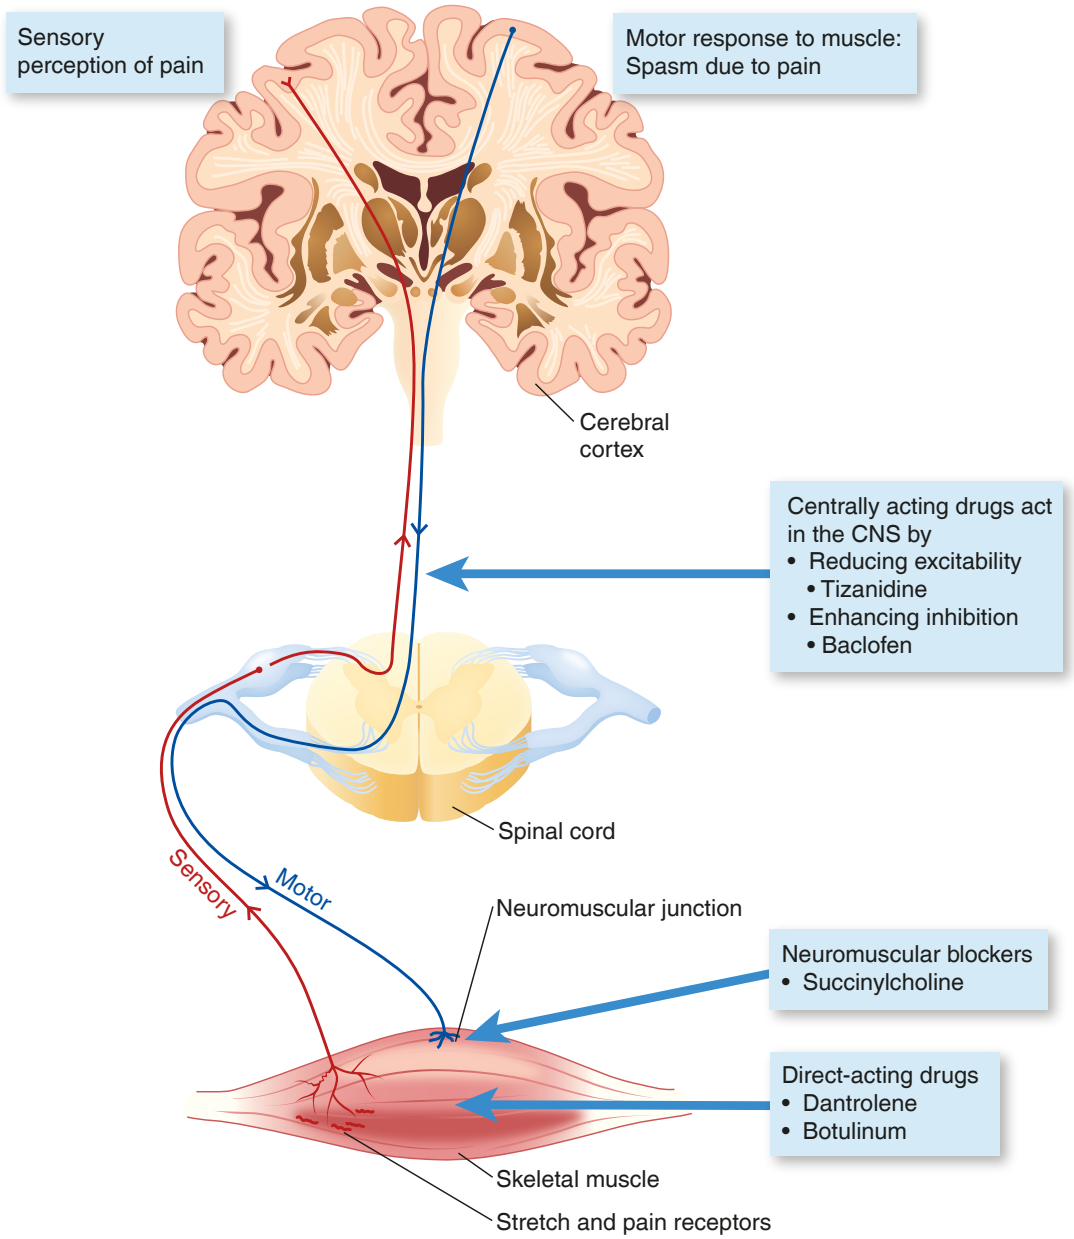
23.3 Nonsteroidal anti-inflammatory drugs and skeletal muscle relaxants are used to treat muscle spasms.

Muscle spasms, especially those caused by injury, are painful and sometimes associated with inflammation. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, naproxen, and ibuprofen are usually the first-line drugs for treating minor to moderate pain due to muscle overexertion. These drugs have the ability to relieve muscle pain and reduce inflammation around the injury site, which can take pressure off the surrounding nerves and enhance mobility. The pharmacology of NSAIDs is presented in Chapter 41.

For more intense muscle spasms, muscle relaxants may be prescribed. Although these drugs are not analgesics, they can promote pain relief by relaxing tight, contracted muscles without interfering with normal muscle function. When skeletal muscle relaxants are used in combination with NSAIDs, pain relief is greater than when either drug is used alone.

CONNECTIONS: Using Research in Practice

Use of Intrathecal Baclofen to Treat Spastic Cerebral Palsy in Children



Between 70% and 90% of patients with CP have spasticity along with other motor disorders. Prior treatment for CP patients with spasticity has included diazepam (Valium), dantrolene (Dantrium), and oral baclofen (Lioresal). Because these drugs are given PO, they may cause significant systemic adverse effects such as drowsiness, confusion, behavior changes, and hypotension. In the early 2000s, the American Academy for Cerebral Palsy and Developmental Medicine (AACPDM) performed a systematic review of treatment and noted beneficial effects of continuous intrathecal baclofen (ITB) in patients with spastic CP, but noted that no well-controlled studies in children had been conducted.

A 2015 Cochrane report (Hasnat & Rice, 2015) confirmed the earlier studies' reports of limited evidence that ITB is an effective therapy for reducing spasticity in children with CP. Although the report found that the research was unsuitable to conduct a meta-analysis, the qualitative summary supported the use of ITB as a treatment. Of the five studies reviewed in the report, one study assessed the effectiveness of implantable ITB pumps over 6 months, and the four other studies looked at the short-term results of ITB on spasticity in children with CP. The results of both the short-term and longer term studies showed improvement in comfort and ease of care and a small improvement in gross motor function and spasticity.

Based on these findings, ITB may offer improved and targeted treatment of the spasticity, pain, loss of ADL ability, and other effects of CP in children, especially for those who have not responded well or at all to traditional PO medications or surgery. Nurses often provide the most direct support and connection to families dealing with the long-term implications of CP. They can provide education on the use and care of the ITB pump, site care, and drug effects to monitor for those families choosing this option. Nurses may also help educate school staff and nurses on the use and care of the pump and the monitoring required for adverse effects.

Pharmacotherapy Illustrated 23.1

Mechanism of Action of Drugs Used to Treat Muscle Spasms and Spasticity

The centrally acting skeletal muscle relaxants relieve muscle spasms by their actions in the CNS. They do not directly affect the neuromuscular junction or muscles themselves. The precise mechanism of action of centrally acting skeletal muscle relaxants is unclear but it is believed they help to restore the balance of excitatory and inhibitory impulses from motor neurons in the CNS. Like the benzodiazepines, they can produce significant drowsiness, especially if combined with alcohol or other CNS depressants. The sedative effects may be beneficial in helping patients with muscle spasms or spasticity to obtain needed sleep. The centrally acting skeletal muscle relaxants include baclofen (Lioresal), cyclobenzaprine (Amrix), deutetrabenazine (Austedo), tetrabenazine (Xenazine), and tizanidine (Zanaflex). Some drugs in this class are used for both muscle spasms and spasticity. Mechanisms of action are shown in Pharmacotherapy Illustrated 23.1. Doses of the centrally acting muscle relaxants are listed in Table 23.2.

Table 23.2 Centrally Acting Skeletal Muscle Relaxants

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
baclofen (Lioresal)	PO: 5 mg tid, increasing gradually to 40–80 mg/day (max: 80 mg/day) Intrathecal: 50-mcg bolus	*Drowsiness, dizziness, weakness, fatigue, confusion, altered mental status, nausea, vomiting, constipation, urinary frequency* QT prolongation, dysrhythmias
carisoprodol (Soma)	Adult: PO: 250–350 mg tid	*Drowsiness, confusion, orthostatic hypotension, nausea, vomiting, hiccups, vertigo, ataxia, tremor, syncope* Anaphylactic shock, physical dependence, profound sedation
chlorzoxazone	PO: 250–500 mg tid–qid (max: 3 g/day)	*Drowsiness, dizziness, anorexia, heartburn, nausea, vomiting, diarrhea, abdominal pain, lightheadedness, overstimulation, rash, pruritus, urticaria, discoloration of urine* Hepatotoxicity, jaundice, anemia, neutropenia
cyclobenzaprine (Amrix)	PO: 5–10 mg tid for tablets; 15 mg once daily for extended release capsules (max: 30 mg/day)	*Drowsiness, xerostomia, dizziness, fatigue, nausea, constipation, dyspepsia* Tongue edema, potential for QT prolongation, hallucinations, serotonin syndrome
deutetrabenazine (Austedo) and tetrabenazine (Xenazine)	PO (Austedo): 6 mg once daily (max: 48 mg/day) PO (Xenazine): 12.5–50 mg/day in divided doses	*Sedation, fatigue, insomnia, depression, akathisia, anxiety, nausea* Neurologic malignant syndrome
metaxalone (Skelaxin)	PO: 800 mg tid–qid	*Nausea, vomiting, GI upset, drowsiness, dizziness, headache, anxiety* Hemolytic anemia, jaundice, hepatotoxicity, anaphylaxis
methocarbamol (Robaxin)	PO: 4 g/day maintenance dose IV/IM: 1–3 g once daily for 3 days	*Drowsiness, dizziness, lightheadedness, fever, pruritus, rash, syncope, thrombophlebitis, pain, blurred vision, headache, tachycardia, syncope* Anaphylactic shock, sloughing of skin with extravasation
orphenadrine	PO: 100 mg bid IM/IV: 60 mg q12h (max: 250 mg/day)	*Dry mouth, drowsiness, weakness, dizziness, agitation, tachycardia, syncope, palpitations, increased ocular tension, blurred vision, nausea, vomiting, abdominal cramps, pruritus, urticaria* Anaphylactic shock, hallucinations
tizanidine (Zanaflex)	PO: 4–8 mg q6–8h (max: 36 mg/day)	*Dry mouth, somnolence, asthenia, fatigue, back pain, dizziness, flulike symptoms* Hepatotoxicity, hypotension, bradycardia, hallucinations

Note: *Italics* indicates common adverse effects. Underline indicates serious adverse effects.

Drugs from a number of other classes have been used to treat and prevent muscle spasms. Calcium channel blockers including diltiazem (Cardizem, Dilacor) and verapamil (Calan) may be used off-label to prevent muscle cramps. The mechanism for this action is unknown but may be related to the drugs' ability to dilate arteries and bring additional oxygen to muscles.

Benzodiazepines such as diazepam (Valium) are occasionally prescribed to relax skeletal muscle. Diazepam may be used as an adjunct to relieve skeletal muscle spasms associated with CP, paraplegia, and tetanus. Diazepam is a featured prototype drug for seizures in Chapter 22.

CONNECTION Checkpoint 23.1

Benzodiazepines are some of the most widely prescribed drugs. From what you learned in Chapter 18, what are the major indications for drugs in this class? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Cyclobenzaprine (Amrix)

Classification **Therapeutic:** Skeletal muscle relaxant
Pharmacologic: Centrally acting antispasmodic

Therapeutic Effects and Uses: Approved in 1977, cyclobenzaprine is indicated for the short-term therapy of acute musculoskeletal conditions that are unrelated to CNS disease. Cyclobenzaprine is not effective for treating muscle spasm due to spinal cord injury or CP. The drug promotes skeletal muscle relaxation, thus decreasing muscle spasms and increasing joint mobility. The manufacturer recommends that treatment not extend beyond 3 weeks. Fibromyalgia is an off-label indication for the drug.

Cyclobenzaprine is chemically related to the tricyclic antidepressants (TCAs) and it exhibits some antidepressant effects. The drug is available by immediate release tablet or extended release capsule. Cyclobenzaprine is occasionally abused as a recreational drug due to its sedative actions.

Mechanism of Action: The action of cyclobenzaprine is thought to occur at the brainstem and spinal cord levels. The drug increases norepinephrine activity by blocking its synaptic reuptake to produce an anticholinergic effect. Cyclobenzaprine acts centrally and thus has no direct action on skeletal muscle.

Pharmacokinetics:

Route(s)	PO
Absorption	Well absorbed in the gastrointestinal (GI) tract
Distribution	It is unknown whether the drug crosses the placenta or is secreted in breast milk; 93% bound to protein
Primary metabolism	Extensive hepatic metabolism via CYP450 enzymes to inactive metabolites
Primary excretion	Renal
Onset of action	1 h
Duration of action	12–24 h

Adverse Effects: Commonly reported adverse effects include drowsiness, dizziness, and xerostomia. Sedation can be a limiting effect with the first few doses. Other adverse effects of cyclobenzaprine include edema of the tongue and face with sweating, myalgia, hepatitis, and alopecia. Potential cardiovascular adverse events include orthostatic hypotension, tachycardia, syncope, palpitations, and vasodilation. The patient may report having an unpleasant taste, a coated tongue with discoloration, vomiting, anorexia, diarrhea with flatulence, or paralysis.

Contraindications/Precautions: Cyclobenzaprine should be used with great caution in patients older than age 65 because this population is more likely to experience confusion, hallucinations, and adverse cardiac events from the drug. Cyclobenzaprine also should be used cautiously in patients who have increased intraocular pressure, prostatic hyperplasia, urinary retention, and seizures. Patients with hypersensitivity to TCAs should not receive this drug. Like the TCAs, cyclobenzaprine can adversely affect the heart and therefore should be used with caution in patients with cardiovascular disease, including those with heart failure or dysrhythmias with heart block. It is contraindicated in patients who have QT interval prolongation on the electrocardiogram (ECG) or who are in the recovery phase of a myocardial infarction (MI). The drug is metabolized in the liver and thus should be administered cautiously to patients with hepatic impairment. Patients with a history of hyperthyroidism should not be administered cyclobenzaprine.

Drug Interactions: Cyclobenzaprine should not be administered with alcohol, opioids, barbiturates, or any other CNS depressants because significant sedation may occur. Phenothiazines and anticholinergic drugs will enhance the anticholinergic adverse effects and are contraindicated with cyclobenzaprine. Use with TCAs may result in additive CNS depression and increased anticholinergic effects. A potentially fatal hypertensive crisis can occur if cyclobenzaprine is used within 14 days of a monoamine oxidase inhibitor. Serotonin syndrome has been reported when cyclobenzaprine is coadministered with other drugs that increase serotonin such as selective serotonin reuptake inhibitors (SSRIs), serotonin–norepinephrine reuptake inhibitors (SNRIs), TCAs, tramadol, bupropion, meperidine, or verapamil. **Herbal/Food:** Additive CNS depression may occur if cyclobenzaprine is administered concurrently with valerian or kava.

Pregnancy: Category B.

Treatment of Overdose: Signs of overdose include CNS depression and tachycardia. Physostigmine (Antilirium) may be administered to reverse serious anticholinergic adverse effects. Overdose is generally not fatal.

Nursing Responsibilities: Key nursing implications for patients receiving cyclobenzaprine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Muscle Spasms and Spasticity.

Drugs Similar to Cyclobenzaprine (Amrix)

The following medications are other centrally acting skeletal muscle relaxants: baclofen, carisoprodol, chlorzoxazone, deutetrabenazine, metaxalone, methocarbamol, orphenadrine, tetrabenazine and tizanidine. Chlorphenesin (Maolate) is a centrally acting muscle relaxant that was removed from the market in the United States.

Baclofen (Lioresal): Approved in 1977, baclofen is used to reduce muscle spasticity in patients with injury or disease of upper motor neurons such as that associated with MS, CP, ALS, and spinal cord trauma. Off-label indications include the treatment of tardive dyskinesia related to long-term pharmacotherapy with antipsychotic drugs, persistent hiccups, and for management of neuropathic pain. The drug resembles the inhibitory neurotransmitter gamma aminobutyric acid (GABA) and acts by inhibiting neuronal activity within the brain and spinal cord. Baclofen is usually administered PO, but it can be administered by infusion delivered directly into the intrathecal space, using a small catheter and a pump. This provides a direct route for the baclofen to reach its target sites in the spinal cord and brain. Because the baclofen is delivered continuously at its site of action, very small amounts are needed to produce a therapeutic effect. The healthcare provider determines the amount of drug to be released by the pump and the

dosing schedule. The pump must be refilled every 1 to 3 months and the battery lasts 5 to 7 years. Several months of therapy may be required to achieve full therapeutic benefit from baclofen.

Adverse effects related to the administration of baclofen include drowsiness, dizziness, weakness, and fatigue. Abrupt discontinuation following prolonged therapy may cause high fever, seizures, severe rebound muscle spasticity, and hallucinations. This drug is pregnancy category C.

Carisoprodol (Soma): An older drug approved by the U.S. Food and Drug Administration (FDA) in 1959, carisoprodol is administered PO for the short-term therapy (up to 3 weeks) of acute, painful musculoskeletal conditions. It is effective in relieving the pain, muscle spasms, and spasticity associated with CP. The drug produces significant sedation in 40% of patients taking it and may cause significant CNS and respiratory depression if taken with alcohol or other CNS depressants. The general sedative nature of the drug is likely responsible for its ability to relieve the pain associated with muscle spasms. Although not a controlled substance, carisoprodol can cause physical dependence and has been abused by recreational drug users. The active metabolite of carisoprodol is meprobamate, a rarely used antianxiety agent and a Schedule IV drug. The drug should be used with caution in patients with a history of substance abuse. The development of newer medications and increased levels of carisoprodol abuse in recent years has led to less frequent prescribing of the drug. This drug is pregnancy category C.

Chlorzoxazone: Chlorzoxazone is an oral centrally acting skeletal muscle relaxant administered for the symptomatic treatment of discomfort associated with acute, painful musculoskeletal conditions. It is ineffective in the treatment of spasticity related to neurodegenerative disorders such as CP. The actions of the drug may be largely due to its sedative effects. It should not be combined with alcohol or other CNS depressants. Chlorzoxazone is hepatotoxic and should not be used in patients with liver impairment. Other adverse effects include anorexia, nausea, vomiting, rash, and red-orange discoloration of urine. Older adults may experience more adverse CNS effects than younger patients. This drug is pregnancy category C.

Deutetrabenazine (Austedo) and tetrabenazine (Xenazine): Deutetrabenazine (approved in 2017) and tetrabenazine (approved in 2008) have nearly identical chemical structures and are used to reduce chorea movements in patients with Huntington's chorea. They act by depleting the amounts of dopamine, serotonin, and norepinephrine at nerve terminals. The two drugs have identical actions and adverse effects except deutetrabenazine has a longer duration of action that allows once-daily dosing. Both drugs contain a black box warning regarding the risk for depression and suicidal thoughts. Tetrabenazine is pregnancy category C.

Metaxalone (Skelaxin): Approved in 1962, metaxalone is administered PO and is indicated for the symptomatic relief of muscle spasm and pain related to musculoskeletal conditions. It is ineffective in the treatment of spasticity-related neurologic disorders. The therapeutic effects of metaxalone are likely due to general CNS depression. Like chlorzoxazone, metaxalone may cause liver injury and is contraindicated in patients with hepatic impairment. It should not be administered to patients over age 65 due to significant anticholinergic effects. Drowsiness, nausea and vomiting, and anxiety are common adverse effects. This drug is pregnancy category C.

Methocarbamol (Robaxin): Approved in 1957, methocarbamol has central sedative effects that likely are responsible for its ability to reduce muscle spasms. It is used as an adjunct to physical therapy interventions. It can be administered intravenously (IV) for the treatment of tetanus or other acute musculoskeletal conditions. Methocarbamol may cause significant dizziness and sedation and should not be taken with alcohol or other CNS depressants. It is contraindicated in patients with chronic kidney disease. It should not be administered to patients over age 65 due to significant anticholinergic effects. This drug is pregnancy category C.

Orphenadrine: Orphenadrine was approved in 1959. It is administered PO or parenterally to relax skeletal muscles and reduce pain. The drug has analgesic properties and may be administered parenterally to produce local anesthetic effects. It may be used off-label as an adjunct in the treatment of the muscular rigidity associated with Parkinson's disease. The most common side effect of orphenadrine is xerostomia. Orphenadrine is structurally very similar to diphenhydramine (Benadryl) and can cause prominent anticholinergic effects; therefore, it should not be used with other anticholinergic drugs due to the risk for additive toxicity. Orphenadrine produces a mild to moderate euphoric effect that has led to its abuse. This drug is pregnancy category C.

Tizanidine (Zanaflex): Approved in 1996, tizanidine is a centrally acting alpha$_2$-adrenergic agonist that inhibits motor neurons mainly at the spinal cord level. It has no direct effect on muscle fibers. Indicated for the management of muscle spasticity, tizanidine is most effective in patients who have significantly diminished muscle tone, including spasticity related to brain or spinal cord injury or MS. Tizanidine is as effective as baclofen in treating muscle spasticity and is considered a first-line drug. One disadvantage of tizanidine is that it has a short duration of action that requires dosing every 6 to 8 hours.

The most common adverse effects of tizanidine include xerostomia, fatigue, weakness, dizziness, and drowsiness. Hypotension is common at higher doses; the drug is closely related to clonidine (Catapres), which is an antihypertensive drug. Hallucinations are uncommon but patients with a history of psychosis should be carefully monitored for this adverse effect. Tizanidine is hepatotoxic and should not be used in patients with liver impairment. Older adults, especially those with chronic kidney disease, may experience adverse effects such as drowsiness, dizziness, dry mouth, and asthenia. This drug is pregnancy category C.

CONNECTION Checkpoint 23.2

Cyclobenzaprine is very similar to the TCAs. From what you learned in Chapter 19, describe the major indications (approved and off-label) for the TCAs. *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PharmFACT

The brain lesions of CP occur in the fetus and through age 3, but the diagnosis may not be made until age 5 or later (Abel-Hamid, 2016).

Pharmacotherapy of Muscle Spasticity

23.4 Direct-acting skeletal muscle relaxants are often used to relieve muscle spasticity.

Medications effective in the treatment of spasticity include muscle relaxants that act at the level of the CNS, neuromuscular junction, or muscle tissue. Some of the centrally acting medications used to treat muscle spasms, such as baclofen (Lioresal) and tizanidine (Zanaflex), are also effective in treating spasticity.

Dantrolene (Dantrium, Revonto) and the botulinum toxins act directly on skeletal muscle to relieve spasticity. These are called direct-acting muscle relaxants or antispasticity drugs. Dantrolene is the prototype for direct-acting drugs. Doses of these drugs are listed in Table 23.3. The mechanisms of action of direct-acting antispasmodics are shown in Pharmacotherapy Illustrated 23.2.

PROTOTYPE DRUG **Dantrolene (Dantrium, Revonto)**

Classification **Therapeutic:** Direct-acting skeletal muscle relaxant, antispasticity drug
Pharmacologic: Calcium release blocker (skeletal muscle cells)

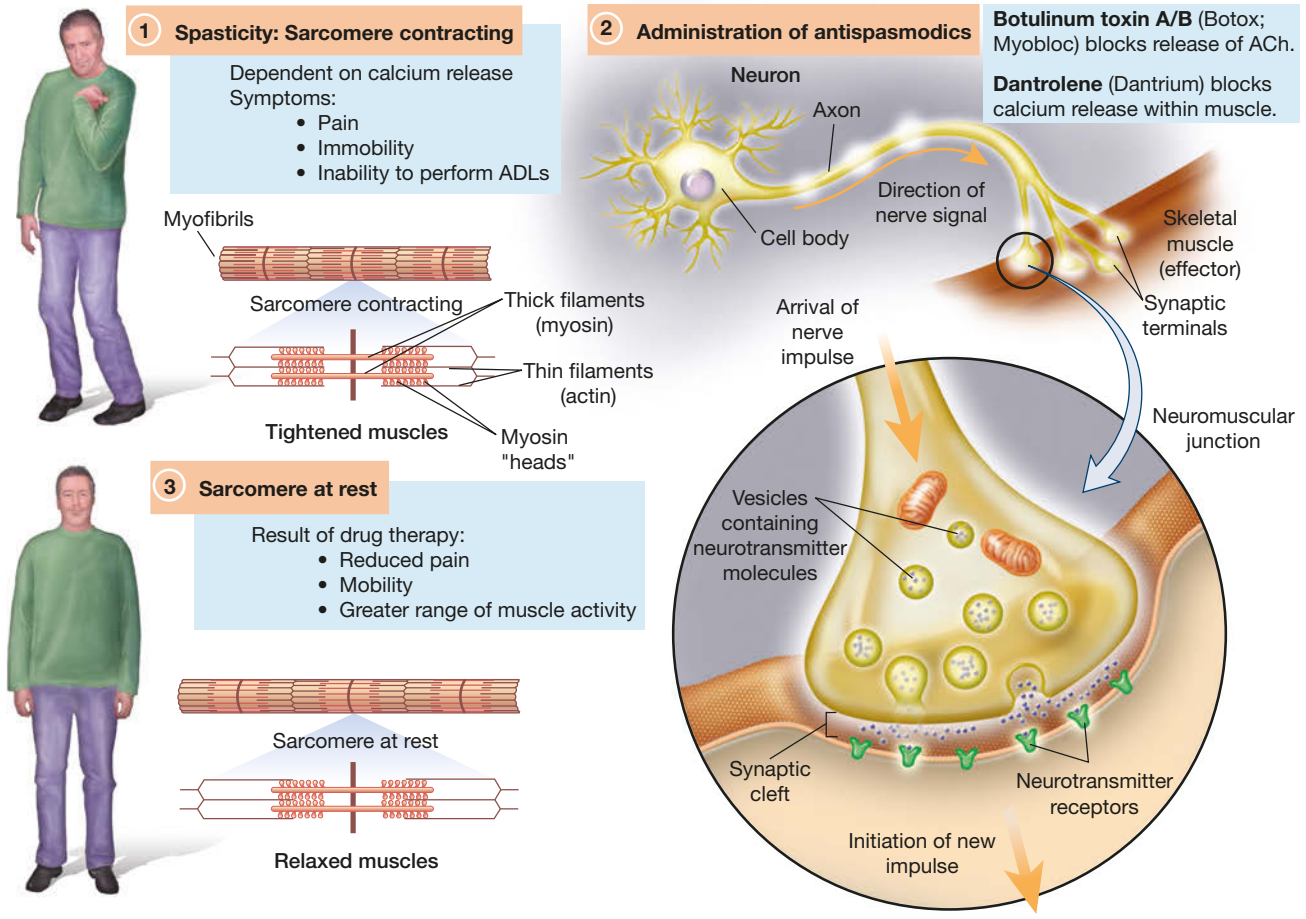


Table 23.3 Direct-Acting Skeletal Muscle Relaxants

Drug	Route and Dose (Maximum Dose Where Indicated)	Adverse Effects
abobotulinumtoxinA (Dysport)	Cervical dystonia: IM: 500 units, in divided doses Glabellar lines: IM: 50 units given in 5 equal doses Upper limb spasticity: IM: 100–400 units depending on muscle injected	*Injection reactions, headache, dysphagia, muscle weakness, pain, tenderness, bruising, flulike symptoms, dry mouth, ptosis of eyelids* Spread of toxin to surrounding muscles, anaphylaxis and other hypersensitivity reactions, difficulty swallowing or breathing (cervical dystonia therapy), corneal ulceration (blepharospasm therapy)
incobotulinumtoxinA (Xeomin)	Cervical dystonia: IM:120 units Blepharospasm: IM: 10–50 units per eye in 6 injections (max: 50 units per eye) Upper limb spasticity: IM: 5–200 units depending on muscle injected	
onabotulinumtoxinA (Botox)	Cervical dystonia: IM: 198–300 units in divided doses (max: 50 units per site) Upper limb spasticity: IM: 75–360 units in divided doses (max: 50 units/site) Axillary hyperhidrosis: IM: 50 units per site Migraines: IM: 155 units in divided doses across specific head and neck regions (max: 5 units per site) Overactive bladder: 100–200 units across 20–30 injections sites in the detrusor muscle	
onabotulinumtoxinA (Botox Cosmetic)	Glabellar lines: IM: 20 units divided among affected muscles	
rimabotulinumtoxinB (Myobloc)	Cervical dystonia: IM: 2500–5000 units divided among affected muscles	
dantrolene (Dantrium, Revonto)	Spasticity: PO: 25 mg once daily (max: 100 mg bid–qid) Malignant hyperthermia: IV push: 1 mg/kg; repeat as needed (max: 10 mg/kg); may continue PO at 1–2 mg/kg qid for 1–3 days	*Hypersensitivity, drowsiness, dizziness, lightheadedness, fatigue, speech disturbance, insomnia, mental depression, blurred vision, diplopia, photophobia, vomiting, anorexia, GI upset, crystalluria, urinary frequency, urinary retention, nocturia, enuresis, difficult erection* Muscle weakness, diarrhea, hepatic necrosis

Note: *Italics* indicates common adverse effects. Underline indicates serious adverse effects.

Pharmacotherapy Illustrated 23.2

Mechanism of Action of Direct-Acting Antispasmodics

Therapeutic Effects and Uses: Approved in 1974, dantrolene is a direct-acting skeletal muscle relaxant indicated for spasticity, especially for spasms of the head and neck muscles following a spinal cord injury, stroke, and in cases of CP or MS. When administered PO, the drug induces relaxation of the skeletal muscles. It may be used off-label to treat malignant neuroleptic syndrome or for the treatment of pain following heavy exercise.

When administered IV, Revonto is a preferred drug for treating **malignant hyperthermia**, a rare condition that is an adverse effect of succinylcholine (Anectine) and some general anesthetics. A patient with malignant hyperthermia will experience a sudden onset of tachycardia, ventricular dysrhythmia, and hypotension. This is due to the rapid release of calcium ions in muscle cells, which produces hypermetabolism and intense muscle rigidity. The muscle metabolic rate becomes so elevated that it quickly raises the body temperature to a dangerous level. There is a strong genetic predisposition to malignant hyperthermia, and patients with a family history of the disorder should not receive drugs that have the potential to cause this adverse effect. It is important for the anesthesia provider and circulating nurse to have phentolamine (Regitine) available in the event of extravasation of dantrolene.

Mechanism of Action: Dantrolene is related to phenytoin (Dilantin), an antiepileptic drug. Dantrolene directly relaxes spastic muscles by interfering with the release of calcium ions that have been stored in the sarcoplasmic reticulum of skeletal muscle.

Pharmacokinetics:

Route(s)	PO, IV
Absorption	Approximately 35% is slowly and incompletely absorbed from the GI tract

Distribution	Crosses the placenta; highly bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	Renal and feces
Onset of action	Peak concentration: 5 h
Duration of action	Half-life: 8.7 h (PO) or 4–8 h (IV)

Adverse Effects: Muscle weakness and drowsiness are the most common adverse effects of dantrolene therapy. Other adverse effects include xerostomia, dizziness, nausea, photosensitivity, diarrhea, tachycardia, erratic blood pressure, and urinary retention. **Black Box Warning:** Hepatitis and deaths due to liver failure have occurred in patients taking dantrolene. Baseline and periodic hepatic function tests should be conducted during therapy. The lowest possible effective dose should be used to avoid hepatotoxicity and the drug should be discontinued if no therapeutic effect is noted after 45 days of treatment.

Contraindications/Precautions: There are no contraindications to the use of dantrolene in treating malignant hyperthermia because this is a fatal condition if left untreated. For spasticity, dantrolene is contraindicated in patients with preexisting hepatic disease. Because it can cause muscle weakness, dantrolene should not be used when spasticity is necessary to sustain an upright position or balance when standing or walking. Dantrolene should be used cautiously in the presence of impaired cardiac or pulmonary function. The risk of dantrolene-induced hepatotoxicity is greatest in women over the age of 35; thus it should be administered cautiously in these patients.

Drug Interactions: Dantrolene interacts with other CNS depressants, including alcohol, to cause additive sedation. The combination of estrogen and dantrolene in women can result in hepatotoxicity. Calcium channel blockers such as verapamil (Calan) place the patient at increased risk of ventricular fibrillation and cardiovascular collapse when dantrolene sodium is administered intravenously. **Herbal/Food:** Use of kava or valerian may result in additive sedation.

Pregnancy: Category C.

Treatment of Overdose: Overdose with dantrolene results in muscle weakness, lethargy, and coma. General supportive measures are administered until the effects of the drug diminish.

Nursing Responsibilities: Key nursing implications for patients receiving dantrolene are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Muscle Spasms and Spasticity.

Drugs Similar to Dantrolene (Dantrium)

Botulinum toxins are also direct-acting muscle relaxants.

Botulinum toxin (Botox, Botox Cosmetic, Dysport, Myobloc, Xeomin): Botulinum toxin is a natural substance obtained from *Clostridium botulinum*, the gram-positive bacterium responsible for botulism. The drug blocks neuromuscular transmission by binding to motor nerve terminals and inhibiting the release of acetylcholine. Without sufficient amounts of acetylcholine, the muscle is unable to contract and flaccid paralysis occurs.

Since its initial approval by the FDA in 1989, several forms of botulinum toxin have been developed and marketed. Each of the formulations differs in potency and they may not be interchanged or substituted for each other. To avoid medication errors, the FDA renamed the various products in 2009. The botulinum products are listed in Table 23.3. Table 23.4 gives the approved indications for the products.

The first botulinum product approved was onabotulinumtoxinA (Botox). This formulation is approved for all

Table 23.4 Indications for Botulinum Toxin

	Axillary Hyperhidrosis	Blepharospasm	Cervical Dystonia	Chronic Migraine	Glabellar Lines	Overactive Bladder	Strabismus	Upper Limb Spasticity
abobotulinumtoxinA (Dysport)			X		X			X
incobotulinumtoxinA (Xeomin)		X	X		X			X
onabotulinumtoxinA (Botox)	X	X	X	X	X	X	X	X
onabotulinumtoxinA (Botox Cosmetic)					X			
rimabotulinumtoxinB (Myobloc)			X					

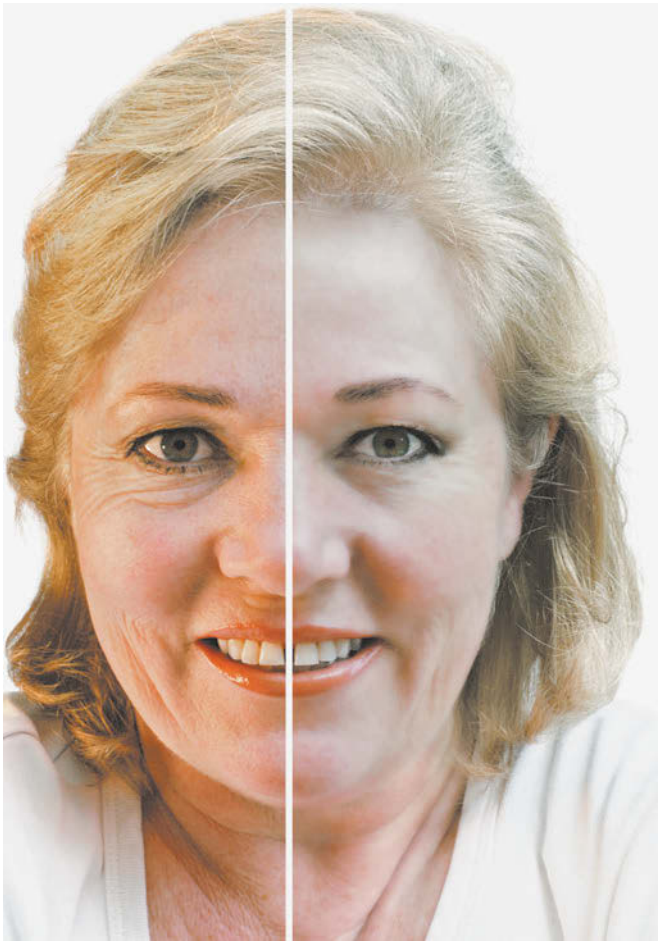

Figure 23.1 Botox therapy: (left) before treatment; (right) after treatment.
Courtesy of Jo Ann Snover/Shutterstock.

indications: blepharospasm, cervical dystonia, glabellar lines (facial wrinkles; Figure 23.1), severe axillary hyperhidrosis (axillary perspiration), upper limb spasticity, strabismus, and chronic migraines. For each of these indications, small doses are injected into the affected muscles. The dose differs for the specific indication.

One of the newer indications for Botox is for the treatment of overactive bladder or urinary incontinence in patients with an associated neurologic condition such as MS. For these indications, the drug is injected directly into the detrusor muscle of the bladder through a cystoscope. A single administration of Botox requires injections at 20 to 30 sites in the detrusor muscle, which may be repeated every 6 to 12 weeks. This therapy is approved only if therapy with an anticholinergic drug has been unsuccessful.

Because of the extreme weakness associated with botulinum, therapies may be needed to improve muscle strength. To circumvent major problems with mobility or posture, administration of botulinum toxin is often limited to the small muscle groups. Sometimes this drug is

CONNECTIONS: Community-Oriented Practice

Botox: Beyond Wrinkles

Botox (botulinum toxin type A) has received tremendous media attention as public figures confess to using, or are suspected of using, it to reduce the appearance of aging. The drug continues to be used cosmetically to enhance appearance, and it has demonstrated effectiveness in other clinical conditions. It is also being used to study how the nerves and brain communicate, potentially leading to new treatments for brain and other disorders.

Besides treating wrinkles and signs of aging, Botox has clinical indications for treating blepharospasm, cervical dystonia, axillary hyperhidrosis, migraines, Parkinson's disease, chronic pain, overactive bladder, and CP. By blocking nerve transmission, spasticity and resulting symptoms, including pain, may be alleviated. Researchers are also using Botox to study how nerve cells use neurotransmitters in the synaptic cleft. By studying how Botox disrupts the processes of neurotransmitters by affecting specific proteins needed for their release and reuptake, new treatments for psychiatric and other disorders where these proteins also work to signal cell response may be possible (Xu et al., 2013).

Botox has another, darker side that often goes unreported in the media. The FDA has issued a black box warning about the serious adverse effects of Botox and botulinum toxins. The FDA (2008, 2009) reported that the most notable adverse effects related to Botox and botulinum toxins have occurred in children with spastic CP and have included effects ranging from muscle flaccidity to system-wide symptoms of botulism with respiratory distress and death. Effects noted in adults have included weakness, dysphagia, dysphonia, dyspnea, and respiratory distress.

The FDA black box warning includes the following:

- Be aware of possible systemic spread of the drug beyond the regional area of injection. These effects may occur within hours as well as weeks to months after the injection.
- Symptoms of botulinum toxin effects include dysphagia, dysphonia, diplopia, blurred vision, ptosis, urinary incontinence, generalized muscle weakness, and respiratory distress.
- The effects above may be observed at both low and higher doses of the drug. While the most frequent incidence of toxicity occurred in children with spastic CP, they also occurred in adults.
- Difficulty swallowing or breathing is potentially life threatening and requires immediate reporting.

Botox and botulinum toxins have earned a place in the treatment of cosmetic conditions as well as more serious medical conditions such as cervical dystonia. The drug is not without risk despite its popularity. Healthcare providers should continuously monitor the patient postadministration, and the patient should be educated about the possibility of adverse effects and when to seek emergency care.

administered with centrally acting PO medications to increase the functional mobility range of muscle groups.

In general, botulinum therapy is well tolerated and adverse effects are related to the dose injected in each muscle. The drug can cause significant pain when it is injected into the muscle. The severity of pain experienced can be blocked by the administration of a local anesthetic. The therapeutic effects of botulinum therapy are effective within 6 weeks and last for 3 to 6 months. All botulinum toxin formulations carry a black box warning that the drug may spread to distant muscles, resulting in a risk for asthenia, generalized muscle weakness, diplopia, blurred vision, dysphagia, dysphonia, urinary incontinence, and breathing difficulties. Swallowing and breathing difficulties can be life threatening. These effects may occur hours or weeks after treatment. The risk is highest for children. Botulinum toxin is pregnancy category C.

CONNECTION Checkpoint 23.3

Myasthenia gravis is a serious skeletal muscular disorder, but it does not result in spasticity. From what you learned in Chapter 13, what are the symptoms of this disorder and what is the primary pharmacotherapy? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Skeletal Muscle Relaxants as Surgical Adjuncts

23.5 Skeletal muscle relaxants are administered during surgery in combination with anesthetic agents.

During certain surgical procedures it is necessary to produce total skeletal muscle relaxation in the patient. Skeletal muscle relaxants such as succinylcholine (Anectine) and tubocurarine are administered in combination with general anesthetics to induce skeletal muscle relaxation, which aids in intubation and other invasive procedures. These drugs are also administered to facilitate endoscopy, to enhance the management of mechanical ventilation, and to control the severity of muscle contractions resulting from electroshock therapy.

The skeletal muscle relaxants used as surgical adjuncts have the ability to produce complete muscle paralysis; thus mechanical ventilation may be necessary. Continuous monitoring is required. Most of these drugs have very rapid onsets of action and brief half-lives; drug effects rapidly diminish following the surgical procedure.

The skeletal muscle relaxants used as surgical adjuncts are presented in Chapter 14. A prototype feature for succinylcholine can be found in that chapter.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Muscle Spasms and Spasticity

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, respiratory, hepatic, renal, or musculoskeletal diseases. Obtain a drug history including allergies, current prescription and over-the-counter (OTC) drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a history of the current condition and symptoms, exacerbating conditions, and ability to carry out ADLs, particularly related to mobility.
- If present, assess the level of pain. Use objective screening tools when possible (e.g., FLACC [face, limbs, arms, cry, consolability] for infants or very young children, Wong-Baker FACES scale for children, numerical rating scale for adults). Assess the history of pain associated with muscle spasms and what has or has not worked for the patient in the past.
- Evaluate appropriate laboratory findings such as hepatic or renal function studies.
- Obtain baseline vital signs, muscle strength, and presence of muscle spasms.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., decreased muscle spasm, rigidity, decreased pain).
- Continue periodic monitoring of vital signs and motor function.
- Assess for and promptly report adverse effects: fatigue, drowsiness, dizziness, dry mouth, orthostatic hypotension, tachycardia, palpitations, swelling of tongue or face, diplopia, urinary retention, diarrhea, or constipation.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. Drug therapy may take several days to have the full effect with lessening pain and tenderness, increased range of motion (ROM), and increased ability to complete ADLs noted. Support the patient in self-care activities as necessary until improvement is observed. (Ability to carry out ADLs gradually improves with consistent usage.)	• Teach the patient that gradual improvement may be noted over several days and full therapeutic effects may take 1 week or longer. Nonpharmacologic measures may be needed until the full medication effect is noted.
Minimizing adverse effects: • Ensure patient safety; monitor motor coordination and ambulation or other essential motor activities.	• Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone if pain, spasms, or rigidity are particularly severe.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Lifespan: Be cautious with older adults who are at increased risk for falls. (Gradual improvement in symptoms may be noticed over several days but pain or spasms may affect motor skills. Particular care with ambulation is required because pain, spasms, or rigidity may increase the risk of falls. Cyclobenzaprine is included in the Beers list of potentially inappropriate drugs for older adults and warrants careful monitoring.)	• Assess the ability of the patient, family, or caregiver to carry out ADLs at home, and explore the need for additional healthcare referrals if disability will require long-term physical therapy (e.g., CP). Evaluate home safety needs. • Instruct the patient to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to monitor vital signs, particularly blood pressure. Take the blood pressure lying, sitting, and standing to detect orthostatic hypotension. **Lifespan:** Be cautious with older adults who are at increased risk for hypotension. Notify the healthcare provider if the blood pressure decreases beyond established parameters, or if hypotension is accompanied by reflex tachycardia. (Orthostatic hypotension is a possible adverse effect and, in conjunction with muscle spasms, pain, or rigidity, may increase the risk of falls or injury. Cyclobenzaprine may cause tachycardia and palpitations.)	• Teach the patient to rise from lying to sitting or standing slowly to avoid dizziness or falls if hypotension is noted. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk, until the sensation passes. • Have the patient immediately report dizziness, lightheadedness, rapid heart rate, palpitations, or syncope.
• Monitor muscle tone, ROM, and degree of muscle spasm. (Improvement should be observed over the first week or two of therapy. Increased ROM and decreased muscle tenderness and rigidity help to determine the effectiveness of the drug therapy.)	• Teach the patient how to perform gentle ROM exercises and to exercise only to the point of mild physical discomfort but never pain, throughout the day.
• Provide additional pain relief measures such as positional support, gentle massage, and moist heat or ice packs. (Supportive nursing measures may increase pain relief and supplement drug therapy.)	• Teach the patient complementary pain interventions such as positioning, gentle massage, application of heat or cold to the painful area, distraction with television or music, or guided imagery.
• Continue to monitor renal and hepatic function periodically if the patient is on long-term use of the drug. (Muscle relaxants and antispasmodic drugs may cause hepatotoxicity as an adverse effect. **Lifespan:** Women over the age of 35 taking these drugs are at greater risk for hepatotoxicity and should be monitored more frequently.)	• Instruct the patient on the need to return periodically for laboratory work.

• Assess bowel sounds periodically if constipation or diarrhea is problematic. Increase fluid and dietary fiber intake to prevent GI effects and to ease dry mouth effects. (Muscle relaxant drugs may decrease peristalsis as an adverse effect. Significantly diminished or absent bowel sounds are immediately reported to the healthcare provider. **Lifespan:** The older adult is at increased risk of constipation due to slowed peristalsis. Additional fluids and fiber may ease constipation and prevent diarrhea, but additional medications such as MiraLAX or Colace may be required if constipation is severe.)	• Instruct the patient to:
	  • Increase fluids to 2 L/day and increase intake of dietary fiber such as fruits, vegetables, and whole grains.
	  • Report severe constipation to the healthcare provider for additional advice on laxatives or stool softeners.

• Assess for tongue or facial swelling. (While rare, cyclobenzaprine may cause swelling of the tongue or face and should be reported immediately.)	• Instruct the patient to immediately report any swelling of the tongue, face, or throat.
• Avoid the use of other CNS depressants, including alcohol, and use with caution with antihypertensive medications given concurrently. (CNS depressants and alcohol may increase sedative properties of the drug. Antihypertensive medication may increase risk of hypotension.)	• Teach the patient to avoid or eliminate alcohol while on the drug. If other sedatives or antihypertensives are ordered, have the patient consult with the healthcare provider about dose and sequencing. Immediately report any dizziness, palpitations, or syncope.
• Assess for urinary retention periodically. (Muscle relaxants and antispasmodics may cause urinary retention as an adverse effect. **Lifespan:** Be aware that older men with an enlarged prostate are at higher risk for mechanical obstruction.)	• Instruct the patient to immediately report an inability to void, increasing bladder pressure, or pain.
• **Lifespan:** Patients who are breastfeeding should talk with their provider about the need to stop nursing and pump breasts, discarding the milk, and using alternative feedings while on these drugs. (It is unknown whether these drugs are secreted in breast milk.)	• Instruct patients who are pregnant or breastfeeding that the provider may recommend discontinuing breastfeeding while on the drug. If so, alternative feeding plans may be discussed.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug and appropriate dose, scheduling, and adverse effects to observe for, and when to report them.
Patient self-administration of drug therapy: • When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug, e.g., take the drug as prescribed when needed. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)	• Instruct the patient in proper administration guidelines. Dose should be taken consistently and not prn for best results unless otherwise ordered. Encourage the patient to maintain a medication log, noting symptoms along with dose and timing of medications and bring the log to each healthcare visit. • Teach patients to not open, chew, or crush extended release tablets (e.g., cyclobenzaprine [Amrix]); swallow them whole with plenty of water. • Take the drug with food or milk if stomach upset occurs.

Understanding Chapter 23

Key Concepts Summary

23.1 Whereas muscle spasms are often caused by overuse of skeletal muscle, muscle spasticity involves damage to motor nerves.

23.2 Nonpharmacologic interventions for treating muscle spasms and spasticity are limited.

23.3 Nonsteroidal anti-inflammatory drugs and skeletal muscle relaxants are used to treat muscle spasms.

23.4 Direct-acting skeletal muscle relaxants are often used to relieve muscle spasticity.

23.5 Skeletal muscle relaxants are administered during surgery in combination with anesthetic agents.

CASE STUDY: Making the Patient Connection

Remember the patient "Andrew Eskew" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Andrew is a 27-year-old landscaper who was building a rock wall yesterday. His job requires lifting, bending, and twisting. On arising today he stated that his back hurts and he cannot move from side to side. The nurse has performed a physical assessment on Andrew, which revealed tightened muscles in the lumbosacral region and limited mobility. The patient describes his pain as a level 7 on a scale of 1 to 10.

Critical Thinking Questions

1. What are the etiology and pathophysiology of Andrew's muscle spasms? What are other possible causes of muscle spasms?
2. Andrew has been prescribed cyclobenzaprine (Amrix) to relieve his back spasms. What is the action of this medication and why has it been prescribed?
3. What should Andrew be instructed regarding the administration of this medication?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

A 46-year-old woman is diagnosed with cervical dystonia. She has difficulty maintaining normal head position and reports neck pain. She is to start on botulinum therapy.

1. What is the action of and rationale for administering botulinum toxin type A?
2. Create a list of adverse effects that this patient may experience due to botulinum therapy.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. A 67-year-old patient experienced a severe back strain while lifting groceries from his car. He is given a prescription for cyclobenzaprine (Amrix). The nurse will include what precautions in the teaching plan for this patient? (Select all that apply.)
    1. Report any palpitations or rapid pulse rate immediately.
    2. Take frequent walks throughout the day to relieve soreness.
    3. Rinse the mouth frequently with an alcohol-based mouthwash to relieve excess secretions.
    4. Be cautious with driving or other activities requiring alertness.
    5. Immediately report any facial or tongue swelling.

2. A patient with spastic cerebral palsy is being treated with oral baclofen (Lioresal). Which patient statement indicates the need for more teaching?
   1. "I will be cautious about activities because I may feel weak."
   2. "It may take several months before I experience the full effects of the drug."
   3. "If I experience unpleasant side effects, I can stop taking the drug."
   4. "I will be sure to get enough fluid and fiber in my diet."

3. A patient has been taught to apply capsaicin to increase mobility and relieve pain. Which instruction is most important for the nurse to give to this patient?
   1. Apply the medication liberally above and below the site of pain.
   2. Apply with a gloved hand only to the site of pain.
   3. Apply to areas of redness and inflammation.
   4. Apply liberally with a bare hand.

4. A patient has been treated for cervical dystonia with an injection of botulinum toxin type A (Botox). Which of the following will the nurse teach the patient to immediately report?
   1. Fever, aches, or chills
   2. Difficulty swallowing, blurred vision, or ptosis
   3. Moderate levels of muscle weakness on the affected side
   4. Continuous spasms and pain on the affected side

5. A patient has been taking cyclobenzaprine (Amrix) for muscle spasms. The patient is admitted to the emergency department with severe central nervous system depression. Which medication will the nurse expect to be ordered and administered?
   1. Naloxone (Narcan)
   2. Meperidine (Demerol)
   3. Diazepam (Valium)
   4. Physostigmine (Antilirium)

6. A female patient, age 45, is receiving dantrolene (Dantrium) for treatment of painful muscle spasms associated with multiple sclerosis. What will the nurse teach the patient? (Select all that apply.)
   1. Increase fluid and fiber intake to prevent constipation.
   2. Inform the healthcare provider if she is taking estrogen products.
   3. Sip water or suck on ice chips or hard candy to relieve xerostomia.
   4. Be sure to obtain 20 minutes of sun exposure per day to boost vitamin D levels.
   5. Return periodically to the provider to monitor her liver function.

Chapter 24
Central Nervous System Stimulants and Drugs for Attention-Deficit/ Hyperactivity Disorder

Chapter Outline

- Characteristics of Central Nervous System Stimulants
- Etiology and Pathophysiology of Attention-Deficit/ Hyperactivity Disorder
- Pharmacotherapy of Attention-Deficit/ Hyperactivity Disorder

  Psychostimulants

  PROTOTYPE *Amphetamine and Dextroamphetamine (Adderall, Adderall XR), p. 380*

  Nonstimulants

  PROTOTYPE *Atomoxetine (Strattera), p. 382*
- Pharmacotherapy of Narcolepsy

  PROTOTYPE *Modafinil (Provigil), p. 384*
- Methylxanthines

  PROTOTYPE *Caffeine, p. 386*

Learning Outcomes

After reading the chapter, the student should be able to:

1. Describe the general actions and pharmacotherapeutic applications of central nervous system stimulants.
2. Identify the signs and symptoms of attention-deficit/hyperactivity disorder and narcolepsy.
3. Compare and contrast the central nervous system stimulants and nonstimulants in treating attention-deficit/hyperactivity disorder.
4. Compare and contrast the different pharmacotherapies available for narcolepsy.
5. Describe the nurse's role in the pharmacologic management of attention-deficit/hyperactivity disorder and narcolepsy.
6. For each class shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
7. Apply the nursing process to care for patients receiving pharmacotherapy with central nervous system stimulants.

Key Terms

anorexiants, 379
attention-deficit/hyperactivity disorder (ADHD), 377
cataplexy, 384
central nervous system (CNS) stimulants, 376
euphoria, 376
hypnagogic hallucinations, 384
methylxanthines, 386
narcolepsy, 384
sleep attacks, 384
sleep paralysis, 384

The central nervous system (CNS) stimulants are a small group of drugs that have limited pharmacotherapeutic applications. Attention-deficit/hyperactivity disorder (ADHD) and narcolepsy are conditions that diminish mental alertness and that may benefit from treatment with these medications. Some of the CNS stimulants such as cocaine and methamphetamine are widely abused. The purpose of this chapter is to examine the actions and pharmacotherapeutic applications of the CNS stimulants.

Characteristics of Central Nervous System Stimulants

24.1 Central nervous system stimulants increase alertness, enhance the ability to concentrate, and delay the symptoms of fatigue.

The **central nervous system (CNS) stimulants** are a diverse group of pharmacologic agents. The stimulants range from widely accessible agents (caffeine) to Schedule I controlled substances (ecstasy). All CNS stimulants have the common action of raising the general alertness level of the brain. Wakefulness and the ability to focus or concentrate are increased. Mood is often elevated, and the individual may temporarily become unaware of physical fatigue. For some of the controlled substances, mood elevation may progress to **euphoria**, an intense sense of happiness and well-being.

Because people generally view the sensations associated with CNS stimulation as desirable, many are driven to repeat the pleasurable experience. With continued use, physical and psychologic dependence occur. Because of this, many CNS stimulants are highly regulated as scheduled drugs (Table 24.1).

Not all effects of these drugs on the CNS are pleasurable. Stimulants have the potential to cause adverse effects due to excessive excitation. Nervousness, dizziness, and irritability are common, and convulsions may occur at higher doses. Most of the stimulants also affect the cardiovascular system and can increase heart rate and cause dysrhythmias. Loss of appetite, or anorexia, occurs with some of the CNS stimulants.

Some medications produce CNS excitation as an adverse effect. For example, antihistamines are prescribed to treat allergy symptoms but may cause CNS stimulation and insomnia in some patients. Albuterol (Proventil) inhalers are used for asthma but the drug may cause nervousness, tremors, and anxiety. Drugs that normally cause CNS depression, such as antidepressants, may cause paradoxical CNS excitement, especially in the very young or very old. Occasionally, drugs are purposefully taken in large amounts for their CNS stimulation adverse effects. For example, the primary over-the-counter (OTC) drug for treating cough, dextromethorphan, is abused by teenagers and can cause dizziness, restlessness, hallucinations, and seizures when taken in very high amounts. Additional information on the substance abuse aspects of the CNS stimulants is presented in Chapter 27.

The therapeutic applications of the CNS stimulants are limited. These include the following:

- ADHD
- Narcolepsy
- Weight management
- Stimulation of respiration
- Migraines

Table 24.1 Central Nervous System Stimulants That Are Scheduled Drugs

Schedule	Central Nervous System Stimulants
I	3,4-methylenedioxymethamphetamine (MDMA, ecstasy), aminorex, cathinone, fenethylline, mephedrone, methcathinone, methylaminorex
II	amphetamine (Adderall, Dexedrine), cocaine, lisdexamfetamine (Vyvanse), methamphetamine (Desoxyn), methylphenidate (Concerta, Ritalin), phenmetrazine (Preludin)
III	benzphetamine (Didrex), chlorphentermine, clortermine (Voranil), dronabinol (Marinol), phendimetrazine (Plegine, Prelu-2)
IV	cathine (norpseudoephedrine), diethylpropion (Tenuate), fencamfamin, fenproporex, mazindol (Sanorex), mefenorex, modafinil (Provigil), phentermine (Adipex, Fastin), pipradrol
V	pyrovalerone

From *Lists of: Scheduling Actions, Controlled Substances and Regulated Chemicals*, U.S. Department of Justice, Drug Enforcement Administration, 2016. Retrieved from http://www.deadiversion.usdoj.gov/schedules/orangebook/orangebook.pdf

If CNS stimulants elevate mood, why are they not used to treat major depressive disorder? In fact, CNS stimulants have been used in the past to treat major depression. CNS stimulants, however, are nonselective in their CNS actions; the excitement produced by these drugs affects all parts of the brain. They produce many potentially serious adverse effects, including physical and psychologic dependence. The atypical antidepressants and the selective serotonin reuptake inhibitors (SSRIs) are more effective and safer than stimulants in the treatment of depression. These drugs are able to elevate mood without causing CNS excitation.

PharmFACT

Approximately 11% of children 4 to 17 years of age take ADHD medication. ADHD is more common in males: 13% of males versus 6% of females. It is estimated that about 17% of children with the disorder are not receiving either medication for ADHD or mental health counseling (Centers for Disease Control and Prevention [CDC], 2016a).

Etiology and Pathophysiology of Attention-Deficit/Hyperactivity Disorder

24.2 Attention-deficit/hyperactivity disorder is characterized by inattention, hyperactivity, and impulsive behavior.

Attention-deficit/hyperactivity disorder (ADHD) is a neuropsychiatric condition that presents in children before age 7 and can extend into adulthood. It is characterized by symptoms of impulsive behavior, lack of attention, and hyperactivity. To receive a diagnosis of ADHD, a patient must exhibit symptoms of inattention and hyperactivity, as listed in Table 24.2 (CDC, 2016b).

Symptoms of ADHD such as impulsive behavior, distractibility, lack of attention, and hyperactivity during the school-age years can lead to poor performance and lack of interest in school activities. The symptoms of inattention and hyperactivity also contribute to difficulty with peer and family relationships. Hyperactive children usually have increased motor activity with impulsivity and a tendency to interrupt at inappropriate times. This behavior can result in disciplinary action by teachers and parents. Some additional symptoms noted include difficulty remembering details and the placement of personal items, changing tasks without completing prior tasks, and disturbances in sleep.

Symptoms continue into adulthood in 35% to 55% of individuals diagnosed with childhood ADHD. Symptoms in adults include workaholic tendencies, being overwhelmed, talking excessively, low tolerance for frustration, chronic boredom, short temper, quitting jobs abruptly, personal relationship problems, and multiple driving violations. Adults with ADHD are more likely to have an addictive personality, which may be exhibited in behavior that includes smoking and using illegal substances. Adult ADHD is treated with the same therapies as childhood ADHD.

Considerable attention has focused on the causes of ADHD, and it is clear that the etiology is complex and involves multiple variables. Studies on twins have indicated that genetics is an important contributor to the development of ADHD. An identical twin has a 92% probability of presenting with ADHD if his or her twin has been diagnosed with the disorder, and about 25% of families with a member diagnosed with ADHD will have other relatives also diagnosed. This percentage is significantly higher than the general population, which is approximately 5%.

Brain injury has been studied as a contributing factor in the development of ADHD because some children who experience head trauma will exhibit symptoms of the disorder. The percentage of brain injuries that lead to a diagnosis of ADHD is small but remains relevant in assessing for the condition as the patient ages.

Environmental agents such as lead can contribute to the development of ADHD in children. Children living in

Table 24.2 Symptoms That May Lead to a Diagnosis of Attention-Deficit/Hyperactivity Disorder

Inattention
1. Often does not give close attention to details or makes careless mistakes in schoolwork, work, or other activities.
2. Often has trouble keeping attention on tasks or play activities.
3. Often does not seem to listen when spoken to directly.
4. Often does not follow instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions).
5. Often has trouble organizing activities.
6. Often avoids, dislikes, or does not want to do things that take a lot of mental effort for a long period of time (such as schoolwork or homework).
7. Often loses things needed for tasks and activities (e.g., toys, school assignments, pencils, books, or tools).
8. Is often easily distracted.
9. Is often forgetful in daily activities.
Hyperactivity and Impulsivity
1. Often fidgets with hands or feet or squirms in seat.
2. Often gets up from seat when remaining in seat is expected.
3. Often runs about or climbs when and where it is not appropriate (adolescents or adults may feel very restless).
4. Often has trouble playing or enjoying leisure activities quietly.
5. Is often "on the go" or often acts as if "driven by a motor."
6. Often talks excessively.
7. Often blurts out answers before questions have been finished.
8. Often has trouble waiting one's turn.
9. Often interrupts or intrudes on others (e.g., butts into conversations or games).

buildings built prior to 1972 have a higher risk of developing lead poisoning. Other environmental agents that contribute to the development of ADHD include alcohol and cigarette smoking by the mother during pregnancy. Food additives and sugar intake by the child have been implicated as causes of ADHD, but research studies have failed to find a strong link.

Differences are seen in the anatomy and physiology of children with ADHD and control participants. Children with a known diagnosis of ADHD possess a smaller brain volume in the frontal lobes, temporal gray matter, caudate nucleus, and cerebellum. Children who are affected by ADHD have a deficiency in the catecholamines dopamine and norepinephrine. The brain of a child with ADHD also has decreased development in the area of self-regulation. This factor yields the development of symptoms such as irritability, aggression, learning disability, and motor disorders when the child is stimulated.

CONNECTIONS: Treating the Diverse Patient

Attention-Deficit/Hyperactivity Disorder and Athletics

ADHD treatment within the athletic population presents a unique challenge. For the athlete with ADHD, sports are a natural outlet and help fulfill the need to be physically active. Reports suggest that the prevalence of ADHD is higher in athletes at both the collegiate and professional levels. Evidence also shows a statistically significant decrease in markers of anxiety and depression among ADHD patients with higher levels of sports participation (Harvey, Wilkinson, Pressé, Joober, & Grizenko, 2014).

The National Collegiate Athletic Association and International Olympic Committee both regulate the use of psychostimulants for treatment of ADHD due to their performance-enhancing effects. Potential performance enhancements include improved concentration and attention to tasks, increased aggression, decreased pain perception, and euphoria. For these reasons stimulant medications are banned substances. When they are absolutely needed by the athlete their use requires the institution to maintain documentation on file including a medical exception request, a written report of the medical evaluation conducted to support the diagnosis of ADHD, and medical treatment notes from the prescribing provider.

Pharmacotherapy of Attention-Deficit/Hyperactivity Disorder

24.3 Psychostimulants are central nervous system stimulants indicated for the treatment of ADHD and narcolepsy.

Medications used to treat patients with ADHD are classified as stimulants or nonstimulants. Stimulants account for 70% to 80% of drugs taken for this disorder. The nonstimulants were not developed until 2003 and generally have a longer duration of action with fewer adverse effects. Successful treatment of ADHD usually requires a combination of pharmacotherapy and behavioral therapies.

The most frequently prescribed medications for ADHD are CNS stimulants: amphetamines and amphetamine-like drugs. During the 1920s, amphetamines were used to treat asthma, hay fever, and the common cold. Amphetamine use became widespread in World War II because these drugs were able to keep soldiers alert and delay fatigue during combat. Amphetamines were not listed as scheduled substances until 1970. Amphetamine sulfate has been used to make several other salts that have psychoactive properties, including methamphetamine and ecstasy (methylenedioxymethamphetamine or MDMA), an illegal substance used to induce euphoria.

CONNECTION Checkpoint 24.1

The older adult may experience different responses to drugs related to the aging process or to adverse effects of drug therapy. From what you learned in Chapter 10, what symptoms might be anticipated in an older adult taking CNS stimulants and what should the nurse do if they occur? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Amphetamine exists in two closely related but distinct chemical forms: d-amphetamine (dextroamphetamine) and l-amphetamine (levoamphetamine). When using the term *amphetamine* it is understood that the drug is a mixture of the d- and l-forms. To be more precise, this mixture is sometimes called racemic amphetamine. The d-form, dextroamphetamine, is marketed separately as Dexedrine. The psychostimulants approved for ADHD include methylphenidate, dextroamphetamine, dexmethylphenidate, and lisdexamfetamine. Doses of these drugs are listed in Table 24.3.

Despite the name *psychostimulant*, these drugs do not act by stimulating the brain in a patient with ADHD. Instead, they increase attention and enhance the child's ability to focus on tasks and improve learning. Significant improvement in academic performance and in peer and family relationships is common. When used appropriately for ADHD, these drugs do not cause euphoria, and dependence has not been a serious problem. Studies have demonstrated that the use of CNS stimulants in childhood does not lead to an increased incidence of alcohol, tobacco or illicit drug use in adulthood. Psychostimulants are the most effective drugs for this disorder, reducing the symptoms of ADHD in 70% to 80% of the treated children.

The stimulants have actions on both the autonomic nervous system and the CNS. Amphetamines are sympathomimetics and activate alpha- and beta-adrenergic receptors by promoting the release of norepinephrine in the

Table 24.3 Central Nervous System Stimulants and Drugs for Attention-Deficit/Hyperactivity Disorder and Narcolepsy

Drug	Route and Dose (Maximum Dose Where Indicated)	Adverse Effects
Amphetamines and Amphetamine-Like Drugs		
amphetamine and dextroamphetamine (Adderall, Adderall XR)	Child ages 3–5: PO: 2.5 mg 1–2 times/day (max: 40 mg/day) Child ages 6–12: PO: 5–10 mg daily to bid (max: 40 mg/day) Adult: PO (extended release): 20 mg once daily (max: 40 mg/day)	*Irritability, dizziness, palpitations, euphoria, insomnia, tachycardia, weight loss, application site reactions (Daytrana)* Sudden death, dependence, psychosis, seizures
dexmethylphenidate (Focalin, Focalin XR)	PO (regular release): 2.5 mg bid (max: 20 mg/day) PO (extended release): 10 mg once daily (max: 20 mg/day)	
lisdexamfetamine (Vyvanse)	PO: 30 mg once daily (max: 70 mg/day)	
methylphenidate (Concerta, Daytrana, Metadate, Methylin, Ritalin, Quillivant XR)	Narcolepsy: Adult: PO: 10 mg bid–tid ADHD: Child: PO: 5–10 mg (max: 60 mg/day) Adult: 20–30 mg (max: 60 mg/day)	
Nonstimulants for ADHD		
atomoxetine (Strattera)	Child less than 70 kg: PO: 0.5 mg/kg/day (max: 1.4 mg/kg or 100 mg) Adult: PO: 40 mg once daily (max: 100 mg/day)	*Headache, palpitations, decreased appetite, insomnia, irritability, fatigue, somnolence, dry mouth, upper abdominal pain, nausea, vomiting, constipation, urinary retention, cough* Suicidal ideation, severe liver injury
clonidine (Kapvay)	Child ages 6–17: PO: 0.1 mg/day (max: 4 mg/day)	*Somnolence, fatigue, upper respiratory tract infection, irritability, sore throat, insomnia, nightmares, emotional disorder, constipation, increased body temperature* Bradycardia, syncope, serious sedation, severe hypotension
guanfacine (Intuniv)	Child ages 6–17: PO: 1 mg/day (max: 4 mg/day)	*Sedation, abdominal pain, dizziness, mild hypotension, dry mouth, constipation* Bradycardia, syncope, serious sedation, severe hypotension
Drugs for Narcolepsy		
armodafinil (Nuvigil)	PO: 150–250 mg/day given as a single dose in the morning or 1 h prior to the start of the work shift	*Dizziness, nausea, insomnia, headache, anxiety* Stevens–Johnson syndrome (SJS), hypersensitivity, mania
modafinil (Provigil)	PO: 200 mg once daily in the morning or 1 h prior to the start of the work shift	*Headache, nausea, nervousness, rhinitis, diarrhea, back pain, anxiety, insomnia, dizziness, dyspepsia* Hypersensitivity reaction, SJS
sodium oxybate (Xyrem)	PO: 2 doses of 2.25 g, the first given at bedtime, the second given 2.5–4 h later (max: 9 g/day)	*Headache, nausea, dizziness, nasopharyngitis, drowsiness, disorientation, irritability* Seizures, respiratory depression, decreased level of consciousness, coma, psychosis
Methylxanthine		
caffeine	Neonatal apnea: PO or IV: 20–30 mg/kg as a loading dose; maintenance dose: 5 mg/kg for 10–12 days Mental alertness: PO: 100–200 mg tid–qid as needed	*Tachycardia, flushing, restlessness, insomnia, irritability, tremor, palpitations* Dysrhythmias, hypotension, seizures, circulatory failure, respiratory arrest
theophylline	PO: 300–600 mg/day in divided doses (max: 900 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

autonomic nervous system (see Chapter 15). Typical symptoms of sympathetic activation caused by amphetamines include vasoconstriction, hypertension (HTN), and tachycardia.

In people without ADHD, the CNS stimulant actions of amphetamines are the result of increased release of dopamine due to inhibition of the reuptake of this neurotransmitter in presynaptic neurons. At very high doses, amphetamines enhance the release of the neurotransmitter serotonin (5-hydroxytryptamine or 5-HT) in the brain, which is responsible for psychotic behaviors. Amphetamines also are **anorexiants**, which means that they

diminish the appetite. This effect is produced by direct inhibition of the appetite center in the hypothalamus. The application of the amphetamines to the pharmacotherapy of obesity is presented in Chapter 63.

Almost from the time they were discovered, amphetamines have been abused for their stimulant effects. These drugs are often abused by those who wish to delay fatigue, for example, truck drivers, students, and healthcare workers working long shifts. Athletes may take amphetamines to increase their energy level and enhance performance. Long-term amphetamine abuse may lead to tolerance, dependence, and serious adverse effects. Amphetamine and methamphetamine are Schedule II drugs.

Cocaine is an illicit drug that has similar sympathomimetic, CNS stimulant, and anorexiant effects to amphetamine. In fact, the signs and symptoms of cocaine abuse are indistinguishable from those of amphetamine abuse. Cocaine has a much shorter half-life, which leads to more frequent repeated doses. Additional details regarding cocaine dependence are included in Chapter 27.

Overall, drugs in the psychostimulant class have equivalent effectiveness and very similar adverse effect profiles. For unknown reasons, however, some patients respond more favorably to one drug over another. Thus the choice of psychostimulant and the dose are largely determined individually, by therapeutic response. Therapy is always begun with a low dose, which is gradually increased until the desired therapeutic effect is attained. Another consideration is the dosing schedule for the medication. Older preparations must be taken every 4 hours, which is inconvenient for the school-age child. Extended duration products are now available that last 10 to 12 hours and provide a consistent therapeutic level throughout the day. For children who have difficulty taking medication by mouth, a transdermal patch is now available. Regardless of the medication taken, it is important for the nurse and caregiver to understand that drugs are used to control but not cure the disorder. Approximately 60% of children with the disorder will continue to need medication into their adult years.

PROTOTYPE DRUG **Amphetamine and Dextroamphetamine (Adderall, Adderall XR)**

Classification **Therapeutic:** Drug for ADHD
Pharmacologic: CNS stimulant, anorexiant, sympathomimetic

Therapeutic Effects and Uses: Adderall is a combination drug containing four different salts of amphetamine and dextroamphetamine. Amphetamine was approved in 1939, Adderall in 1996, and Adderall XR, an extended duration form, in 2001. A short-acting form of the drug, Evekeo, was approved in 2014 to treat ADHD, as well as narcolepsy and obesity.

Adderall increases motor activity, alertness, and wakefulness and elevates the patient's mood. In children with ADHD the medication produces a paradoxical sedation effect. The mechanism of this effect is unclear. The drug affects the satiety center in the hypothalamus, causing anorexiant effects that lead to loss of appetite and weight.

Amphetamines are used to treat ADHD and narcolepsy. Although an effective appetite suppressant, amphetamine is rarely used for weight loss therapy because its inhibition of appetite is short term, and dependence results from long-term use. Illegal forms of amphetamine may be smoked, inhaled, or injected.

Mechanism of Action: Adderall produces sympathomimetic effects as well as central stimulation actions

CONNECTIONS: Using Research in Practice

Assessing Cardiovascular Risk of Attention-Deficit/Hyperactivity Disorder Medications

In the largest study conducted among adults, Habel et al. (2011) reported that use of ADHD medications among healthy young and middle-age adults, compared with those who were not using ADHD medications, was not associated with an increased risk of serious cardiovascular events. Another large study of adults showed there was no significant association between serious cardiovascular events and the use of ADHD medications (Peyre et al., 2014).

The findings from these two studies should be interpreted with caution. ADHD medications may not produce an increased risk of cardiovascular events in the majority of patients; however, there is an increased risk for sudden death in patients with structural cardiac abnormalities. Although these events are rare, the U.S. Food and Drug Administration (FDA) has recognized the increased risk and requires their citation in a black box warning in the drug literature for ADHD medications. The current guidelines, which recommend a medical evaluation prior to starting stimulant treatment and periodic monitoring of pulse and blood pressure during treatment, should be followed.

The patient history is a crucial tool that nurses use to assess cardiovascular risk. A personal or family history of murmurs or cardiac defects at birth, or current history of cardiac problems or palpitations, may suggest the need for ECG monitoring. Genetic conditions such as Marfan and Turner syndromes have also been linked to a high incidence of cardiovascular disease and should be assessed during the initial patient history. Blood pressure and pulse rate should be assessed prior to any medication therapy and at each office visit thereafter.

on the cerebral cortex and the reticular activating system (RAS). The actions of the medication are due to the release of norepinephrine and dopamine. The benefits of the drug in treating ADHD may also be due to its effects on the neurotransmitter serotonin in the brain.

Pharmacokinetics:

Route(s)	Oral (PO)
Absorption	Rapidly absorbed
Distribution	Widely distributed to all tissues, including the CNS; secreted in breast milk
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	30–60 min
Duration of action	Up to 10 h

Adverse Effects: Symptoms of excessive CNS and peripheral stimulation by Adderall include irritability, insomnia, nervousness, palpitations, elevated blood pressure, and tachycardia. Weight loss is noted with the medication. Impotence and change in libido may occur with high doses. Long-term use of amphetamines has been reported to cause growth inhibition in children; however, discontinuation of the drug often results in rebound growth. Psychiatric symptoms associated with amphetamine abuse include euphoria, hallucinations, delusions, paranoia, delirium, and depression.

Long-term users of amphetamine will experience tolerance to the mood-elevating effects of the drug. This results in abusers requiring increasingly higher doses to achieve the same stimulant effect. **Black Box Warning:** All amphetamine-containing products, including Adderall, have a high potential for abuse and administration for prolonged periods may lead to drug dependence. In addition, amphetamines may cause sudden death due to serious cardiac events. This has occurred primarily in children with preexisting cardiac abnormalities.

Contraindications/Precautions: Patients with hypersensitivity to sympathomimetic amines (e.g., epinephrine or norepinephrine) or who have a history of drug abuse should not be prescribed Adderall. Because the conditions may worsen, Adderall is contraindicated in patients with the following disorders: diabetes, glaucoma, hyperthyroidism, moderate to severe HTN, cardiac disorders, and Tourette's syndrome. Patients with bipolar disorder may exhibit signs of mania when administered amphetamines. Amphetamines should be discontinued gradually to prevent withdrawal symptoms such as severe depression, anxiety, agitation, hypersomnia, dysphoric mood, or suicidal ideation.

Drug Interactions: Alkaline drugs such as acetazolamide and sodium bicarbonate decrease the elimination of Adderall from the body and prolong its half-life. On the other hand, acidic drugs such as ammonium chloride and ascorbic acid increase the elimination of Adderall from the body. The administration of Adderall with furazolidone can cause an increase in blood pressure effects. Monoamine oxidase inhibitors such as selegiline can precipitate a hypertensive crisis; thus, they are contraindicated within 14 days of amphetamine administration. **Herbal/Food:** Foods and fluids containing caffeine can cause additive CNS stimulation and increase insomnia, nervousness, and anxiety. Melatonin should be avoided because it may enhance the CNS stimulation from Adderall.

Pregnancy: Category C.

Treatment of Overdose: The treatment of amphetamine and amphetamine-related medication overdosage includes gastric lavage and the administration of chlorpromazine. Chlorpromazine contains strong alpha-adrenergic blocking actions that counteract the effects of amphetamine. In the event that overdosage results in severe HTN, phentolamine is administered intravenously (IV). Acidification of the urine can speed the renal elimination of the drug.

Nursing Responsibilities: Key nursing implications for patients receiving amphetamine and dextroamphetamine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Central Nervous System Stimulants.

Drugs Similar to Amphetamine and Dextroamphetamine (Adderall, Adderall XR)

Other psychostimulants for ADHD include dexmethylphenidate, lisdexamfetamine, and methylphenidate. Benzphetamine (Didrex) is an amphetamine indicated for obesity (see Chapter 63). Pemoline (Cylert), an amphetamine-like drug used for ADHD and narcolepsy, was removed from the market in 2005 due to incidences of fatal hepatic failure.

Dexmethylphenidate (Focalin, Focalin XR): Approved in 2001, dexmethylphenidate has effects identical to methylphenidate and the amphetamines. The drug blocks the reuptake of norepinephrine and dopamine in presynaptic neurons. It is used to manage symptoms of ADHD. A once-daily extended release capsule (Focalin XR) is available. The most common adverse effects are abdominal pain, nausea, fever, and decreased appetite. Although not common, twitching and vocal or motor tics may cause discontinuation of therapy. Inhibition of growth is a potential long-term adverse effect of the use

of stimulants in children. Dexmethylphenidate should not be administered to patients who have primary psychiatric disorders because the drug may worsen these conditions. The drug has a high potential for dependence and is a Schedule II substance. This drug is pregnancy category C.

Lisdexamfetamine (Vyvanse): Approved in 2007, lisdexamfetamine is a prodrug of dextroamphetamine approved for the treatment of ADHD. Because the drug is rapidly metabolized to dextroamphetamine, the actions and adverse effects are identical to those of other psychostimulants. This drug is a Schedule II controlled substance and is pregnancy category C.

Methylphenidate (Concerta, Daytrana, Metadate, Methylin, Ritalin, Quillivant XR): Although structurally dissimilar to amphetamine, methylphenidate shares the same mechanism of action, pharmacologic actions, and adverse effects. Methylphenidate is approved for the treatment of ADHD and narcolepsy. Rarely, it may be used off-label for major depression refractory to more traditional therapies. In treating ADHD, it is as effective as the amphetamines. The patient's condition should be regularly assessed and drug-free periods may be ordered during prolonged therapy. The drug is available in several extended release forms for once-daily dosing. A transdermal patch (Daytrana) was approved by the FDA in 2006 for children ages 6 to 12. The patch is generally worn for 9 hours. The extended duration forms benefit children because they do not require the school nurse to administer a dose during the school day. It is important to note that this medication is contraindicated in children under the age of 6. Like other amphetamine-like drugs, methylphenidate is a Schedule II controlled substance.

Methylphenidate is well tolerated and produces fewer peripheral adverse effects than amphetamine. Physical dependence is uncommon at therapeutic doses, although it may occur with the illicit parenteral or inhaled forms of the drug. Withdrawal symptoms are uncommon when the drug is discontinued. Nervousness, loss of appetite, and insomnia are the most common adverse effects. Methylphenidate should not be used in patients with severe anxiety, psychoses, or bipolar disorder because it may worsen these conditions. Sudden unexplained cardiac death has occurred in some people taking this drug; therefore, all patients should be screened for preexisting cardiac disease, especially structural abnormalities or ventricular dysrhythmias. In 2013, the FDA issued a safety announcement that all forms of methylphenidate may cause priapism, a prolonged and painful penile erection. In addition a warning was added that the drug is associated with an increased risk for peripheral vasculopathy, specifically Raynaud's disease. This drug is pregnancy category C.

24.4 Several nonstimulants are effective in treating symptoms of attention-deficit/hyperactivity disorder.

The first nonstimulant for the treatment of ADHD, atomoxetine (Strattera), was approved in 2002. Clonidine and guanfacine were subsequently approved in 2010 and 2006, respectively. The three nonstimulants do not have any abuse potential and are not controlled substances. These drugs offer alternatives for parents who are hesitant to place their children on CNS stimulants. The doses for these drugs are listed in Table 24.3.

Tricyclic antidepressants (TCAs) that have been used off-label for ADHD include imipramine (Tofranil), desipramine (Norpramin), and nortriptyline (Aventyl). The TCAs are less effective than the psychostimulants, can cause significant anticholinergic adverse effects such as dry mouth and constipation, and are cardiotoxic when taken in high doses. Bupropion (Wellbutrin) and venlafaxine (Effexor) are antidepressants that have been used off-label for treating ADHD. Antidepressants are considered second-line therapy for ADHD and are usually used only when the patient has not responded adequately to psychostimulants or has a comorbid condition such as depression or anxiety.

CONNECTION Checkpoint 24.2

From what you learned in Chapter 19, what class of antidepressants contains the preferred drugs for major depressive disorder? To what antidepressant class does bupropion belong? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG **Atomoxetine (Strattera)**

Classification **Therapeutic:** Drug for ADHD
Pharmacologic: Nonstimulant, norepinephrine reuptake inhibitor

Therapeutic Effects and Uses: Atomoxetine is administered to improve attentiveness and the ability to follow tasks in patients with ADHD. The medication decreases distraction and forgetfulness. It has the ability to diminish symptoms of ADHD in children and adults, and it is approved for patients ages 6 years and older. Unlike the stimulants that have an onset of action of 1 hour, atomoxetine takes 2 to 4 weeks for optimal reduction of ADHD symptoms.

Mechanism of Action: Atomoxetine is a selective norepinephrine reuptake inhibitor (SNRI), which allows for increased concentration of the neurotransmitter in the prefrontal cortex. This region of the brain is associated with control of social behavior, personality expression, and short-term memory.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Distributed to most tissues; unknown if secreted in breast milk; 98% bound to protein
Primary metabolism	Hepatic, by CYP2D6
Primary excretion	Renal; small amounts in feces
Onset of action	2–4 weeks for ADHD symptoms
Duration of action	Half-life: 5.2 h

Adverse Effects: Common adverse effects with atomoxetine include xerostomia, headache, decreased appetite, and insomnia. CNS adverse effects include mood swings, irritability, and agitation. Because rare incidences of liver injury have been reported, patients with elevated hepatic enzymes or symptoms such as jaundice, nausea, vomiting, or anorexia should immediately discontinue the drug. Cardiovascular adverse effects include orthostatic hypotension, tachycardia, HTN, and palpitations. The patient may experience cough due to rhinorrhea, nasal congestion, and sinusitis. Weight loss and anorexia, along with urinary retention, urinary hesitancy, impotence, delayed menses, and menstrual irregularities, have been reported. **Black Box Warning:** Atomoxetine has been associated with a small increased risk for suicidal ideation. Caregivers should immediately report suicidal thoughts or unusual behavioral changes to their healthcare provider.

Contraindications/Precautions: If the patient has received a monoamine oxidase inhibitor (MAOI) in the past 14 days, the administration of atomoxetine should be delayed due to the risk of neuroleptic malignant syndrome or hypertensive crisis. Administration of the medication to any patient who has jaundice or elevated liver enzymes should be delayed until enzyme levels are in the normal range. Atomoxetine is also contraindicated in those diagnosed with closed-angle glaucoma because the drug is associated with an increased risk of mydriasis in some patients. It is important to administer atomoxetine cautiously in patients with HTN, tachycardia, moderate to severe hepatic insufficiency, and cardiovascular disease.

Drug Interactions: The elimination of atomoxetine is prolonged if it is administered with fluoxetine, paroxetine, or quinidine. Concurrent administration of albuterol with atomoxetine can result in increased heart rate and HTN. Drugs that activate the sympathetic nervous system should be used cautiously with atomoxetine due to the possibility of HTN. Some common sympathomimetics include amphetamines, pseudoephedrine, ephedrine, phenylephrine, dopamine, and norepinephrine. **Herbal/Food:** It is recommended that the patient not consume any herbal supplements while taking atomoxetine.

Pregnancy: Category C.

Treatment of Overdose: Overdose with atomoxetine will cause agitation, abnormal behavior, and signs of sympathetic stimulation such as mydriasis, dry mouth, and tachycardia. The patient should receive supportive treatment for cardiopulmonary effects. Gastric lavage and repeated applications of activated charcoal may prevent systemic absorption.

Nursing Responsibilities: Key nursing implications for patients receiving atomoxetine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Central Nervous System Stimulants.

Drugs Similar to Atomoxetine (Strattera)

Other nonstimulant drugs approved for ADHD include clonidine and guanfacine.

Clonidine (Kapvay): Clonidine, an older drug that was originally approved to treat HTN in 1974, was approved in 2010 to treat ADHD. In addition, it has been used off-label to treat a number of conditions, including pain, hot flashes, Tourette's syndrome, and withdrawal symptoms from alcohol, opioids, and nicotine. Clonidine is a centrally acting alpha$_2$-adrenergic agonist but it is not known how this mechanism improves the clinical symptoms of ADHD. It is not a psychostimulant and there is no risk of physical dependence. The extended release tablet offers the advantage of once-daily dosing. The tablets should not be crushed, chewed, or broken. Kapvay is not interchangeable with other forms of clonidine. Kapvay can cause sedation and fatigue, especially during the early stages of therapy.

Blood pressure should be monitored during therapy because the drug can cause hypotension, syncope, and bradycardia. Clonidine should be discontinued gradually to prevent rebound hypotension. Caution should be used if other antihypertensives or CNS depressants are concurrently administered. Drugs that affect sinus node function may interact with clonidine to cause bradycardia and AV block. The drug has not been approved to treat adult patients with ADHD. This drug is pregnancy category C.

Guanfacine (Intuniv): Originally approved in 1986 for the treatment of HTN, guanfacine was reformulated as an extended release tablet for ADHD in 2009. Approved for children ages 6 to 17, it may be used as monotherapy or in combination therapy with stimulant-type ADHD medications. Like clonidine, guanfacine is an alpha$_2$-adrenergic agonist. It is not a psychostimulant, and it does not cause

dependence. The extended release tablet offers the advantage of once-daily dosing. The tablets should not be crushed, chewed, or broken. Because the drug is a known antihypertensive, blood pressure should be monitored during therapy; some patients have experienced bradycardia and syncope due to reduced blood pressure. The drug should not be abruptly discontinued because transient rebound HTN may result. Sedation and lethargy are common, especially at the start of therapy. Caution should be used if other antihypertensives or CNS depressants are concurrently administered. Guanfacine is pregnancy category B.

Pharmacotherapy of Narcolepsy

24.5 Narcolepsy is characterized by excessive daytime sleepiness and is treated with central nervous system stimulants and antidepressants.

Narcolepsy is a chronic neurologic disorder in which the patient experiences excessive daytime sleepiness. The disorder affects 1 in 2000 Americans and usually begins in childhood, although it may not be diagnosed until adulthood. Narcolepsy is caused by a deficiency in certain neurotransmitters in the neurons in the hypothalamus, a region responsible for controlling sleep patterns. The patient experiences an abnormal pattern of rapid eye movement (REM) sleep during the night, which causes the patient to have a "deficit" of restful sleep. There is a genetic predisposition to acquiring the disorder.

Narcolepsy is characterized by four symptoms, which separate it from other types of sleep disorders. Patients with narcolepsy may not experience all four symptoms:

- **Sleep attacks. Sleep attacks** are sudden bouts of sleep that last 10 to 30 minutes and may occur during the daytime without warning.
- **Cataplexy.** Approximately 90% of patients who have narcolepsy experience **cataplexy**, a bilateral loss of muscle tone and emotion. The cataplexy may last from several seconds to minutes, and symptoms range from clumsiness to complete collapse.
- **Sleep paralysis.** Approximately 60% of patients diagnosed with narcolepsy experience **sleep paralysis**, which is the temporary inability to move after waking up from sleep.
- **Hypnagogic hallucinations. Hypnagogic hallucinations** are vivid, dreamlike sensations, sometimes of a frightening nature, that occur with sleep paralysis.

Severe narcolepsy can be disabling and interfere with normal activities such as employment or success at school. To accommodate the disorder, the patient may require a schedule that includes several 15-minute daytime naps.

PharmFACT

After obstructive sleep apnea and restless leg syndrome, narcolepsy is the third most frequently diagnosed primary sleep disorder found in patients seeking treatment at sleep clinics. Up to 10% of patients diagnosed with narcolepsy and cataplexy together report having a close relative with the same symptoms (National Institute of Neurological Disorders and Stroke, n.d.).

The goal of narcolepsy pharmacotherapy is to reduce the incidence of daytime drowsiness and other symptoms associated with the disorder. Traditional therapies have focused on CNS stimulants. Dextroamphetamine and methylphenidate are approved to treat narcolepsy (see Section 24.3). The CNS stimulants are effective at reducing daytime drowsiness but may cause nervousness, insomnia, and dependence. A newer stimulant, modafinil, has become widely used in the treatment of narcolepsy and is the prototype for this disorder.

CNS stimulants are not effective at treating cataplexy. Antidepressants such as selegiline (Eldepryl), imipramine (Tofranil), and fluoxetine (Prozac) have been used off-label to treat cataplexy and provide symptomatic relief in about 80% of patients. The only drug specifically approved by the FDA for treating cataplexy is sodium oxybate (gamma-hydroxybutyrate [GHB], Xyrem). Sodium oxybate reduces daytime sleepiness as well as episodes of cataplexy, sleep paralysis, and hypnagogic hallucinations.

PROTOTYPE DRUG **Modafinil (Provigil)**

Classification **Therapeutic:** Drug for narcolepsy
Pharmacologic: CNS stimulant

Therapeutic Effects and Uses: Approved in 1998, modafinil is an oral drug used to treat patients with narcolepsy and to treat the excessive sleepiness associated with shift work (circadian rhythm disruption). The drug increases daytime alertness and locomotor activity. Modafinil may also be prescribed to treat fatigue related to Parkinson's disease, obstructive sleep apnea, and multiple sclerosis.

Similar to amphetamines, modafinil can induce euphoria and psychoactive symptoms. Although the abuse potential for modafinil is less than that of other CNS stimulants, it is still classified as a Schedule IV controlled substance. It does not appear to suppress appetite or promote weight loss.

Mechanism of Action: The mechanism by which modafinil exerts its wake-promoting effects is unknown. The drug increases dopamine levels in the brain by inhibiting dopamine uptake.

Pharmacokinetics:

Route(s)	PO
Absorption	Rapidly absorbed
Distribution	Distributed to most tissues; unknown if secreted in breast milk; 60% bound to protein
Primary metabolism	Hepatic by multiple CYP450 enzymes
Primary excretion	Renal
Onset of action	Peak: 2–4 h
Duration of action	Half-life: 15 h

Adverse Effects: Serious adverse effects from modafinil are infrequent. The primary CNS adverse effects are headache, nervousness, insomnia, cataplexy, and paresthesia. Cardiovascular adverse effects include increased and decreased blood pressure, vasodilation, and syncope. Nausea, vomiting, diarrhea, and dry mouth are frequent gastrointestinal (GI) adverse effects. Pulmonary effects include pharyngitis, rhinitis, and dyspnea. Serious rashes, including cases of Stevens–Johnson syndrome (SJS), requiring hospitalization and discontinuation of treatment, have been reported with the use of modafinil. Modafinil can be abused or lead to dependence. This drug should be stored in a safe place to prevent misuse and abuse.

Contraindications/Precautions: Modafinil should not be administered to patients who have had an acute myocardial infarction (MI) or those with valvular heart disease or a hypersensitivity to modafinil. The safety of the medication has not been established in patients younger than age 16. The drug should be discontinued at the first sign of rash because SJS has been reported with the use of modafinil. The drug should be used with caution in patients with schizophrenia because it may worsen symptoms of psychotic disorders and may cause suicidal ideation. The drug should be used with caution in those with a history of substance abuse. Severe hepatic impairment may increase serum modafinil levels as much as 50%; doses in these patients must be reduced to prevent toxicity. This drug is not approved for use in children for any indication.

Drug Interactions: CYP450 enzymes metabolize modafinil, and the drug can inhibit and induce different isozymes. For example, modafinil inhibits CYP2C19, the primary metabolic enzyme for phenytoin, diazepam, and propranolol; levels of these drugs increase when given concurrently with modafinil. When modafinil is administered with cyclosporine, the therapeutic levels of cyclosporine decrease. Modafinil may increase the levels of clomipramine and warfarin. TCA levels increase with modafinil. Modafinil may decrease the effectiveness of oral contraceptives and cause unplanned pregnancies.

Herbal/Food: Foods and beverages containing caffeine may worsen insomnia.

Pregnancy: Category C.

Treatment of Overdose: Overdose causes agitation, insomnia, anxiety, aggressiveness, palpitations, and confusion. Overdoses are usually not fatal. The patient should receive supportive treatment and gastric lavage.

Nursing Responsibilities: Key nursing implications for patients receiving modafinil are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Central Nervous System Stimulants.

Drugs Similar to Modafinil (Provigil)

Antidepressants used to treat narcolepsy are presented in Chapter 19, and the amphetamines are discussed in Section 24.3. Armodafinil and sodium oxybate are other drugs specifically indicated for narcolepsy.

Armodafinil (Nuvigil): Approved in 2007, armodafinil is closely related to modafinil and exhibits the same actions and adverse effects. It is approved to treat narcolepsy and shift work sleep disorder and to improve wakefulness in patients with obstructive sleep apnea who often experience daytime drowsiness. Like modafinil, serious rashes, including cases of SJS, have been reported with the use of the drug. Armodafinil is a Schedule IV controlled substance and is pregnancy category C.

Sodium oxybate (Xyrem): Sodium oxybate is a very unusual drug because it is the sodium salt of GHB, a Schedule I controlled substance. GHB can produce euphoria, sedation, and amnesia and is known as a "date rape" drug (see Chapter 27). Classified as a Schedule III controlled substance, sodium oxybate is only available from a centralized pharmacy to approved healthcare providers due to its abuse potential. It has strong hypnotic effects and is given in 2 doses: one at bedtime and one 4 hours later. It is approved for excessive daytime sleepiness associated with narcolepsy and for symptoms of cataplexy. The drug is sometimes administered with CNS stimulants in the management of narcolepsy. The most frequently reported adverse effects are headache, nausea, vomiting, dizziness, depression, and drowsiness. Sodium oxybate carries a black box warning that the drug is associated with adverse CNS events that include seizures, respiratory depression, profound decreases in level of consciousness, coma, and death. This drug is pregnancy category C.

CONNECTION Checkpoint 24.3

From what you learned in Chapter 18, during which stage of sleep does most of an individual's active dreaming occur? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Methylxanthines

24.6 Methylxanthines are central nervous system stimulants used for their ability to increase alertness or their effects on the respiratory system.

Methylxanthines are substances similar to xanthine, a chemical produced during the breakdown of deoxyribonucleic acid (DNA). Unlike the other CNS stimulants discussed in this chapter, the methylxanthines are not used for their effects on the brain. Instead, the methylxanthines are associated with treating patients with chronic obstructive pulmonary disease (COPD), asthma, and other restrictive lung diseases due to their ability to relax bronchial smooth muscle. The methylxanthines include caffeine, theophylline, and theobromine. Caffeine is the prototype drug for the methylxanthines. The dose of caffeine is listed in Table 24.3.

Theophylline and theobromine are formed by the metabolic breakdown of caffeine in the liver. Although rarely used, theophylline is still available as a drug to treat asthma that is resistant to other therapies. Theobromine is a natural substance found in chocolate that once was used as a drug to treat HTN and other vascular disorders. Although similar to caffeine, it has very little CNS stimulant activity.

PROTOTYPE DRUG Caffeine

Classification **Therapeutic:** CNS and respiratory stimulant
Pharmacologic: Methylxanthine

Therapeutic Effects and Uses: Caffeine is a methylxanthine naturally found in over 60 plant species. Most consumption in the United States is from coffee, tea, soft drinks, chocolate, and energy beverages. Caffeine has potent psychoactive properties. When taken PO it quickly restores mental alertness and aids in wakefulness. In addition to its consumption in beverages and food, caffeine is also available in OTC products designed to increase alertness and delay fatigue.

The only FDA-approved indication for caffeine is as a respiratory stimulant in the management of apnea in premature infants. For this indication, caffeine (Cafcit) may be administered IV or PO (e.g., added to formula feedings).

Caffeine also has a number of off-label indications. In patients with asthma, orally administered caffeine will produce bronchodilation and smooth muscle relaxation. Caffeine produces a mild diuresis due to increased blood flow to the glomerulus and has been used as an OTC diuretic product. Caffeine can be administered IV to relieve headache associated with lumbar puncture.

Caffeine itself has no analgesic properties. However, it enhances pain relief when administered with a narcotic analgesic. Caffeine is also combined with ergotamine (Cafergot) in the treatment of migraine headaches. It may be administered parenterally in emergency situations to treat circulatory collapse.

Mechanism of Action: Caffeine is metabolized in the liver to theobromine and theophylline, both of which are active metabolites that enhance the CNS and respiratory stimulant effects of caffeine. When higher doses are administered, the medulla, respiratory center, and vagus nerve are stimulated and produce a relaxation of smooth muscle, which is particularly evident in the bronchi and coronary and systemic blood vessels.

Pharmacokinetics:

Route(s)	PO, intramuscular (IM), IV
Absorption	Rapidly absorbed
Distribution	Widely distributed; crosses the blood–brain barrier and the placenta; secreted in breast milk; 36% bound to plasma proteins
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	15–45 min
Duration of action	Half-life: 3–5 h in adults; 36–144 h in neonates

Adverse Effects: Caffeine may cause adverse effects at therapeutic doses, many of which are extensions of its pharmacologic actions. Excessive CNS stimulation may cause nervousness, insomnia, tremors, and restlessness. The cardiovascular effects of caffeine include tingling of the face, palpitations, tachycardia, bradycardia, and ventricular ectopic beats. GI effects noted with the administration of caffeine are related to the stimulation of the vagus nerve and include nausea, vomiting, epigastric pain, hematemesis, and kernicterus in neonates. Clonic seizures can result in rare instances. Caffeine withdrawal can produce symptoms of irritability, headache, lethargy, or anxiety.

Contraindications/Precautions: Caffeine should not be administered during acute MI or to patients with cardiac dysrhythmias because the drug increases the workload of the heart. Caffeine increases the secretion of gastric acid; therefore, patients who have peptic ulcer disease should limit their caffeine intake. Patients with anxiety disorders, insomnia, or panic attacks should not be administered caffeine because it may worsen these conditions. It should be used cautiously in patients with diabetes mellitus, hiatal hernia, HTN, and heart disease. Patients with hepatic impairment or chronic kidney disease should receive lower doses because the drug may accumulate to toxic levels.

Drug Interactions: Caffeine administered with cimetidine will increase the effect of cimetidine.

Beta-adrenergic agonists administered with caffeine will result in increased cardiovascular stimulation. Additive effects are likely if the drug is taken concurrently with other CNS stimulants. Patients taking drugs for insomnia or anxiety should limit their intake of caffeine. Caffeine is a substrate of hepatic cytochrome CYP1A2. Drugs that enhance or inhibit this enzyme may interact with caffeine. **Herbal/Food:** Food and fluids that contain caffeine will increase the insomnia or restlessness that is normally noted with methylxanthines.

Pregnancy: Category B. (Cafcit is labeled as category C.)

Treatment of Overdose: Caffeine overdose can potentially cause dysrhythmias, insomnia, delirium, and seizures. The patient is supported through symptom management. High serum levels of caffeine can be dialyzed with peritoneal dialysis or hemodialysis.

Nursing Responsibilities: Key nursing implications for patients receiving caffeine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy with Central Nervous System Stimulants.

Drugs Similar to Caffeine

Theophylline is the only other methylxanthine used as a drug.

Theophylline: Theophylline is not used to treat ADHD, but it is administered to produce bronchodilation in patients with acute bronchospasm. It decreases wheezing and obstructed airways in asthma and bronchitis. It is important to note that the medication is a CNS stimulant that can produce restlessness, insomnia, and irritability. Close monitoring is required to prevent drug toxicity. Once widely prescribed, theophylline use has declined due to the development of safer drugs for patients with asthma (see Chapter 44).

PharmFACT

Caffeine passes through the placenta to the fetus. Because of this, pregnant women should limit their caffeine intake to 200 mg/day, the equivalent of a 12-ounce cup of coffee. Energy drinks contain large amounts of caffeine and should be avoided altogether during pregnancy (March of Dimes, 2015).

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy with Central Nervous System Stimulants

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including hepatic, renal, cardiovascular, or neurologic disease, including epilepsy, and neonatal or previously existing symptoms of cardiac problems. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Obtain a social and behavioral history. Use objective screening tools when possible.
- Obtain a nutritional history and assess normal sleep patterns.
- Obtain baseline vital signs, height, and weight.
- Evaluate appropriate laboratory findings (e.g., electrolytes, complete blood count [CBC], hepatic, and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., increased ability to focus, normalized activity levels with lessened impulsivity, maintenance of normal appetite and sleep patterns).
- Continue periodic monitoring of electrolytes, CBC, and hepatic and renal function studies.
- Continue to monitor vital signs, especially pulse, blood pressure, and height and weight weekly. **Lifespan:** Be aware that the child, adolescent, or older adult is at greater risk for cardiovascular effects and may be more likely to experience adverse effects related to anorexia from the drug.
- Assess for and promptly report adverse effects: dizziness, lightheadedness, anxiety, agitation, excessive physical activity, tachycardia, increased blood pressure, HTN, palpitations.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. (Therapeutic effects of ADHD drugs include the ability to focus and stay on task, lessened impulsivity, and improved social interactions.)	• Teach the patient, family, or caregiver to keep a social and behavioral diary. Involve school faculty and other caregivers (e.g., after-school care).
Minimizing adverse effects: • Continue to monitor pulse and blood pressure on healthcare visits. (Tachycardia, increased blood pressure, or HTN may occur if dose is excessive. An increased risk of dysrhythmias and sudden death has been noted with some drugs.)	• Teach the patient, family, or caregiver to take the pulse along with weekly height and weight, or any time symptoms warrant (e.g., child reports chest discomfort or palpitations). Assist the patient, family, or caregiver to find the pulse location most easily felt and have the patient, family, or caregiver return demonstrate pulse taking before going home.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Weigh the patient weekly and obtain height. Report any weight loss or failure to gain weight during expected growth periods. Assess nutrition and use of other stimulating products (e.g., energy drinks and caffeinated beverages). (Diminished appetite or anorexia from stimulating effects of the drug, or use of other stimulants, may impair normal nutrition needed for growth and development. **Lifespan:** Children, adolescents, and older adults are more likely to experience adverse effects related to anorexia from the drug.)	• Teach the patient, family, or caregiver to obtain height and weight weekly and to report any loss of weight or lack of expected growth. Ensure proper use and functioning of any home equipment used (e.g., electronic scale). • Discuss the need to avoid or eliminate all foods, beverages, or OTC drugs that contain caffeine or other stimulants.
• Continue to monitor sleep patterns. (Stimulatory effects of the drug may affect normal sleeping patterns and may indicate excessive dosage.)	• Instruct the patient, family, or caregiver to inform the provider of disruption to sleep, increased agitation during the day (possible effect from lack of sleep), or excessive sleepiness during the day. • Have the patient take the dose early in the day and before 4 p.m. to help alleviate insomnia unless extended release formulation is used. Take extended release formulations in the morning.
• Assess for excessive stimulatory effects: agitation, aggression, tremors, or seizures and report immediately. (Excessive CNS stimulation may cause seizures as an adverse effect.)	• Instruct the patient, family, or caregiver to report tremors or seizures to the healthcare provider immediately.
• Assess for urinary retention periodically. (Atomoxetine [Strattera] and other norepinephrine reuptake inhibitors may cause urinary retention as an adverse effect. **Lifespan:** Be aware that the older male adult with an enlarged prostate is at higher risk for mechanical obstruction.)	• Instruct the patient to immediately report an inability to void, increasing bladder pressure, or pain.
• Continue to monitor for dermatologic effects including red or purplish skin rash, blisters, or sunburn. (Armodafinil and methylphenidate have been associated with severe skin effects including SJS and exfoliative dermatitis. Sunscreen and protective clothing should be used.)	• Teach the patient to wear sunscreen and protective clothing for sun exposure and to avoid tanning beds. Immediately report any severe sunburn or rashes.
• Assess the need for continuous medication or the need for drug holidays with the patient, family caregiver, and the healthcare provider based on social and behavioral diary findings. (Dependent on the degree of behavior, drug holidays on nonschool days or vacation periods may be recommended.)	• Teach the patient, family, or caregiver about the use of drug holidays and explore options. If the drug dose is at the upper range, consider tapering the dose prior to beginning the drug holiday to avoid rebound hyperactivity or agitation.

• Assess the home environment for medication safety and need for appropriate interventions. Advise the family on restrictions of prescription renewal. (Some of these drugs are scheduled drugs and may not be used by any individual other than the patient. Safeguard the medication in the home to prevent overdose.)	• Instruct the patient, family, or caregiver about:
	  • Proper medication storage and the need for the drug to be used by the patient only.
	  • Prescription renewal restrictions (i.e., new prescription each time, no refills, and prescription may not be called in) and explore school policies regarding in-school use (e.g., single dose sent each day, and secured blister pack used if multiple doses are sent).

• Assess for increasing depression, agitation, delusional thoughts, or expressions of suicide or self-harm. Promptly refer any of these symptoms to the provider. (Atomoxetine has been associated with an increased risk of suicide. Modafinil and armodafinil have been associated with an increased risk of psychiatric symptoms, including paranoia and suicidal ideations.)	• Teach the family or caregiver to be alert for signs of increased depression, confusion, paranoia, or expressions of suicide. Promptly notify the provider if symptoms are noted.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, and caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in proper self-administration of the drug (e.g., take the drug as prescribed and do not substitute brands). (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient the following:
	  • Take the medication exactly as ordered and in the morning to prevent insomnia.
	  • Do not take double or extra doses to increase mental focus or prevent sleepiness. The drug will not achieve these effects but will increase the adverse effects of the drug.
	  • Do not abruptly discontinue the medication without consulting the healthcare provider.
	  • Do not open, chew, or crush extended release tablets; swallow them whole with plenty of water.

Understanding Chapter 24

Key Concepts Summary

24.1 Central nervous system stimulants increase alertness, enhance the ability to concentrate, and delay the symptoms of fatigue.

24.2 Attention-deficit/hyperactivity disorder is characterized by inattention, hyperactivity, and impulsive behavior.

24.3 Psychostimulants are central nervous system stimulants indicated for the treatment of ADHD and narcolepsy.

24.4 Several nonstimulants are effective in treating symptoms of attention-deficit/hyperactivity disorder.

24.5 Narcolepsy is characterized by excessive daytime sleepiness and is treated with central nervous system stimulants and antidepressants.

24.6 Methylxanthines are central nervous system stimulants used for their ability to increase alertness or their effects on the respiratory system.

CASE STUDY: Making the Patient Connection

Remember the patient "Jonathon Hogan" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Jonathon Hogan has had trouble at school beginning in kindergarten and for the past year. His teachers have consistently reported that he is easily distracted and wanders around the classroom even during a lesson. Getting him to do his homework after school has been a struggle. Jonathon loves art and does well at video games. Because he is a happy-go-lucky child, his parents have assumed that Jonathon's right-brain dominance has created trouble with left-brain logical work. With more homework now in second grade, Jonathon is struggling to keep up in school. The school nurse suspects he may have ADHD. She has recommended an appointment with Jonathon's healthcare provider and told his parents that Adderall may help Jonathon focus on his schoolwork.

Critical Thinking Questions

1. What is ADHD and why would Jonathon be experiencing more difficulty as he becomes older?
2. How might amphetamine sulfate and dextroamphetamine (Adderall) help Jonathon with his ADHD?
3. What caregiver education would be appropriate regarding dextroamphetamine and amphetamine sulfate (Adderall)?
4. What are other nonpharmacologic treatments for ADHD?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Anna Steinmetz has graduated from nursing school and is working nights. She is having difficulty adjusting to her night schedule. Her healthcare provider suggested she utilize a medication to assist with her adjustment to shift work. She has been prescribed modafinil (Provigil).

1. What effect does modafinil (Provigil) have on the patient's ability to maintain alertness during shift work?
2. What teaching will you provide to the patient regarding this medication?
3. The patient reports feelings of lightheadedness with position changes. What interventions will assist in maintaining patient safety?

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. An elementary school nurse is providing education to the faculty on the use of central nervous system stimulants to treat attention-deficit/hyperactivity disorder. Of the following, which is most important for the nurse to convey to the faculty?
   1. Have the child bring the drug dose in a lunch bag and come to the office to take it to avoid being teased.
   2. Request that the parents leave an extra copy of the prescription at the school in case the dose runs out.
   3. Suggest that the parents have two prescriptions filled, one for home and one to keep at school.
   4. Keep the drugs in a locked drawer, clearly labeled with the student's name and only the number of doses allowed by school policy.

2. Which therapeutic outcome would the nurse consider most significant in evaluating a patient who started atomoxetine (Strattera) 6 months ago?
   1. Decrease in attention
   2. Decrease in hyperactivity
   3. Development of mydriasis
   4. Elevated liver enzymes

3. A patient who has overdosed on amphetamine sulfate and dextroamphetamine (Adderall XR) is admitted to the emergency department. The nurse would anticipate which medications to be administered to assist in counteracting the effects of the overdosage?
   1. Chlorpromazine (Thorazine)
   2. Phenytoin (Dilantin)
   3. Propofol (Diprivan)
   4. Dexamethasone (Decadron)

4. A high school student taking atomoxetine (Strattera) for attention-deficit/hyperactivity disorder visits the school nurse's office and confides, "I am so depressed. The world would be better off without me." Which action would the nurse take for this patient?
   1. Tell the patient to stop taking atomoxetine immediately and not to take it until checking with the provider.
   2. Assure the patient that these are normal symptoms because the drug may take 3 or 4 weeks to work.
   3. Alert the family or caregiver that immediate attention and treatment are needed for these symptoms.
   4. Have the patient increase intake of caffeine by consuming cola products, coffee, or tea to counteract the depressive effect.

5. An office worker has made an appointment with a healthcare provider for heart palpitations, dysrhythmias, and facial tingling. The nurse is taking the patient's history. Which of the following does the nurse note may explain the symptoms?
   1. The patient takes zolpidem (Ambien) for occasional insomnia.
   2. The patient has been working late frequently and has relied on coffee to maintain alertness.
   3. The patient is taking gabapentin (Neurontin) for pain associated with herpes zoster.
   4. The patient has been under stress at work and has switched to using herbal teas.

6. A patient who is taking methylphenidate (Concerta, Metadate, Ritalin) for attention-deficit/hyperactivity disorder reports having insomnia. Which intervention will assist in the promotion of sleep?
   1. Have a glass of wine with dinner.
   2. Eat a chocolate bar at bedtime.
   3. Take the drug before 4 p.m.
   4. Switch to decaffeinated coffee.

Chapter 25
Pharmacotherapy of Severe Pain and Migraines

Chapter Outline

- General Principles of Pain Management
- Pain Management with Opioids
  - Opioid Analgesics
    - **PROTOTYPE** *Morphine Sulfate (Astramorph PF, Duramorph RF, Roxanol, Others), p. 402*
  - Mixed Agonist-Antagonist Opioids
- Pain Management with Nonopioids
  - Nonopioid Analgesics
    - Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) and Acetaminophen
    - Centrally Acting Analgesics
      - **PROTOTYPE** *Tramadol (Ultram, Others), p. 406*
    - Adjuvant Analgesics
- Pharmacotherapy with Opioid Antagonists
- Pharmacotherapy of Migraines
  - **PROTOTYPE** *Sumatriptan (Imitrex, Onzetra), p. 415*

Learning Outcomes

After reading this chapter, the student should be able to:

1. Identify key principles of pain management.
2. Describe the assessment and classification of pain.
3. Refute the common pain myths, using objective evidence.
4. Explain the phases of pain physiology: transduction, transmission, perception, and modulation.
5. Describe pharmacologic and nonpharmacologic therapies used in pain management.
6. Describe the types of opioid receptors in the central nervous system.
7. Identify the classes of drugs used for minor, moderate, and severe pain.
8. Compare and contrast the actions of opioid agonists, mixed opioid agonists-antagonists, and opioid antagonists.
9. Describe the use of nonopioids and adjuvant analgesics in the treatment of pain.
10. Compare and contrast the actions and adverse effects of the opioids and nonopioids for analgesia.
11. Explain the role of opioid antagonists in the diagnosis and treatment of acute opioid toxicity.
12. Compare the types of drugs used for preventing migraines to those for terminating migraines.
13. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
14. Apply the nursing process to care for patients receiving pharmacotherapy for pain and for migraines.

Pain is a subjective experience that has both physiologic and emotional components. Often associated with trauma or disease, pain may be viewed as a natural defense mechanism that helps people avoid potentially damaging situations and encourages them to seek medical help. Pain medications are some of the most frequently used drugs in medicine. This chapter examines the drug classes used in pain management and for the pharmacotherapy of migraines.

General Principles of Pain Management

25.1 The primary goal of pain management is to reduce pain to a level that allows the patient to continue normal daily activities.

Pain management is one of the most important tasks for healthcare providers. It is also one of the most difficult because the experience of pain by patients and its assessment by healthcare providers are subjective. The perception of pain is clearly influenced by comorbid conditions such as anxiety, fatigue, and depression. For example, knowing that healthcare providers and caregivers are attentive and actively engaged in pain management may lower patients' anxiety, thus reducing pain perception and increasing pain tolerance. Listening carefully, showing respect, and helping patients to understand their treatment options are important steps to attaining optimal pain relief.

The immediate goal of pain management is to reduce pain to a level that allows the patient to perform reasonable activities of daily living (ADLs) such as sleeping, eating, and normal physical activities. For some disorders, the patient should understand that the total elimination of pain may not be a realistic goal, or that the pain may require a long period of treatment. Several key principles underlie the nursing management of pain:

- The patient should be considered the expert on his or her own pain; the nurse should always believe the patient's self-assessment of pain.
- Pain management is a patient right and should be based on the patient's goals. The patient should be screened for pain during an initial assessment and periodically thereafter. If pain cannot be effectively managed, then a pain management specialist should be consulted.
- Nonpharmacologic interventions such as massage or the application of heat or cold should be encouraged in pain management. A combination of therapies is optimal because different modalities work by different mechanisms, thus improving the effectiveness of pain management.
- Dosing should be individualized and adjusted to produce the established pain management goal in each patient.
- Adverse effects from pain medications should be anticipated and prevented whenever possible. Should they appear, adverse effects should be immediately addressed.
- Around-the-clock dosing for moderate to severe pain should be implemented because it is much easier to *maintain* a pain-free level than to *eliminate* existing or escalating pain.

25.2 Proper assessment and classification of pain guides its treatment.

Pain assessment includes documenting the location, intensity, and quality (sharp, dull, burning) of the pain and any precipitating or relieving factors. For most adults, the 0-to-10 numerical rating scale is the standard for rating pain intensity, with 0 being no pain and 10 being the greatest pain imaginable. The pain rating is used as a reference point, initially as a baseline level of pain and later as an indicator of effectiveness as to how well the treatment is achieving the patient's goals.

Pain may be classified as acute or chronic. Acute pain has an abrupt onset but brief duration; it subsides as healing takes place or the pain stimulus ceases. Examples of acute pain include that associated with surgical incisions, labor and delivery, sprained joints, or myocardial infarction (MI). Although it may be severe, acute

pain is often self-limiting; high doses of pain medication may be necessary, but therapy is usually of short duration. There is little risk of chronic drug adverse effects or dependence because of the relatively brief treatment period.

Chronic pain is pain that persists longer than 6 months, can interfere with ADLs, and is sometimes associated with feelings of helplessness or hopelessness. Chronic pain can be further grouped as either nonmalignant or malignant (cancer) pain. Chronic nonmalignant pain is not life threatening and usually responds favorably to a consistent, stable dose of pain medication as part of a treatment regimen. The most common example is low back pain. Cancer pain ends with control of the disease or death. Although the majority of patients with cancer experience pain during the advanced stages of the disease, 90% of the cancer pain can be controlled with oral (PO) drugs, using around-the-clock dosing, with as-needed (prn) doses for breakthrough pain.

PharmFACT

Low Back Pain in America

- Eighty percent of adults experience low back pain in their lifetime.
- The first attack of low back pain most often occurs between the ages of 30 and 50 due to the aging process and too little exercise.
- Carrying heavy backpacks can cause muscle strains in children. A child's backpack should weigh no more than 15% to 20% of the child's weight (National Institute of Neurological Disorders and Stroke, 2014).

Another useful method for classifying pain is according to its source: nociceptor or neuropathic. **Nociceptors** are the sensory nerve receptors located throughout the body that initiate pain transmission when stimulated. For example, a needlestick will activate receptors in the finger, producing **nociceptor pain**. This type of pain may be further subdivided into somatic pain, which produces sharp, localized sensations usually experienced in muscles and joints, or visceral pain, which is described as a generalized dull, throbbing, or aching pain usually located in internal organs. Nociceptor pain responds quite well to **analgesics**, which are medications that relieve pain.

In contrast, **neuropathic pain** is caused by injury or irritation to nerve tissue and typically is described as burning, shooting, or numbing pain. The cause of neuropathic pain is sometimes difficult to determine. Analgesic treatment of neuropathic pain is often unsuccessful or high doses may be required. Neuropathic pain responds well to adjuvant analgesics such as antiseizure drugs and antidepressants (see Section 25.11).

25.3 Healthcare providers and patients sometimes hold myths about pain that impede optimal pain management.

Commonly held but untrue beliefs by both patients and healthcare providers may interfere with effective pain management. For example, healthcare providers may undertreat pain because of common misconceptions about pain. Furthermore, patients may not report their pain accurately or may refuse pain medications because of similar misconceptions.

A pervasive myth is that healthcare professionals can successfully recognize pain, independent of the patient's report. The nurse must understand that patients are the authorities on their own pain. Pain is whatever the patient says it is, existing whenever the patient says it does. Patient self-report of pain is sufficient for a nursing diagnosis of pain.

A closely related myth is that someone in pain must look and act like he or she is in pain. Some patients do not show or report pain accurately because they feel it is a sign of weakness. In addition, vital signs are sometimes unreliable indicators of pain. Although they may be elevated during the initial experience of acute pain owing to sympathetic arousal, vital signs return to normal as the body adapts. A related misconception is the belief that if an individual is able to sleep, he or she must not be experiencing much pain. Although it is certainly true that pain can interfere with sleep quality and quantity, social withdrawal and excessive sleep may be indicators of coping mechanisms for some people with severe or chronic pain.

Both patients and healthcare providers may share the myth that the use of potent analgesics inevitably leads to addiction. **Addiction** is the continued use of a substance despite serious health and social consequences (see Chapter 27). The incidence of addiction to opioids, which are used in the treatment of severe pain, is less than 1% in patients with no previous history of drug abuse. Related to this myth is the belief that patients experiencing chronic pain overreport pain because they are addicted to opioids.

Another contradictory myth is the belief that the more pain an individual experiences, the more he or she is likely to tolerate it. In fact, the opposite is more likely to occur. Unrelieved pain creates anxiety and fatigue, both of which increase pain perception and decrease tolerance. A related myth is that there is no physiologic basis for the moderating effects of emotions on pain perception.

25.4 Pain transmission processes allow multiple targets for pharmacologic intervention.

Pain physiology may be divided into four phases: transduction, transmission, perception, and modulation. These phases are illustrated in Figure 25.1.

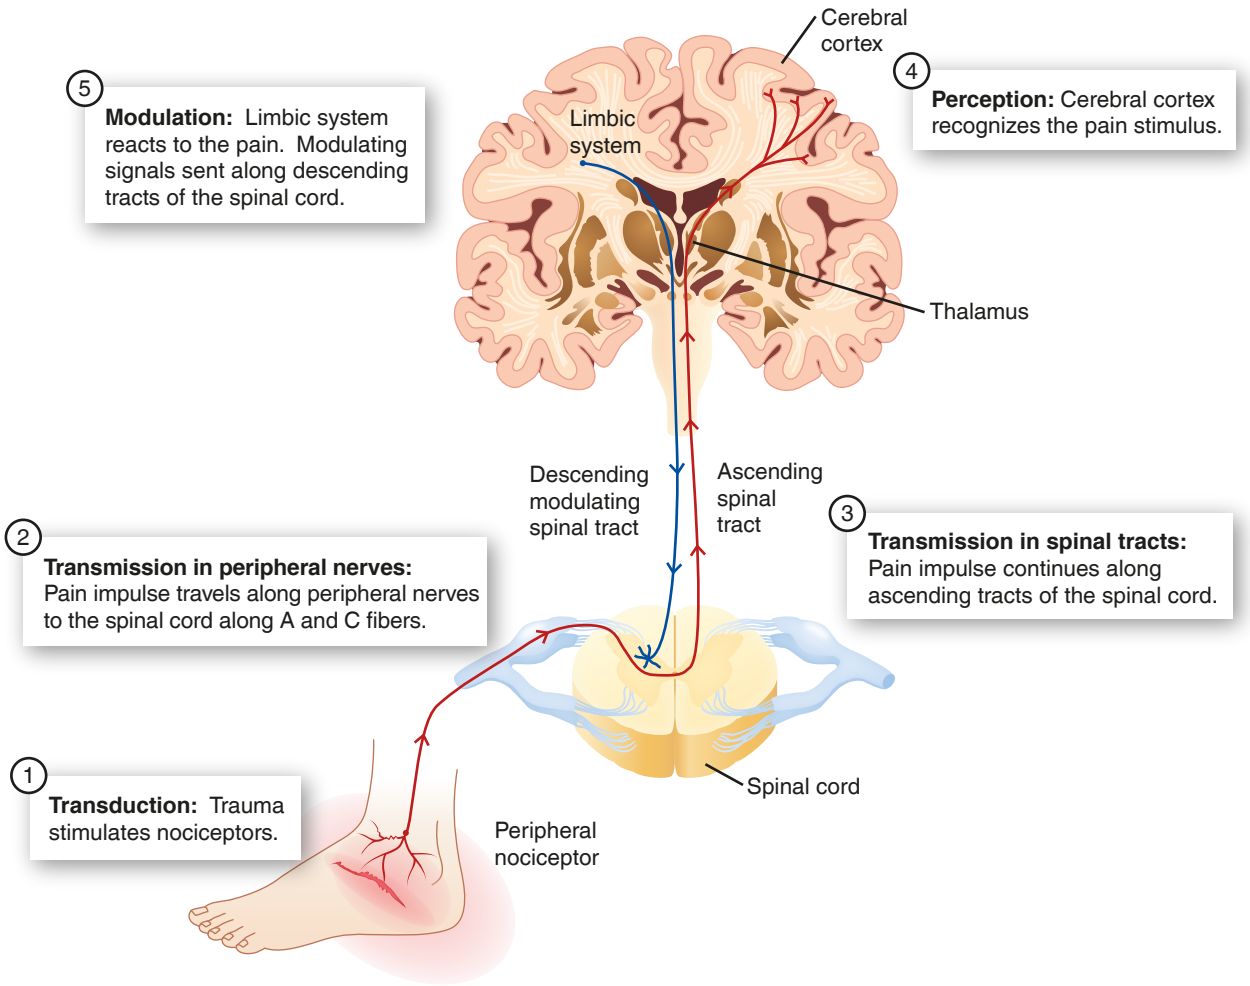

Figure 25.1 Phases of pain physiology.

Pain transduction: Pain transduction begins when nociceptor nerve endings in the peripheral nervous system are stimulated. This occurs when local tissue injury causes the release of chemical mediators of inflammation, including prostaglandins, leukotrienes, histamine, bradykinin, and substance P. These substances sensitize peripheral nociceptors, making them easier to activate.

Pain transmission: The nerve impulse signaling the pain travels from the nociceptor to the spinal cord along two types of sensory neurons called A and C fibers. A fibers are wrapped in myelin, a lipid substance that speeds nerve transmission, and carry signals for intense, well-defined pain. In contrast, C fibers are unmyelinated and thus carry information more slowly and conduct poorly localized pain, which is often perceived as burning or a dull ache.

A fibers have three subtypes: alpha (α), beta (β), and delta (Δ). Aα fibers have the fastest transmission and respond to touch and pressure on muscle; Aβ fibers are slower and respond to touch and pressure on skin. Finally, AΔ fibers are the slowest of the A fibers and respond to tissue injury, producing the sensation of sharp pain.

The sensory nerve fibers enter the dorsal horn of the spinal cord and have adjacent synapses in an area called the substantia gelatinosa. The **gate control theory** proposes a gating mechanism for the transmission of pain in the spinal cord. Signals from faster Aα or Aβ fibers reach the spinal cord and close the gate before those of C fibers reach the region (or gate), in effect blocking the transmission of these types of pain impulses. The gate control theory, proposed in 1965, has withstood the test of time and has been found to be more complex than originally proposed. The "gates" can also be closed when flooded with nonnociceptor impulses. Gate control explains the effectiveness of massage, transcutaneous electrical nerve stimulation, and, possibly, acupuncture in reducing pain.

Once a pain impulse reaches the spinal cord, neurotransmitters are responsible for passing the message along to the next neuron. At the spinal cord level, glutamate is the neurotransmitter for A fibers, whereas both glutamate and substance P are neurotransmitters for C fibers. Impulse transmission from the spinal cord to the brain is moderated by both excitatory and inhibitory neurotransmitters. The activity of substance P may be affected by other neurotransmitters released from neurons in the

central nervous system (CNS). One group of neurotransmitters functions as endogenous opioids, or natural pain modifiers; these include **endorphins** and enkephalins.

Pain perception: Perception, the conscious experience of pain, occurs in the brain. Numerous cortical structures and pathways are involved in perception, including the reticular activating system, the somatosensory system, and the limbic system (see Chapter 17). When the pain impulse reaches the brain, it may respond to the sensation with a wide variety of possible actions, ranging from signaling the skeletal muscles to jerk away from a sharp object to mental depression in those experiencing chronic pain.

Pain modulation: Modulation involves descending nervous impulses traveling down the spinal cord that inhibit afferent pain transmission via a feedback mechanism. Neurotransmitters such as serotonin, norepinephrine, and endogenous opioids (endorphins and enkephalins) inhibit pain transmission.

The four phases of pain physiology allow for multiple targets for pharmacologic intervention. The two primary classes of analgesics act at different locations: The nonsteroidal anti-inflammatory drugs (NSAIDs) act at the peripheral level, whereas the opioids act on the CNS. Drugs that affect or mimic the inhibitory neurotransmitters are used as adjuvant analgesics.

25.5 Both pharmacologic and nonpharmacologic therapies are used in pain management.

Effective pain management requires a holistic approach to meet the patient's need for pain relief. In some cases, such as a headache, pain relief is easy to accomplish using over-the-counter (OTC) medications or relaxation or biofeedback therapies. In other cases, such as during cancer treatment, prescription medications must be used to reduce pain levels. For these patients, pain management requires considerable skill on the part of the healthcare provider.

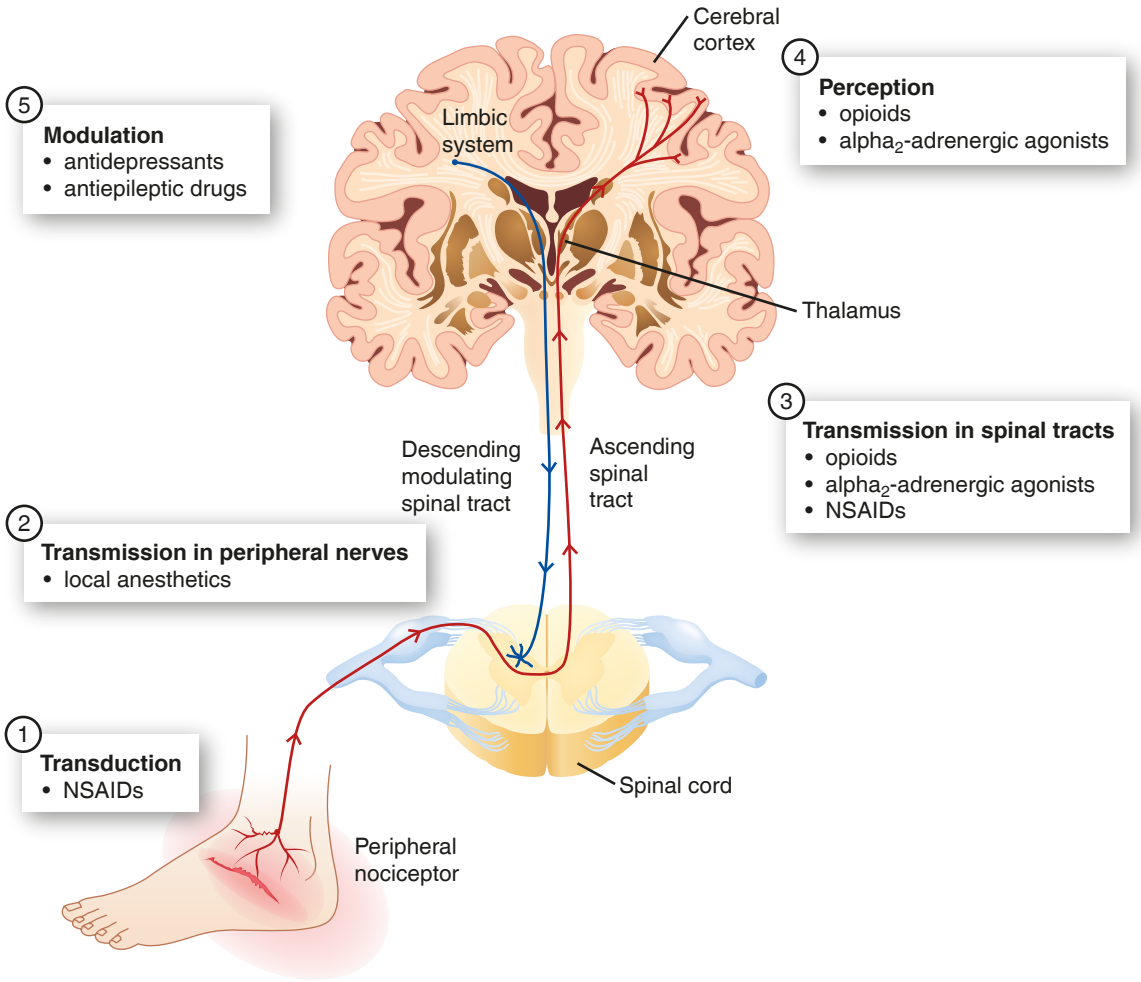
Nonpharmacologic therapies: Nonpharmacologic techniques may be used to attain adequate pain relief in place of drugs, or they may serve as adjuncts to analgesics. When used concurrently with medication, nonpharmacologic techniques allow for improved comfort, lower doses, and the potential for fewer drug-related adverse events. Nondrug interventions should routinely be considered in the nursing plan of care for patients with pain. Some complementary and alternative therapies used for reducing pain include the following:

- Acupressure and acupuncture
- Application of cold or heat
- Biofeedback therapy
- Distraction, including art or music therapy, or laughter
- Electrical nerve stimulation
- Hypnosis
- Massage
- Meditation
- Physical therapy
- Yoga.

CONNECTIONS: Lifespan Considerations

Pain Assessment in the Very Young

According to Voepel-Lewis, Zanotti, Danmeyer, and Merkel (2010), behavioral rating scales such as the FLACC scale have been used with children as young as 3 months. Developed by the University of Michigan Health System, FLACC stands for the five categories assessed: face, legs, activity, cry, and consolability. Each category is scored 0 to 2 and then added to get a rating of 0 to10. For example, an infant with a pain rating of 0 would have no particular facial expression (F), legs relaxed (L), be lying quietly (A), without crying (C), and relaxed (C). At the other extreme, a rating of 10 would be seen as an infant crying steadily, with a rigid body and drawn up or kicking legs, clenched jaw or quivering chin, and who is difficult to console or comfort. The scale has undergone extensive testing for construct validity and reliability over the years since it was developed and is now used for assessing pain in nonverbal patients of all ages.



Pharmacologic therapies: Dozens of OTC and prescription pain medications are available, and the selection of a specific one depends on many factors. Foremost is the severity of the pain. The drug selected must be capable of providing adequate pain relief. Secondarily, the choice of analgesic depends on potential adverse events and drug interactions and contraindications. A key point is that every analgesic, even an OTC pain reliever, has the potential to cause serious adverse effects in susceptible patients. This reinforces the need to utilize nonpharmacologic therapies for pain relief whenever possible.

The two broad categories of analgesics are the opioids and nonopioids. A third category of drugs for the management of pain is the adjuvant analgesics. The adjuvant analgesics have no pain relief activity when used alone, but they are able to enhance the analgesic action of opioids and nonopioids.

The most effective drug class for relieving severe pain is the opioids. Minor to moderate pain is treated with nonopioids such as NSAIDs, centrally acting drugs, or acetaminophen. There are dozens of opioids and NSAIDs to choose from and it is difficult for beginning students, and even experienced healthcare providers, to learn the subtle differences of drugs within each class. Although the large number of analgesics appears overwhelming, many of them are quite similar and prescribers most often use only a few drugs in each class. The various drugs used for analgesia and the levels at which they act are shown in Pharmacotherapy Illustrated 25.1.

Pharmacotherapy Illustrated 25.1

Sites of Analgesic Action

The pharmacologic management of acute and chronic pain is based on the analgesic ladder proposed by the World Health Organization. Pain ratings of less than 4 are treated with nonopioid analgesics, complementary and alternative therapies (CATs), or a combination of the two. When pain ratings become moderate (4 to 6), PO opioids are added to the baseline treatment. When pain is severe (7 to 10), parenteral opioids are used. If chronic pain has neuropathic qualities, adjuvant analgesics are added.

Combination drugs: Healthcare providers often use opioid and nonopioid analgesics concurrently in the pharmacotherapy of pain. For convenience, these combinations are available as fixed-dose tablets or capsules. The two classes of analgesics work synergistically to relieve pain, and the dose of opioid can be lowered to avoid dependence and opioid-related adverse effects. Use of these combinations in chronic pain management has a dose ceiling due to the toxicities of the nonopioid analgesic. For example, patients taking a combination product containing acetaminophen need to be aware of the risk of acute liver failure with high doses. Liver enzyme levels should be monitored regularly, and care must be taken not to exceed the maximum daily dosages for acetaminophen. It is important to note that the U.S. Food and Drug Administration (FDA) requested that manufacturers limit the dose of acetaminophen in prescription products to a maximum of 325 mg per dosage unit. However, the maximum daily dose of acetaminophen remains at 4000 mg/day. Therefore, the healthcare provider can still prescribe 12 dosage units per day of the drug and remain below the maximum. Common combination analgesics include:

- Endocet (oxycodone, 5–10 mg; acetaminophen, 325 mg)
- Norco (hydrocodone, 7.5–10 mg; acetaminophen, 325 mg)
- Percocet (oxycodone, 2.5–10 mg; acetaminophen, 325 mg)
- Percodan (oxycodone, 4.8355 mg; aspirin, 325 mg)
- Lortab 5 (hydrocodone, 5 mg; acetaminophen, 300 mg)
- Vicodin HP (hydrocodone, 10 mg; acetaminophen, 300 mg).

CONNECTIONS: Patient Safety

Medication Errors and Patient-Controlled Analgesia

The use of PCA pumps to help manage pain has become accepted medical practice and is generally considered safe and effective. In fact, The Joint Commission (2012), in its Sentinel Event Alert, "Safe Use of Opioids in Hospitals," recommends the use of PCA to help avoid adverse events associated with the use of opioids. However, it is not known exactly how often adverse drug events (ADEs) are associated with PCAs due to severe underreporting of errors involving medical devices.

In 2013, a national survey of hospitals was conducted to determine practices around PCA pumps (Wong, Mabuyi, & Gonzalez, 2013). The survey showed that there is indeed a cause for concern about patient safety. According to reports made to the FDA between 2005 and 2009, more than 56,000 adverse events and 700 patient deaths were linked to PCA pumps. One out of 378 postsurgical patients was harmed or died from errors related to PCA pumps. The study found that safety procedures were not followed consistently by hospitals across the country, resulting in misprogramming of the pump, use of the wrong drug or pump cartridge, and IV flow issues. These types of errors accounted for the largest proportion of ADEs and deaths associated with PCA use.

PCA pumps provide an important mechanism for delivering analgesia but can result in respiratory depression and cardiovascular collapse. Adverse events can be averted and costs and expenses reduced by hospitals that continuously monitor their patients with pulse oximetry. What other strategies can the nurse implement to prevent complications for patients using PCAs?

Answers to Patient Safety questions are available on the faculty resources site. Please consult with your instructor.

Management of cancer pain: Patients with intractable cancer pain require more invasive techniques because rapidly growing tumors often press on vital tissues and nerves. Furthermore, chemotherapy and surgical treatments for cancer can cause severe pain. Radiation therapy may provide pain relief by shrinking solid tumors that may be pressing on nerves. Surgery may be used to reduce pain by removing part of or the entire tumor. Injection of alcohol or another neurotoxic substance into neurons is occasionally performed to cause nerve blocks. Nerve blocks irreversibly stop impulse transmission along the treated nerves and have the potential to provide total pain relief. Injection of local anesthetics or steroid hormones as nerve blocks can provide relief for months and is used for pain resulting from pressure on spinal nerves.

Patient-controlled analgesia: Patient-controlled analgesia (PCA) is a method of drug delivery that uses an infusion pump to deliver a prescribed amount of opioid by patient self-administration. By pressing a button, the patient can self-administer the opioid, thus relieving the anxiety of waiting for a prn drug administration. The patient does not have unlimited access to the drug; the infusion pump is programmed by the nurse to deliver a prescribed amount of drug over a designated time period. If the patient attempts to self-administer the drug too often, the patient is locked out until the next dose interval. The program is adjusted depending on the patient's response to the drug. Morphine is the opioid usually used for PCA; however, fentanyl or hydromorphone may be used.

PCA allows patients to participate in their own care. Frequent, small doses of analgesics give a more consistent serum drug level than would be obtained by administering larger doses 3 to 4 times per day. PCA requires that the patient be conscious and capable of understanding the operation of the pump. Patients should be taught not to be overly concerned about activating the pump because the program is set to prevent the possibility of overdose. Nurses, family members, or visitors should not use the device to give the patient more medication, but should consult with the healthcare provider if they feel that the patient's pain is not relieved.

Pain Management with Opioids

25.6 Opioid analgesics exert their effects by interacting with specific receptors in the central nervous system.

Opium is one of the oldest known natural remedies; it has been used to relieve pain for thousands of years. Extracted from the unripe seeds of the poppy plant, *Papaver somniferum*, **opium** is a milky substance that contains over 20 different chemicals having pharmacologic activity. Opium contains 9% to 14% morphine and 0.8% to 2.5% codeine. Natural substances obtained from opium (such as morphine and codeine) are called **opiates**.

In the late 1800s, scientists began to create synthetic and semisynthetic substances with morphine-like properties. More than a dozen different synthetic drugs with morphine-like activity are now available. **Opioid** is a general term referring to any of these substances, natural or synthetic, and is often used interchangeably with the term *opiate.*

Pharmacotherapy with opioids is predominantly used to relieve moderate to severe pain. With proper dosing, opioids can relieve any degree of pain; they are most effective in treating constant, dull types of pain. In large quantities opioids produce euphoria and severe CNS depression that can lead to stupor, coma, or death. When used for prolonged periods at high doses, opioids cause physical and psychologic dependence.

Narcotic is a term commonly used to describe certain medications. In the context of law enforcement, *narcotic* is

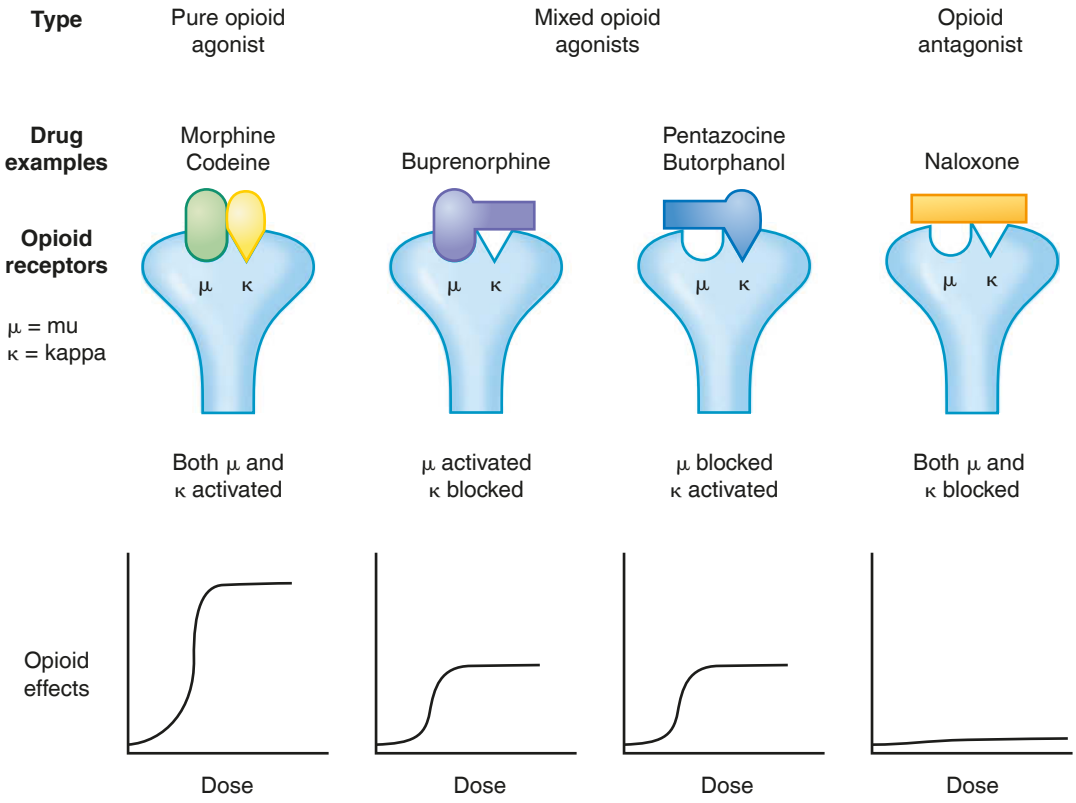


Figure 25.2 Types of opioid receptors.

used to describe a broad range of abused illegal drugs such as hallucinogens, cocaine, amphetamines, and marijuana. In medical settings, however, narcotic is more restrictively defined as a morphine-like drug used to alleviate pain. To avoid confusion, it is best to use the combined term *narcotic analgesic* rather than simply *narcotic*. In clinical practice, a narcotic analgesic is the same as an opioid, and the terms may be used interchangeably.

Opioids exert their actions by interacting with at least six types of receptors in the CNS: mu, kappa, and delta are the three major receptor types. From the perspective of pain management, the **mu** and **kappa receptors** are the most important, as shown in Figure 25.2. Activation of the mu receptor is responsible for the analgesic properties of the opioids as well as some of the adverse effects such as respiratory depression and physical dependence (see Chapter 27). Drugs that activate opioid receptors are called opioid agonists; those that block these receptors are called opioid antagonists. Because there are multiple opioid receptors, three general types of drug–receptor interactions are possible:

- **Opioid agonist.** Drugs that activate both mu and kappa receptors; for example, morphine and codeine (see Section 25.7)
- **Mixed opioid agonist-antagonist.** Drugs that occupy one receptor and block (or have no effect) on the other; for example, buprenorphine (Buprenex), pentazocine (Talwin), and butorphanol (Stadol) (see Section 25.8)
- **Opioid antagonist.** Drugs that block both mu and kappa receptors; for example, naloxone (Narcan) (see Section 25.12)

The types of agonist actions produced by activating the mu and kappa receptors are shown in Table 25.1. Analgesia is obviously the desired response in pain management. The other responses constitute adverse effects of opioid therapy and must be assessed, prevented, or managed as part of the plan of care for a patient receiving opioid therapy (see Nursing Practice Application for Patients Receiving Pharmacotherapy for Pain).

Opioids neither lower the threshold for pain at the nociceptor level nor slow or block the transmission of the pain impulse. It is the *perception and emotional response to pain* that is altered by these medications. Essentially the

Table 25.1 Responses Produced by Activation of Specific Opioid Receptors

Response	Mu Receptor	Kappa Receptor
Analgesia	Yes	Yes
Decreased GI motility	Yes	Yes
Euphoria	Yes	No
Miosis	No	Yes

* Dose in milligrams that produces the same degree of analgesia as that produced by 10 mg of morphine.

Y = low incidence, YY = moderate incidence, YYY = high incidence, YYYY = highest incidence.

patient knows that the pain still exists, but it does not cause concern or anxiety.

25.7 Opioids are the preferred drugs for moderate to severe pain that cannot be controlled with other classes of analgesics.

Over 20 different opioids are available as medications. This large group is split into subclasses by similarities in their chemical structures, mechanisms of action, and effectiveness. Each classification is useful in explaining some of the similarities and differences among the opioids. The most basic classification is by effectiveness, which places opioids into the two basic categories of strong or moderate analgesic activity. The opioids are listed in Table 25.2. The opioids that have very short durations of action are used primarily as anesthesia adjuncts and are presented in Chapter 26.

Opioids produce many important physiologic actions in addition to analgesia. They are effective at suppressing the cough reflex and at slowing the motility of the gastrointestinal (GI) tract in patients with severe diarrhea. Opioids are powerful CNS depressants and can cause sedation, which may be considered a therapeutic effect or an adverse effect, depending on the patient's disease state. Some patients experience euphoria and intense relaxation, which are reasons why these drugs are frequently abused.

Table 25.3 Management of Opioid Adverse Effects

Adverse Effect	Management
Constipation	Assume it will occur and initiate preventive measures: Increase dietary fiber and fluid intake; use stool softeners and mild laxatives if needed.
Nausea	Usually transient. Antiemetics are administered, as needed.
Orthostatic hypotension	Assess blood pressure before ambulation; change positions slowly; assist with ambulation if needed.
Respiratory depression	Monitor respiratory status frequently—especially initially and with dosage increases. Avoid other CNS depressants that could have additive effects such as alcohol, antidepressants, and barbiturates. Use coughing, deep breathing, and incentive spirometry. If the patient is unresponsive and the respiratory rate is less than 12 breaths/min, administer naloxone per protocol.
Sedation	Common with initiation of therapy or during dosage increase. Tolerance develops in several days. Use safety precautions, especially with ambulation.
Urinary retention	Monitor for bladder distention. More common in older adult men. Tolerance usually develops with long-term dosing. Monitor; if receiving epidural administration, use an indwelling catheter.

Opioids have the potential to produce many serious adverse effects, including respiratory depression, sedation, nausea, vomiting, and constipation. Table 25.2 compares the major adverse effect potentials of the individual opioids.

Management of opioid adverse effects is summarized in Table 25.3. Through activation of primarily the mu receptors, opioids can cause profound respiratory depression, which is the most serious adverse effect of these medications. Respiratory depression is most problematic during the initial period of drug administration and with patients who have not previously taken these drugs (opiate naïve). Patients at greatest risk include those with preexisting respiratory impairment or those concurrently taking other respiratory depressant drugs. A current medication history is very important, especially alcohol use and other CNS depressants, because these drugs will cause additive respiratory depression and sedation. Tolerance to respiratory depression usually occurs within 48 to 72 hours of initiation of therapy.

Respirations should be monitored before initiating therapy and regularly throughout opioid pharmacotherapy. The drugs should be withheld if respirations fall below 12 breaths/min. Narcotic antagonists such as naloxone (Narcan) should be readily available if respirations fall below 10 breaths/min (see Section 25.12). If opioids are administered by continuous epidural or intravenous (IV) routes, interventions should be taken to reduce the risk of respiratory depression. These include frequent monitoring of vital signs, level of consciousness, and pain rating as well as proper body positioning. Airway equipment and narcotic antagonists are usually kept at the bedside.

Opioids can cause orthostatic hypotension by inhibiting the baroreceptor reflex and by causing peripheral vasodilation. Dizziness and fainting are possible; assistance may therefore be needed with ambulation. Hydromorphone and meperidine are especially prone to causing hypotension. Patients with hypovolemia are more sensitive to this hypotensive effect; therefore, volume deficiencies should be corrected before initiating opioid therapy.

Increased intracranial pressure (ICP) is a severe adverse reaction that can occur as an indirect result of respiratory depression. When respiration is suppressed, the CO_2 content of the blood increases. The result is vasodilation of cerebral blood vessels and rising ICP. This is of particular concern in patients with conditions that might cause elevated ICP, such as those with head injury, intracranial bleeding, or brain tumors. Narcotic analgesics are usually contraindicated in these patients.

Opioids promote urinary retention by increasing the tone in the bladder sphincter and by suppressing stimuli that normally signal bladder fullness. If the patient has not voided within 6 hours, especially after surgery, insertion of a urinary catheter may be necessary. Patients prone to urinary hesitancy, such as those with benign prostatic hyperplasia, must be carefully monitored.

Constipation, nausea, and vomiting frequently occur during opioid administration. Constipation occurs because the drugs suppress intestinal peristalsis, increase the tone of the anal sphincter, and inhibit secretion of fluids into the intestine. Bowel function should be closely monitored, especially after surgery or with long-term use. The plan of care for these patients should include a bowel program to prevent or manage constipation. A baseline program would include increased dietary fiber, adequate fluid intake, and a stool softener such as docusate sodium. More active interventions are implemented if the patient does not resume or maintain normal bowel elimination. The constipation-promoting effect of the opioids is used to advantage in the treatment of severe diarrhea (see Chapter 60).

Opioids directly stimulate the chemoreceptor trigger zone in the medulla to cause intense nausea and vomiting in certain patients. An antiemetic such as promethazine (Phenergan) or ondansetron (Zofran) may be indicated. Orders for prn antiemetics should be made available whenever parenteral opioids are used.

Prolonged use of opioids results in tolerance. Typically, tolerance is noted when patients report that the duration of analgesia is decreasing or admit to taking the drug more frequently as therapy progresses. Increasingly higher doses will be needed to produce the same degree of analgesia. Tolerance does not develop equally for all opioid actions. Whereas tolerance to respiratory depression, sedation, and euphoria develops rapidly, tolerance never develops to the constipation or miosis effects. Remember that as doses of opioids are increased to more effectively manage pain, the incidence of adverse effects will also increase.

All of the narcotic analgesics have the potential to cause physical and psychologic dependence (see Chapter 27). Dependence is most likely to occur when high doses are taken for extended periods. Healthcare providers and nurses are sometimes hesitant to administer the proper amount of opioid analgesics for fear of causing patient dependence or of producing serious adverse effects such as sedation or respiratory depression. Undermedication, however, results in patients not receiving adequate pain relief. When used according to accepted medical practice, patients can, and indeed should, receive the pain relief they need without fear of dependence or serious adverse effects.

Opioids are frequently abused for nonmedical purposes. The risk of abuse is especially high in patients with a history of substance abuse. Opioids are frequently diverted from medical sources (e.g., patients, pharmacies, hospitals), either stolen or sold for criminal intent. Opioids are even stolen from family members, especially older adults. Illicit users may "doctor shop" and obtain opioids from different prescribers and then sell the pills for profit.

Many patients who experience an adverse reaction to an opioid will report that they are allergic to these drugs. For example, patients who experience nausea, vomiting, or severe dizziness will often state they are allergic to narcotics. True allergic (Type I hypersensitivity) reactions to opioids, however, are actually rare. Although some of the opioids do indeed cause direct histamine release from mast cells, these types of idiosyncratic reactions do not result in the classic signs of anaphylaxis; thus they are not true allergic reactions. Morphine, codeine, and meperidine have the highest potential for nonimmune histamine release. When a real immune hypersensitivity reaction does occur, it may extend to other drugs in the opioid class.

Equianalgesic use in pain management: Table 25.2 includes a column labeled "Equianalgesic Dose." It is often necessary to change the route of a patient's pain medication or even the drug itself. One of the most frequently occurring examples that a nurse may encounter is the transition a patient makes from IV medications after surgery to PO analgesics prior to discharge. Using relative potency information (equivalent dose), the primary healthcare provider can determine the appropriate new dose. Following surgery, it is not unusual to have orders for a parenteral opioid for severe pain, an oral opioid for moderate pain, and a combination opioid and nonopioid for mild pain. The nurse can use these same equivalencies in choosing the drug and dose when a range of analgesic options is ordered.

CONNECTION Checkpoint 25.1

A common abbreviation for morphine sulfate is MS. From what you learned in Chapter 6, why should this abbreviation be avoided and what can you do to prevent this type of medication error? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

PROTOTYPE DRUG Morphine Sulfate (Astramorph PF, Duramorph RF, Roxanol, Others)

Classification **Therapeutic:** Narcotic analgesic
Pharmacologic: Opioid agonist

Therapeutic Effects and Uses: Morphine sulfate is the narcotic analgesic of choice for the management of most types of acute and severe chronic pain. The drug was in use for thousands of years prior to its approval by the FDA in 1939 and is still obtained from unripe seeds of the poppy plant.

In addition to relieving severe pain, morphine is used off-label to treat several other conditions. Its CNS depressant action may be used to provide preanesthetic sedation and to calm severely agitated patients. In patients who are terminally ill, its respiratory depressant action may be used to relieve the shortness of breath associated with end-stage cancer, heart failure, or pulmonary edema.

The advantages of morphine therapy, especially in the treatment of chronic cancer pain where dosing increases over time, are that morphine has no upper end dose limit, and that patients develop tolerance to all the adverse effects except constipation. Extended release tablets (MS Contin, Oramorph SR) or capsules (Avinza, Kadian) are available. Initiation of therapy is usually begun with shorter acting drugs. Once the correct dose has been titrated, the patient may be switched to extended release formulations. An extended release liposome injection (DepoDur) is available, which is given by a single epidural injection for postsurgical pain.

Mechanism of Action: Morphine occupies mu and kappa receptor sites in the brain and dorsal horn of the spinal cord that alter the release of afferent neurotransmitters. The dominant effect alters the perception of and emotional response to pain, producing analgesia and euphoria. The drug mimics the actions of endogenous endorphins.

Pharmacokinetics:

Route(s)	PO, IV, subcutaneous, intramuscular (IM), rectal, epidural, intrathecal
Absorption	PO variable, 30%; subcutaneous or IM may be erratic or delayed
Distribution	Widely distributed; crosses the placenta; is secreted in breast milk
Primary metabolism	Hepatic; significant first-pass metabolism
Primary excretion	Renal; 7–10% in bile and feces
Onset of action	PO: 30–60 min; IV: rapid; epidural: 15–30 min
Duration of action	PO: 4–7 h; IV: 4–5 h; epidural: 4–24 h

Adverse Effects: Morphine depresses the CNS, causing sedation, dizziness, anxiety, and a feeling of floating

or disorientation. Tolerance often develops to these CNS effects after a few days of therapy. Hallucinations and seizures may occur at high doses. Morphine reduces the sensitivity of the respiratory center to CO_2, thus decreasing tidal volume and rate and producing respiratory depression. The resulting increase in CO_2 produces cerebral vasodilation and increases cerebrospinal fluid (CSF) pressure. Morphine stimulates the chemoreceptor trigger zone in the medulla, producing nausea and vomiting, which may require the administration of an antiemetic drug during the first few days of therapy. The drug delays digestion, increases smooth muscle tone in the intestinal tract, and slows peristalsis in the colon, leading to constipation. Morphine also causes spasm of the sphincter of Oddi, which can result in intense pain (biliary colic) and potential obstruction of bile flow. Urinary retention may occur due to increasing bladder sphincter tone. Peripheral vasodilation may cause orthostatic hypotension. Pruritus is more common when morphine is given by the IV and epidural routes and is not considered a sign of hypersensitivity in the absence of skin rash. **Black Box Warning:** Morphine is a Schedule II controlled substance with a high potential for physical and psychologic dependence. The extended release forms are prescribed for opioid-tolerant patients only and are not intended for prn use. The extended release forms should never be opened, chewed, dissolved, or crushed because this can lead to fatal overdose. Alcohol and products containing alcohol should never be consumed when taking Avinza.

Contraindications/Precautions: Morphine is contraindicated in patients with hypersensitivity to opioids. Premature infants are especially sensitive to the effects of morphine; thus the drug should not be used during pregnancy or during the delivery of premature infants. It should be used with caution in older adults and in those with undiagnosed abdominal pain, hepatic impairment, chronic kidney disease (CKD), shock, CNS depression, head injury or increased ICP, chronic obstructive pulmonary disease (COPD), or other conditions with decreased respiratory reserve, including severe obesity. Mothers should wait 4 to 6 hours after a dose of morphine before breastfeeding; withdrawal symptoms have been noted in nursing infants whose mothers abruptly discontinue opioid use. Morphine should never be withdrawn abruptly in patients who have been on prolonged therapy because this will precipitate symptoms of acute opioid withdrawal. Discontinuation should be conducted gradually over several days.

Drug Interactions: When morphine is used with other CNS depressants, including alcohol, skeletal muscle relaxants, and monoamine oxidase inhibitors (MAOIs), increased sedation will result. Administration of an opioid antagonist such as naloxone will reverse the effects of morphine and may produce immediate withdrawal symptoms. Concurrent use with antidiarrheal drugs such as loperamide will cause additive constipation. **Herbal/Food:** Use of kava, valerian, or chamomile can increase CNS depression. St. John's wort may decrease the analgesic action of morphine.

Pregnancy: Category C.

Treatment of Overdose: Morphine overdose can cause coma and life-threatening respiratory depression and requires immediate treatment. Naloxone is a specific antidote for morphine intoxication (see Section 25.12).

Nursing Responsibilities: Key nursing implications for patients receiving morphine are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Pain.

Drugs Similar to Morphine Sulfate (Astramorph PF, Duramorph RF, Roxanol, Others)

Other opioids used for pain management are listed in Table 25.2. Propoxyphene (Darvon, Darvocet), once a widely used opioid, was removed from the U.S. market in 2010 due to an unacceptable risk of cardiac rhythm abnormalities. The following are descriptions of opioids with pure agonist activity. All these medications have the same actions and adverse effects as morphine. All are controlled substances.

Codeine: Approved by the FDA in 1939, codeine can be administered by the PO, subcutaneous, or IM routes. Because it has stronger antitussive action than morphine, it is often used for suppression of severe cough. At the low doses needed for cough suppression, codeine does not produce serious adverse effects in adults. When used to treat cough and other severe cold symptoms, low doses are usually combined with guaifenesin (a nonnarcotic antitussive), promethazine (a phenothiazine with antihistamine action), phenylephrine (a decongestant), or brompheniramine (an antihistamine). Doses required to produce analgesia are much higher than those needed for cough suppression. When prescribed for analgesia, it is usually in combination with acetaminophen and its use is often limited by nausea and vomiting. During the metabolism of codeine in the CNS, about 10% is converted to morphine, which is partly responsible for its analgesic effects. Codeine may also be used off-label to treat serious diarrhea. In 2017, the FDA issued a contraindication that codeine should not be used for cough or pain in children younger than 12 years of age. The warning also stated that breastfeeding may cause serious adverse reactions in infants. This drug is pregnancy category C; the category changes to D if used in high doses or close to term.

Fentanyl (Abstral, Actiq, Duragesic, Fentora, Onsolis, Sublimaze): Originally approved in 1968 as an IV anesthetic (Sublimaze) for short-term surgical procedures, fentanyl has since been introduced in multiple formulations. These include oral tablets (Fentora), buccal film (Onsolis), sublingual tablets (Abstral), oral transmucosal lozenges (Actiq), and transdermal patches (Duragesic).

The nonanesthetic formulations of fentanyl are restricted to the management of breakthrough pain in patients who are already receiving and who are tolerant to around-the-clock opioid therapy for their chronic, persistent pain. This includes intractable cancer pain. Giving these formulations to patients who are opioid naïve can result in serious or fatal respiratory depression. Generally, the initial dose depends on how much morphine the patient has been receiving, that is, how tolerant the patient has become to the effects of opioids. Doses are gradually increased until the breakthrough pain is relieved. The buccal, transdermal, and transmucosal forms of fentanyl have black box warnings regarding the dependence potential for this drug and the serious adverse effects that can occur if the drug is misused.

Several other opioids, for example, remifentanil (Ultiva), alfentanil (Alfenta), and sufentanil (Sufenta), are closely related to fentanyl and are used as IV anesthetics. These drugs and a prototype feature for fentanyl are presented in Chapter 26.

Hydrocodone (Hycodan, others): Approved in 1957, hydrocodone is used for analgesia, most often combined with acetaminophen, aspirin, or ibuprofen in fixed dose combinations such as Vicodin, Lortab, and Norco. Acetaminophen has a dose ceiling that limits the use of such combinations in chronic pain management. Hydrocodone is an effective antitussive and is combined with decongestants or antihistamines for severe cold and flu symptoms. Although it is slightly more effective than codeine as an antitussive, it causes more sedation. This drug is pregnancy category C; the category changes to D if used in high doses or close to term.

Hydromorphone (Dilaudid, Exalgo): Approved in 1984, hydromorphone is available by the PO, rectal, and parenteral routes. Its primary application is analgesia, including PCA. Hydromorphone produces less nausea but more orthostatic hypotension than morphine. It has a more rapid onset of action and a shorter duration of activity than morphine, requiring PO dosing every 3 to 6 hours. An extended duration formulation of the drug (Exalgo) is available. Hydromorphone has black box warnings regarding the dependence potential for this drug and the serious adverse effects that can occur if the drug is misused. This drug is pregnancy category C.

Levorphanol (Levo-Dromoran): Approved in 1953, levorphanol is a pure opioid agonist available by the PO and parenteral routes for severe pain. At equianalgesic doses, levorphanol exhibits the same actions and adverse effects as morphine. It offers no advantages over the use of other drugs in this class. This drug is pregnancy category B; the category changes to D if used in high doses or close to term.

Meperidine (Demerol): Approved in 1942, meperidine is available by both the PO and parenteral routes for the treatment of severe pain. Toxicity can occur due to its active metabolite, called normeperidine, which is a CNS stimulant with a half-life of 15 to 30 hours. Accumulation of this metabolite can result from doses greater than 400 to 600 mg/day or administration longer than 48 hours. Normeperidine can cause tremors and seizures, which are not reversed with narcotic antagonists (naloxone). For this reason, meperidine is not recommended for use longer than 48 hours, for chronic pain, or for use in PCA. When meperidine is used in high doses or longer than 48 hours, the nurse needs to consult with the prescriber and report any incidences of tremors and irritability before giving the next dose. Because of these adverse effects, meperidine is considered a second-line medication that is used when other opioids are contraindicated. An off-label use for meperidine is for the management of shivering, a common complication in the postoperative period. The drug has a short half-life that requires dosing every 3 to 4 hours. This drug is pregnancy category C; the category changes to D if used in high doses or close to term.

Methadone (Dolophine): Approved in 1947, methadone is an oral preparation with pharmacologic effects similar to those of morphine; adverse effects are similar with lower incidence. Methadone is frequently prescribed in the management of opiate dependency (see Chapter 27) and is increasingly used for management of chronic pain. Methadone has a long duration of action and can be dosed once daily. Oral liquid (Methadose) and dispersible tablets (Diskets) are available for treating opiate withdrawal symptoms because they offer less risk for abuse than regular tablets. IV methadone is used for the short-term therapy of hospitalized patients. A black box warning indicates that when converting from other analgesics to methadone particular diligence is necessary because deaths have been reported during the conversion period. The deaths were likely due to raising the dose of methadone too quickly, resulting in cardiac and respiratory failure. This drug is pregnancy category C.

Oxycodone (OxyContin, others): Approved in 1976, oxycodone is an oral opioid that is often combined with acetaminophen (Endocet, Percocet) or with aspirin (Percodan) for the management of moderate to severe pain. The drug is used when around-the-clock analgesia is needed for an extended period of time. It is not indicated for short-term or prn use. Oxycodone causes less nausea, vomiting, and hallucinations than morphine. The immediate release forms of this drug have a short duration of action, requiring dosing every 3 to 4 hours. The extended release form

(OxyContin) can be dosed twice a day. OxyContin has become a frequent drug of abuse (see Chapter 27). A black box warning states that all patients receiving oxycodone should be routinely monitored for signs of misuse, abuse, and addiction. Breaking, cutting, chewing, crushing, or dissolving the extended release tablets may result in a potentially fatal overdose. This drug is pregnancy category B; the category changes to D if used in high doses or close to term.

Tapentadol (Nucynta): Tapentadol was approved in 2008 and is indicated for moderate to severe pain. The immediate release form (Nucynta) is for acute pain, whereas the extended release form (Nucynta ER) is for chronic pain and pain associated with diabetic neuropathy. Tapentadol acts by dual mechanisms: It is used as a mu-receptor agonist and blocks the reuptake of norepinephrine. It has the same abuse potential (Schedule II) as other drugs in this class and has the same spectrum of adverse effects. The most common adverse effects include nausea, constipation, dizziness, headache, and somnolence. The incidence of GI-related adverse effects may be lower with tapentadol than with other drugs in this class. This drug is pregnancy category C.

25.8 Mixed agonist and antagonist opioids exhibit moderate analgesia with less risk of dependence than morphine.

The mixed agonist-antagonist opioids are narcotic analgesics that were developed with the intention of producing drugs with strong analgesia that have fewer adverse effects than morphine and other pure opioid agonists. The four drugs in this class are used to treat moderate pain but are not as effective as morphine in treating severe pain. Their advantage is that they cause less respiratory depression and have a lower potential for dependence. These drugs have some abuse potential but less so than the pure opioid agonists. The types of adverse effects, contraindications, and nursing responsibilities are similar to those of the pure opioid agonists (see Section 25.7).

With both agonist and antagonist actions, what would happen if an individual addicted to morphine or heroin took one of the drugs in this class? Blocking opioid receptors would likely cause the patient to experience opioid withdrawal symptoms. In fact, some of the mixed agonist-antagonist drugs are indicated for the induction of opioid withdrawal and the maintenance of opioid dependence (see Chapter 27).

Buprenorphine (Buprenex, Butrans, Suboxone): Originally approved in 1981, buprenorphine is a partial agonist at the mu receptors and an antagonist at the kappa receptors. It is indicated for the relief of moderate to severe pain when given by the parenteral route (Buprenex). Sublingual (Suboxone) and orally disintegrating tablet (Zubsolv) forms combine buprenorphine with naloxone for the management of opioid withdrawal and dependence. A transdermal patch system (Butrans) is available that provides 7 days of analgesia. Abuse of buprenorphine has been reported but is less common because the drug produces less euphoria than the pure opioid agonists. Withdrawal symptoms from buprenorphine are generally mild and its onset may be delayed 1 to 2 weeks. Buprenorphine is a Schedule III drug. Respiratory depression can be a serious adverse effect at high doses. A black box warning states that when using the transdermal form of the drug, a dose of 20 mcg/h (the highest dose patch, worn for 7 days) should not be exceeded due to a risk of QT interval prolongation. The patch application site should not be subjected to high external temperatures because this increases drug release and can cause overdose or death. This drug is pregnancy category C. A prototype drug feature for buprenorphine with naloxone (Suboxone, Zubsolv, others) can be found in Chapter 27.

Butorphanol (Stadol): Approved in 1978, butorphanol is an agonist at the kappa receptors and is a weak antagonist at the mu receptors. Delivered by the IV or IM route, it is approved for moderate to severe pain and as a preanesthetic medication that supplements general anesthesia. A nasal spray form of the drug (Stadol NS) has a fast onset of 20 to 40 minutes, but it must be repeated every 4 to 6 hours for continuous pain control. Drowsiness and dizziness are experienced by a large number of patients, and the intranasal form can cause nasal congestion. Like buprenorphine, the drug is not commonly abused and withdrawal symptoms are mild. Butorphanol is a Schedule III drug. This drug is pregnancy category C.

Nalbuphine (Nubain): Approved in 1979, nalbuphine is an agonist at the kappa receptors and a weak antagonist at the mu receptors. Given by the IV, IM, or subcutaneous route, it is approved for moderate to severe pain and as a preanesthesia or general anesthesia adjunct. Drowsiness is the most common adverse effect. The risk for dependence is low, and nalbuphine is not a scheduled drug. Abrupt discontinuation, however, can precipitate mild opioid withdrawal symptoms. This drug is pregnancy category B (category D with prolonged use or high doses at term).

Pentazocine (Talwin): Approved in 1967, pentazocine was the first of the agonist-antagonist opioids marketed. Available by both the PO and parenteral routes, it is approved to treat moderate to severe pain and as a supplement to general anesthesia. The drug is available in combination tablets with acetaminophen and naloxone. The drug acts as an agonist at the kappa receptors and a weak antagonist at the mu receptors. Pentazocine causes less nausea, vomiting, and respiratory depression than morphine. Like other drugs in this class, drowsiness and dizziness are common adverse effects. Also like other mixed agonists-antagonists, pentazocine does not produce euphoria and has a low potential for abuse (Schedule IV). Withdrawal symptoms are similar to those of other opioids

but milder. A major advantage is that overdose with pentazocine does not result in the high mortality observed with morphine. This drug is pregnancy category C.

Pain Management with Nonopioids

25.9 Nonsteroidal anti-inflammatory drugs are the preferred medications for mild to moderate pain.

The **nonopioid analgesics** include NSAIDs, acetaminophen, and a few centrally acting medications. NSAIDs, such as aspirin and ibuprofen, are preferred medications for relieving mild to moderate pain, especially for pain associated with inflammation. Nonopioids have significant advantages over the opioids. Acetaminophen, aspirin, and many NSAIDs are available OTC and are inexpensive. They are available in many different formulations, including those designed for pediatric patients. For most patients, they are safe when used as directed on the labels. NSAIDs have antipyretic and anti-inflammatory actions as well as analgesic properties. Indeed, some NSAIDs are used primarily for their anti-inflammatory effects. The doses and roles of NSAIDs in the treatment of inflammation and fever are discussed in Chapter 41. Prototype features for aspirin and ibuprofen are also included in Chapter 41. Nursing practice applications for the nonopioid analgesics are similar to those for the opioid analgesics and are presented in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Pain. Additional nursing responsibilities for the nonopioids can be found with the prototype drugs and the Nursing Practice Application for Patients Receiving Pharmacotherapy for Inflammation and Fever in Chapter 41.

NSAIDs act at peripheral sites by inhibiting pain mediators at the nociceptor level. When tissue is damaged, chemical mediators, including histamine, potassium ion, hydrogen ion, and bradykinin, are released locally. Also released during tissue damage is arachidonic acid, which is metabolized into chemical mediators of inflammation and pain such as prostaglandins. Prostaglandins can induce pain through the formation of free radicals.

NSAIDs inhibit cyclooxygenase, an enzyme responsible for the formation of prostaglandins. Because they act by a different mechanism than opioids, NSAIDs do not produce the severe adverse effects observed with the narcotic analgesics. The most prominent effects are GI related and include nausea, vomiting, anorexia, dyspepsia, and ulceration of the GI mucosa. At high doses, the ulceration can be severe, resulting in bleeding and even perforation. A fixed dose combination of naproxen and omeprazole (Vimovo) is approved to reduce the potential for developing NSAID-induced gastric ulcers. Other common NSAID adverse events include dizziness, headache, and rash. These drugs do not cause physical or psychologic dependence. When combined with opioids in fixed dose combinations, NSAIDs produce a synergistic analgesic effect that allows the dose of opioid to be lowered.

Acetaminophen is an important nonopioid analgesic that is not classified as an NSAID. Its effectiveness in relieving pain and reducing fever is equal to that of aspirin and ibuprofen. Acetaminophen is featured as a prototype antipyretic in Chapter 41.

25.10 A few miscellaneous analgesics reduce pain by acting on the central nervous system.

Two analgesics suppress pain by acting on the CNS but are not classified as opioids. Clonidine (Catapres, Duraclon) and ziconotide (Prialt) act by unique mechanisms in the CNS. Tramadol (Ultram, others) has mixed opioid-nonopioid analgesic actions and is the most widely prescribed drug in this class for pain. The doses of these centrally acting medications are listed in Table 25.4.

PROTOTYPE DRUG **Tramadol (Ultram, Others)**

Classification **Therapeutic:** Analgesic
Pharmacologic: Mixed opioid-nonopioid analgesic

Therapeutic Effects and Uses: Tramadol was approved for the treatment of moderate pain in 1995. The immediate release formulations are indicated for short-term

Table 25.4 Nonopioid Centrally Acting Analgesics

Drug	Route and Adult Dose for Pain (Maximum Dose Where Indicated)	Adverse Effects
clonidine (Catapres, Duraclon)	Epidural: 30–40 mcg/h by continuous infusion or 100–900 mcg bolus	*Drowsiness, orthostatic hypotension, dry mouth, anxiety, constipation* Severe hypotension, dysrhythmias
tramadol (Ultram, others)	PO (immediate release): 25–100 mg q4–6h prn (max: 400 mg/day) PO (extended release): 100 mg once daily (max: 300 mg/day)	*Dizziness, nausea, vomiting, constipation, lethargy* Hallucinations, emotional lability, respiratory depression
ziconotide (Prialt)	Intrathecal: 0.1 mcg/h via infusion; may increase as needed up to 0.1 mcg/h no more than every 2–3 days (max: 0.8 mcg/h)	*Dizziness, nausea, diarrhea, somnolence, asthenia* Confusion, memory impairment, hallucinations

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

(5 days or less) relief of acute pain, whereas the extended release products (ConZip, Ryzolt, Tramadol ER) are approved to treat moderate to moderately severe chronic pain that requires around-the-clock analgesia. An orally disintegrating tablet (Rybix ODT, Ultram ODT) is available for patients who have difficulty swallowing. Ultracet is a fixed dose combination of tramadol and acetaminophen. Off-label uses of tramadol include treatment of neuropathic pain and restless leg syndrome.

Mechanism of Action: Tramadol has a unique mechanism that involves both opioid and nonopioid actions. The drug and one of its metabolites bind to the opioid mu receptor. This opioid agonist activity is weak: approximately 10 times weaker than that of codeine. In addition to its central opioid action, tramadol inhibits norepinephrine and serotonin reuptake in spinal neurons, which inhibits the transmission of pain impulses.

Pharmacokinetics:

Route(s)	PO
Absorption	75% absorbed
Distribution	Widely distributed; crosses the placenta; small amounts secreted in breast milk; 20% bound to protein
Primary metabolism	Hepatic by CYP450 enzymes to an active metabolite; significant first-pass metabolism
Primary excretion	Renal
Onset of action	30–60 min
Duration of action	9 h

Adverse Effects: Tramadol is well tolerated, and its most common adverse effects are vertigo, dizziness, headache, nausea, vomiting, constipation, and lethargy. Because it acts centrally, symptoms of CNS stimulation such as nervousness, tremor, anxiety, agitation, confusion, visual impairment, and hallucinations are possible. Some patients experience drowsiness or depression rather than CNS excitation. Seizures have been reported, especially in patients who are concurrently taking antidepressants. Although respiratory depression can occur, it is not as severe as that caused by opioids. Physical dependence is possible although at much less risk than morphine; tramadol is not a controlled substance. Symptoms of opioid withdrawal, such as anxiety, sweating, tremors, panic attacks, and paresthesias, may occur if the drug is abruptly discontinued.

Contraindications/Precautions: Patients with a history of hypersensitivity to tramadol should not be given the drug. Caution should be exercised in patients allergic to codeine and other opioid agonists because cross hypersensitivity is possible. Although the risk for dependence is low, the drug should be used with caution in patients with a history of substance abuse. Tramadol should not be administered to patients with a history of depression or suicidal ideation because the drug can be fatal in overdose situations, especially if combined with alcohol or other CNS depressants. Because tramadol causes some degree of respiratory depression, it should be used cautiously in patients with COPD. The drug should be used with caution in patients with CKD or hepatic impairment or in those with increased ICP. Because tramadol lowers the seizure threshold, it should be used with caution in patients with a history of seizures. Tramadol should be avoided during pregnancy and lactation because its chronic use can cause physical dependence and postpartum withdrawal symptoms in the newborn. In 2017, the FDA issued a new notice that tramadol is contraindicated in children younger than age 12.

Drug Interactions: Use of tramadol concurrently with carbamazepine or certain antidepressants increases the risk of seizures. Carbamazepine also has additive CNS depressant effects and may reduce the analgesic activity of tramadol. Ethanol combined with tramadol may result in death. When used with other CNS depressants, the dose of tramadol should be reduced. Concurrent use of tramadol with MAOIs can result in seizures or serotonin syndrome. Procarbazine, rasagiline, and selegiline should not be given concurrently with tramadol because these drugs increase serotonin levels and may result in serotonin syndrome. Tramadol is changed to an active metabolite by the hepatic CYP2D6 enzyme. If inhibitors of this enzyme (e.g., amiodarone, chloroquine, haloperidol, ritonavir, quinidine) are given concurrently with tramadol, a reduced analgesic effect may result. **Herbal/Food:** Food significantly affects the absorption of the extended release form of tramadol. St. John's wort is contraindicated due to the possibility of serotonin syndrome. Caution should be observed when using herbs such as valerian or kava that may have an additive CNS depressant effect.

Pregnancy: Category C.

Treatment of Overdose: Overdose with tramadol can result in serious CNS depression, respiratory depression, and death. Administration of naloxone will reduce some of the symptoms of tramadol overdose and may precipitate convulsions.

Nursing Responsibilities: Key nursing implications for patients receiving tramadol are similar to those for opioids and are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Pain.

Drugs Similar to Tramadol (Ultram)

The two other centrally acting analgesics are clonidine and ziconotide. These drugs act by very different mechanisms than tramadol and are less frequently prescribed.

Clonidine (Catapres, Duraclon): Originally approved as an oral drug for hypertension (Catapres) in 1974, clonidine has been used off-label for a large number of other indications, including hot flashes, Tourette's syndrome, and withdrawal from ethanol, nicotine, and opioids. It has a very limited role in treating severe, intractable cancer pain that is refractory to other drugs, including opioids. For this indication, it is administered as an epidural infusion, usually in combination with opioids. Clonidine activates alpha$_2$-adrenergic receptors in the spinal cord, resulting in decreased pain signals reaching the brain. Because this drug is absorbed into the circulation, the most serious adverse effects from the epidural use of clonidine are the same as those from PO administration: severe hypotension and bradycardia. When given by epidural infusion, clonidine carries a black box warning that it should not be used for obstetric, postpartum, or perioperative pain management. Clonidine is also available as a transdermal patch (clonidine TTS), which releases the drug over 7 days. Clonidine (Kapvay) was approved by the FDA to treat attention-deficit/hyperactivity disorder (ADHD) in children (see Chapter 24). The antihypertensive actions of clonidine are discussed in Chapter 34. Clonidine is pregnancy category C.

Ziconotide (Prialt): Ziconotide, approved in 2004, is unusual in that it was originally obtained from a species of saltwater snail. Like clonidine, its use is limited to patients whose pain is refractory to all other analgesics, including morphine. It is administered only by intrathecal infusion. An off-label use is for severe muscle spasticity due to spinal cord injury. The drug provides analgesia by blocking N-type calcium channels at the presynaptic nerve terminals in the spinal cord. This prevents neurotransmitter release, thus blocking pain transmission. Ziconotide has the potential for frequent and serious adverse effects. The drug carries a black box warning regarding the potential for severe psychiatric symptoms and neurologic impairment, including impaired cognition, decreased consciousness, and hallucinations. Dizziness, nausea, and vomiting occur in about half the patients receiving the drug. Although these adverse effects are serious, the student should remember that patients with cancer receiving this drug are terminally ill, and pain relief is often the primary therapeutic goal. This drug is pregnancy category C.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Pain

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, neurologic, respiratory, hepatic, renal, cancer, gallbladder or urologic disease, pregnancy, or breastfeeding. Note recent surgeries or injuries. Obtain a drug history including allergies, current prescription and OTC drugs, and herbal preparations. Be alert to possible drug interactions.
- Assess the level of pain. Use objective screening tools when possible (e.g., FLACC [face, limbs, arms, cry, consolability] for infants or very young children, Wong-Baker FACES scale for children, numerical rating scale for adults). Assess pain history and what has worked successfully or not for the patient in the past.
- Obtain baseline vital signs and weight.
- Evaluate appropriate laboratory findings (e.g., complete blood count [CBC], hepatic, and renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., absent or greatly diminished pain, ability to move more easily without pain or carry out postoperative treatment care). Continue to use pain rating scale to quantify level of improvement.
- Continue periodic monitoring of CBC, hepatic, and renal function studies.
- Assess vital signs, especially blood pressure, pulse, and respiratory rate.
- Assess for and report adverse effects: excessive dizziness, drowsiness, confusion, agitation, hypotension, tachycardia, bradypnea, pinpoint pupils.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. Give the drug before the start of acute pain and encourage regularly scheduled doses for the first 24 to 48 hours postoperatively for adequate pain relief. Provide additional comfort measures to supplement drug therapy. (Consistent use of a pain rating scale by all providers will help quantify level of pain relief and leads to better pain control. Watch for subtle signs of pain: hesitancy to move, shallow breaths to avoid increasing pain, grimacing on movement. Encouraging the patient to maintain regular doses around the clock during the acute postoperative or pain period may provide better relief than giving prn doses on request when pain has increased to the point medication is needed.)	• Teach the patient that pain relief, rather than merely control, is the goal of therapy. • Encourage the patient to take the drug consistently during the acute postoperative or procedure period rather than requesting only when pain is severe. • Explain the rationale behind the pain rating scale (i.e., it allows consistency among all providers). • Encourage the patient, family, or caregiver to use additional, nonmedicinal pain relief techniques (e.g., distraction with television or music, massage, or guided imagery).

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Minimizing adverse effects: • Continue to monitor vital signs, especially respirations and pulse oximetry as ordered, postoperatively and in patients with acute pain. For terminal cancer pain, obtain instructions from the oncologist or hospice provider on any dose restrictions. (Respiratory depression is most common with the first dose of an opioid and when given in the presence of other CNS depressants, e.g., postoperatively when the patient may still be experiencing the effects of general anesthesia drugs. Count respirations before giving the opioid drug, and contact the provider before giving if the respirations are below 12 breaths/min in the adult patient, or as ordered in the child. Continue to assess the respiratory rate every 15 to 30 minutes for the first 4 hours. For terminal cancer pain, the drug might not be withheld regardless of respiratory rate, dependent on the provider.)	• Encourage the patient to take deep breaths in the postoperative period. • Encourage consistent pain medication usage to increase activity tolerance. • Encourage patients with terminal cancer to take the dose consistently around the clock with prn doses as required. Advise the family or caregiver of the provider's instructions for adequate pain relief, and to contact the provider if any pain remains.
• Monitor blood pressure and pulse periodically or if symptoms warrant. Ensure patient safety; monitor ambulation until the effects of the drug are known. **Lifespan:** Be particularly cautious with older adults who are at increased risk for falls. (Opioids may cause hypotension as an adverse effect and increase the risk of falls.)	• Teach the patient to rise from lying or sitting to standing slowly to avoid dizziness or falls. If dizziness occurs, the patient should sit or lie down and not attempt to stand or walk until the sensation passes. • Instruct the patient to call for assistance prior to getting out of bed or attempting to walk alone, and to avoid driving or other activities requiring mental alertness or physical coordination until the effects of the drug are known.
• Continue to assess bowel sounds. Increase fluid and dietary fiber intake. (Decreased peristalsis is an adverse effect of opioid drugs. **Lifespan:** The older adult is at increased risk of constipation due to slowed peristalsis as a result of the aging process. Significantly diminished or absent bowels sounds should be reported to the healthcare provider immediately. Additional fluids and fiber may ease constipation but additional medications such as MiraLAX or Colace may be required.)	• Teach the patient to increase fluids to 2 L/day and increase intake of dietary fiber such as fruits, vegetables, and whole grains. • Instruct the patient to report severe constipation to the healthcare provider for additional advice on laxatives or stool softeners.
• Monitor for itching or reports of itching. (Opioids may cause histamine release with itching or a sensation of itching. In severe cases, antihistamines may be required. Assess for itching as an expected side effect versus signs and symptoms of true allergy or anaphylaxis: changes in vital signs especially hypotension, tachycardia, dyspnea, or urticaria.)	• Teach the patient to report itching to the healthcare provider, especially if severe or increasing. • Instruct the patient to immediately report any itching associated with dizziness or lightheadedness, difficulty breathing, palpitations, or significant hives.
• Assess for changes in level of consciousness, disorientation or confusion, agitation, headache, sluggish or pinpoint pupils, or seizures immediately. (Neurologic changes may indicate overmedication, increased ICP, or adverse drug effects. **Lifespan:** Older adults may be at risk for confusion and falls.)	• Instruct the patient, family, or caregiver to immediately report increasing lethargy, disorientation, confusion, changes in behavior or mood, agitation or aggression, slurred speech, ataxia or seizures. • Ensure patient safety if disorientation is present.
• Assess for urinary retention, especially in the postoperative period. (Opioids may cause urinary retention as an adverse effect. **Lifespan:** Be aware that the older male adult is at higher risk for mechanical obstruction due to an enlarged prostate.)	• Encourage the patient to move about in bed and to start early ambulation as soon as allowed postoperatively. Assist to normal voiding position if unable to use the bathroom or commode. • Instruct the patient to immediately report the inability to void, increasing bladder pressure, or pain.
• Administer antiemetics 30 to 60 minutes before opioid dose if nausea and vomiting occur. (Nausea and vomiting are common adverse effects.)	• Encourage the patient to report nausea if it occurs. Small amounts of food intake (e.g., dry crackers) and sips of carbonated beverages (e.g., ginger ale) may help if the patient is not NPO.
• Monitor pain relief in patients on PCA pumps. If a basal dose is not given continuously, assess that pain relief is adequate and contact the provider if pain remains present. Teach and encourage the patient to use the self-medication control button whenever pain is present or increasing, or before activities. (PCA-administered pain control has greatly improved pain relief for patients with regular dosing, but is effective only when taken as needed. Review dosage history and patient symptoms to ensure adequate pain relief. Contact the provider if dose, frequency, or basal dose seems inadequate for relief.)	• Instruct the patient, family, or caregiver on the use of the PCA pump. Encourage use on an as-often-as-needed basis, and emphasize the limitations present to protect the patient (i.e., overdose is not possible).
• For IV push administration, dilute the drug with 4 to 5 mL of sterile normal saline and administer over 4 to 5 minutes unless otherwise ordered. The patient should remain supine to prevent dizziness or hypotension. Monitor blood pressure, pulse rate, and respiratory rate before and after the dose. (Opioids may cause hypotension and significant dizziness. Keeping the patient supine will limit these effects.)	• Explain the rationale to the patient for the need to remain flat during the drug administration and for 15 to 30 minutes after the dose, and to call for assistance before getting out of bed.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Assess the home environment for medication safety and need for appropriate interventions. Advise the family on restrictions of prescription renewal. (Opioids are scheduled drugs and may not be used by any individual other than the patient. Safeguard medication in the home to prevent overdose.)	• Instruct the patient, family, or caregiver in proper medication storage and need for the drug to be used by the patient only. • Teach the family or caregiver about prescription renewal restrictions (i.e., new prescription each time, no refills, prescription may not be called in) as appropriate for the schedule of the drug.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of drug (e.g., take the drug as prescribed when needed). (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to take the medication:
	  • Before the pain becomes severe and for cancer pain, as consistently as possible.
	  • With food to decrease GI upset.
	  • Instruct the patient:
	  • If using a PCA pump, use the self-dosage button whenever pain begins to increase or before activities such as sitting at the bedside.
	  • Do not open, chew, or crush extended release tablets (e.g., oxycodone [OxyContin]); swallow them whole with plenty of water.
	  • Because opioids are scheduled drugs (most often C-II through IV), federal law restricts their sale and use to the individual receiving the prescription only. Additional prescriptions may be necessary if the drug is continued beyond the first prescription (e.g., phone-in refills are not allowed for C-II drugs). Do not share with any other individual and do not discard unused drug down drains or in the garbage or flush it down the toilet. Return the drug to the pharmacy or healthcare provider for proper disposal.

25.11 Adjuvant analgesics have primary indications other than pain control but can enhance analgesia.

Some types of pain are not adequately relieved by analgesics alone. **Adjuvant analgesics** are a diverse group of drugs that are used to enhance analgesia for specific indications. All of these drugs have other primary classifications, such as antidepressant, antiseizure, tranquilizer, or anti-inflammatory. The use of adjuvant analgesics includes two primary indications:

- Pain that is refractory to opioids, such as intractable cancer pain
- Neuropathic pain, which is caused by damage to the nerve itself, and pain caused by swelling in the CNS, which puts pressure on nerves.

In patients with intractable cancer pain, adjuvant analgesics are used in combination with analgesics to enhance the level of pain relief. It is important to understand that these medications supplement pain relief; they do not substitute for proper dosing of opioid analgesics in patients with severe pain. Adjuvant analgesics are generally not used if the pain is well managed with opioids, because these drugs have additional adverse effects and drug interactions that can complicate therapy.

Neuropathic pain is difficult to control with analgesics. The most common cause of neuropathic pain is diabetes, but herpes zoster infections, acute trauma, cancer, and certain autoimmune conditions can also cause this type of pain. Neuropathic pain is commonly described as steady burning, electric shock, or "pins and needles" sensations. Rather than treat with high doses of opioids, several adjuvant analgesics have been found to be effective at relieving neuropathic pain. These drugs may be used alone or in combination with opioids.

Adjuvant analgesics can be added at any step in the pain management ladder; they are usually dosed on a regular schedule as opposed to prn. The use of specific adjuvant analgesics and their doses are often guided by experience, rather than controlled clinical trials, and the majority of these drugs are prescribed off-label for their analgesic effects. Table 25.5 summarizes the effects and uses of selected adjuvant analgesics.

Antidepressants: Some of the most commonly prescribed adjuvant analgesics come from the antidepressant drug class. Both of the common classes of antidepressants, tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), are used as adjuncts in the management of neuropathic pain. Although the TCAs seem to be more effective, the SSRIs cause fewer serious adverse effects. These drugs increase the levels of the inhibitory

Table 25.5 Adjuvant Analgesics

Drug Class	Examples	Effect	Use
Antiseizure drugs	carbamazepine (Tegretol) clonazepam (Klonopin) gabapentin (Gralise, Neurontin)	Decrease nerve impulse transmission and spontaneous neuron firing.	Reduce peripheral nerve pain in diabetic neuropathy, post-herpetic neuralgia, and trigeminal neuralgia.
Benzodiazepines	diazepam (Valium) lorazepam (Ativan)	Potentiate effects of gamma aminobutyric acid (GABA) and other inhibitory neurotransmitters.	Relax skeletal muscle in muscle spasm; reduce anxiety in terminal dyspnea.
Bisphosphonates	pamidronate (Aredia) zoledronate (Reclast, Zometa)	Inhibit bone resorption.	Reduce cancer-related bone pain.
Corticosteroids	dexamethasone (Decadron) prednisone (Deltasone, others)	Reduce cerebral and spinal edema via various mechanisms in prostaglandin cascade.	Reduce swelling and pain in CNS cancer, spinal cord compression, postspinal surgery.
Selective serotonin reuptake inhibitors (SSRIs)	citalopram (Celexa) fluoxetine (Prozac) fluvoxamine (Luvox) sertraline (Zoloft)	Increase concentrations of inhibitory neurotransmitters (serotonin and norepinephrine) in the CNS.	Reduce neuropathic pain.
Tricyclic antidepressants (TCAs)	amitriptyline (Elavil) amoxapine desipramine (Norpramin) doxepin (Sinequan) imipramine (Tofranil) nortriptyline (Aventyl) protriptyline (Vivactil)	Increase concentrations of inhibitory neurotransmitters (serotonin and norepinephrine) in the CNS.	Reduce neuropathic pain.

neurotransmitters serotonin and norepinephrine in the CNS, resulting in increased pain modulation and decreased pain perception. Patients experiencing neuropathic pain may need trials with different antidepressants until the right combination of effectiveness and tolerable adverse effects is found. Doses of these medications are generally lower than those used to treat depression, and the drugs act to relieve pain within 5 to 7 days. If improvement in pain relief is not noted within 1 week, the drug is discontinued. Duloxetine (Cymbalta) was the first of the antidepressants to receive approval for the treatment of diabetic peripheral neuropathic pain, chronic musculoskeletal pain, and fibromyalgia pain. Other drugs used for this purpose include amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), paroxetine (Paxil), and venlafaxine (Effexor).

CONNECTION Checkpoint 25.2

Use of tricyclic antidepressants has declined in recent decades due to a higher incidence of adverse effects compared to drugs in the SSRI class, but they are useful in the treatment of neuropathic pain. From what you learned in Chapter 19, what type of adverse effects would likely be observed in patients taking TCAs for migraines? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Antiseizure drugs: Antiseizure drugs commonly prescribed for neuropathic pain include gabapentin (Neurontin), valproic acid (Depakene), phenytoin (Dilantin), and carbamazepine (Tegretol). The antiseizure drugs act by suppressing neuronal discharges and reducing the hyperexcitability that occurs after nerve injury. These drugs may cause nausea, vomiting, sedation, confusion, or dizziness. Gabapentin is considered a first-line drug for treating neuropathic pain, and an extended release tablet form of the drug (Gralise) is approved to treat post-herpetic neuralgia.

Corticosteroids: Corticosteroids are used as adjuvants in pain management because they reduce inflammatory swelling and pressure on the brain, spinal cord, and spinal nerves. Dexamethasone (Decadron) is a preferred drug when given parenterally to reduce either cerebral or spinal cord edema; oral prednisone (Deltasone) may follow for a period of time. Steroids can also be injected directly into joints in refractory arthritis, or epidural-spinal tracts for chronic musculoskeletal pain. Their effects are discussed in Chapter 68.

Local anesthetics: Mexiletine (Mexitil) is a Class IB antidysrhythmic drug with anesthetic properties that is given PO for neuropathic pain refractory to other analgesics. Caution must be used when giving this drug to patients with heart disease or dysrhythmias. Short IV infusions of lidocaine (Xylocaine) may also provide temporary relief for some patients. A 5% lidocaine patch is approved for post-herpetic neuralgia.

Muscle relaxants: Muscle relaxants such as the benzodiazepines may be used effectively as adjuvant analgesics when muscle spasm is a component of the pain. Muscle spasm can be present following orthopedic injury or with musculoskeletal disease or degenerative nervous system conditions. Benzodiazepines can also be used to reduce anxiety in the terminal dyspnea of heart failure or end-stage respiratory disease. Examples include diazepam (Valium), lorazepam (Ativan), and oxazepam (Serax).

Bone-specific medications: Patients with bone cancer or metastases may experience severe pain. For palliative care, the administration of calcitonin, either subcutaneously or intranasally, may provide some relief for bone pain. The adjuvant analgesic activity of the bisphosphonates such as pamidronate (Aredia) and zoledronate (Reclast, Zometa) has been well established. The use of calcitonin and bisphosphonates in treating bone disorders is presented in Chapter 72.

Miscellaneous drugs: Capsaicin is a product obtained from chili peppers that is available as a cream to treat minor musculoskeletal pain. A prescription patch containing 8% capsaicin (Qutenza) was approved in 2010 for the relief of pain associated with post-herpetic neuralgia. Milnacipran (Savella) is a serotonin–norepinephrine reuptake inhibitor (SNRI) approved in 2009 for the treatment of fibromyalgia. Although the exact mechanism by which milnacipran acts is unknown, it is believed that pain relief occurs through regulation of abnormal serotonergic and noradrenergic pathways.

Pharmacotherapy with Opioid Antagonists

25.12 The primary indication for an opioid antagonist is opioid-induced respiratory depression.

Opioid overdose can result from excessive doses during pain therapy, or from attempted suicide or substance abuse. Any opioid may be abused for its psychoactive effects; however, morphine, meperidine, and heroin are preferred by abusers due to their potency. Although heroin is currently available as a legal analgesic in many countries, it is deemed too dangerous for therapeutic use by the FDA, and it is a major drug of abuse. Once injected or inhaled, heroin rapidly crosses the blood–brain barrier to enter the brain, where it is metabolized to morphine. Thus, the effects of heroin administration are actually caused by activation of the mu and kappa receptors from its morphine metabolite. The initial effect is an intense euphoria, or rush, followed by several hours of deep relaxation.

In recent years, OxyContin has become a major drug of abuse. Because this long-acting form of oxycodone is especially beneficial to patients with chronic pain who need around-the-clock relief, it has become a first-line drug in pain management. Abusers use the drug either for its effective pain relief action or for its side effects such as relaxation or euphoria. Many of the opioid drugs are given in combination with aspirin or acetaminophen, which causes dose-limiting adverse effects. OxyContin, however, contains only oxycodone and it could be crushed by abusers and injected or snorted for an even greater drug experience. In response to the widespread abuse, the manufacturer of OxyContin reformulated the drug so that it is highly resistant to crushing, breaking, or dissolving. OxyContin is a frequent target for "doctor shoppers" who visit multiple healthcare providers, often reporting fictitious symptoms, to obtain prescriptions. It is a potent and dangerous drug that can cause death when misused or abused.

Acute opioid intoxication is a medical emergency, with respiratory depression being the most serious medical challenge. Infusion with the opioid antagonist naloxone (Narcan) may be used to reverse respiratory depression and other acute symptoms. In administering naloxone, small doses are used and repeated until the respiratory depression is reversed and the patient begins to exhibit opioid withdrawal symptoms. The patient must be constantly monitored to ensure that the effects of the drug are sufficiently long to outlast the respiratory depression caused by the opioid overdose; IV doses of naloxone only last 1 hour. Maintenance of a patent airway is essential and resuscitation equipment should be immediately available. It is important to understand that naloxone will reverse both the toxic and therapeutic effects of opioids. Thus if the patient was using the opioid for analgesia, naloxone will reverse this effect and pain will quickly return.

In 2014, the FDA approved Evzio, a handheld autoinjector containing naloxone. This device is designed to be used by family members or caregivers to treat an individual with a known or suspected opioid overdose. Once turned on, the device gives verbal instructions for injecting the drug by either the IM or subcutaneous route. A training device is included with the packaging. The caregivers should seek emergency medical care for the patient immediately after Evzio use.

If an opioid antagonist fails to quickly reverse the acute symptoms, the overdose was likely due to a nonopioid substance. Doses for the opioid antagonists are listed in Table 25.6. The fixed dose combination of naloxone and buprenorphine (Suboxone, Zubsolv, others) has become a first-line therapy for the maintenance treatment of opioid dependence. Naloxone with buprenorphine is a prototype drug in Chapter 27.

When abusing an opioid, the user usually develops tolerance to the euphoric effects of the drug and quickly

Table 25.6 Opioid Antagonists

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
naloxone (Narcan, Evzio)	IV: 0.4–2 mg; may be repeated every 2–3 min up to 10 mg if necessary	*Muscle and joint pains, difficulty sleeping, anxiety, headache, nervousness, withdrawal symptoms, vomiting* Hepatotoxicity
naltrexone (ReVia, others)	PO: 25 mg followed by another 25 mg in 1 h if no withdrawal response (max: 800 mg/day)	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

escalates the dose. Following therapy with an opioid antagonist, however, the patient will become much more sensitive to the effects of opioids. If the patient returns to drug-taking behavior at the same dose used prior to opioid antagonist therapy, death may result.

Another indication for opioid antagonists is for the treatment of opioid-induced constipation or postoperative ileus. Alvimopan (Entereg) and methylnaltrexone (Relistor), both approved in 2008, act as mu receptors in the GI tract. Because they do not cross the blood–brain barrier, these drugs do not interfere with the central effects of opioids such as analgesia.

CONNECTION Checkpoint 25.3

Prochlorperazine (Compazine) is an antiemetic drug in the phenothiazine class that may be prescribed to decrease the nausea and vomiting caused by opioids. From what you learned in Chapter 20, what conditions are drugs in the phenothiazine class used to treat? Considering the adverse effects of the phenothiazines, what additive effects are more likely to occur when taking a phenothiazine and an opioid analgesic together? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

Pharmacotherapy of Migraines

25.13 Migraines are a severe type of headache related to specific triggers.

Headaches are some of the most common complaints of patients. The pain and inability to concentrate causes a significant number of work-related absences and can interfere with activities of daily life. When the headaches are persistent, or manifest as migraines, drug therapy is warranted.

Why does a headache hurt? Although the skull and the brain lack pain receptors, the muscles of the scalp, face, and neck are abundantly supplied with nociceptors. These receptors can be stimulated by muscle tension, dilated blood vessels, and other headache triggers.

Of the several varieties of headaches, the most common type is the **tension headache**. This occurs when muscles of the head and neck become tight due to stress, causing a steady and lingering pain. Although quite painful, tension headaches are self-limiting and more of an annoyance than an emergency. Tension headaches can be effectively treated with OTC analgesics such as aspirin, acetaminophen, or ibuprofen. Table 25.7 differentiates the two common types of headaches.

The most painful type of headache is the **migraine**, which is characterized by throbbing or pulsating pain, sometimes preceded by an aura. **Auras** are sensory warnings of an imminent migraine attack. Examples include flashing lights, visual blind spots, and arm or leg tingling. Nausea, vomiting, and extreme sensitivity to light and sound accompany most migraines. A positive family history is present in the majority of people who experience migraines.

Patients who get migraines appear to have blood vessels that overreact to various triggers. Triggers for migraines include foods containing nitrates or MSG, alcohol (especially red wine), perfumes, food additives, caffeine, chocolate, aspartame, and hormonal and environmental changes. Some patients can prevent or reduce the frequency of migraine attacks by avoiding known triggers.

The neurotransmitter serotonin (5-hydroxytryptamine or 5-HT) appears to be a key factor (although not the only factor) in the pathogenesis and treatment of migraines. What is the connection between serotonin levels and migraines? During a migraine, the amount of serotonin in the brain declines, causing the vessels to dilate. Nerves surrounding the dilated vessels become inflamed, resulting in pain. As neurons in the brain generate additional serotonin, or serotonin agonist drugs are administered, the vessels dilate and pain diminishes.

PharmFACT

Migraine Statistics

- About 70% of patients with migraines have a first-degree relative with a history of migraine.
- Before puberty, more boys have migraines than girls; after puberty, women are 3 times more likely to have migraines than men.
- History of migraine is associated with an increased incidence of major cardiovascular disease, especially if the patient experiences migraines with aura.
- Migraines are rare after age 50 (Chawla, 2016).

Table 25.7 Differentiation of Major Headache Types

Characteristics	Vascular (Migraine) Headache	Tension Headache
Pain quality	Pulsating or throbbing	Steady pressure or tightness
Pain location	Unilateral (more often) or bilateral	Bilateral (headband or ice tongs) pattern
Pain severity	Moderate to severe	Mild to moderate
Duration	4–72 h	Usually several hours
Precursors or triggers	Hormonal changes in women; stress or heightened emotions; bright or flickering lights; change in weather or altitude Foods: alcohol, aged cheeses, chocolate, caffeine, fermented or pickled foods, aspartame, monosodium glutamate (MSG)	Stress or anxiety
Associated symptoms	May be preceded by aura, nausea, vomiting, extreme sensitivity to light or sound; aggravated by physical activity	Uncommon

25.14 Analgesics and triptans are the primary classes of drugs used to abort acute migraine pain.

The two primary goals of migraine pharmacotherapy are to terminate an acute migraine in progress and to prevent or reduce the frequency of the disorder. Drugs used to stop a migraine in progress are different from those used for prophylaxis. The prophylactic medications are discussed in Section 25.15.

Migraine pharmacotherapy is more successful if therapy begins before the pain reaches a severe level. Drug therapy is conducted in stages based on the severity of the migraine.

- **Mild migraine (occasional headaches with no other functional impairment).** NSAIDs offer the safest and least expensive therapy; thus they are tried initially. Acetaminophen is generally not effective alone but offers additive pain relief when combined with an NSAID and caffeine. Oral serotonin (5-HT) agonists (triptans or ergot alkaloids) are initiated in persistent mild migraines that are refractory to NSAIDs.
- **Moderate migraine (moderate pain, nausea, and some functional impairment).** Oral, intranasal, or subcutaneous serotonin (5-HT) agonists are the preferred drugs. If serotonin agonists are contraindicated or ineffective, dopamine agonists such as metoclopramide (Reglan) or prochlorperazine (Compazine) may be prescribed.
- **Severe migraine (severe pain more than 3 times per month, marked nausea or vomiting, and functional impairment).** Subcutaneous, IM, or IV serotonin agonists may be indicated. A secondary choice would be a parenteral dopamine agonist, either as monotherapy or in combination with a serotonin agonist. Narcotic analgesics are effective at terminating pain from migraines that have proven to be refractory to other therapies.

The two major drug classes used to terminate migraines, the triptans and the ergot alkaloids, are both serotonin receptor agonists. About 90% of the serotonin receptors (also called serotonergic receptors) are located in the intestine, with the remaining 10% occurring throughout the CNS and in platelets. In the CNS, serotonin is responsible for moderating diverse responses such as anger, anxiety, depression, sleep, appetite, and vomiting. At least seven serotonin receptor subtypes have been identified. Other drugs acting at serotonin receptors include certain antianxiety medications, antidepressants, antiemetics, and various hallucinogens. Doses for the triptans and ergot alkaloids are listed in Table 25.8.

Table 25.8 Drugs Used to Terminate Acute Migraines

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Triptans		
almotriptan (Axert)	PO: 6.25–12.5 mg, may repeat in 2 h (max: 2 doses/24 h)	*Paresthesia, tingling, dry mouth, warming sensation, dizziness, vertigo*
eletriptan (Relpax)	PO: 20–40 mg, may repeat in 2 h (max: 80 mg/24 h)	Coronary artery vasospasm, MI, cardiac arrest
frovatriptan (Frova)	PO: 2.5 mg, may repeat in 2 h (max: 3 doses/24 h)	
naratriptan (Amerge)	PO: 1–2.5 mg, may repeat in 4 h (max: 5 mg/24 h)	
rizatriptan (Maxalt)	PO: 5–10 mg, may repeat in 2 h (max: 30 mg/24 h)	
sumatriptan (Imitrex, Onzetra)	PO: 25–100 mg, may repeat in 2 h (max: 200 mg/24 h) Intranasal (Onzetra): 22 mg, may repeat once (max: 44 mg/24 h) Subcutaneous: 6 mg, may repeat in 1 h, once in 24 h	
zolmitriptan (Zomig, Zomig ZMT)	PO: 2.5 mg or less, may repeat in 2 h (max: 10 mg/24 h) PO (orally disintegrating tablet): 1.25–2.5 mg (max: 5 mg) Nasal: 5 mg, may repeat once after 2 h (max: 10 mg/24 h)	
Ergot Alkaloids		
dihydroergotamine (DHE 45, Migranal)	Nasal: 1 spray (0.5 mg) each nostril, may repeat once in 15 min (max: 3 mg/24 h, 4 mg/wk) IM/subcutaneous: 1 mg, repeat at 1-h intervals for total 3 mg (max: 6 mg/wk)	*Weakness, nausea, vomiting, abnormal pulse, throat irritation, nasal irritation, or dysgeusia (distorted sense of taste)* Delirium, seizures, cerebrovascular events (hemorrhage), intermittent claudication, birth defects, inhibition of lactation or cause of infant vomiting, physical dependence, withdrawal resembles migraine
ergotamine (Ergostat; with caffeine: Cafergot; with caffeine, belladonna, pentobarbital: Cafergot P-B)	Sublingual: 2 mg, may repeat in 30 min for total 3 doses/24 h or 5 doses/wk PO: 2 tablets (2 mg), 1 additional tablet repeated every 30 min (max: 6 mg/attack or 10 mg/wk) Rectal: 2 mg, may repeat once in 1 h	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Triptans: The first of the triptans, sumatriptan (Imitrex, Onzetra), was marketed in the United States in 1992. This drug was quickly followed by the introduction of the "second-generation" triptans with improved pharmacokinetic profiles: more thorough absorption, faster onset of action, and longer duration. Although all triptans have very similar actions and adverse effects, individual patients may respond more favorably, and with fewer adverse effects, to one triptan over another. The longer duration triptans are believed to be better at preventing the migraine from recurring following its termination.

Triptans are selective for the 5-HT_1 receptor subtype, and they are thought to act by constricting certain intracranial vessels. They are effective in aborting migraines with or without auras. Although the PO forms of the triptans are most convenient, patients who experience nausea and vomiting during the migraine may require an alternate dosage form. Intranasal formulations are available and prefilled syringes of triptans may be used for patients who are able to self-administer the medication.

Triptans are not effective at preventing migraines. Other drugs, accompanied by lifestyle changes, must be used for prophylaxis (see Section 25.15).

Ergot alkaloids: For patients who are unresponsive to triptans, the ergot alkaloids may be used to abort migraines. They should be separated from triptan use by at least 24 hours. The first purified alkaloid, ergotamine (Ergostat), was isolated from the ergot fungus in 1920, although the actions of the ergot alkaloids had been known for thousands of years. Ergotamine is an inexpensive drug that is available in PO, sublingual, and suppository forms. Modification of the original molecule has produced a number of other pharmacologically useful drugs, such as dihydroergotamine (Migranal), which is available parenterally and as a nasal spray. Because the ergot alkaloids interact with adrenergic, dopaminergic, and serotonergic receptors, they produce multiple actions and adverse effects. The ergot alkaloids promote vasoconstriction, which terminates a migraine in progress. Adverse effects may include nausea, vomiting, weakness in the legs, myalgia, numbness and tingling in fingers and toes, angina-like pain, and tachycardia. Toxicity may be evidenced by constriction of peripheral arteries: cold, pale, numb extremities and muscle pain. Other possible adverse effects include dizziness, drowsiness, vasoconstriction, warming sensations, tingling, lightheadedness, weakness, and neck stiffness.

Ergot alkaloids, which constrict both arteries and veins, are contraindicated in peripheral vascular disease, coronary artery disease, and severe hypertension because they decrease blood flow. Metoclopramide or prochlorperazine may be administered concurrently with ergot alkaloids to reduce or prevent nausea and vomiting. Many ergot alkaloids are pregnancy category X drugs and should not be used by women who may become pregnant. These drugs may inhibit lactation or cause vomiting in breastfed infants. Regular daily use can cause physical dependence. Withdrawal symptoms of headache, nausea, and vomiting resemble the symptoms of migraines. Dosing and duration of use need to be restricted. Dangers of overuse and dependence should be included in patient and family teaching.

PROTOTYPE DRUG **Sumatriptan (Imitrex, Onzetra)**

Classification **Therapeutic:** Antimigraine drug
Pharmacologic: Serotonin (5-HT_1) receptor agonist

Therapeutic Effects and Uses: Available by the PO, intranasal, and subcutaneous routes, sumatriptan is used to relieve acute migraines. It was the first triptan approved by the FDA in 1992. It is not effective for long-term prophylaxis of migraines; other drugs must be used for this purpose. Sumavel DosePro consists of a subcutaneous dose of sumatriptan with an autoinjector pen. Treximet is a fixed dose combination of sumatriptan and naproxen that is approved for the treatment of acute migraines. Onzetra uses a breath-powered nasal delivery system called Xsail that offers pain relief in about 30 minutes.

Mechanism of Action: Sumatriptan is structurally similar to serotonin. Sumatriptan activates the 5-HT_1 serotonin receptors on intracranial and extracerebral blood vessels, resulting in vasoconstriction and reduced transmission in trigeminal pain pathways. It has no intrinsic analgesic activity.

Pharmacokinetics:

Route(s)	PO, intranasal, subcutaneous
Absorption	15% PO; 97% subcutaneous
Distribution	Widely distributed; crosses the placenta; secreted in breast milk; less than 21% bound to plasma protein
Primary metabolism	Hepatic
Primary excretion	60% renal; 40% feces
Onset of action	PO: 30–60 min; intranasal: 30 min; subcutaneous: 10–15 min
Duration of action	PO: 6–8 h; intranasal: unknown; subcutaneous: 4–6 h

Adverse Effects: Sumatriptan has infrequent adverse effects that include mild and transient dizziness or nausea, diarrhea, myalgia, and inflammation and pain at the subcutaneous injection site. Headache recurrence occurs in a large percentage of patients taking sumatriptan. Although rare, serious cardiac events have been documented with sumatriptan use. These events include coronary artery vasospasm, myocardial ischemia, dysrhythmias, and MI. These serious events are more likely to occur in patients with preexisting cardiac disease.

Contraindications/Precautions: Sumatriptan is contraindicated in patients with coronary artery disease, cerebrovascular disease, or peripheral vascular disease. This drug is not recommended for patients with uncontrolled hypertension, hypercholesterolemia, or those who have a strong family history of cardiovascular disease. Sumatriptan is contraindicated in patients with serious CKD or hepatic impairment. Patients with a history of epilepsy have an increased risk for seizures when taking sumatriptan. The drug is associated with fetal deformities and demise in animal studies; it should be avoided in pregnant women. Overuse of abortive therapies for migraines can lead to rebound headaches.

Drug Interactions: Sumatriptan is metabolized by monoamine oxidase and should not be used within 2 weeks of MAOIs or SSRIs. Use of sumatriptan should be avoided within 24 hours of ergot alkaloids or any other 5-HT_1 agonist due to risk of vasospastic reactions. Serotonin syndrome is possible when giving sumatriptan with other drugs that increase serotonin levels or activity, including buspirone (BuSpar), other triptans, amphetamines, sibutramine, trazodone, TCAs, lithium, duloxetine, venlafaxine, or meperidine. **Herbal/Food:** St. John's wort and feverfew should be avoided during therapy with sumatriptan.

Pregnancy: Category C.

Treatment of Overdose: Few overdoses have been recorded. Treatment of overdose is supportive.

Nursing Responsibilities: Key nursing implications for patients receiving sumatriptan are included in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Migraines.

Drugs Similar to Sumatriptan (Imitrex, Onzetra)

Other triptans include almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and zolmitriptan. All of the triptans have the same therapeutic effects and spectrum of adverse effects. All of the drugs in this class are pregnancy category C.

Almotriptan (Axert): Almotriptan was approved as an oral antimigraine drug in 2001. The drug is well absorbed and has an onset of action of 1 to 3 hours. The drug is extensively metabolized to inactive metabolites by CYP450 enzymes, and 75% is excreted via the kidneys. Drug–drug interactions with agents metabolized in the liver may occur.

Eletriptan (Relpax): Approved in 2002, eletriptan is a newer triptan with improved GI absorption and a more rapid onset of action than sumatriptan. It also has a longer duration. Less than 10% is excreted via the kidneys, making the drug safe to use in patients with CKD. The drug is extensively metabolized by CYP450 enzymes and thus has the potential for drug–drug interactions with agents metabolized in the liver.

Frovatriptan (Frova): Approved in 2001, frovatriptan has the same effects as sumatriptan but has a slow onset and a very long duration. The 26-hour half-life results in less pain recurrence with this drug. This drug is extensively metabolized by hepatic CYP450 enzymes, and the majority is eliminated in the feces.

Naratriptan (Amerge): Approved in 1998, this drug has a relatively slow onset of action (3–4 hours) but with a longer duration of action than sumatriptan. This drug is extensively metabolized to inactive metabolites by CYP450 enzymes and is excreted by the kidneys.

Rizatriptan (Maxalt): Approved in 1998, rizatriptan is absorbed more quickly than sumatriptan, with an onset of 60 to 90 minutes. It is available as PO disintegrating tablets (Maxalt-MLT), which are allowed to dissolve on the tongue and be swallowed with saliva. Hepatic CYP450 enzymes do not significantly metabolize the drug. The most common adverse effects include asthenia, fatigue, somnolence, pain or pressure sensation, and dizziness.

Zolmitriptan (Zomig, Zomig ZMT): Zolmitriptan is an oral drug that has the same effects as sumatriptan but is available in additional formulations as a nasal spray and as orally disintegrating tablets (Zomig ZMT). This drug is metabolized to an active metabolite in the liver, which is responsible for some of its antimigraine activity. The most common adverse effects include neck, throat, and jaw pain, dizziness, paresthesia, somnolence, warm or cold sensation, nausea, and dry mouth. Zolmitriptan should not be used to treat cluster headaches.

25.15 Drugs from many different classes are used for migraine prophylaxis.

Prior to initiation of drug therapy for migraine prophylaxis, patients should attempt lifestyle changes and nonpharmacologic therapies. First and foremost, the patient needs to identify personal triggers for migraines. The nurse can help by guiding the patient through the process of assessing and identifying those triggers. Foods are a common culprit, especially those containing nitrates or MSG. Omitting common migraine triggers from the diet is a first step in prophylaxis. Other lifestyle changes that may help include adopting regular sleep patterns and meals, participating in aerobic exercise (start slowly because sudden intense activity may cause headaches), avoiding alcohol (especially red wine), and smoking cessation. Other helpful self-care measures include keeping a diary that notes when headaches start, how long they last, what provides relief, what the response is to the medication, and food intake or stress in the past 24 hours. Relaxation exercises, meditation, yoga, or progressive muscle relaxation may help. Nontraditional therapies may also be useful in preventing migraines in some patients.

Drugs for migraine prophylaxis include various classes of drugs that are discussed in other chapters of this

Table 25.9 Drugs Used for Migraine Prophylaxis

Drug Class	Examples
Antiseizure drugs	gabapentin (Neurontin)
	topiramate (Topamax)
	valproic acid (Depakene, Depakote)
Beta-adrenergic blockers	atenolol (Tenormin)
	metoprolol (Lopressor)
	propranolol (Inderal)
	timolol (Blocadren)
Calcium channel blockers	nifedipine (Procardia)
	nimodipine (Nimotop)
	verapamil (Isoptin)
Tricyclic antidepressants	amitriptyline (Elavil)
	imipramine (Tofranil)
	protriptyline (Vivactil)
Miscellaneous	methysergide (Sansert)

CONNECTIONS: Complementary and Alternative Therapies

Natural Therapies for Migraines

- Acupuncture may be helpful to relieve pain. The acupuncturist uses thin, disposable needles at specific points on the body to treat the pain.
- Massage therapy may be useful in preventing and reducing the frequency of migraines. This is especially true for tension headaches.
- Biofeedback can be learned and used to stop or relieve migraine pain. Biofeedback is a relaxation technique that uses special equipment to teach the patient how to respond to stress by controlling responses such as muscle tension.
- Doses of riboflavin (vitamin B_2), Coenzyme Q10, and magnesium may reduce the frequency of migraines.

Used with permission from Mayo Foundation for Medical Education & Research, n.d. All Rights Reserved.

textbook. These include beta-adrenergic blockers, calcium channel blockers, antidepressants, and antiseizure drugs. Because all of these drugs have the potential to produce adverse effects, prophylaxis is only initiated if the incidence of migraines is high and the patient is unresponsive to the drugs used to abort migraines. Example prophylactic antimigraine drugs are given in Table 25.9. Doses for these drugs are found in the chapters where their primary indication is presented.

Preventive treatment is recommended for headaches that occur 3 or more times a month. Of the various medications, the beta-adrenergic blocker propranolol (Inderal) is one of the most commonly prescribed, although other drugs in this class have similar effectiveness. The use of beta blockers is particularly beneficial in patients with comorbid conditions such as hypertension or angina.

TCAs, especially amitriptyline (Elavil), have been used for decades to prevent migraines and are preferred for patients who may have a mood disorder or insomnia in addition to their migraines. The antimigraine action of these drugs is independent of their antidepressant action. SSRIs such as fluoxetine (Prozac) have been prescribed off-label for migraines because they exhibit fewer adverse effects than the TCAs.

Other classes of drugs used for migraine prevention include calcium channel blockers, certain antiseizure drugs, estrogens for menstrual migraines, and miscellaneous drugs such as methysergide (Sansert). An extended release form of valproic acid (Stavzor) was approved for migraine prophylaxis. OnabotulinumtoxinA (Botox), a drug often used to erase facial wrinkles, was approved to treat chronic migraines in 2010 (see Chapter 23).

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving Pharmacotherapy for Migraines

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, neurologic, hepatic, or renal disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Obtain baseline vital signs, apical pulse, level of consciousness, and weight.
- Assess level of pain. Use objective screening tools when possible (e.g., Wong-Baker FACES scale for children, numerical rating scale for adults). Assess history of pain and what has worked successfully or not for the patient in the past.
- Evaluate appropriate laboratory findings (e.g., CBC, hepatic, or renal function studies).
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., headache pain is decreased or absent).
- Continue monitoring level of consciousness and neurologic symptoms (e.g., numbness or tingling).
- Assess vital signs, especially blood pressure and pulse periodically.
- Continue periodic monitoring of hepatic and renal function studies.
- Assess stress and coping patterns for possible symptom correlation (e.g., existing or perceived stress, duration, coping mechanisms, or remedies).
- Assess for and promptly report adverse effects: chest pain or tightness, palpitations, tachycardia, hypertension, dizziness, lightheadedness, confusion, numbness, or tingling in extremities.

(*continued*)

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. Give the drug before the start of acute pain when possible. (Consistent use of a pain rating scale by all providers will help quantify the level of pain relief and leads to better pain control. Encourage the patient to start medication before the headache becomes severe for better control. Pain relief begins within several minutes after administration.)	• Teach the patient that pain relief, rather than merely control, is the goal of therapy. • Encourage the patient to take the drug before a headache becomes severe, and to take it consistently as ordered. • Explain the rationale behind the pain rating scale (i.e., it allows consistency among all providers). • Encourage the patient to use additional, nonmedicinal pain relief techniques (e.g., quiet, darkened, cool room).
Minimizing adverse effects: • Monitor blood pressure and pulse periodically, especially in patients at risk for undiagnosed cardiovascular disease. Cardiovascular status should be monitored frequently following the first dose given. (Triptans and ergot alkaloids cause vasoconstriction. **Lifespan:** Postmenopausal women, men over age 40, smokers, and people with other known coronary artery disease risk factors may be at greatest risk. Older adults may have undetected cardiovascular disease, placing them at greater risk for adverse effects.)	• Instruct the patient to immediately report any chest pain or tightness, or throat pain that is severe or continues following drug dosage.
• Observe for changes in severity, character, or duration of headache. (Sudden severe headaches of "thunderclap" quality can signal subarachnoid hemorrhage. Headaches that differ in quality and are accompanied by such signs as fever, rash, or stiff neck may herald meningitis.)	• Instruct the patient to immediately report changes in character or duration of headache or if accompanied by additional symptoms such as fever, rash, or stiff neck.
• Continue to monitor neurologic status periodically. (Dizziness or lightheadedness may be related to headache, an adverse drug effect, or may signal cerebral ischemia.)	• Instruct the patient to immediately report increasing dizziness, lightheadedness, or blurred vision.
• Monitor dietary intake of foods that contain tyramine, caffeine, alcohol, or other food triggers. (Some foods or beverages may trigger an acute migraine. Correlating symptoms with food or beverages assists in avoiding the cause of the headache.)	• Encourage the patient to keep a food diary and correlate symptoms with specific foods or beverages. Teach the patient to avoid or limit foods containing tyramine, such as pickled foods, beer, wine, and aged cheeses, which are often known triggers for migraines.
• Encourage the patient to discuss other methods of migraine control if ergot alkaloids are required for more than short-term use. (Ergot alkaloids cause significant vasoconstriction and cause dependence. Other, safer drugs may be needed for long-term relief of migraines.)	• Instruct the patient to discuss treatment options for long-term migraine relief with the healthcare provider.
• **Lifespan:** Women who are planning a pregnancy, pregnant, or breastfeeding, should discuss the use of drug therapy and alternative treatment before using antimigraine drugs. (Triptans are known to cause birth defects in animals. Ergotamine and other ergot alkaloids are category X drugs.)	• Teach women of childbearing age to discuss the use of antimigraine drugs before planning a pregnancy and to discontinue use if pregnant or breastfeeding unless directed otherwise by the provider.
Patient understanding of drug therapy: • Use opportunities during administration of medications and during assessments to discuss the rationale for drug therapy, desired therapeutic outcomes, commonly observed adverse effects, parameters for when to call the healthcare provider, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient, family, or caregiver should be able to state the reason for the drug, appropriate dose and scheduling, what adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering the medication, instruct the patient, family, or caregiver in the proper self-administration of drug (e.g., take the drug as prescribed when needed). (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient:
	  • Take the medication at the first symptoms of a migraine if possible, before the pain becomes severe.
	  • Use the drug exactly as prescribed; overuse can lead to rebound headaches.
	  • Proper administration of subcutaneous medication and have the patient or caregiver return demonstrate the technique. (Pain or redness at the injection site is common but usually disappears within an hour after the dose is taken.)
	  • Appropriate intranasal dose is one spray into one nostril unless otherwise ordered by the healthcare provider.

Understanding Chapter 25

Key Concepts Summary

25.1 The primary goal of pain management is to reduce pain to a level that allows the patient to continue normal daily activities.

25.2 Proper assessment and classification of pain guides its treatment.

25.3 Healthcare providers and patients sometimes hold myths about pain that impede optimal pain management.

25.4 Pain transmission processes allow multiple targets for pharmacologic intervention.

25.5 Both pharmacologic and nonpharmacologic therapies are used in pain management.

25.6 Opioid analgesics exert their effects by interacting with specific receptors in the central nervous system.

25.7 Opioids are the preferred drugs for moderate to severe pain that cannot be controlled with other classes of analgesics.

25.8 Mixed agonist and antagonist opioids exhibit moderate analgesia with less risk of dependence than morphine.

25.9 Nonsteroidal anti-inflammatory drugs are the preferred medications for mild to moderate pain.

25.10 A few miscellaneous analgesics reduce pain by acting on the central nervous system.

25.11 Adjuvant analgesics have primary indications other than pain control but can enhance analgesia.

25.12 The primary indication for an opioid antagonist is opioid-induced respiratory depression.

25.13 Migraines are a severe type of headache related to specific triggers.

25.14 Analgesics and triptans are the primary classes of drugs used to abort acute migraine pain.

25.15 Drugs from many different classes are used for migraine prophylaxis.

CASE STUDY: Making the Patient Connection

Remember the patient "Larry Smith" at the beginning of the chapter? Now read the remainder of the case study. Based on the information presented within this chapter, respond to the critical thinking questions that follow.

Larry Smith was being seen for an outpatient presurgery workup the evening before scheduled urologic surgery. The nurse conducts a thorough history and examination related to his back pain and current pain management. His anticipated hospital stay is 2 days postsurgery.

Larry Smith is a 68-year-old man. Vital signs are blood pressure, 108/64 mmHg; pulse, 88 beats/min; respirations, 16 breaths/min. He has a well-healed midline scar on his back from lumbar vertebrae surgery, with a shorter scar over his right iliac crest. He moves a bit slowly with some limited lumbar range of motion. He also uses a cane for ambulating any distance. He describes his pain as a constant dull ache in the lower back that increases with prolonged standing or walking. Larry also reports a feeling of "cold electricity" down both legs, with the left greater than the right, which increases with standing and walking, as well as numbness of the middle toes on his left foot. He has been using mixed opioid and nonopioid analgesics for the past 8 years and previously had used SSRI antidepressants as adjuvant for his pain. His current healthcare provider weaned him off Vicodin ES about a year ago. He now takes methadone 20 mg twice a day. When the pain is not relieved, he uses Norco for breakthrough pain. His use of Norco is 1 to 2 doses per day. Constipation is an ongoing problem, requiring stool softeners and occasional laxatives.

Critical Thinking Questions

1. How should Larry's postoperative pain be managed? Is there a referral the nurse can make to facilitate effective pain management?
2. How could the nurse best communicate Larry's needs to the postoperative nursing staff?
3. What should be included in the care plan for postoperative management of analgesic adverse effects?

Answers to Critical Thinking Questions are available on the faculty resources site. Please consult with your instructor.

Additional Case Study

Rita Manson presents to the emergency department with vomiting, severe abdominal and back pain, and jaundice. Her jaundice is recent but the pain and vomiting have continued for a couple of months. Her diagnostic workup reveals advanced pancreatic cancer with metastasis to the spine.

1. What is the preferred drug for Rita's pain management? Which route of administration would be expected initially?
2. Her prescribed pain medication is morphine sulfate 2 to 10 mg IV every 2 hours as needed for pain. Outline a nursing approach to pain management for the first 24 hours.
3. What adverse effects would the nurse expect?
4. As part of the patient's pain management, dexamethasone (Decadron) 5 mg IV is prescribed every 6 hours for 2 days. Explain the use of corticosteroids in pain management.

Answers to Additional Case Study questions are available on the faculty resources site. Please consult with your instructor.

Chapter Review

1. The nurse is monitoring the patient for adverse effects associated with morphine. Which adverse effects would be expected? (Select all that apply.)
   1. Respiratory depression
   2. Hypertension
   3. Urinary retention
   4. Constipation
   5. Nausea

2. Several days postoperative bowel surgery, the patient is eating soft food, ambulating regularly, and using hydrocodone (Vicodin) for pain. What should the nursing care plan include?
   1. Monitoring vital signs for respiratory depression
   2. Inserting a urinary catheter for urinary retention
   3. Weaning pain medication to prevent addiction
   4. Increasing dietary fiber and fluids and administering a stool softener if needed

3. A patient who has migraines self-administered sumatriptan (Imitrex) for the first time yesterday. Today, the patient informs the nurse that after taking the medication, the patient began to experience chest pain. The patient further states that the drug was effective in relieving the headache. The nurse should:
   1. Encourage the patient to continue using the drug because it was effective.
   2. Advise the patient to tell the healthcare provider about the chest pain at the next visit.
   3. Instruct the patient to contact the healthcare provider to report the chest pain today and to not use the sumatriptan until the healthcare provider has been consulted.
   4. Encourage the patient to lie down in a quiet room and use cold packs during the next migraine.

4. A patient with diabetes reports increasing pain and numbness in his legs. "It feels like pins and needles all the time, especially at night." Which drug would the nurse expect to be prescribed for this patient?
   1. Ibuprofen (Motrin)
   2. Gabapentin (Neurontin)
   3. Naloxone (Narcan, Evzio)
   4. Methadone

5. The emergency department nurse is caring for a patient with a migraine. Which drug would the nurse anticipate administering to abort the patient's migraine?
   1. Morphine
   2. Dihydroergotamine (Migranal)
   3. Propranolol (Inderal)
   4. Ibuprofen (Motrin)

6. The nurse is caring for several patients who are receiving opioids for pain relief. Which patient is at the highest risk of developing hypotension, respiratory depression, and mental confusion?
   1. A 23-year-old woman, postoperative ruptured appendix
   2. A 16-year-old adolescent, post–motorcycle injury with lacerations
   3. A 54-year-old woman, post–myocardial infarction
   4. An 86-year-old man, postoperative femur fracture

Patient "Elena Moore"

Chapter 26
Anesthetics and Anesthesia Adjuncts

Chapter Outline

- Types of Anesthesia
- Principles of General Anesthesia
- Intravenous Anesthetics
  - Opioid Anesthetics
    - **PROTOTYPE** *Fentanyl (Sublimaze), p. 425*
  - Benzodiazepine Anesthetics
    - **PROTOTYPE** *Midazolam (Versed), p. 427*
  - Miscellaneous Intravenous Anesthetics
    - **PROTOTYPE** *Propofol (Diprivan), p. 428*
- Inhalation Anesthetics
  - **PROTOTYPE** *Nitrous Oxide, p. 430*
  - **PROTOTYPE** *Isoflurane (Forane), p. 432*
- Local Anesthetics
  - Classification of Local Anesthetics
  - Esters
    - **PROTOTYPE** *Procaine (Novocaine), p. 438*
  - Amides
    - **PROTOTYPE** *Lidocaine (Anestacon, Xylocaine, Zingo, Others), p. 439*
- Adjuncts to Anesthesia

Learning Outcomes

After reading this chapter, the student should be able to:

1. Compare and contrast the four basic types of anesthesia.
2. Explain the five general purposes of balanced anesthesia.
3. Compare and contrast the four stages of general anesthesia.
4. Identify drug classes used to produce general anesthesia.
5. Describe the nursing care associated with the administration of regional and general anesthesia.
6. Explain the rationale for using adjunct agents during general anesthesia.
7. For each of the classes shown in the chapter outline, identify the prototype and representative drugs and explain the mechanism(s) of drug action, primary indications, contraindications, significant drug interactions, pregnancy category, and important adverse effects.
8. Apply the nursing process to care for patients receiving local or general anesthesia.

Key Terms

amide, 439
balanced anesthesia, 423
dissociative anesthesia, 429
esters, 437
general anesthesia, 423
local anesthesia, 423
minimum alveolar concentration, 430
monitored anesthesia care (MAC), 423
neurolept analgesia, 424
regional anesthesia, 423
surgical anesthesia, 424

Throughout history, the application of anesthesia has allowed patients to experience a temporary loss of sensation, resulting in comfort during surgical intervention. The use of opium as an anesthetic was recorded as far back as 4200 BC, and the ancient Chinese recorded acupuncture as a form of anesthesia. The modern implementation of anesthesia dates back to 1846 when Dr. John C. Warren performed a surgical procedure using ether. Modern anesthesia now offers safer and more effective drugs. This chapter introduces drugs used for general and local anesthesia along with the adjuvant medications administered during surgical procedures.

Types of Anesthesia

26.1 Anesthesia is used to produce a controlled loss of sensation during a diagnostic or surgical procedure.

Certain medical procedures produce a significant degree of pain and would not be possible without anesthesia. There are four types of anesthesia. The type of anesthesia selected depends on the degree of sedation and analgesia needed to conduct the procedure.

General anesthesia is the loss of sensation throughout the entire body, accompanied by loss of consciousness. General anesthesia is necessary for major surgical procedures.

The application of **local anesthesia** results in loss of sensation to a limited body region without loss of consciousness. It affects only the immediate area that surrounds where the anesthetic is administered. **Regional anesthesia** is similar, except that it encompasses a larger body area, such as an entire limb. Local and regional anesthesias produce fewer adverse effects than general anesthesia and are thus the methods of choice where applicable.

A fourth type of anesthesia is **monitored anesthesia care (MAC)**, which uses sedatives, analgesics, and other low-dose drugs that allow patients to remain responsive and breathe without assistance during a medical procedure. This type of anesthesia is used during diagnostic procedures and minor surgeries to supplement local and regional anesthesias. Subtypes of MAC are based on the degree of sedation produced:

- **Minimal sedation (anxiolysis).** Patients respond to verbal commands. Airway, ventilation, and cardiovascular functions are normal.
- **Moderate (conscious) sedation.** Patients respond to verbal or light tactile prompting. Airway, ventilation, and cardiovascular functions are usually adequate.
- **Deep sedation and analgesia.** Patients are aroused by repeated or painful stimulation. Airway and ventilation intervention may be required. Cardiovascular functions are usually adequate.

Principles of General Anesthesia

26.2 Balanced anesthesia uses multiple drugs to provide for the safe induction and maintenance of general anesthesia.

General anesthesia is accomplished by the administration of a variety of drugs. The purposes of general anesthesia include the following:

- Analgesia: blocking the sensation of pain
- Relaxation: relieving the intense anxiety associated with medical procedures
- Hypnosis: producing unconsciousness to block awareness of the procedure
- Amnesia: blocking memory of the events associated with the procedure
- Loss of reflexes: blocking autonomic and other reflexes that may be affected by the procedure.

Because no single drug can safely accomplish all five purposes, a pharmacologic approach called balanced anesthesia is used. **Balanced anesthesia** is the use of a combination of medications to produce general anesthesia. Drugs administered to achieve balanced anesthesia include neuromuscular blockers, short-acting benzodiazepines, opioids, and general anesthetics. The purpose of combining these medications is to provide sedation, rapid induction of unconsciousness, muscle relaxation, and analgesia. The use of multiple drugs reduces the need for large amounts of inhaled anesthetics, which increases patient safety.

Balanced anesthesia involves the administration of intravenous (IV) medications prior to the general anesthetic. The IV medications produce muscle relaxation, diminish pain, and promote sleep. After the patient loses consciousness, inhaled general anesthetics are

Table 26.1 Stages of General Anesthesia

Stage	Characteristics
1	*Analgesia:* The patient loses general sensation but may remain awake. This stage progresses until the patient loses consciousness.
2	*Excitement and hyperactivity:* The patient may become delirious and attempt to resist treatment. The heart rate and respiratory rate may become irregular. The patient's blood pressure may increase. The administration of IV agents may calm the patient.
3	*Surgical anesthesia:* The patient's skeletal muscles become relaxed and delirium stabilizes. The cardiopulmonary effects stabilize. The patient becomes still with diminished eye movements. The surgical procedure is begun. The patient remains in stage 3 until the procedure ends.
4	*Paralysis of the medulla:* If breathing and cardiac function cease, death could result. This stage of general anesthesia is avoided.

administered to maintain the anesthetized state. For short procedures, lower amounts of anesthesia are administered, or parenteral agents alone may be sufficient.

General anesthesia is a progressive process that occurs in distinct phases, which are described in Table 26.1. The most effective medications can quickly induce all four stages, whereas others are able to induce only stage 1. Major surgical procedures require the patient to be maintained in stage 3, which is referred to as **surgical anesthesia**. The patient should progress from stage 2 to stage 3 rapidly because stage 2 produces excitement, hyperactivity, and a feeling of panic. During stage 2 the patient is monitored closely for heart rate irregularities and increases in blood pressure. During recovery from general anesthesia, the patient moves in reverse order back up through the four stages.

PharmFACT

About 60% of women giving birth in hospitals receive regional anesthesia. Regional anesthesia includes epidural analgesia, spinal analgesia, or a combination of the two (Satpathy, 2015).

Intravenous Anesthetics

26.3 Intravenous anesthetics include opioids, benzodiazepines, and several miscellaneous agents.

IV anesthetics are important components of balanced anesthesia. After a single IV bolus, these drugs enter the brain, allowing the patient to quickly progress through stages 1 and 2. They are occasionally used alone for minor diagnostic and surgical interventions. Concurrent administration of IV and inhaled anesthetics allows the dose of the inhaled anesthetic to be reduced. The lower dosage of inhaled anesthetic produces a better surgical outcome and lowers the risk of serious adverse effects from the anesthesia. The combined use of IV and inhaled anesthesia also allows for a greater degree of analgesia and muscle relaxation than when inhalation anesthetics are used alone.

Fewer than a dozen drugs are used as IV anesthetics. Some of these drugs also have nonanesthetic indications. Drugs from the following classes are used for IV anesthesia:

- Opioids
- Benzodiazepines
- Miscellaneous agents.

PharmFACT

Certified registered nurse anesthetists administer about 43 million anesthetics each year. Nurse anesthetists are the primary providers of anesthesia care for U.S. armed forces (American Association of Nurse Anesthetists, 2016).

26.4 Opioids are used as intravenous anesthetics to provide analgesia and to accomplish neurolept anesthesia.

As presented in Chapter 25, the opioids, or narcotic analgesics, are the most effective drugs available for pain relief, including perioperative pain management. To produce deep anesthesia, however, opioids must be combined with other anesthetics. Combinations allow lower doses to be used and provide the necessary analgesia for painful procedures.

Alfentanil (Alfenta), fentanyl (Sublimaze), remifentanil (Ultiva), and sufentanil (Sufenta) are opioids used as IV anesthetics. These medications are opioid receptor agonists that provide a rapid onset of action with a short duration of 10 to 30 minutes. Their primary disadvantage is respiratory depression. Muscle rigidity may occur, which can further impair ventilation. A complete discussion of the mechanisms, actions, and adverse effects of the opioids is included in Chapter 25. A prototype feature for morphine can be found in that chapter. Doses for the opioid anesthetics are listed in Table 26.2.

The combination of droperidol and fentanyl produces a type of anesthesia called **neurolept analgesia**. Neurolept analgesia produces feelings of indifference to the patient's surroundings. The patient appears to be asleep but does not lose consciousness. Fentanyl is a potent opioid agonist with pharmacologic action that is similar to that of morphine. Droperidol is an antipsychotic drug related to haloperidol. It has the ability to reduce the nausea and vomiting adverse effects of opioids and produces sedation by reducing anxiety and motor activity.

Table 26.2 Intravenous Anesthetics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Opioids		
alfentanil (Alfenta)	IV: 8–20 mcg/kg for surgery lasting longer than 30 min Maintenance anesthesia: 3–5 mcg/kg in incremental doses Continuous infusion: 0.5–1 mcg/kg/min Total dose: 8–40 mcg/kg	*Skeletal muscle rigidity, nausea, vomiting, postoperative drowsiness, shivering, HTN, bradycardia, prolonged QT interval, constipation* Apnea, respiratory depression, laryngospasm, bronchospasm, circulatory depression, cardiac arrest, respiratory depression, respiratory arrest, anaphylactoid reaction
fentanyl (Sublimaze)	IM/IV: 2–100 mcg/kg with dosage individualized to patient and indication	
remifentanil (Ultiva)	IV: 0.5 mcg/kg/min or 1 mcg/kg IV bolus	
sufentanil (Sufenta)	IV: 1–8 mcg/kg; may give additional doses of 10–50 mcg if needed Primary anesthetic: 1–30 mcg/kg IV administered with 100% oxygen	
Benzodiazepines		
diazepam (Valium)	IV: 5–10 mg, repeat every 10–15 min as needed	*Drowsiness, hypotension, tachycardia, retrograde amnesia* Cardiovascular collapse, respiratory arrest, laryngospasm
midazolam (Versed)	IV (premedication): 0.15–0.25 mg/kg over 20–30 sec IV (unpremedicated patients): 0.3–0.35 mg/kg over 20–30 sec	
Miscellaneous IV Anesthetics		
etomidate (Amidate)	IV: 0.2–0.6 mg/kg over a period of 30–60 sec for induction	*Pain on injection, transient skeletal muscle movements* Changes in ventilation (hyper or hypo) and blood pressure (hyper or hypo)
ketamine (Ketalar)	IV: 1–4 mg/kg IM: 6.5–13 mg/kg	*Respiratory depression, laryngospasm, apnea, nausea, vomiting* HTN, tachycardia, vivid dreams, hallucinations, delirium
methohexital (Brevital)	IV: For induction: 1–1.5 mg/kg at a rate of 1 mL every 5 sec	*Postoperative psychomotor impairment, retrograde amnesia, hypothermia, sloughing with extravasation, skeletal muscle hyperactivity* Circulatory depression, respiratory depression, respiratory arrest, apnea, anaphylaxis
propofol (Diprivan)	IV: 2–2.5 mg/kg every 10 sec until induction onset	*Pain at injection site, skeletal muscle movements* Dysrhythmias, hypotension

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

PROTOTYPE DRUG **Fentanyl (Sublimaze)**

Classification **Therapeutic:** Analgesic, anesthetic
Pharmacologic: Opioid agonist

Therapeutic Effects and Uses: Fentanyl is an opioid analgesic that is administered IV for short-duration analgesia as part of premedication, balanced anesthesia, induction and maintenance of anesthesia, and for postoperative pain. When given IV, it has an immediate onset of action, and its analgesic effects last about 60 minutes. As an anesthetic it may be administered with oxygen in high-risk patients, such as those undergoing open heart surgery or certain complicated neurologic or orthopedic procedures.

Since its approval in 1968 as an IV anesthetic, fentanyl has been introduced in multiple formulations, including oral (PO) tablets (Fentora), buccal film (Onsolis), sublingual tablets (Abstral), transmucosal lozenges (Actiq), intranasal spray (Lazanda), and transdermal patches (Duragesic). All of these nonanesthetic formulations of fentanyl are prescribed for the management of breakthrough pain in patients who are already receiving and who are tolerant to around-the-clock opioid therapy for their chronic, persistent pain. Opioids such as fentanyl will result in tolerance if taken in high drug dosages over an extended time. Doses need to be adjusted periodically for adequate pain management. Physical and psychologic dependence may occur with continued use. Abrupt discontinuation of the drug may cause intense withdrawal symptoms (see Chapter 27). Fentanyl is a Schedule II controlled substance. When taken illegally, fentanyl gives the same effects as heroin.

Mechanism of Action: Fentanyl is an opioid agonist at the mu and kappa receptors. The mechanism of action is the same as that of morphine and other opioids. Fentanyl has a more rapid onset of action than morphine.

Pharmacokinetics:

Route(s)	IV, intramuscular (IM), transdermal, transmucosal, epidural
Absorption	Rapid
Distribution	Crosses the placenta; secreted in breast milk; 80% bound to protein
Primary metabolism	Hepatic (CYP3A4)
Primary excretion	Renal
Onset of action	IV: immediate; IM: 7–15 min; transdermal: 24–72 h peak; transmucosal: 20–30 min peak; epidural: 10–15 min
Duration of action	IV: 0.5–1 h; IM: 1–2 h; transdermal: 17-h half-life; transmucosal: unknown; epidural: 2–3 h

Adverse Effects: The most common adverse effects of fentanyl include respiratory depression, apnea, skeletal muscle rigidity, and bradycardia. The peak respiratory depression occurs 5 to 15 minutes after an IV dose. The respiratory depression, however, will continue postoperatively and outlast the analgesic effects of the drug. Nausea, vomiting, and constipation are common adverse effects produced by most opioids. Fentanyl may cause syncope and severe bradycardia and hypotension. Transdermal patches can cause localized pain, irritation, ulceration, and bleeding. **Black Box Warning:** Fentanyl carries several black box warnings. This drug has significant abuse potential and should not be prescribed to patients with a high risk for misuse, abuse, or diversion. The drug carries a high risk for death due to overdose or respiratory depression. Concurrent use with CYP3A4 inhibitors will increase fentanyl plasma concentrations and the risk of serious adverse effects. Concurrent use with other central nervous system (CNS) depressants such as benzodiazepines or alcohol may result in profound sedation, respiratory depression, coma, and death.

Contraindications/Precautions: Patients with respiratory impairment should be administered fentanyl with caution due to the respiratory depression caused by the drug. Patients with hepatic or chronic kidney disease should receive lower doses. The drug may worsen bradydysrhythmia. Patients with head trauma should not receive fentanyl because intracranial pressure (ICP) may increase. Fentanyl is secreted in breast milk and can cause sedation and respiratory depression in the neonate; thus it should not be administered during lactation.

Drug Interactions: Extreme caution should be used when administering fentanyl with alcohol or other CNS depressants due to additive sedation and respiratory depression. Fentanyl is metabolized by CYP450 enzymes (CYP3A4) in the liver and intestinal mucosa and has the potential to interact with other drugs that induce or inhibit this enzyme. Cardiovascular depression may occur if nitrous oxide is used with high doses of fentanyl. **Herbal/Food:** St. John's wort may intensify or prolong the effects of fentanyl anesthesia and may induce the metabolism of fentanyl via CYP3A4. Use of valerian or kava may cause additive CNS depression.

Pregnancy: Categories B (parenteral) and C (transdermal and transmucosal forms).

Treatment of Overdose: In the event of an overdose, the patient is supported with mechanical ventilation until the drug is metabolized and the effects diminish. The patient may be administered a narcotic antagonist such as naloxone (Narcan) to reverse serious respiratory depression.

Nursing Responsibilities: Key nursing implications for patients receiving fentanyl are included in the Nursing Practice Application for Patients Receiving General Anesthesia in this chapter and in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Pain in Chapter 25.

Drugs Similar to Fentanyl (Sublimaze)

Additional opioid IV general anesthetics include alfentanil, remifentanil, and sufentanil.

Alfentanil (Alfenta): Approved in 1996, alfentanil is an opiate agonist that has a more rapid onset and a shorter duration of action than fentanyl. It is administered IV to provide analgesia as a component of balanced anesthesia. Uses include assisting in intubation, promoting the induction of anesthesia, and as an infusion for the maintenance of anesthesia. A labeled indication is for the management of severe postoperative pain when given by the epidural route. The most common adverse effects are respiratory depression, nausea, vomiting, and muscle rigidity. Respiratory depression may be delayed; thus the patient should be monitored for some time after surgery. Alfentanil must be used with caution with other CNS depressants. Other actions and adverse effects are the same as those for fentanyl.

Remifentanil (Ultiva): Approved in 1996, remifentanil is an IV opioid that is similar to fentanyl. It is rapidly metabolized, which allows for a shorter duration of respiratory depression than fentanyl. Recovery from anesthesia occurs 5 to 10 minutes after discontinuation of the drug. This agent is administered during the induction and maintenance of general anesthesia to provide analgesia during the postoperative period. Although it does not produce deep anesthesia, remifentanil may be used alone or in combination with midazolam in monitored anesthesia care. Hypotension is greater with remifentanil than with fentanyl. Respiratory depression, pruritus, sweating, nausea, and vomiting are other

adverse effects. Other actions and adverse effects are the same as those for fentanyl.

Sufentanil (Sufenta): Approved in 1984, sufentanil is an IV opioid used as a component of balanced anesthesia or as a primary anesthetic agent. As a primary anesthetic the patient should be administered 100% oxygen. During IV use, the onset of action is immediate and recovery time is comparable to that of fentanyl. It is sometimes administered with bupivacaine as an epidural anesthesia adjunct during labor and delivery. During epidural use, the onset of action is about 10 minutes and recovery time is 1.7 hours. Sufentanil is 5 to 10 times more potent than fentanyl. The most common adverse effects are respiratory depression and muscle rigidity, and the drug must be used with caution with other CNS depressants.

CONNECTION Checkpoint 26.1

In pain management, opioids are often available in fixed-dose combinations with nonopioids. From what you learned in Chapter 25, what is the rationale for using a nonopioid analgesic with an opioid? What specific nonopioid analgesic is most frequently found in these combination drugs? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

26.5 Benzodiazepines are used in anesthesia to produce relaxation, sedation, and amnesia.

The primary indication for benzodiazepines is to treat symptoms of anxiety (see Chapter 18). For anesthesia, drugs in this class are used at high doses to cause sedation and induce unconsciousness. Benzodiazepines are a component of balanced anesthesia, most often administered in combination with inhalation anesthetics to allow the patient to feel less anxiety and experience amnesia. They may be administered PO as a premedication to relax the patient prior to minor medical procedures. The most commonly utilized benzodiazepine for surgical procedures is midazolam (Versed). Diazepam (Valium) and lorazepam have a slower onset and longer duration than midazolam and are occasionally used as anesthesia adjuncts. A detailed discussion of benzodiazepines is found in Chapter 22, along with a prototype feature for diazepam. Doses for the two benzodiazepines used as IV anesthetics are listed in Table 26.2.

PROTOTYPE DRUG **Midazolam (Versed)**

Classification **Therapeutic:** IV anesthetic
Pharmacologic: Benzodiazepine, gamma aminobutyric acid (GABA) receptor agonist

Therapeutic Effects and Uses: Approved in 1985, midazolam is administered to reduce the anxiety and stress associated with surgery. It is approved by the U.S. Food and Drug Administration (FDA) for the induction of amnesia, induction and maintenance of general anesthesia, and sedation prior to short diagnostic procedures such as an endoscopy. Off-label uses include status epilepticus that is refractory to other drugs and for sedation of mechanically ventilated patients. Midazolam syrup is indicated for use in children to produce sedation, anxiolysis, and amnesia prior to minor medical procedures or induction of anesthesia.

Induction of anesthesia occurs in 1 to 2 minutes following an IV bolus of midazolam. If the patient has received an opioid premedication, induction is even more rapid. Awakening and complete recovery of memory occurs in about 2 hours but may extend to 6 hours in older adults or those with heart failure or hepatic impairment.

Midazolam is a Schedule IV controlled substance. It has abuse potential similar to that of other benzodiazepines.

Mechanism of Action: Midazolam acts at the limbic, thalamic, and hypothalamic regions of the brain to produce CNS depression and skeletal muscle relaxation. This is the same mechanism of action as other benzodiazepines.

Pharmacokinetics:

Route(s)	IV, IM, PO
Absorption	Rapid absorption
Distribution	Widely distributed; crosses the blood–brain barrier and the placenta; secreted in breast milk; 97% protein bound
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	IV: 1.5 min; IM: 5–15 min; PO: 10–30 min
Duration of action	IV/IM/PO: 2–6 h

Adverse Effects: Respiratory depression and apnea are potentially serious adverse events. CNS adverse effects include drowsiness, fatigue, ataxia, slurred speech, and tremor. Potentially serious cardiovascular effects include hypotension, tachycardia, and cardiovascular collapse. Laryngospasm is the most severe pulmonary complication noted with the administration of midazolam. Paradoxical reactions such as hyperactivity or aggressive behavior have been reported in pediatric patients and in those with preexisting psychiatric disorders. **Black Box Warning:** Respiratory depression and arrest have occurred with midazolam use. Respiratory status must be continuously monitored and resuscitative equipment must be readily available. When used concurrently with benzodiazepines or opioids, the dosage and duration of midazolam anesthesia should be limited to the minimum required.

Contraindications/Precautions: Patients who have acute, closed-angle glaucoma should not be administered midazolam because the drug may increase intraocular pressure. Patients experiencing acute alcohol intoxication,

shock, coma, or depressed vital signs should not be administered benzodiazepines because the drug may worsen these conditions.

Drug Interactions: The administration of benzodiazepines with any medication that depresses the CNS, including alcohol, increases the patient's risk for sedation. Use of benzodiazepines and phenytoin (Dilantin) will result in an increased serum phenytoin level and additive CNS depression. Midazolam is metabolized by hepatic CYP3A4 enzyme, and inhibitors or inducers of this enzyme may interact with midazolam. **Herbal/Food:** Increased sedation may occur if benzodiazepines are administered with kava or valerian. Grapefruit juice may increase the serum concentration of midazolam. Melatonin should be avoided because it may increase sedation.

Pregnancy: Category D.

Treatment of Overdose: Overdose with midazolam causes sedation, confusion, diminished reflexes, and coma. General supportive measures should be taken, and the patient may be treated with flumazenil (Romazicon), which is a specific benzodiazepine antagonist. Flumazenil acts within minutes but may induce seizures with rapid reversal.

Nursing Responsibilities: Key nursing implications for patients receiving midazolam are included in the Nursing Practice Application for Patients Receiving General Anesthesiain this chapter and in the Nursing Practice Application for Patients Receiving Pharmacotherapy for Anxiety or Sleep Disorders in Chapter 18.

Drugs Similar to Midazolam (Versed)

The only other benzodiazepine administered to produce anesthesia is diazepam.

Diazepam (Valium): Diazepam has been widely prescribed for anxiety and as an adjunct in seizure management. In the surgical suite diazepam is used as a premedication (by the IM route) for relief of anxiety associated with the surgical procedure. It is used by the IV route prior to cardioversion for the relief of anxiety and tension and to produce amnesia. When administered parenterally, it has an onset of action of 1 to 5 minutes and produces short-acting effects. Diazepam decreases the patient's anxiety and relaxes the skeletal muscles. Diazepam impairs the patient's ability to remember the perioperative events. A prototype feature for diazepam may be found in Chapter 22.

CONNECTION Checkpoint 26.2

Benzodiazepines are sometimes used for seizure control. From what you learned in Chapter 22, what are the indications for lorazepam and diazepam in treating seizures? *Answers to Connection Checkpoint questions are available on the faculty resources site. Please consult with your instructor.*

26.6 Propofol and ketamine are widely used intravenous drugs for inducing and maintaining anesthesia.

Several miscellaneous drugs are used as parenteral anesthetics. Propofol (Diprivan) and ketamine (Ketalar) are two of the widely used IV anesthetics. The two drugs are not related chemically, but both have short durations and can induce anesthesia rapidly. Etomidate (Amidate) and methohexital (Brevital) are much less frequently used in balanced anesthesia. Doses for these drugs are listed in Table 26.2.

PROTOTYPE DRUG **Propofol (Diprivan)**

Classification **Therapeutic:** IV anesthetic, sedative–hypnotic drug
Pharmacologic: N-methyl-D-aspartate (NMDA) receptor agonist

Therapeutic Effects and Uses: Approved in 1989, propofol has become the most widely used IV anesthetic due to its effectiveness and relative safety profile. It is indicated for the induction and maintenance of general anesthesia. In the intensive care unit (ICU), the drug may be administered to intubated, mechanically ventilated adult patients to provide continuous sedation and control of stress responses. It has an almost immediate onset of action and is used effectively for conscious sedation. Emergence from anesthesia is rapid, and few adverse effects occur during recovery. Unlike other anesthetics that cause nausea and vomiting, propofol has an antiemetic effect that can prevent nausea and vomiting in patients receiving chemotherapy. Off-label uses include refractory migraines, refractory status epilepticus, and the treatment of agitation associated with alcohol withdrawal.

Mechanism of Action: The exact mechanism by which propofol produces anesthesia is not clear. It is believed to act by activating GABA receptors, which causes a general inhibition of CNS activity.

Pharmacokinetics:

Route(s)	IV
Absorption	Rapid
Distribution	Widely distributed to body tissues; highly protein bound
Primary metabolism	Hepatic
Primary excretion	Renal
Onset of action	Immediate
Duration of action	IV: 10–15 min

Adverse Effects: Injection-site pain, apnea, respiratory depression, and hypotension are common adverse effects. Propofol has been associated with a collection of metabolic abnormalities and organ system failures, referred to

as propofol infusion syndrome (PRIS). The syndrome is characterized by severe metabolic acidosis, hyperkalemia, lipemia, rhabdomyolysis, hepatomegaly, and cardiac and kidney failure. PRIS is usually associated with prolonged, high-dose infusions of the drug. Deaths have resulted from this syndrome.

Contraindications/Precautions: Propofol is contraindicated in patients who have a known hypersensitivity reaction to the medication or its emulsion, which contains soybean and egg products. The emulsion supports rapid microorganism growth; unused portions must be discarded. Obstetric patients and those with increased ICP should not be administered propofol. The drug should be used with caution in patients with cardiac or respiratory impairment. It is not recommended for induction of anesthesia in children younger than 3 years. Although not a controlled substance, incidences of propofol abuse have occurred, including the high-profile case of Michael Jackson, a famous musician, who used this medication (among others) to induce sleep.

Drug Interactions: The dose of propofol should be reduced in patients receiving preanesthetic medications such as opioids or benzodiazepines. Use with other CNS depressants can cause additive CNS and respiratory depression. **Herbal/Food:** Unknown.

Pregnancy: Category B.

Treatment of Overdose: Overdose will produce cardiac and respiratory depression. The treatment includes mechanical ventilation of the patient, increasing the flow rate of IV fluids, and administering vasopressor agents as needed to maintain blood pressure.

Nursing Responsibilities: Key nursing implications for patients receiving propofol are included in the Nursing Practice Application for Patients Receiving General Anesthesia.

Drugs Similar to Propofol

Other miscellaneous IV anesthetics include etomidate, ketamine, and methohexital. Thiopental sodium (Pentothal) was the gold standard for IV anesthetics for over 70 years. The sole U.S. manufacturer of this drug decided to discontinue the drug in the United States in 2010, likely because of the greater effectiveness, and relative safety of propofol.

Etomidate (Amidate): Approved in 2007, etomidate is a hypnotic drug indicated for the IV induction of general anesthesia for short medical–surgical procedures such as cardioversion, endotracheal intubation, or reduction of dislocations. It is also approved to supplement anesthesia produced by low-potency drugs such as nitrous oxide. It has a very rapid onset of action and hypotension is uncommon. It provides only 5 to 10 minutes of anesthesia. A major adverse effect is that it suppresses corticosteroid synthesis and can cause dangerous adrenal insufficiency if used for long periods. Concurrent use of opioids or benzodiazepines can worsen this suppression. This drug is pregnancy category C.

Ketamine (Ketalar): Approved in 1970, ketamine is an IV anesthetic that was initially used in veterinary medicine. It is a rapid-acting drug that produces a trance-like feeling of being separated from the environment called **dissociative anesthesia**. When used alone, ketamine is indicated during surgeries and brief diagnostic procedures that do not require skeletal muscle relaxation. It is also used prior to the administration of other general anesthetic agents. Ketamine is used with pediatric patients due to its rapid induction of general anesthesia and the fact that it lasts up to 25 minutes. Ketamine has strong analgesic actions and immediately increases blood pressure and skeletal muscle tone. The patient's eyes may be open during the surgical procedure.

Ketamine is a common drug of abuse that is known by the names jet, super acid, Special K, green K, and cat Valium. It is a club drug that is similar to phencyclidine (PCP), which is popular among teens and young adults. It is easily added to drinks or administered through injection to cause temporary amnesia and is sometimes referred to as a date-rape drug (see Chapter 27). Potentially serious cardiovascular adverse effects of ketamine include hypertension (HTN) and tachycardia. Respiratory depression occurs with the administration of IV ketamine. The most serious neurologic adverse effect is emergence phenomena in adult patients, which can occur for 24 hours postoperatively. Emergence phenomena include delirium, hallucinations, confusion, excitement, and irrational behavior. Ketamine is a Schedule III drug and is pregnancy category C.

Methohexital (Brevital): Approved in 2001, methohexital is a barbiturate general anesthetic agent that can be used to induce general anesthesia or administered as a continuous IV infusion. It is also approved to supplement anesthesia produced by low-potency drugs such as nitrous oxide. Like other IV anesthetics, it has a rapid onset, a short duration of action, and a relatively fast recovery period. IM and rectal forms are available for use in children. Severe adverse reactions include respiratory depression, laryngospasm, and hypotension. Adverse CNS effects may persist for 24 hours and include confusion, delirium, somnolence, anxiety, and seizures. Other adverse events include shivering, nausea, vomiting, and anaphylaxis. Methohexital is a Schedule IV controlled substance. Details on the mechanisms of action of barbiturates and their applications as sedatives may be found in Chapter 18. This drug is pregnancy category B.

Inhalation Anesthetics

26.7 Inhalation anesthetics used to produce loss of consciousness are classified as gases or volatile liquids.

Following the administration of IV agents, inhalation anesthetics are given to rapidly produce unconsciousness and total analgesia. Inhalation anesthetics are supplied as gases or volatile liquids. These drugs produce their effects on the CNS by inhibiting the flow of sodium into neurons, which delays the nerve impulses and dramatically reduces the activity of the neurons. Although the mechanism of action is incompletely understood, inhibitory GABA receptors in the brain become active and are thought to be responsible for the anesthetic action. This action is similar to that of the antiepileptic medications described in Chapter 22. Other CNS neurotransmitters likely contribute to the sedative effects of the inhalation anesthetics.

The first general anesthetic was the gas diethyl ether, which was discovered in the 1840s. Although popular for over 100 years, gaseous anesthetics were explosive and presented a danger to the surgical team members, who were exposed to fumes from the drugs. Furthermore, the gases produced a very high incidence of nausea and vomiting following the procedure. The only gaseous anesthetic in use today is nitrous oxide.

The potency of inhalation anesthetics is described by the **minimum alveolar concentration**: the concentration of drug vapor in the alveoli that prevents a motor response in 50% of patients when exposed to a painful stimulus. A low value of minimum alveolar concentration indicates that a very small amount of anesthetic is needed to immobilize the patient. Inhalation anesthetics have low minimum alveolar concentrations and are thus very potent. The exception is nitrous oxide, which is a low-potency anesthetic with a high minimum alveolar concentration value. The minimum alveolar concentration changes with the age of the patient. It is lowest in newborns, peaks in infants, and gradually declines with age.

Inhalation anesthetics are rapidly absorbed from the alveoli into the general circulation. The anesthesiologist controls the length and depth of anesthesia by delivering the exact concentration of drug needed to maintain a desirable degree of immobility. These drugs are very lipid soluble and quickly cross the blood–brain barrier to produce sedating effects. Metabolism of inhalation anesthetics is minimal, and elimination of the drug is mostly by exhalation. Modern anesthetics are designed to have a fast recovery time so that the patient regains consciousness soon after the infusion is stopped. Because anesthetics are lipid soluble, they are stored in fat and slowly released, which explains why patients with obesity may take longer to recover from anesthesia.

CONNECTIONS: Using Research in Practice

Malignant Hyperthermia and Anesthetic Agents

Malignant hyperthermia is a rare and potentially fatal condition that occurs when a susceptible individual receives certain triggering medications (e.g., succinylcholine) during anesthesia. A genetic predisposition to malignant hyperthermia has been discovered, and recent research suggests a potential link between a previous diagnosis of statin-associated myopathy from the cholesterol drug group and the risk of malignant hyperthermia (Hedenmalm, Granberg, & Dahl, 2015). Patients with other preexisting musculoskeletal conditions, especially those that are genetically linked, may be at greater risk, even if the true incidence of malignant hyperthermia occurring in these populations is unknown. It has also been noted that the onset of malignant hyperthermia is different for different anesthetic agents. Patients given the anesthetic halothane had earlier onset of malignant hyperthermia than those given other anesthetics when succinylcholine was used concurrently (Visolu, Young, Wieland, & Brandom, 2014). It is also known that not all cases of malignant hyperthermia occur immediately, but instead occur over a longer period of time with insidious onset of hypermetabolic symptoms such as hypercapnia, elevated temperature, and evidence of rhabdomyolysis (Heytens, Forget, Scholtès, & Veyckemans, 2015).

The nurse plays a key role in assessing a patient for possible malignant hyperthermia risk during the preoperative period. Existing myopathies, unusual heat-associated illnesses in a child or adult, or previous history of statin-associated myopathy should be noted and the anesthesiologist or anesthetist alerted. A personal or immediate-family history of problems with previous anesthetic use should also be noted. Symptoms of malignant hyperthermia often begin with unexplained tachycardia. Jaw muscle spasms and rigidity may occur, followed by a dramatic increase in body temperature, rhabdomyolysis indicated by dark brown-colored urine, dysrhythmias, and potential death. Any patient experiencing mild spasms in the jaw muscles must be observed more closely for development of malignant hyperthermia for at least 10 hours postprocedure. Patients with darkened urine or with severe jaw rigidity should be hospitalized overnight postoperatively to observe for the development of malignant hyperthermia.

PROTOTYPE DRUG **Nitrous Oxide**

Classification **Therapeutic:** Gaseous general anesthetic
Pharmacologic: GABA-receptor agonist, opioid agonist

Therapeutic Effects and Uses: Nitrous oxide is an odorless, nonirritating, inorganic gas used for a large number of medical and surgical procedures. When administered

alone it is one of the least potent anesthetics and is unable to induce deep anesthesia at therapeutic doses. Because of its low potency, the use of nitrous oxide is either limited to minor surgical procedures or combined with the IV anesthetic agents for more complex procedures. The majority of patients requiring sedation for dental, diagnostic, and surgical procedures are administered nitrous oxide.

One major advantage of nitrous oxide is that it has strong analgesic properties. At a concentration of 20%, nitrous oxide delivers analgesic efficiency equaling that of morphine. This agent has a low potency and does not produce loss of consciousness or profound skeletal muscle relaxation.

Nitrous oxide is always combined with oxygen (25–30%) and is administered in a semiclosed method. The patient may be administered an IV anesthetic to produce sedation. When drowsy or asleep, the patient inhales the nitrous oxide through a tube or by mask. Nitrous oxide is also used for dental procedures in which the mask is placed over the nose. Other procedures in which nitrous oxide is administered include those related to obstetrics and surgery. Nitrous oxide lowers the minimum alveolar concentration of other anesthetics, essentially making them more potent. This permits a decrease in the dosages required for IV and inhalation anesthetics.

Nitrous oxide has been used illegally to produce relaxation, euphoria, and hallucinations. Abusers may steal the nitrous oxide tanks from medical facilities. The gas has also been used as a propellant in whipped cream canisters and cooking sprays, and abusers can obtain small amounts from those sources. Long-term abuse can lead to anemia, depletion of vitamin B_{12}, tinnitus, and peripheral neuropathy.

Mechanism of Action: The mechanism of action of nitrous oxide is not fully known. Its analgesic effects are believed to be due to activation of opioid receptors in the midbrain. The relaxation properties of the drug are likely due to activation of GABA receptors, which inhibits neuronal firing.

Pharmacokinetics:

Route(s)	Inhalation
Absorption	Rapid
Distribution	Crosses the blood–brain barrier to concentrate in the nerve cells
Primary metabolism	Not metabolized
Primary excretion	100% through the lungs, unchanged
Onset of action	2–5 min
Duration of action	Half-life is variable; peak effect: less than 10 min

Adverse Effects: When administered in low to moderate doses, nitrous oxide produces few adverse effects. When administered in higher doses, patients exhibit some adverse effects of stage 2 anesthesia such as anxiety, excitement, and combativeness. Lowering the inhaled dose quickly reverses these adverse effects. Because nitrous oxide is exhaled, the patient may temporarily have some difficulty breathing at the end of the procedure.

Rapid diffusion of the gas from the bloodstream back into the lungs causes alveolar hypoxia, with symptoms that include nausea, vomiting, lethargy, and dizziness. Some patients describe these symptoms as equivalent to a "hangover" from too much alcohol consumption. Alveolar hypoxia can be prevented by breathing 100% oxygen for several minutes following the conclusion of nitrous oxide therapy.

Contraindications/Precautions: When patients must be awake and follow the instructions of the physician or dentist, nitrous oxide is contraindicated in those with an impaired level of consciousness or an inability to comply with instructions. Because the diffusion of nitrous oxide may lead to expansion of closed spaces, its use in patients with conditions such as undiagnosed abdominal pain, abdominal distention, bowel obstruction, head injury, or pneumothorax is contraindicated. Patients who have hypotension, shock, chronic obstructive pulmonary disease, cyanosis, or chest pain should not be administered nitrous oxide.

Drug Interaction: The administration of adrenergic agonists (such as epinephrine) or caffeine with nitrous oxide may exacerbate dysrhythmias. Use with CNS depressants may cause additive sedation and respiratory depression. Excessive hypotension may result if amiodarone or antihypertensive drugs are used concurrently with nitrous oxide. **Herbal/Food:** Milk thistle taken before and after anesthesia may lower the potential risk of liver damage. St. John's wort should be discontinued 2 to 3 weeks prior to administration of general anesthetics due to possible hypotension risk.

Pregnancy: Category C.

Treatment of Overdose: Effects of the drug usually diminish quickly after the gas is discontinued. Metoclopramide (Reglan) or another antiemetic agent may be administered to reduce the nausea and vomiting associated with nitrous oxide.

Nursing Responsibilities: Key nursing implications for patients receiving nitrous oxide are included in the Nursing Practice Application for Patients Receiving General Anesthesia.

Drugs Similar to Nitrous Oxide

Nitrous oxide is the sole gaseous general anesthetic.

PharmFACT

The recreational use of nitrous oxide is rising, especially at festivals and clubs. In these circumstances, the drug is inhaled from gas-filled balloons and produces hallucinations and confusion as desired effects (Kaar et al., 2016).

26.8 Volatile liquid general anesthetics are used to induce and maintain deep anesthesia.

The volatile liquids form a second class of inhalation anesthetics. The volatile liquid drugs have a low vapor pressure that allows them to vaporize (form a gas) at low temperatures and pressures. An anesthesia machine is used to vaporize the liquid, mix the vapors with oxygen and air, and deliver them to patients in precisely controlled amounts. The anesthesia machine also establishes a partial pressure gradient that ensures the anesthetic will continue to flow from the machine to the alveoli, to the blood, and eventually to the brain. Like the gases, the volatile liquid anesthetics are lipid soluble and rapidly cross the blood–brain barrier to cause sedation.

Desflurane (Suprane), isoflurane (Forane), and sevoflurane (Ultane) are the most widely used of the volatile liquid anesthetics. All of these drugs have a rapid onset of action.

The minimum alveolar concentrations of the volatile liquid anesthetics are very low, making them very potent. This factor contributes to the ability of these drugs to rapidly produce unconsciousness at low doses. Although they have the ability to produce deep anesthesia, they produce little analgesia and are usually used in combination with nitrous oxide and opioids as part of balanced anesthesia.

Some volatile liquid anesthetics sensitize the heart to the action of catecholamines such as epinephrine, norepinephrine, and dopamine and can cause serious dysrhythmias. These drugs also depress cardiovascular and pulmonary function, placing the patient at risk for laryngospasm or respiratory arrest. The gaseous and volatile liquid anesthetics are listed in Table 26.3.

PROTOTYPE DRUG **Isoflurane (Forane)**

Classification **Therapeutic:** Inhaled general anesthetic
Pharmacologic: GABA and glutamate receptor agonist

Therapeutic Effects and Uses: Approved in 1979, isoflurane has become a preferred inhalation anesthetic due to its effectiveness and favorable safety profile. Isoflurane provides smooth and rapid induction of general anesthesia with a low degree of metabolism by the body. It is almost entirely eliminated through respirations. The drug provides excellent muscle relaxation. It is FDA approved for the induction and maintenance of general anesthesia and may be used off-label as adjuvant therapy in the treatment of status asthmaticus.

Isoflurane does not sensitize the myocardium for dysrhythmias, and it produces fewer cardiovascular effects than other general anesthetics. Isoflurane does not cause the hepatotoxicity observed with halothane.

Mechanism of Action: The exact mechanism of action of isoflurane is unknown. It interacts with multiple receptors in the brain, including glutamate and GABA receptors.

Pharmacokinetics:

Route(s)	Inhalation
Absorption	Rapidly absorbed by the lungs
Distribution	Crosses the blood–brain barrier to concentrate in neurons; unknown if it is secreted in breast milk
Primary metabolism	Minimal metabolism
Primary excretion	95% pulmonary
Onset of action	7–10 min for surgical anesthesia
Duration of action	Patient begins to regain consciousness less than 1 h after drug is discontinued

Table 26.3 Inhalation Anesthetics

Drug	Adult Concentration	Adverse Effects
Gas		
nitrous oxide	70% with 30% oxygen	*Anxiety, nausea, vomiting* Hypoxia, hallucinations, disorientation
Volatile Liquids		
desflurane (Suprane)	7.3% concentration	*Nausea, vomiting, shivering* Laryngospasm, hypotension, apnea, increased secretions, vasodilation, respiratory depression, tachycardia, malignant hyperthermia,
enflurane (Ethrane)	0.5–3% concentration	
isoflurane (Forane)	0.1–2% concentration	
sevoflurane (Ultane)	0.5–3% concentration	

Note: *Italics* indicate common adverse effects. Underline indicates serious adverse effects.

Adverse Effects: Mild nausea, vomiting, and tremor are common adverse effects. The drug produces a dose-dependent respiratory depression and a reduction in blood pressure. Malignant hyperthermia with elevated temperature and unstable blood pressure has been reported, although the incidence is rare.

Contraindications/Precautions: Patients with a known history or genetic predisposition to malignant hyperthermia should not use isoflurane. Caution should be used when treating patients with head trauma or brain neoplasms due to possible increases in ICP. Safety has not been established in patients under age 18. Older adult patients are more susceptible to the cardiovascular effects of the drug. Patients with a prolonged QT interval should be administered isoflurane with caution.

Drug Interactions: Coughing, breath holding, or laryngospasm may occur when used concurrently with nitrous oxide. Skeletal muscle weakness, respiratory depression, or apnea may occur if isoflurane is administered concurrently with systemic polymyxin or aminoglycosides. Additive effects can occur if isoflurane is administered with other skeletal muscle relaxants. Additive hypotension may result if used concurrently with antihypertensive medications such as beta-adrenergic blockers. Epinephrine, norepinephrine, dopamine, and other adrenergic agonists should be administered with caution because of the possibility of dysrhythmias. Levodopa should be discontinued 6 to 8 hours before isoflurane administration. Isoflurane should be administered with caution with other drugs that prolong the QT interval, such as amiodarone, ibutilide, droperidol, and phenothiazines. **Herbal/Food:** St. John's wort should be discontinued 2 to 3 weeks prior to administration of general anesthetics due to possible hypotension risk.

Pregnancy: Category C.

Treatment of Overdose: Isoflurane causes profound respiratory depression. The patient is treated symptomatically until the effects of the drug diminish.

Nursing Responsibilities: Key nursing implications for patients receiving isoflurane are included in the Nursing Practice Application for Patients Receiving General Anesthesia.

Drugs Similar to Isoflurane (Forane)

Volatile liquid anesthetics similar to isoflurane include desflurane, enflurane, and sevoflurane. Halothane (Fluothane), the historical prototype for this drug class, was voluntarily removed from the market due to a small incidence of fatal hepatitis associated with the drug.

Desflurane (Suprane): Desflurane, approved in the 1990s, produces a rapid induction of general anesthesia. It is administered to induce and maintain anesthesia in adults. When administered to children it is used to maintain anesthesia. Adverse effects of desflurane are laryngospasm, apnea, and increased pulmonary secretions. The drug produces a dose-dependent reduction in blood pressure, and malignant hyperthermia has been reported. Desflurane must be used with IV anesthetics because it may cause coughing and excitation during induction. It does not sensitize the myocardium for dysrhythmias. This is a pregnancy category B drug.

Enflurane (Ethrane): Approved in 1972, enflurane is administered for induction and maintenance of general anesthesia, usually in conjunction with other agents as a component of balanced anesthesia. It is approved for obstetric anesthesia. It has strong muscle relaxant properties. It does not sensitize the myocardium for dysrhythmias, and postanesthesia nausea, vomiting, and CNS stimulation are uncommon. When administered in high concentrations, however, it can cause seizures and is thus contraindicated in patients with a history of seizure disorders. Rare cases of malignant hyperthermia have been reported, and enflurane is contraindicated in patients with a history of this disorder. This is a pregnancy category B drug.

Sevoflurane (Ultane): Approved in 1995, sevoflurane is a volatile liquid general anesthetic agent that is administered to induce and maintain sedation. It has a faster uptake, distribution, and elimination than isoflurane. It also does not cause the cardiovascular reactions commonly encountered with some of the other general anesthetics, and it is safer to use in patients with coronary artery disease. Sevoflurane does not cause respiratory irritation and is safe for administration with children. Furthermore, this drug does not cause coughing and excitation during induction and can thus be used without IV anesthetics. Sevoflurane produces a dose-dependent reduction in blood pressure, and malignant hyperthermia has been reported. This is a pregnancy category B drug.

Local Anesthetics

26.9 Local anesthetic agents block pain transmission in peripheral nerves and are grouped in two major classes.

Local anesthesia results in the loss of sensation to a small, limited area of the body. The primary advantage of local anesthesia is that pain relief can be provided without causing generalized depression of the CNS and respiratory systems. The nausea, vomiting, tremors, and anxiety associated with general anesthetic recovery are avoided. The types of adverse events associated with local anesthesia are relatively minor relative to the potential risks of general anesthesia.

CONNECTIONS: NURSING PRACTICE APPLICATION

Patients Receiving General Anesthesia

Assessment

Baseline assessment prior to administration:

- Obtain a complete health history including cardiovascular, respiratory, hepatic, renal, or neurologic disease, pregnancy, or breastfeeding. Obtain a drug history including allergies, current prescription and OTC drugs, herbal preparations, caffeine, nicotine, and alcohol use. Be alert to possible drug interactions.
- Assess for previous history of anesthesia and note any significant reactions. Obtain family history of anesthesia problems, particularly related to use of neuromuscular blockers (e.g., succinylcholine), or any unusual effects related to surgery.
- Obtain baseline vital signs, height, and weight. Note day and hour the patient last ate or drank.
- Evaluate laboratory findings appropriate to the procedure (e.g., complete blood count [CBC], electrolytes, hepatic or renal function studies, MRI or CT scan results).
- Obtain required preoperative paperwork (e.g., informed consent, completed history and physical examination).
- Administer any preoperative adjunctive drugs (e.g., sedative, analgesic) as ordered.
- Assess the level of anxiety, and any concerns or questions the patient, family, or caregiver may have. Reinforce preoperative teaching, including deep-breathing exercises. Provide the family or caregiver with information on the anticipated length of the procedure, the waiting room area, and telephone and cafeteria or food availability.
- **Lifespan**: For pediatric patients, allow the parents or caregiver to stay with the child as long as agency policy permits to decrease patient anxiety. Provide a simple explanation of the procedure appropriate for the age of the child.
- **Lifespan**: When working with older adults, note assistive devices (e.g., glasses, hearing aids) and remove only when necessary. Give to the family or caregiver or provide for safekeeping. Ensure that devices are available in the postoperative period.
- Initiate IV access site if required for the procedure.
- Assess the patient's ability to receive and understand instructions. Include family and caregivers as needed.

Assessment throughout administration:

- Assess for desired therapeutic effects (e.g., diminished level of consciousness).
- Assess vital signs, especially blood pressure and pulse, frequently. Report blood pressure less than 90/60 mmHg, pulse above 100 beats/min, or per the parameters as ordered by the healthcare provider.
- Maintain operative sterility throughout the procedure.
- Assess level of consciousness in the postoperative period. Continue frequent monitoring of vital signs and pulse oximetry.
- Assess for and promptly report adverse effects: bradycardia or tachycardia, hypotension or HTN, dysrhythmias, dyspnea, jaw muscle rigidity, or dark brown-colored urine.

Implementation

Interventions and (Rationales)	Patient-Centered Care
Ensuring therapeutic effects: • Continue assessments as above for therapeutic effects. Provide for patient safety during preoperative and operative periods, and assess level of consciousness, vital signs, and return of motor and sensory sensation postoperatively. (Duration of anesthetic action will depend on the drugs used and adjunctive or reversal agents used.)	• Provide a quiet environment postoperatively, and frequently orient the patient to the postanesthesia care unit (PACU).
• Assess for shivering in the postoperative period and provide additional blankets or warmth as needed. (General anesthetics depress the CNS and some autonomic activity. As autonomic activity returns, shivering is common. Warm blankets provide comfort during this period.)	• Continue to orient the patient in the postoperative period, and allay anxiety about shivering.
Minimizing adverse effects: • Continue to monitor vital signs frequently, including temperature. Report blood pressure below 90/60 mmHg or per the parameters as ordered by the healthcare provider, tachycardia or significant bradycardia, dysrhythmias, or dyspnea. Report any jaw muscle rigidity or brown-colored urine and fever immediately. (CNS depression will cause decreases in all vital signs but significant bradycardia, hypotension, decreased respiratory rate, or dyspnea should be reported promptly. **Lifespan:** The older adult is more sensitive to the effects of anesthesia and may be more likely to experience adverse effects such as hypotension and delirium. Malignant hyperthermia associated with succinylcholine and some anesthetics is a rare but potentially fatal adverse effect. Early symptoms include unexplained tachycardia, jaw muscle spasms or rigidity, and brown-colored urine.)	• Explain all procedures and monitoring to the patient. Continue to reorient the patient to surroundings frequently in the postoperative period.
• Provide adequate pain relief in the immediate postoperative period. (General anesthetics do not necessarily provide analgesia, dependent on the agent. Adequate pain relief begins ideally in the preoperative period. Assess for nonverbal signs of pain such as restlessness or grimacing as the patient regains consciousness.)	• Provide the rationale for pain relief preoperatively and encourage the patient to request pain medication as able. Assure the patient, family, or caregiver that pain needs will be frequently monitored.
• Encourage the patient to take deep breaths and move lower extremities frequently in the postoperative period. (General anesthetics given by inhalation are excreted via the lungs. Deep breathing assists in removing remaining anesthetic. Early range-of-motion exercises may help prevent venous thrombosis and complications.)	• Teach the patient deep-breathing exercises in the preoperative period, and that early movement of legs will be encouraged in the early postoperative period, unless otherwise ordered by the provider.

CONNECTIONS: NURSING PRACTICE APPLICATION (*continued*)

Implementation	
Interventions and (Rationales)	**Patient-Centered Care**
• Ensure patient safety in the postoperative period. Frequently orient the patient to surroundings, day, and time and maintain a safe environment. (During the period of anesthesia, consciousness is lost along with the ability to orient to day, time, and person. Confusion related to these effects in the postoperative period is common. Use of safety measures such as side rails may be necessary until the patient regains consciousness.)	
• For patients receiving ketamine and other drugs causing neurolept analgesia, provide a quiet, calm environment postprocedure. Avoid overstimulating the patient while taking vital signs. Use a soft touch and voice to explain all procedures performed. (During recovery from neurolept analgesia drugs, confusion and misinterpretation of sensory stimulation may cause extreme anxiety, fear, or paranoia. Keep all stimuli to a minimum until the patient regains full consciousness.)	• Explain the full procedure and required postprocedural care to the patient, family, or caregiver. Alert the family or caregiver that visiting may be restricted during the immediate recovery period in order to minimize sensory stimulation.
• **Lifespan and Diverse Patients:** Continue to monitor hepatic function. (*Lifespan:* Normal physiologic changes related to aging may increase the risk of toxicity in the older adult requiring drugs with hepatic metabolism. *Diverse Patients:* Because drugs such as fentanyl and midazolam are metabolized through the CYP450 system, they may result in less than optimal results based on differences in enzymes.)	• **Lifespan:** Monitor hepatic laboratory values pre- and postoperatively and report abnormalities. • **Diverse Patients:** Monitor for therapeutic and adverse effects frequently in ethnically diverse patients.
Patient understanding of drug therapy: • Use opportunities during the preoperative period to discuss the rationale for the drug therapy, desired therapeutic outcomes, commonly observed adverse effects, and any necessary monitoring or precautions. (Using time during nursing care helps to optimize and reinforce key teaching areas.)	• The patient should be able to state the reason for the drug(s), anticipated sensations, and adverse effects to observe for, and when to report them.

Patient self-administration of drug therapy:
• When administering fentanyl for analgesia, instruct the patient, family, or caregiver in the proper self-administration of the drug. (Utilizing time during nurse administration of these drugs helps to reinforce teaching.)
	• Teach the patient to:
	  • Remove old fentanyl patches and dispose of them safely because they may still contain some medication.
	  • Apply the new fentanyl patch to clean, dry skin. Press firmly on the patch for 30 seconds to ensure proper skin contact.
	  • Not split, chew, or swallow the transmucosal or buccal forms of fentanyl.

Several techniques are used to deliver local and regional anesthesia. The method employed is dependent on the location and extent of the desired anesthesia (Figure 26.1):

- **Topical (surface) anesthesia.** The drug is applied or sprayed directly on the surface of the skin or mucous membrane. The anesthesia does not penetrate into deeper skin layers. This is used to provide relief for minor skin irritations or prior to needlesticks.
- **Nerve block.** The drug is injected surrounding a peripheral nerve and all regions innervated by the nerve lose sensation. This is used for dental procedures or for regional anesthesia.
- **Infiltration anesthesia.** The drug is injected into deeper skin layers and travels to surrounding regions. This provides pain relief during minor skin surgeries or dental procedures, or prior to deep needlesticks.
- **Spinal anesthesia.** The drug is injected into the cerebrospinal fluid, usually in the lumbar region. This procedure is used to block sensation to larger areas of the lower abdomen or pelvis.
- **Epidural anesthesia.** The drug is injected into the epidural space surrounding the spinal cord. The anesthetic blocks sensation to multiple nerve roots supplying limited regions of the chest, pelvis, abdomen, or limbs. It is used for urologic and obstetric procedures.

Although safer than general anesthetics, the healthcare provider has less control over the onset and duration of drug action with local anesthetics. The onset of local anesthesia is dependent on the drug's ability to diffuse from the application site to the surrounding nerves. In general, local anesthetics are small, lipid-soluble molecules that can move quickly through tissues and spaces to enter neurons. Local anesthetics are nonselective; they will block transmission at all types of sensory nerves. The sense of sharp pain is usually affected first, followed by other senses such as warmth, cold, touch, and pressure. Motor fibers are also affected by local anesthetics.

Termination of local anesthetic action depends on blood flow to the region. Local blood vessels carry the drug away from the application site to the systemic circulation, where it is metabolized and excreted. Usually only minimal systemic effects are observed because absorption into the general circulation is slow and the drug is sufficiently diluted by the blood.

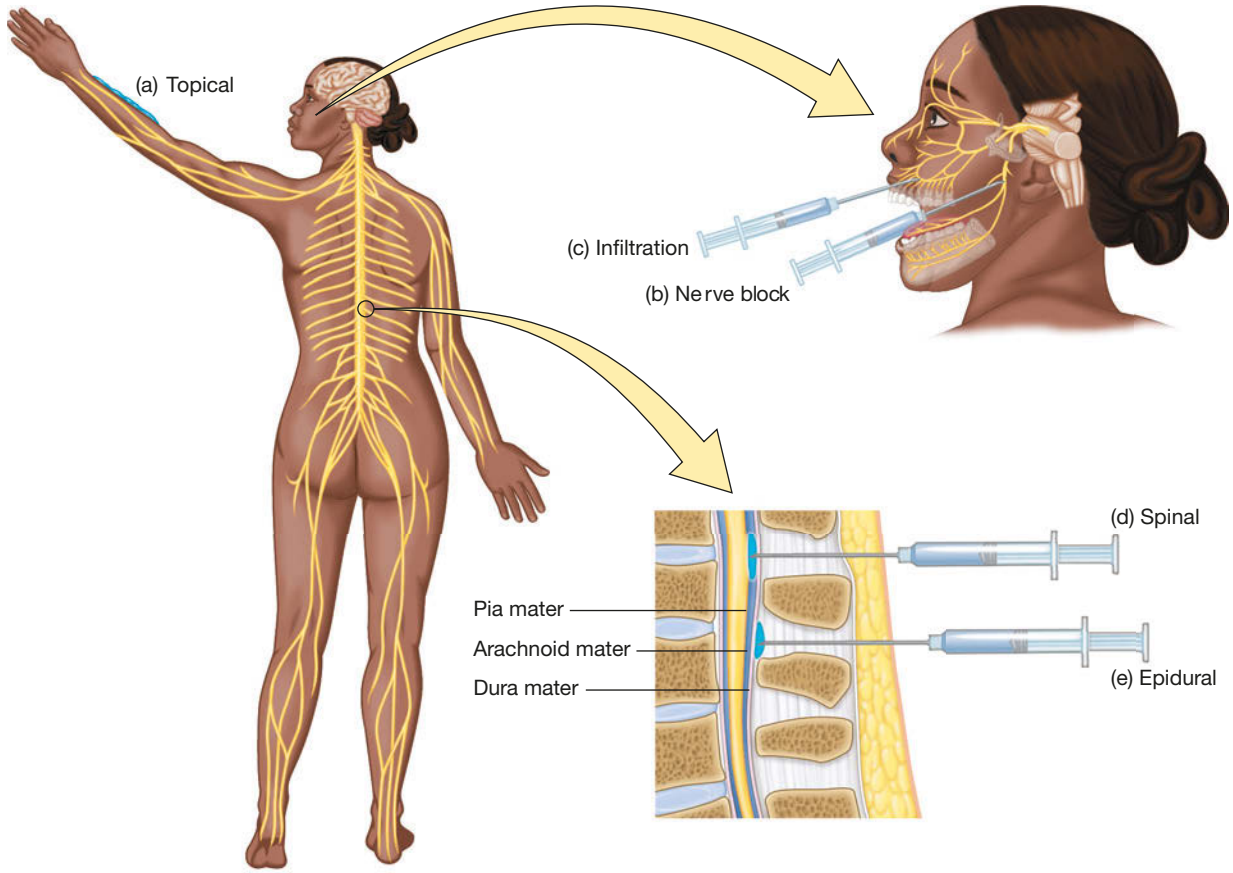

Figure 26.1 Techniques for applying local anesthesia: (a) topical; (b) nerve block; (c) infiltration; (d) spinal; (e) epidural.

The duration of anesthetic action may be extended by injecting a vasoconstrictor such as epinephrine in combination with the local anesthetic. The epinephrine reduces blood flow to the region and slows absorption of the anesthetic. This not only extends the duration of anesthesia, it also prevents the anesthetic from reaching the circulation too quickly, which could result in systemic toxicity. The amount of epinephrine used in local anesthesia is very small and it is released very slowly into the systemic circulation; therefore, adverse effects from the epinephrine are rare.

The two major classes of local anesthetics are named by their chemical structures: esters and the amides. The two classes differ primarily by their incidence of allergic reactions, with the amide type having the lower incidence. Although they vary in time of onset and duration of action, most local anesthetics have equivalent effectiveness. The local anesthetics are listed in Table 26.4.

CONNECTIONS: Lifespan Considerations

Postoperative Cognitive Dysfunction and Delirium in the Older Adult After Surgery

Postoperative cognitive dysfunction (POCD) has been noted after cardiac surgery in the older adult population. Symptoms include transient confusion and declines in cognitive skills such as word recall, word learning, and memory. POCD also occurs after other types of surgeries as well. Older adults are also at greater risk for delirium, with an estimated 13% to 50% of older adult patients developing delirium postoperatively (Inouye, Westendorp, & Saczynski, 2014). Adults with a higher risk included those over the age of 70, those with a history of dementia or cognitive dysfunction, and those with a history of alcohol abuse or with the use of preoperative opioids (Murthy, Hepner, Cooper, Bader, & Neuman, 2015).

The American Geriatrics Society and the American College of Surgeons have published best practice guidelines for managing the perioperative course of older adults (American Geriatrics Society Expert Panel on Perioperative Delirium in Older Adults, 2015; Mohanty et al., 2016). To reduce the risk of postoperative delirium, it is recommended that benzodiazepines, meperidine, and drugs with anticholinergic side effects such as antihistamines (H_1 blockers) be avoided.

Table 26.4 Local Anesthetics

Drug	Route and Adult Dose (Maximum Dose Where Indicated)	Adverse Effects
Ester Type		
benzocaine (Americaine, Anbesol, others)	Topical: 5–8% spray, cream, ointment 20% spray, ointment, gel, liquid, otic solution	**Topical applications:** *Erythema, dermatitis, burning* Anaphylaxis **Infiltration, nerve block, epidural applications:** *Postspinal headache, sedation, paresthesia, blurred vision, urinary retention* Myocardial depression, anaphylactic reactions, cardiac arrest, respiratory arrest, seizures, fetal bradycardia
chloroprocaine (Nesacaine)	Infiltration and nerve block: 1–2% solution (max: 800 mg without epinephrine, 1 g with epinephrine) Caudal and epidural block: 2–3% solution (max: 800 mg without epinephrine, 1 g with epinephrine)	
procaine (Novocaine)	Spinal: 10% solution diluted in normal saline at 1 mL/5 sec subcutaneous Infiltration or peripheral nerve block: 0.25–0.5% solution subcutaneous	
tetracaine (Pontocaine)	Topical: 1–2 drops of 0.5% solution or 1.25–2.5 cm of ointment or 0.5% solution to the nose or throat Spinal: 1% solution diluted with equal volume of 10% dextrose injected in the subarachnoid space	
Amide Type
