This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals

are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

LWW.com

We dedicate this book to all our students. This book never would have come to fruition without the impact of the students who have touched our lives. It is our hope that this book and its evolution into the fourth edition has influenced more than just our students but that it has helped to promote excellence in patient care through all of its users.

PREFACE

Pharmacotherapeutics for Advanced Practice originated from our combined experience in teaching nurse practitioners and in practice in primary care. As a nurse practitioner and educator herself, Virginia saw a need for practical exposure to the general principles of prescribing and monitoring drug therapy, particularly in the Family Practice arena. As a PharmD, Andrew saw a need to be able to teach new prescribers how to think about prescribing systematically, regardless of the disease state. For this edition, we have expanded the editorial staff to include Veronica F. Wilbur and Jennifer Reinhold. Veronica, a Family Nurse Practitioner and PhD in Nursing, has extensive experience in education of Advanced Practice Nurses and primary care practice. Jennifer, a PharmD, has expertise in pharmacotherapy and prescribing in primary care. Both of these colleagues were contributors in previous editions and understand the focus, intent, and direction of this text.

This edition still provides basic pharmacology, while also providing a process and framework through which learners can begin to think pharmacotherapeutically. The text still allows learners to identify a disease, review the drugs used to treat the disease, select treatment based on goals of therapy and special patient considerations, and adjust therapy if it fails to meet goals.

This text meets the needs of both students and practitioners in a practical approach that is user friendly. It teaches the practitioner how to prescribe and manage drug therapy in primary care. The book has evolved over the years, based on input from students, academicians, and practitioners. Long-standing contributors were asked to update their chapters, and new contributors were selected based on their academic or practice expertise to provide a combination of evidence-based medicine and practical experience. The text considers disease- and patient-specific information. With each chapter, there are tables and evidence-based algorithms that are practical and easy to read and that complement the text.

Additionally, the text guides the practitioner to a choice of second- and third-line therapy when the first line of therapy fails. Since new drugs are being marketed continually, drug classes are discussed with a focus on how the broader, class-specific properties can be applied to new drugs. Each chapter ends with a simple case study or series of questions designed to prompt the learner to think systematically and the teacher to ask critical questions. Also, the disorder chapter's case study asks the same questions; reinforcing a clinical decision-making process and promoting critical thinking skills. There are no answers to the questions in the text since the authors believe that the purpose of the case studies is to promote discussion and that there may be more than one correct answer to each question, especially as new drugs are developed. However, one potential answer to each question in the case is available online for use by faculty. Additionally, there is an

additional case with several sample multiple-choice questions for each chapter online. We realize that there may be several answers to these questions and the authors have just provided one option. To assist faculty in the classroom, there are power point slides available online for each chapter. To assist the student, the acronyms contained in each chapter are defined in a separate file online as well.

ORGANIZATION OF THE BOOK

Unit 1—Principles of Therapeutics

As with previous editions, the Principles Unit of the book reviews basic elements of therapeutics necessary for safe and effective prescribing. The first chapter introduces the prescribing process, including how to avoid medication errors. The next two chapters provide the foundation of therapeutics, including information on the pharmacokinetics and pharmacodynamics of drugs and drug–drug/drug–food interactions. The following three chapters review how these foundations change in pediatric, pregnant, and geriatric patients. Similarly, the basics of the principles of pain management and infectious disease therapy are reviewed in the next two chapters so that the reader can learn how these concepts are applied to the disorders discussed in the following units. Updated Complementary and Alternative Medicine (CAM) and Pharmacogenomics chapters are included in this unit, recognizing the growing use of these modalities in all aspects of patient care.

Units 2 through 12—Disorders

This section of the book, consisting of 41 chapters, reviews commonly seen disorders in the primary care setting. Although not all-inclusive, the array of disorders allows the reader to gain an understanding of how to approach the pharmacotherapeutic treatment of any disorder. The chapters are designed to give a brief overview of the disease process, including the causes and pathophysiology, with an emphasis placed on how drug therapy can alter the pathologic state. Diagnostic Criteria and Goals of Therapy are discussed and underlie the basic principles of treating patients with drugs. Osteoarthritis and rheumatoid arthritis have been split and each has a chapter devoted to it. A new chapter on Parkinson Disease has been added since this is frequently treated in primary care. Each chapter has been updated with the newest therapies available at the time of writing.

The drug sections review the agents' uses, mechanism of action, contraindications and drug interactions, adverse effects, and monitoring parameters. This discussion is organized primarily by drug class, with notation to specific drugs within the text and the tables. The tables provide the reader with quick access to generic and trade names and dosages, adverse events, contraindications, and special considerations. Used together, the text and tables provide the reader with sufficient information to begin to choose drug therapy.

The section on Selecting the Most Appropriate Agent aids the reader in deciding which drug to choose for a given patient. This section contains information on first-line, second-line, and third-line therapies, with rationales for why drugs are classified in these categories. Accompanying this section is an algorithm outlining the thought process by which clinicians select an initial drug therapy. Again, the text organization and the illustrative algorithms provide readers with a means of thinking through the process of

selecting drugs for patients. In the third edition, we have kept the Recommended Order of Treatment tables and updated them, along with the algorithms and drug tables, to reflect current knowledge. Each chapter has been updated to reflect the most current guidelines available at the time of writing. However, medicine and pharmacotherapy are constantly changing, and it remains the clinician's responsibility to identify the most current information.

Included in each chapter is a section on Monitoring Patient Response. This encompasses clinical and laboratory parameters, times when these items should be monitored, and actions to take in case the parameters do not meet the specified goals of therapy. In addition, special patient populations are discussed when appropriate. These discussions include pediatric and geriatric patients but may also include ethnic- or sex-related considerations. Last, this section includes a discussion of patient education material relevant to the disease and drugs chosen. In each chapter, there is a patient education section that includes information on CAM related to that disorder as well as sections on external information for patients and practitioners.

Each of the case studies has been reviewed and updated as appropriate. However, the pedagogical style of reasoning remains the same. As previously stated, answers to these case studies are not supplied since the purpose is to promote discussion and evoke a thought process. Also, as time changes, so do therapies. The cases are short, compelling the learner to ask questions about the patient and allowing flexibility for multiple correct answers to be developed by the instructor as they work through the clinical decision-making process.

Units 13 and 14—Pharmacotherapy in Health Promotion and Women's Health

These units discuss several areas of interest for promoting health or maintaining a healthy lifestyle using medications, including smoking cessation, immunizations, and weight management; the chapter on travel medicine has been eliminated since there are specialty clinics that provide this service, and it is not done frequently in primary care. The four chapters in Women's Health assist the learner to recognize the special nature of care that this population deserves.

Unit 15—Integrative Approach to Patient Care

While there are only two chapters in this unit, they represent the culmination of the text. Practitioners need to have an understanding of the economics of pharmacotherapeutics in order to effectively prescribe medications and treat patients. This chapter is updated with information on the Affordable Care Act and its impact on therapeutic decision making while still being anchored in the basics of pharmacoeconomics, formulary decision making, co-pays, prior authorizations, and Medicare as well as managed care as it applies to prescribing medications.

The last chapter, Integrative Approaches to Pharmacotherapy, is an attempt to examine

real-life, complex cases. Each case addresses the nine questions posed in the individual chapter case studies, but now provides the reader with examples of how to approach the case studies and examines issues to consider when presented with more than one diagnosis. These cases are more complex, requiring the reader to think through multiple diseases and therapies instead of a single disorder in isolation. Within this chapter, we do offer potential answers to the cases. These may not be the only answers but indicate some of the thought processes that go into the decision-making process in the pharmacologic management of a problem.

Chapter Organization

This edition continues the consistent format approach throughout each disorder chapter. Each chapter begins with the background and pathophysiology of the disorder, followed by a discussion of the relevant classes of drugs. These broad categories are then integrated in the section on Selecting the Most Appropriate Agent.

Drug Overview Tables are also organized consistently, giving the reader much information on each drug, including the usual dose, contraindications and side effects, and any special considerations a prescriber should be aware of during therapy. Algorithms provide the reader with a visual cue on how to approach treating a patient.

Recommended Order of Treatment tables provide the reader with basic drug therapy selection, from first-line to third-line therapies for each disorder. These, coupled with the algorithms and the drug tables, are the core of the text.

A Case Study is provided for each disorder discussed. These short cases are designed to stimulate discussion among students and with instructors. The nine questions at the end of each case are tailored to each disorder but remain similar across all cases to reinforce the process of thinking pharmacotherapeutically.

Pharmacotherapeutics for Advanced Practice continues to provide primary care students with a reasoned approach to learning pharmacotherapeutics and to serve as a reference for the seasoned practitioner. Prescribing is becoming more and more complex, and the information in this book has helped us in our own practices. As experienced educators and practitioners, we are dedicated to providing you with a textbook that will meet your needs.

ACKNOWLEDGMENTS

We would like to thank Shannon Magee, Maria McAvey, and Marian Bellus, from Wolters Kluwer/Lippincott Williams & Wilkins and Tom Conville, Development Editor, for all their invaluable assistance. We are also forever indebted to the contributors who spent countless hours on this project. Without them, this would never have become a reality.

In addition, we would like to thank our families who supported us throughout the project and understand the importance of this book to us.

UNIT 1
Principles of Therapeutics

1 Issues for the Practitioner in Drug Therapy

Virginia P. Arcangelo ■ Veronica F. Wilbur

Drug therapy is often the mainstay of treatment of acute and chronic diseases. An important role of health care practitioners is to develop a treatment plan with the patient; an integral part of the treatment plan of disease and health promotion is drug therapy. According to the Health in the United States (2014), from 2009 to 2012, of those persons aged 55 to 64, 55.6% used one to four prescription drugs and 20.3% used five or more during the last 30 days. Additionally, according to the National Ambulatory Medical Survey (2010), there were 2.6 billion drugs (75.1%) prescribed during office visits, 329.2 million drugs (72.5%) prescribed during visits to a hospital outpatient department, and 286.2 million drugs (80.3%) prescribed during visits to a hospital emergency department. The overall growth in spending on prescription drugs has slowed to 2.9% by 2011, but the overall spending equals $263 billion and accounts for a large share of national health care expenditures (CDC, FastStats, 2014). Therefore, it is imperative that prescribers have the best knowledge about principles of prescribing.

In developing a treatment plan that includes drug therapy, the prescribing practitioner considers many issues in achieving the goal of safe, appropriate, and effective therapy. Among them are drug safety and product safeguards, the practitioner's role and responsibilities, the step-by-step process of prescribing therapy and writing the prescription, and follow-up measures. Particularly important are promoting adherence to the therapeutic regimen and keeping up-to-date with the latest developments in drug therapy.

Drug Safety and Market Safeguards

In the United States, drug safety is ensured in many ways, but primarily by the U.S. Food and Drug Administration (FDA), which is the federal agency charged with conducting and monitoring clinical trials, approving new drugs for market and manufacture, and ensuring safe drugs for public consumption. Although the federal government provides guidelines for a pure and safe drug product, guidelines for prescribers of drug therapy are dictated both by state and federal governments and by licensing bodies in each state.

Clinical Trials

Various legislated mechanisms are in place to ensure pure and safe drug products. One of these mechanisms is the clinical trial process by which new drug development is carefully monitored by the FDA. Every new drug must successfully pass through several stages of development (see Figure 1.1). The first stage is preclinical trials, which involve testing in animals and monitoring efficacy, toxic effects, and untoward reactions. Application to the FDA for investigational use of a drug is made only after this portion of research is completed.

FIGURE 1.1 Phases of drug development.

Clinical trials, which begin only after the FDA grants approval for investigation, consist of four phases and may last up to 9 years before a drug is approved for general use. During clinical trials, performed on informed volunteers, data are gathered about the proposed drug's purity, bioavailability, potency, efficacy, safety, and toxicity.

Phase I of clinical trials is the initial evaluation of the drug. It involves supervised studies on 20 to 100 healthy people and focuses on absorption, distribution, metabolism (sometimes interchangeable with biotransformation), and elimination of the drug. In phase I, the most effective administration routes and dosage ranges are determined. During phase II, up to several hundred patients with the disease for which the drug is intended are subjects. The testing focus is the same as in phase I, except that drug effects are monitored on people with disease.

Phase III begins once the FDA determines that the drug causes no apparent serious adverse effects and that the dosage range is appropriate. Double-blind research methods (in which neither the study and control subjects nor the investigators know who is receiving the test drug and who is not) are used for data collection in this phase, and the proposed drug is compared with placebo. Usually several thousand subjects are involved in this phase, which lasts several years and during which most risks of the proposed drug are discovered. At the completion of phase III, the FDA evaluates data presented and accepts or rejects the application for the new drug. Approval of the application means that the drug can be marketed—but only by the company seeking the approval.

Once on the market, the drug enters phase IV or postmarketing surveillance.

Objectives at this stage are (1) to compare the drug with others on the market, (2) to monitor for long-term effectiveness and impact on quality of life, and (3) to analyze cost-effectiveness (Center Watch, 2015). During postmarketing surveillance, drugs can be taken off the market or restricted due to additional findings about the drug and side effects.

Prevention of Harm and Misuse

The passage of the FDA's Controlled Substances Act of 1970 established the schedule of ranking of drugs that have the potential for abuse or misuse. Drugs on the schedule are considered controlled substances. These drugs have the potential to induce dependency and addiction, either psychologically or physiologically. Box 1.1 defines the five categories of scheduled drugs, with Schedule 1 drugs having the greatest potential for abuse and Schedule 5 drugs the least.

BOX 1.1 Scheduled Drugs

Schedule 1 drugs have a high potential for abuse. There is no routine therapeutic use for these drugs, and they are not available for regular use. They may be obtained for "investigational use only" by applying to the U.S. Drug Enforcement Agency. Examples include heroin and LSD.

Schedule 2 drugs have a valid medical use but a high potential for abuse, both psychological and physiologic. In an emergency, a Schedule 2 drug may be prescribed by telephone if a written prescription cannot be provided at the time. However, a written prescription must be provided within 72 hours with the words *authorization for emergency dispensing* written on the prescription. These prescriptions cannot be refilled. A new prescription must be written each time. Examples include certain amphetamines and barbiturates.

Schedule 3 drugs have a potential for abuse, but the potential is lower than for drugs on Schedule 2. These drugs contain a combination of controlled and noncontrolled substances. Use of these drugs can cause a moderate to low physiologic dependence and a higher psychological dependence. A verbal order can be given to the pharmacy, and the prescription can be refilled up to five times within 6 months. Examples include certain narcotics (codeine) and nonbarbiturate sedatives.

Schedule 4 drugs have a low potential for abuse. They can cause psychological dependency but limited physiologic dependency. Examples include nonnarcotic analgesics and antianxiety agents, such as lorazepam (Ativan).

Schedule 5 drugs have the least potential for abuse. They contain a moderate amount of opioids and are used mainly as antitussives and antidiarrheals. Examples include antitussives and antidiarrheals with small amounts of narcotics.

Schedule drugs can be prescribed only by a practitioner who is registered and approved by the U.S. Drug Enforcement Agency (DEA), and in some states, practitioners must possess a controlled substance (CS) license as well. The DEA issues approved applicants a number, which must be written on the prescription for a controlled substance for the prescription to

be valid. The prescriber's DEA number must also appear on a prescription that is being filled in another state.

Currently, in the United States, overdose emergencies and abuse of schedule drugs have become epidemic with over 259 million prescriptions written for painkillers (CDC Vital Statistics, 2014). To assist health care providers with safe prescribing practices, many states have enacted prescription drug monitoring programs (PDMPs). These programs are established and run by individual states through electronic databases that collect information on designated substances dispensed in the state. The DEA does not have involvement in any state PDMP program. According to the National Association of State Controlled Substance Authorities (NASCSA), in 2014, only one state did not have a PDMP. The program allows prescribers of controlled substance to look up patients for previous prescriptions of controlled substances including type of medication, amount, and name of the prescriber. The information obtained from this program helps to reveal those patients who prescriber shop and are receiving too many controlled substances. It also helps to start a conversation with the patients, exploring their health care needs.

National Provider Identifier

The Administrative Simplification provisions of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) mandated the adoption of standard unique identifiers for health care providers and health plans. This identification system improves the efficiency and effectiveness of electronically transmitting health information. The Centers for Medicare & Medicaid Services (CMS) has developed the National Plan and Provider Enumeration System (NPPES) to assign each provider a unique National Provider Identifier (NPI). Covered health care providers and all health plans and health care clearinghouses must use NPIs in the administrative and financial transactions adopted under HIPAA. The NPI is a 10-position, intelligence-free numeric identifier (10-digit number). The NPI does not carry other information about the health care provider, such as the health care provider's specialty or in which state he or she practices. The NPI must be used in lieu of legacy provider identifiers in HIPAA standard transactions. Covered providers must also share their NPI with other providers, health plans, clearinghouses, and any entity that may need it for billing purposes.

The purpose of the NPI is to identify all health care providers by a unique number in standard transactions such as health care claims. NPIs may also be used to identify health care providers on prescriptions, in internal files to link proprietary provider identification numbers and other information, in coordination of benefits between health plans, in patient medical record systems, in program integrity files, and in other ways. HIPAA requires that covered entities (i.e., health plans, health care clearinghouses, and those health care providers who transmit health information in electronic form in connection with a transaction for which the Secretary of Health and Human Services has adopted a standard) use NPIs in standard transactions. The NPI is the only health care provider identifier that can be used in standard transactions by covered entities.

A health care provider may apply for an NPI through a web-based application process at https://nppes.cms.hhs.gov or by filling out and mailing a paper application to the NPI Enumerator. A copy of the application (CMS-10114), which includes the NPI Enumerator's mailing address, is available upon request through the NPI Enumerator at 1-800-465-3203, TTY 1-800-692-2326.

When applying for an NPI, providers are asked to include their Medicare identifiers as well as those issued by other health plans. A Medicaid identification number must include the associated state name. The legacy identifier information is critical for health plans to aid in the transition to the NPI. When the NPI application information has been submitted and the NPI assigned, NPPES sends the health care provider a notification that includes their NPI. This notification is proof of NPI enumeration and helps to verify a health care provider's NPI.

Prescription versus Nonprescription Drugs

Many drugs may now be obtained that were previously available only with a prescription, and at the prescription dosage. Although these drugs are commonly and legally obtained over the counter (OTC) without a prescription, approval for the drug must still be obtained from the FDA for specific uses in specific doses.

These drugs carry user warnings on the labels. Many have the potential for interacting adversely with prescribed drugs or complicating existing disease. The self-prescribed use of OTC drugs may delay diagnosis and treatment of potentially serious problems. On the other hand, the use of OTC drugs can be beneficial for treatment of self-limiting disorders that are not serious.

Generic Drugs versus Brand Name Drugs

Substituting a generic drug for a brand name drug is a common practice. In many states, it is required. When the patent on a brand name drug expires, other drug manufacturers can then produce the same drug formula under its generic name (the generic name and formula of a drug are always the same; only the brand names change). This practice not only benefits the manufacturer but also decreases the cost to the consumer.

To ensure safety, the FDA must grant approval for these drugs, and rigorous testing is again required to ensure that all generic drugs meet specifications for quality, purity, strength, and potency. Generic drugs must demonstrate therapeutic equivalence to the brand name equivalent. They must be manufactured under the same strict standards and meet the same batch requirements for identity, strength, purity, and quality as the brand name drug. To obtain FDA approval, the generic drug is administered in a single dose to at least 18 healthy human subjects. Next, peak serum concentration and the area under the plasma concentration curve (AUC) are measured. The values obtained for the generic drug must be within 80% to 125% of those obtained for the brand name drug. Most generic drugs have a mean AUC within 3% of the brand name drug. There has been no reported therapeutic difference of a serious nature between brand name products and FDA-approved generic products. For more information, see Table 1.1, which presents FDA equivalency ratings for brand name and generic drugs.

TABLE 1.1 FDA Therapeutic Equivalence Ratings

Rating Scale	Definition
A	*Therapeutically Equivalent*
AA	Products in conventional dosage forms not presenting bioequivalence problems
AB	Products meeting necessary bioequivalence requirements
AN	Solutions and powders for aerosolization
AO	Injectable oil solutions
AP	Injectable aqueous solutions and, in certain instances, intravenous nonaqueous solutions
AT	Topical products
B	*Not Therapeutically Equivalent*
BB	Drug products requiring further FDA investigation and review to determine therapeutic equivalence
BC	Extended-release dosage forms (capsules, injectables, and tablets)
BD	Active ingredients and dosage forms with documented bioequivalence problems
BE	Delayed-release oral dosage forms
BN	Products in aerosol–nebulizer drug delivery systems
BP	Active ingredients and dosage forms with potential bioequivalence problems
BR	Suppositories or enemas that deliver drugs for systemic absorption
BS	Products having drug standard deficiencies
BT	Topical products with bioequivalence issues
BX	Drug products for which the data are insufficient to determine therapeutic equivalence
AB	Potential equivalence problems have been resolved with adequate in vivo or in vitro evidence supporting bioequivalence

U.S. Department of Health and Human Services, Food and Drug Administration, Center for Drug Evaluation and Research, Office of Pharmaceutical Science, Office of Generic Drugs. (2010). *Approved drug products with therapeutic equivalence evaluation* (30th ed.).

Complementary and Alternative Medicine

In the United States, the use of herbal preparations as treatments for disease and disease prevention has increased tremendously. According to the National Center for Complementary and Integrative Health, in 2012 approximately 33% of adults and 11% of children use some form of complementary approach to health care. The findings mirror similar surveys from 2007. The most popular products for adults (7.8%) and children (1.1%) are fish oils/Omega-3 fatty acids. These are followed by glucosamine and/or chondroitin (2.6%), probiotics/prebiotics (1.6%) and melatonin (1.3%) for adults, and for children melatonin (0.7%) (Clarke et al., 2015).

Historically, herbs were the first healing system used. Herbal medicines are derived from plants and thought by many to be harmless because they are products of nature. Some prescription drugs in current use, however, such as digitalis, are also "natural," which is not synonymous with "harmless." Before 1962, herbal preparations were considered to be drugs, but now they are sold as foods or supplements and therefore do not require FDA approval as drugs. Hence, there are no legislated standards on purity or quantity of active ingredients in herbal preparations. The value of herbal therapy is usually measured by anecdotal reports and not verified by research. Like synthetic products, herbal preparations may interact with other drugs and may produce undesirable side effects as well.

The Dietary Supplement Health and Education Act (1994) requires labeling about the effect of herbal products on the body and requires the statement that the herbal product has not been reviewed by the FDA and is not intended to be used as a drug. Complementary and alternative medicine (CAM) is discussed in Chapter 9.

Foreign Medications

In today's global society, practitioners will experience encounters with patients from many countries. These individuals may request refills of drugs for treating their chronic conditions. These drugs may have unrecognizable names, different dosages/dosage forms, or different active ingredients. Additionally, patients may get their drugs from online pharmacies in other countries because they are less expensive. Today, there is a proliferation of these online pharmacies, and only 3% comply with U.S. pharmacy laws (FDA, 2013). According to the World Health Organization, 80% of drugs are counterfeited in some countries (FDA, 2014). The Food and Drug Administration (FDA) has many resources for the practitioner to guide patients toward sound decision making about prescription drug acquisition.

Disposal of Medications

Many medications can be potentially harmful if taken by someone other than the person for whom they are prescribed. Understand that improperly disposed drugs can leak into the environment, and the best disposal method is through community drug take-back programs. Almost all medicines can be safely disposed of if they are mixed with an undesirable substance, such as cat litter or coffee grounds, and placed in a closed container. Any personal information should be removed from the container by using a black marker or duct tape. Many communities have a drug take-back program for disposal, or drugs can be disposed of when the community collects hazardous material. Drugs should not be flushed down the toilet or drain unless the dispensing directions say this is permitted. Drugs permitted to be flushed can be found on the Web site http://www.fda.gov/Drugs/ResourcesForYou/Consumers/BuyingUsingMedicineSafely/Ensu

Practitioner's Role and Responsibilities in Prescribing

Before prescribing therapy, the practitioner has a responsibility to gather data by taking a thorough history and performing a physical examination. Once the data are gathered and evaluated, one or more diagnoses are formulated and a treatment plan established. As noted, the most frequently used treatment modality is drug therapy, usually with a prescription or OTC drug.

If a drug is deemed necessary for therapy, it is essential for the practitioner to understand the responsibility involved in prescribing that drug or drugs and to consider seriously which class of medication is most appropriate for the patient. The decision is reached based on a thorough knowledge of diagnosis and treatment.

Drug Selection

To determine which therapy is best for the patient, the practitioner conducts a risk–benefit analysis, evaluating the therapeutic value versus the risk associated with each drug to be prescribed. The practitioner then selects from a vast number of pharmacologic agents used for treating the specific medical problem. Factors to consider when selecting the drug or drugs are the subtle or significant differences in action, side effects, interactions, convenience, storage needs, route of administration, efficacy, and cost. Another factor in the decision may involve the patient pressuring the practitioner to prescribe a medication (because that is the expectation of many patients at the beginning of a health care encounter). Clearly, many responsibilities are inherent in prescribing a medication, and serious consequences may result if these responsibilities are not taken seriously and the prescription is prepared incorrectly.

Initial questions to ask when selecting drug therapy include "Is there a need for this drug in treating the presenting problem or disease?" and "Is this the best drug for the presenting problem or disease?" Additional questions are listed in Box 1.2.

BOX 1.2 Questions to Address When Prescribing a Medication

- Is there a need for the drug in treating the presenting problem?
- Is this the best drug for the presenting problem?
- Are there any contraindications to this drug with this patient?
- Is the dosage correct? Or is it too high or too low?
- Does the patient have allergies or sensitivities to the drug?
- What drug treatment modalities does the patient currently use, and will the potential new drug interact with the patient's other drugs or treatments?
- Is there a problem with storage of the drug?
- Does the dosage regimen (schedule) interfere with the patient's lifestyle? For example, if a child is in school, a drug with a once- or twice-daily dosing schedule is more realistic than one with a four-times-daily schedule.
- Is the route of administration the most appropriate one?
- Is the proposed duration of treatment too short or too long?
- Can the patient take the prescribed drug?
- Has the patient been informed of possible side effects and what to do if they occur?
- Is there a genetic component to consider?
- What is the cost of the drug?
- What, if any, prescription plan does the patient have?

Concerns Related to Ethics and Practice

Certain ethical and practical issues must be considered as well. One overriding issue may be the lack of a clinical indication for using a medication. As mentioned, many patients visit a practitioner with the sole purpose of obtaining a prescription. In seeking medical attention, the ill patient expects the health care provider to promote relief from symptoms. In today's world, an abundance of information available in books, magazines, television, Web sites, and other media suggests that the health care provider can do this by prescribing a special medication. This expectation—that a magic pill or potion—the prescription—is the ticket that will relieve reflux, kill germs, end pain, and restore health—puts pressure on the practitioner to prescribe for the sake of prescribing. A common example of this involves the patient with a cold who seeks an antibiotic, such as penicillin. In such a situation, the practitioner has a responsibility to prescribe only medications that are necessary for the well-being of the patient and that will be effective in treating the problem. In the example of the patient with an uncomplicated head cold, an antibiotic would not be effective, and the responsible practitioner must be prepared to make an ethical and judicious decision not to prescribe an antibiotic and explain it to the patient.

Patient Education

An integral part of the practitioner's role and responsibility is educating the patient about drug therapy and the intended therapeutic effect, potential side effects, and strategies for dealing with possible adverse drug reactions. This may be explained verbally, with written instructions given, when appropriate. Instructions that are printed and handed to the patient must be readable, in a language that the patient can understand, and at the appropriate health literacy. If side effects are discussed in advance, the patient will know what to expect and will contact the prescriber with symptoms. There may be less likelihood that the patient will discontinue the drug before discussing it with the prescriber.

Medications can also have a placebo effect. Patients must believe that the drug will work for them to be committed to taking it as recommended. If that belief is not instilled in patients, the drug may not be perceived as effective and may not be taken as directed.

The practitioner may want to advise the patient to use only one pharmacy when filling prescriptions. The choice of only one pharmacy has several advantages, which include maintaining a record of all medications that the patient currently receives and serving as a double-check for drug–drug interactions.

Prescriptive Authority

Prescribing practices of each practitioner are regulated by the state in which he or she practices. Each state determines practice parameters by statutes (laws enacted by the legislature), rules, and regulations (administrative policies determined by regulatory agencies). Each practitioner is responsible for knowing the laws and regulations in the state of practice.

Prescriptive authority is regulated by the State Board of Nursing, Board of Medicine, or Board of Pharmacy, depending on the state. States allow full practice authority, collaborative practice, supervised practice, or delegated practice. Full practice authority has no requirements for mandatory physician collaboration or supervision. Collaborative practice requires a formal agreement with a collaborating physician, ensuring a referral–consultant relationship. Supervised practice is overseen or directed by a supervisory physician. Delegated practice means that prescription writing is a delegated medical act. Regulations can be found at the Division of Professional Regulation for prescribers in each state.

Related to prescriptive authority issues is the issue of drug samples. Most drug companies engage in the promotional practice of distributing sample drugs to practitioners for use by patients. The Prescription Drug Marketing Act (PDMA), which was enacted in 1988 to protect the American consumer from ineffective drugs, also affects the receipt and dispensing of sample drugs. Prescription drugs can be distributed only to licensed practitioners (one licensed by the state to prescribe drugs) and health care entity pharmacies at the request of a licensed practitioner. PDMA protects the public in several ways. It forbids foreign countries to reimport prescription drugs; bans the sale, trade, and purchase of drug samples; prohibits resale of prescription drugs purchased by hospitals, health care entities, and charitable organizations; requests practitioners to ask for drug samples in writing; and regulates wholesale distributors of prescription drugs by requiring licensing in states where facilities are located. There are penalties for violation of the act. This act affects the distribution and use of pharmaceutical samples.

Because these samples are freely available, it might be assumed that they can be distributed by all practitioners, but this is not the case. The practitioner must be aware of the rules that govern requesting, receiving, and distributing these agents because the rules vary from state to state.

Specific procedures are required with drug samples. The pharmaceutical representative's Sample Request Form must be signed. It includes the name, strength, and quantity of the sample. The sample must be then recorded on the Record of Receipt of Drug Sample sheet. The samples must be stored away from other drug inventory and where unauthorized access is not allowed or in a locked cabinet or closet in a public area. Samples are to be inspected monthly for expiration dates, proper labeling and storage, presence of intact packaging and labeling, and appropriateness for the practice. If a sample has expired,

it must be disposed of in a manner that prevents accessibility to the general public. It cannot be disposed into the trash.

When distributing samples, each must be labeled with the patient's name, clear directions for use, and cautions. All samples are to be dispensed free of charge along with pertinent information. The medication is then documented in the patient's chart with dose, quantity, and directions.

Adverse Drug Events

Prescription and nonprescription drugs are an increasing part of life in the United States. Between the years of 2009 and 2012, there were 48.7% of individuals who took at least one prescription drug in the last 30 days (CDC, FastStats, 2015). Adverse drug events (ADE) have consequently become an increasing problem resulting in adverse events both in the inpatient and outpatient settings. Due to the magnitude of the problem, the Home of the Office of Disease and Health Promotion have created a National Action Plan for Adverse Drug Event Prevention 2014 (http://health.gov/hcq/ade.asp). Therefore, the prudent prescriber must always be aware of any medications presenting for health care. Chapter 3 reviews the impact of ADE in depth.

Lack of Drug Knowledge

There can be a lack of knowledge about indications and contraindications for drugs. This includes underuse, overuse, and misuse of drugs. An example of underuse is failure to prescribe an inhaled corticosteroid for an asthmatic patient who uses his albuterol daily. An example of overuse is prescribing an antibiotic for a cold or prescribing an antihypertensive drug for someone whose blood pressure is elevated because he is taking pseudoephedrine (Sudafed). An example of misuse is prescribing penicillin to someone for a strep throat who has identified a clear allergy to the drug.

Dosing errors occur when a larger dose is prescribed than needed or the conversion from oral to intravenous is too high. This is especially problematic with pediatrics for antibiotics (Aseeri, 2013). For example, prescribing a dose of Augmentin that is greater than the suggested amount or starting a patient on 30 mg paroxetine instead of 20 mg may increase anxiety.

Lack of knowledge about drug–drug interactions can also cause errors. For example, many drugs interfere with warfarin and cause increased bleeding if taken together. The prescriber must be aware of the potential for drug–drug interactions (see Chapter 3 for more information).

Lack of Patient Information

A common error in prescribing is failure to obtain an adequate history from the patient. Often an adequate drug history is not obtained and the provider does not specifically inquire about herbal preparations or OTC medications. Also, information on allergies to medications is not always obtained. In addition to allergies, it is imperative to ascertain the reaction to the medication. Nausea is not considered an allergic reaction. An allergy history should be taken and documented at each visit before a new medication is prescribed. Additionally, asking multiple times about allergies or reactions to drugs during a visit is a safety cross-check to responsible prescribing.

Poor Communication

Poor communication between health care providers, pharmacists, and patients can be a result of poor handwriting, incorrect abbreviations, misplaced decimals, and misunderstanding of verbal prescriptions. These potential errors can be mitigated through the use of electronic health record (EHR); however, new errors can occur if the practitioner does not click on the correct medication. Additionally, there are areas in the United States where providers still handwrite prescriptions. Poor communication also results when the prescriber fails to discuss potential side effects or ask about side effects at subsequent visits.

Special Population Considerations

Doses for children are usually based on weight in kilograms. The prescriber has a responsibility to calculate the dose and write the correct dose, rather than relying on the pharmacist to calculate the dose. See Chapter 4 for more information about pediatric drug dosing.

Elderly patients may have some difficulty hearing or reading small print. Additionally, they may be taking multiple prescription medications and OTC medications. The prescriber needs to be specific about when the patient should take each medication and if one drug cannot be taken with others. When the practitioner prescribes for the elderly, he or she must consider renal function because some medications can cause toxicity, even in small doses, with decreased renal function. Chapter 6 reviews the considerations necessary for good prescribing in the elderly.

Pharmacogenomics

Recently, pharmacogenomics has gained importance in prescribing medication. The way a person responds to a drug is influenced by many different genes. Without knowing all of the genes involved in drug response, it has not been possible to develop genetic tests that could predict a person's response to a particular drug. Knowing that people's genes show small variations in the DNA base makes genetic testing for predicting drug response possible. Genetic factors can account for 20% to 95% variability of the patient's reaction to a drug. Pharmacogenomics examines the inherited variations in genes that dictate drug response and explores the ways these variations can be used to predict the response a patient will have to a drug. Pharmacogenetic testing may enable providers to understand why patients react differently to various drugs and to make better decisions about therapy. This understanding may allow for highly individualized therapeutic regimens. This concept is discussed in detail in Chapter 10.

Steps of the Prescribing Process

At each visit, a medication history is obtained with the name of the drug, dosage, and frequency of administration. Information on any allergies should also be obtained. It is also helpful if the patient brings his or her actual drugs to the visit.

Multiple steps (Figure 1.2) are involved in prescribing drugs and evaluating their effectiveness. Again, the first step is determining an accurate diagnosis based on the patient's history, physical examination, and pertinent test findings.

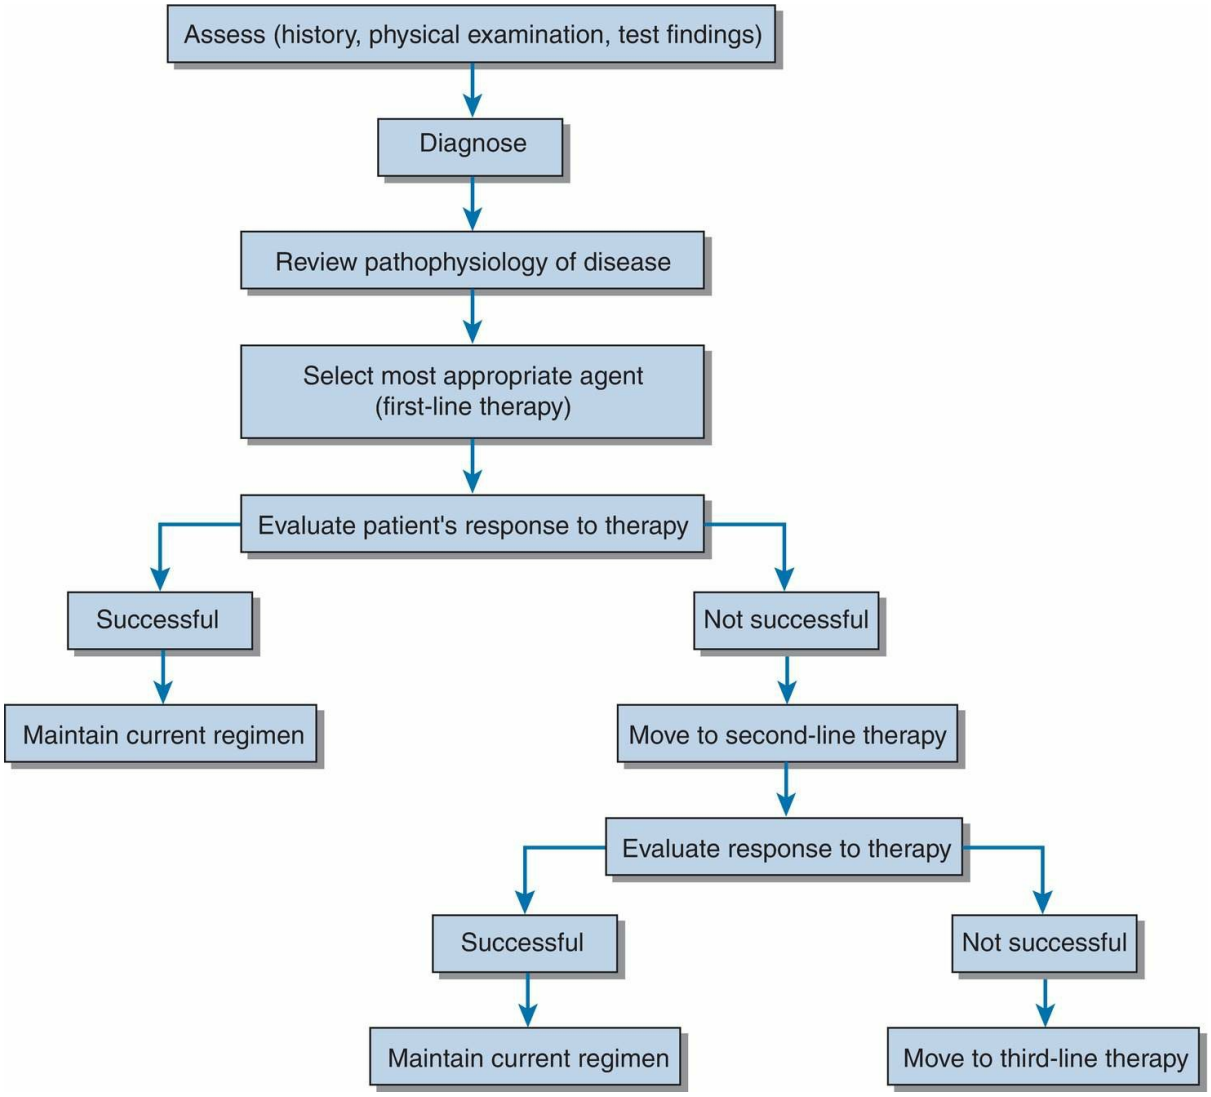

FIGURE 1.2 Process for prescribing.

Next, in selecting the best agent, the practitioner thoroughly evaluates the patient's condition, taking into consideration the effect that various medications may have on the patient and the disorder, the expected outcomes of therapy, and other variables (Box 1.3). When prescribing any drug therapy, the practitioner must have a solid knowledge and background in the pathophysiology of disease, pharmacotherapeutics, pharmacokinetics, pharmacodynamics, and any interactions (see Chapters 2 and 3).

BOX 1.3 Variables to Consider in Prescribing a Medication

Age
Sex
Race

- Weight
- Culture
- Allergies
- Pharmacogenomics
- Other diseases or conditions
- Other therapies
  - Prescription medications
  - Over-the-counter medicines
  - Alternative therapies
- Previous therapies
  - Effectiveness
  - Adverse effects
  - Adherence
- Socioeconomic issues
  - Insurance status
  - Income level
  - Daily schedule
  - Living environment
  - Support systems
- Health beliefs

The practitioner needs to be knowledgeable about the best class of drugs for the diagnosed disorder or presenting problem, the recommended dosage, potential side effects, possible interactions with other drugs, and special prescribing considerations, such as required laboratory tests, contraindications, and patient instructions. To select the correct medication, the practitioner must thoroughly understand the pathophysiology of the condition being treated and the natural history of the disease. This information allows the practitioner to decide at which point in the disease process intervention with drug therapy is indicated because in many diseases or disorders, nonpharmacologic therapies are tried before drug therapy is initiated.

Next, the practitioner sets goals for therapy. Goals need to be realistic and outcomes measurable. All interventions, nonpharmacologic and pharmacologic, are initiated to meet these goals, and evaluation of the therapy's efficacy is based on these goals.

Selecting Most Appropriate Agent

For most disease entities, there is a recommended first-line therapy—that is, research shows certain agents to be more effective than others. Once initiated, the first-line therapy is evaluated and either continued or changed. If the desired goals are not achieved, or if an adverse reaction occurs, second-line therapy is initiated. The second-line therapy is then evaluated. If this therapy is not tolerated or efficacious, a third-line therapy is initiated, and so on. The practitioner continually evaluates the patient's response to therapy and maintains current therapy or changes it as indicated by the patient's response. For more information, see the case study outlining the prescribing process. Case studies such as this one are used throughout the text.

Consideration of Special Populations

Another step in prescribing drugs is considering specific concerns related to special populations, such as children, pregnant or breast-feeding women, and the elderly. Cultural beliefs are also considered to ensure that the drug regimen honors individual and family customs and preferences. Pharmacogenomics are gaining in popularity when considering which drug to prescribe.

Identifying Outcomes

Expected outcomes can include improvement in clinical symptoms or pathologic signs or changes in biochemistry as determined by laboratory tests. To assess whether expected outcomes have been achieved, the practitioner reviews data collected on subsequent visits, evaluates the effectiveness of drug therapy, and investigates any adverse reactions.

The frequency of follow-up visits is determined by the disease and the patient's response to treatment. While outcomes are being assessed, the practitioner educates the patient about the outcomes of therapy as well. Topics for discussion include drug benefits, side effects, dosage adjustments, and monitoring parameters.

The patient as well as the practitioner must be informed about any undesirable outcomes of therapy with a prescription drug. Reactions that may be expected and must be discussed include side effects, drug or food interactions, and toxicity. Unexpected reactions include allergic reactions or intolerance to a drug. If a patient experiences a serious adverse drug reaction, the practitioner files a report with the FDA's MedWatch program on a special form obtainable from MedWatch (5600 Fishers Lane, Rockville, MD 20852-9787 or it can be reported online at https://www.accessdata.fda.gov/scripts/medwatch/; see Chapter 3 for a sample of the MedWatch form). Similarly, adverse reactions to vaccines are reported through the Vaccine Adverse Event Reporting System (VAERS) online at http://vaers.hhs.gov/esub/index#Online or by mail by completing a VAERS form requested by calling 1-800-822-7967 and mailing it to VAERS, P.O. Box 1100, Rockville, MD 20849-1100. Adverse events are discussed in Chapter 4.

Writing the Prescription

The practice of handwriting prescriptions is slowly becoming an exercise of the past; however, there are still instances where a practitioner needs to know the steps. The prescription is a form of communication between the practitioner and the pharmacist. It is also the basis for written directions to patients, and it is a legal document. Each prescription should be clearly written to avoid errors of misinterpretation in filling the prescription. Although potentially serious errors occur infrequently, they are avoidable and should not occur at all.

An early step in the prescribing process involves ensuring that common but potentially serious errors are not made. The first is failure to identify a patient's allergies, particularly to a medication. In identifying a drug allergy, the practitioner should also investigate the kind of reaction experienced with the medication to differentiate between a true, life-threatening drug allergy and less serious drug sensitivity. Some cross-sensitivities must also be considered. Another error is failure to instruct the patient to stop a previously prescribed medication that treats the same condition. In some instances, an additional medication may be prescribed to increase the effect for the same problem, but the patient must be made aware of this. Otherwise, the original medication must be canceled. Failure to recognize the effect of a prescribed drug on other diseases or drugs can lead to potentially serious effects. There are now programs that can do multiple checks for interactions. One of these is Epocrates for mobile devices and desktops.

Date, Name, Address, and Date of Birth

There are standard components of any prescription. One is the date and another is the full name, address, and date of birth of the patient. The name should be the patient's given name (the one on the medical record) and not a nickname. If a different name is used each time, the patient could have multiple records in pharmacy record-keeping systems. The address should be the current home address of the patient and not a work address or a post office box.

Prescriber's Name, Address, and Phone Number

The next components are the name, address, and phone number of the prescriber and the collaborating physician if required by state law or regulations. This enables the pharmacist to contact the prescriber if there is a question about the prescription.

Name of Drug

Of course, the name of the drug is the most essential part of the prescription. Ideally, the generic name (with the trade or brand name in parentheses) is used. The name must be legible to avoid errors in filling the prescription correctly. For instance, some drugs have names that are commonly confused or misread, such as Norvasc and Navane, Prilosec and Prozac, carboplatin and cisplatin, and Levoxine and Lanoxin. Severe problems may result if the wrong drug is supplied erroneously. Adding the diagnosis to the prescription, although optional, can help the pharmacist avoid misinterpreting the prescribed drug.

Dose, Dosage Regimen, and Route of Administration

The drug dose is essential because many drugs are available in various strengths. The dose is written in numerals. If the dose is a fraction of 1, it is written in decimal form with a leading zero to the left of the decimal point (e.g., 0.75). However, a whole number should not be followed by a decimal point and a trailing zero (10.0 could be misinterpreted as 100). The numeric dose is followed by the correct metric specification such as milligram (mg), gram (g), milliliter (mL), or microgram (mcg). Many practitioners spell out *microgram* to avoid confusion with *milligram*. Some drugs are manufactured in units that should be specified, and the term *unit* should be written out (insulin 10 units, not 10 U). Usually, the strength of drugs that are combination products or that are manufactured only in one strength do not need to be included. The route of the drug is specified as well. (Routes of administration are discussed in Chapter 2.)

The prescription also specifies how frequently the drug is to be taken. A drug prescribed to be taken as needed is termed a *prn* drug. For example, dosage frequency can be written as "prn every 4 hours" (or another appropriate interval) for the problem for which the drug is prescribed (e.g., "as needed for nausea"). It is good practice to write out the number (10–ten), especially with controlled substances. Any special instructions, such as "after meals," "at bedtime," or "with food," also should be specified. If the dose is once a day it is safer practice to write out daily than to write OD because this can be confused with every other day.

The prescription also includes the number of pills, vials, suppositories, or containers or amount in milliliters or ounces to be dispensed. Prescription reimbursement or health care insurance programs often allow for 30- or 90-day supplies to be dispensed at a time, working with the pharmacist is imperative for optimal prescribing practices. They are the best connection regarding the rules of various prescription plans. The prescription indicates whether the prescription may be refilled and the number of refills permitted.

When prescribing a new drug for a patient, the practitioner may want to consider prescribing just a few doses or a 7-day supply initially. Alternatively, samples may be provided, if allowed by law or regulations. This allows the prescriber to determine if the patient can tolerate the drug and if it is effective. When deciding on the number of refills, the practitioner may decide when the patient should return for a follow-up visit and allow just the number of refills that will take the patient until the next visit to ensure that the patient returns. Some drug prescriptions cannot be refilled. For all Schedule 2 drugs, for example, a new prescription must be written each time.

Allowable Substitutions

There are many generic equivalents for brand name drugs. Indication of whether a substitution is allowed is a part of the prescription. As discussed earlier, a generic drug substitute must have the same chemical composition and dosage as the brand name drug originally prescribed. In many states, a generic drug will automatically be substituted for a brand name drug. If there is a medical reason to require a brand name drug (that has a generic equivalent), "Brand Medically Necessary" must be written on the prescription.

Prescriber's Signature and License Number

The signature of the prescriber is required. It should be legible and should be the person's legal signature. The license number of the prescriber or the collaborating physician is required on the prescription in some, but not all, states depending on the rules and regulations that govern the prescriber. In some instances, the DEA number of the prescriber is also required, especially when prescribing between states or prescribing a controlled substance. Figure 1.3 illustrates a blank prescription and a completed prescription. Each state has specific requirements for components on a printed prescription. The practitioner must be in compliance with state regulations and may prescribe only in the state in which he or she holds a license. Although the prescription may be filled in another state (if allowed by state regulations), a DEA number is usually required. An NPI number must be on each prescription along with a serial number of the prescription form. If the practitioner is a federal employee, he or she may prescribe in any federal facility.

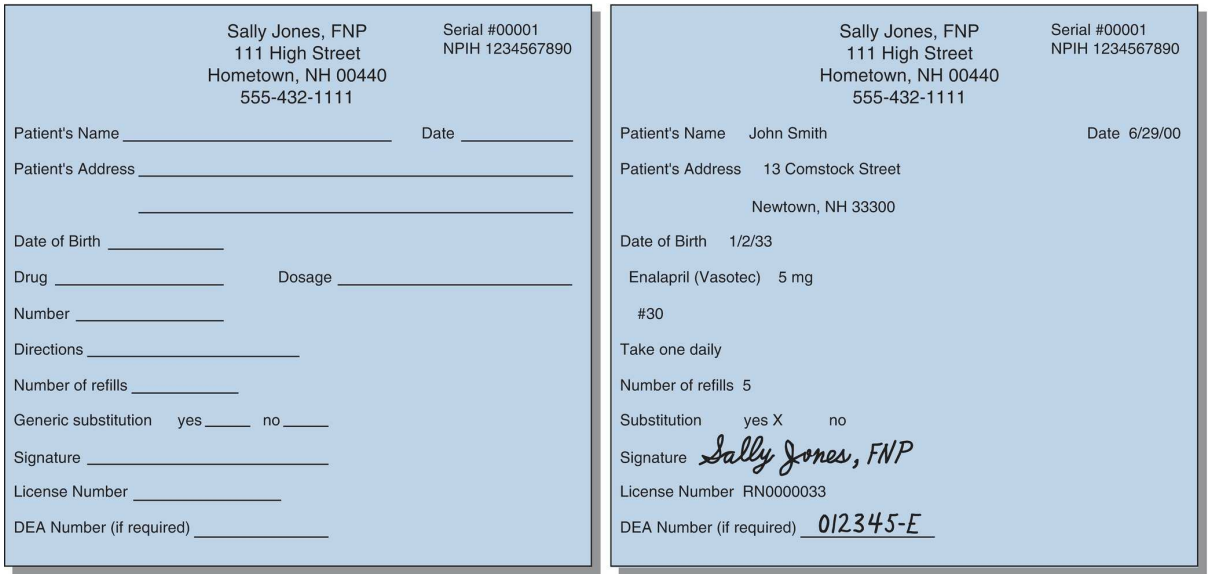

FIGURE 1.3 Example of a blank prescription form (left) and a completed form (right).

Any drug prescribed should be clearly documented in the medical record with date of order, dosage, amount prescribed, and number of refills. It is helpful to have a specific area in the record to record all drugs taken by the patient—prescription, OTC, and CAM—for ease of audit, reference, and communication among health care professionals.

Electronic Prescriptions

Electronic prescribing has become increasingly popular. Health care technology reduces medication errors with the use of drug-checking software, which checks the medication dose, potential interactions with other medications the patient may be taking, and the patient's known allergies. This drug-checking software may be part of the EHR or of a freestanding e-prescribing system. Integrated EHRs can calculate dosing based on a patient's weight and carry out other contextual medication checking against a patient's laboratory results, age, and disease states. In addition, computer systems provide pick lists of each clinician's favorite medications with a precalculated dose, frequency, and route, reducing the opportunity for clinicians to order inappropriate amounts of medications with the wrong frequency and route.

E-Prescribing improves the legibility of prescriptions and the rate of completed prescriptions. Patients no longer need to carry paper copies of a prescription to a pharmacy and are more likely to have formulary-compliant medications prescribed for them and to find their prescriptions waiting for them when they arrive at the pharmacy. This leads to greater patient convenience, shorter wait times, and increased compliance with formulary requirements. Electronic prescribing has been said to show a 12% to 20% decrease in ADEs (Figge, 2009).

With electronically generated prescriptions, there are no handwriting misinterpretations and no manual data entry. Correct dosages are built into the software. They assist with formulary requirements based on the patient's insurance and maintain allergy profiles and ADEs. They also serve to decrease drug–drug interactions.

Adherence Issues

A prescribed drug must be used correctly to produce optimal benefits. Patient nonadherence to a prescribed regimen leads to less-than-optimal outcomes, such as progression of the disease state and an increased incidence of hospitalizations. Studies demonstrate that the more complex the treatment regimen, the less likely the patient is to follow it. Benner (2009) studied 5,759 patients taking antihypertensive and lipid-lowering drugs. In patients with 0, 1, and 2 prior medications, 41%, 35%, and 30% of patients were adherent, respectively, to antihypertensive and lipid-lowering therapy. Of patients with 10 or more prior medications, 20% were adherent.

Karter (2009) studied 27,329 subjects prescribed new medications. Pharmacy utilization data were used. It was found that 22% of patients had the prescription filled zero or one times. The proportion of newly prescribed patients who never became ongoing users was eight times greater than the proportion who maintained ongoing use, but with inadequate adherence. Four percent of those who had the prescription filled at least two times discontinued therapy during the 24-month follow-up. Nonadherence was significantly associated with high out-of-pocket costs and clinical response to therapy.

Several variables are associated with improved adherence to a drug regimen. These include variables associated with the patient's perception of the encounter and of the benefit of the treatment. If a patient is nonadherent to the prescribed regimen, it is important to document that in the chart. The risks of nonadherence are discussed, and that discussion is documented. It is essential to ask why the patient is not following the prescribed treatment, and actions to rectify the problem should be taken. All of this is documented. One issue may be that the patient is unable to swallow the pill. The medicine may be available in liquid form, or the pill may be split or crushed. The practitioner needs to review and understand the factors that affect adherence to a regimen (Box 1.4).

BOX 1.4 Factors Influencing the Patient's Adherence to a Medication Regimen

- Approachability of the health care provider
- Perception of respect with which he or she is treated by the practitioner
- Belief that the therapy is beneficial
- Belief that the benefits of therapy outweigh the risks or side effects
- Degree to which the patient participates in developing the treatment regimen
- Cost of the regimen
- Simplicity of the regimen
- Understanding of the treatment regimen
- Degree to which the patient feels that expectations are being met

- Degree to which the patient perceives his or her concerns are important and being addressed
- Degree to which the practitioner motivates the patient to adhere to the regimen
- Degree to which the regimen is compatible with the patient's lifestyle

Updating Drug Information

Many sources of drug information can be accessed by practitioners who must keep current on changes in drug therapy and continually update their fund of knowledge. Resources include reference books, pharmacists (who are expertly informed about drugs, interactions, dosages, etc.), easy-to-carry drug handbooks and pocket guides for quick reference, and online databases and programs for mobile devices and desktop computers (Tables 1.2 and 1.3).

TABLE 1.2 Common Drug Reference Books

Reference	Features
American Hospital Formulary Service. Bethesda, MD: American Society of Health System Pharmacists.	Drug entries are indexed by generic and brand names and organized by pharmacologic–therapeutic class.
Drug Facts and Comparisons. Philadelphia, PA: Wolters Kluwer Health.	Drugs are indexed by generic and brand names and organized by major classes of drugs. Updates are issued monthly (in print and CD-ROM).
Physician's Desk Reference (PDR). Montvale, NJ: Medical Economics.	Drugs are indexed by manufacturer, brand name, generic name, and product category. Volume contains product identification section. Information replicates the official package insert from the drug manufacturer.

Case Study*

A.J. is a 16-year-old who has just started soccer practice at school. She complains of increased shortness of breath with exercise, and describes having a hard time catching her breath when she runs, which she does five to six times a week. She does not wake up at night with a cough or shortness of breath, and has no problems at any other time except in the spring when the trees start to blossom. The soccer coach advised A.J.'s mother to seek health care because A.J. had a very difficult time breathing at practice that afternoon. A.J. also has a history of eczema and seasonal allergies for which she takes an over-the counter antihistamine when symptoms get severe.

Social History: Nonsmoker. Lives in an urban area with mother, father, and brother. Does not use street drugs.
Family History: Father has a history of asthma.
Physical examination:
Nose: Mucosa pale and boggy bilaterally
Lungs: Respirations 26 and shallow; diffuse expiratory wheezing; peak flow 340
Diagnosis: Mild persistent asthma

Questions

1. List specific goals of therapy for A.J.
2. What drug therapy would you prescribe and why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?

* Answers can be found online.

2 Pharmacokinetic Basis of Therapeutics and Pharmacodynamic Principles

Andrew M. Peterson

The art and science of clinical practice is based on understanding the relationship between the person and the disease and determining the most appropriate means for alleviating symptoms, curing disease, or preventing severe morbidity or even mortality. Very often, medications are prescribed to accomplish one or more of these goals.

Underpinning this treatment process is the intricate relationship between the body and the medication. Often, practitioners seek to understand the effect a drug has on the body (whether therapeutic or harmful) but neglect to consider the effect that the body has on the drug—even though one cannot be understood without the other. How the body acts on a drug and how the drug acts on the body are the subjects of this chapter.

Pharmacokinetics refers to the movement of the drug through the body—in essence, how the body affects the drug. This involves how the drug is administered, absorbed, distributed, and eventually eliminated from the body. *Pharmacodynamics* refers to how the drug affects the body—that is, how the drug initiates its therapeutic or toxic effect, both at the cellular level and systemically. Box 2.1 lists terms and definitions used throughout this chapter.

BOX 2.1 Definitions of Terms Related to Pharmacokinetics and Pharmacodynamics

Affinity: The attraction between a drug and a receptor.

Allosteric site: A binding site for substrates not active in initiating a response; a substrate that binds to an allosteric site may induce a conformational change in the structure of the active site, rendering it more or less susceptible to response from a substrate.

Bioavailability (F): The fraction or percentage of a drug that reaches the systemic circulation.

Biotransformation: Metabolism or degradation of a drug from an active form to an inactive form.

Chirality: Special configuration or shape of a drug; most drugs exist in two shapes.

Clearance: Removal of a drug from the plasma or organs.

Downregulation: Decreased availability of drug receptors.

Enantiomer (also called isomer): A mirror-image spatial arrangement, or shape, of a drug

that suits it for binding with a drug receptor.

Enterohepatic recirculation: The process by which a drug excreted in the bile flows into the gastrointestinal tract, where it is reabsorbed and returned to the general circulation.

First-pass effect: The phenomenon by which a drug first passes through the liver where it may be degraded before distribution to the tissues.

Half-life ($t_{1/2}$): The time required for half of a total drug amount to be eliminated from the body.

Hepatic extraction ratio: A comparison of the percentage of drug extracted and the percentage of drug remaining active after metabolism in the liver.

Ligand: Any chemical, endogenous or exogenous, that interacts with a receptor.

Pharmacodynamics: Processes through which drugs affect the body.

Pharmacokinetics: Processes through which the body affects drugs.

Prodrug: A drug that is transformed from an inactive parent drug into an active metabolite; in effect, a precursor to the active drug.

Receptor: The site of drug action.

Second messenger: A chemical produced intracellularly in response to a receptor signal; this second messenger initiates a change in the intracellular response.

Therapeutic window: The range of drug concentration in the blood between a minimally effective level and a toxic level.

Threshold: The level below which a drug exerts little to no therapeutic effect and above which a drug produces a therapeutic effect at the site of action.

Upregulation: Increased availability of receptors.

Volume of distribution (V_d): The extent of distribution of a drug in the body.

The purpose of pharmacokinetic processes is to get the drug to the site of action where it can produce its pharmacodynamic effect. There is a minimum amount of drug needed at the site of action to produce the desired effect. Although the amount of drug concentrated at the site of action is difficult to measure, the amount of drug in the blood can be measured. The relationship between the concentration of drug in the blood and the concentration at the site of action (i.e., the drug receptor) is different for each drug and each person. Therefore, measuring blood concentrations is only a surrogate marker, an indication of concentration at the receptor. Figure 2.1 shows the relationship between pharmacokinetics and pharmacodynamics.

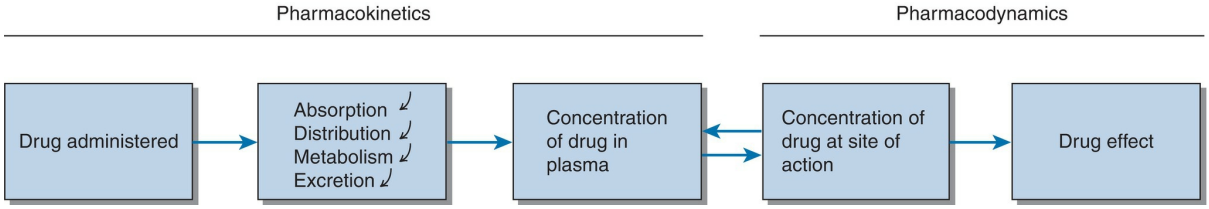

FIGURE 2.1 Relationship between pharmacokinetics and pharmacodynamics. Note the two-way relationship between the concentration of drug in the plasma and the concentration of drug at the site of action, depicting the interrelationship between pharmacokinetics and pharmacodynamics.

Pharmacokinetics

Pharmacokinetics relates to how the drug is absorbed, distributed, and eliminated from the body. In reality, it is the study of the fate of medications administered to a person. It is sometimes described as *what the body does to the drug*. In theory, pharmacokinetics not only deals with medications, it deals with the disposition of all substances administered externally to any living organism. Pharmacokinetics can help the clinician determine the onset and duration of a drug's action as well as determine blood levels that would produce therapeutic and toxic effects. As such, one can determine the blood levels necessary to produce a desired effect. This target drug concentration is key to monitoring the effects of many medications. Assuming that the magnitude of the drug concentration at the site of action influences the drug effect, whether desired or undesired, it can be inferred that a range of drug levels produces a range of effects (Figure 2.2). Below a specific level, or threshold, the drug exerts little to no therapeutic effect. Above this threshold, the concentration of drug in the blood is sufficient to produce a therapeutic effect at the site of action. However, as the drug concentration increases in the blood, so does the concentration at the site of action. Above a specific level, an increased therapeutic effect may no longer occur. Instead, an unacceptable toxicity may occur because the drug concentration is too high. Between these two levels—the minimally effective level and the toxic level—is the *therapeutic window*. The therapeutic window is the range of blood drug concentration that yields a sufficient therapeutic response without excessively toxic reactions. This range should not be considered absolute because it varies from individual to individual and therefore serves only as a guide to the practitioner.

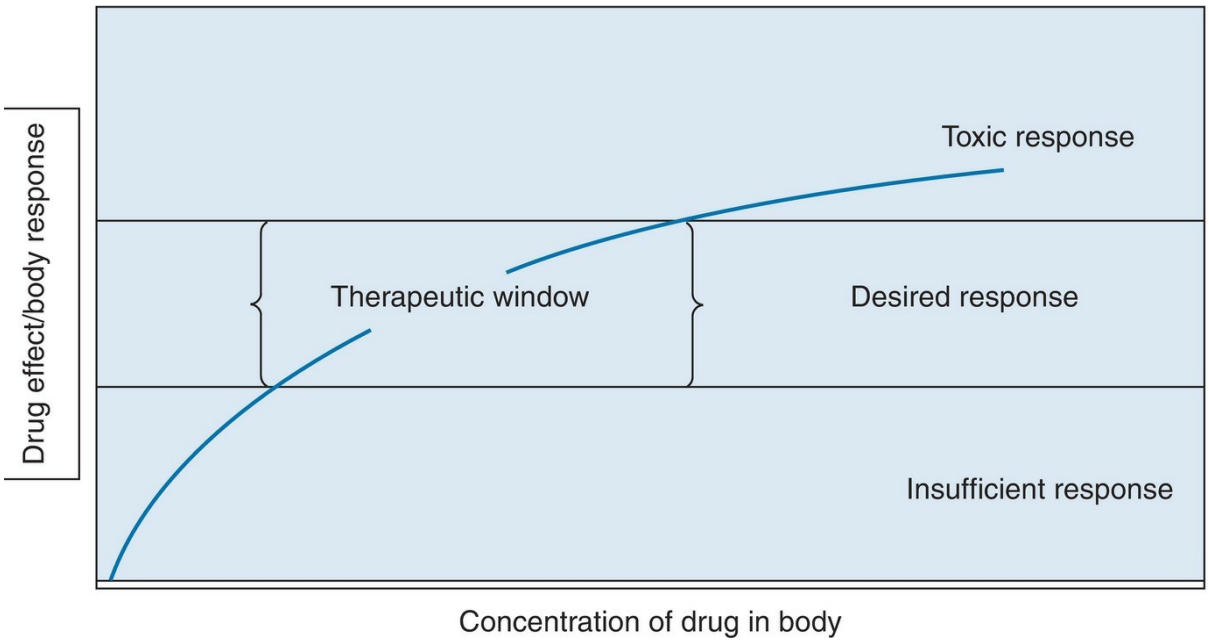

FIGURE 2.2 Therapeutic window: concentration versus response. The concentration of the drug in the body produces specific effects. A low concentration is considered

subtherapeutic, producing an insufficient response. As the concentration increases, the desired effect is produced at a given drug level. A drug concentration that exceeds the upper limit of the desired response may produce a toxic reaction. The concentration range within which a desired response occurs is the therapeutic window.

Absorption

The first aspect of pharmacokinetics to consider is how drugs are administered, how they are absorbed into the body, and how they eventually reach the bloodstream. Merely introducing the drug into the body does not ensure that the compound will reach all tissues uniformly or even that the drug will reach the target site. Commonly recognized methods of absorption include enteral absorption (after the drug is administered by the oral or rectal route) and parenteral absorption (associated with drugs administered intramuscularly [IM], subcutaneously, or topically). The various administration routes and other factors affect a drug's ability to enter the bloodstream.

The extent to which the drug reaches the systemic circulation is referred to as *bioavailability*, or F, which is defined as the fraction or percentage of the drug that reaches the systemic circulation. Drugs administered intravenously are 100% bioavailable. Drugs administered by other routes (e.g., oral, IM) may be 100% bioavailable, but more often, they are less than 100% bioavailable. Therefore, bioavailability depends on the route of administration and, equally important, the drug's ability to pass through membranes or barriers in the body. Box 2.2 discusses the specific case of oral bioavailability.

BOX 2.2 Oral Bioavailability and the First-Pass Effect

Drugs given orally may be subject to the first-pass effect, by which drugs are metabolized by the liver before passing into circulation. After absorption from the alimentary canal, drugs go directly to the liver through the portal vein. In the liver, hepatic enzymes act on the drug, reducing the amount of active drug reaching the bloodstream and decreasing the amount available to the body. The fraction (or percentage) of medication reaching systemic circulation after the first pass through the liver is referred to as the drug's bioavailability (F).

The first-pass effect is not the only factor contributing to the oral bioavailability of a drug. Poorly soluble drugs and drugs adversely affected by gastric pH or other presystemic factors can also have a low bioavailability.

Drugs not usually subject to the liver's first-pass effect are known as drugs with a low hepatic extraction ratio because the liver does not extract a large percentage of the drug before releasing it into the circulation. Usually, drugs with a low extraction ratio have high oral bioavailability. In contrast, drugs with a high extraction ratio have low oral bioavailability. For example, lidocaine has a hepatic extraction ratio of 0.7; that is, the liver metabolizes 70% of the drug before the drug reaches the circulation and, as such, only 30% remains available systemically. This is one reason lidocaine is administered parenterally. In other words, the first-pass effect for lidocaine is of such magnitude that an

alternative route of administration is required. Giving large oral doses of a drug to compensate for the high extraction ratio is often an alternative to parenteral administration. For example, because of the high extraction ratio of propranolol, a 1-mg dose administered intravenously is approximately equivalent to a 40-mg dose administered orally.

Examples of drugs with a high hepatic extraction ratio (70% or more) are imipramine (Tofranil), lidocaine (Xylocaine), and meperidine (Demerol); drugs with intermediate rankings are codeine, nortriptyline (Aventyl), and quinidine (Quinaglute); and some drugs with a low extraction ratio (30% or less) are barbiturates, diazepam (Valium), theophylline (Theo-Dur), tolbutamide (Orinase), and warfarin (Coumadin).

Factors Affecting Absorption

A variety of factors affect absorption, such as the presence or absence of food in the stomach, blood flow to the area for absorption, and the dosage form of the drug. The following sections discuss some of the major factors affecting absorption.

Movement through Membranes and Drug Solubility

Throughout the body, biologic membranes act as barriers, blocking or permitting the passage of various substances. These membranes protect certain areas of the body from harmful chemicals and allow other areas to be accessed as needed.

Biologic membranes composed of cells serve as barriers primarily because of the structure and function of the cells that make up the membrane. Cell membranes are composed of lipids and proteins, creating a phospholipid bilayer. This bilayer acts as a barrier that is almost impermeable to water, other hydrophilic (water-loving) substances, and ionized substances. However, the bilayer does allow most lipid-soluble (hydrophobic) compounds to pass through readily. Interspersed throughout this bilayer are protein molecules and small openings, or pores. The proteins may act as carrier molecules, bringing molecules through the barrier. The pores allow hydrophilic molecules to pass through if they are small enough. Therefore, drugs and other compounds that pass through membrane barriers can do so by passive or active means.

Passive Diffusion

Drugs can pass through membrane barriers by diffusion. In passive diffusion, molecules move from one side of a barrier to another without expending energy. In passing, the molecules move down a concentration gradient—that is, they move from an area of higher concentration to an area of lower concentration. The rate of diffusion depends on the differences in concentrations, the relative strength of the barrier, the distance that the molecules must travel, and the size of the molecules. This relationship is known as Fick's law of diffusion. In essence, Fick's law states that the greater the distance to travel and the

larger the molecule, the slower the diffusion.

Another major barrier to the absorption of a drug is its solubility. To facilitate drug absorption, the solubility of the administered drug must match the cellular constituents of the absorption site. Lipid-soluble drugs can penetrate fatty cells; water-soluble drugs cannot. For example, a water-soluble drug such as penicillin cannot easily pass through the barrier between the blood and brain, whereas a highly lipid-soluble drug such as diazepam (Valium) can. The relative strength of the barrier is important because the barrier must be permeable to the diffusing substance. Drugs diffuse more readily through the lipid bilayer if they are in their neutral, nonionized form. Most drugs are weak acids or weak bases, which have the potential for becoming positively or negatively charged. This potential is created through the pH of certain body fluids. In the plasma and in most other fluids, most drugs remain nonionized. However, in the gastric acid of the stomach, weak bases become ionized and are more difficult to absorb. As this weak base progresses through the alkaline environment of the small intestines, it becomes nonionized and therefore more easily absorbed. Similarly, weak acids remain nonionized in the stomach and become ionized in the small intestines. The result is reduced absorption by the intestines.

Active Transport

In active transport, membrane proteins act as carrier molecules to transport substances across cell membranes. The role of active transport in moving drugs across cell membranes is limited. To be carried through by a protein, the drug must share molecular similarities with an endogenous substance the transport system routinely carries. Cells can accomplish this through the process of endocytosis. In this process, the cell forms a vesicle surrounding the molecule, and it is subsequently invaginated in the cell. Once inside the cell, the vesicle releases the molecule into the cytoplasm of the cell.

Pharmaceutical Preparation

Drugs are formulated and administered in such a way as to produce either local or systemic effects. Local effects (e.g., antiseptic, anti-inflammatory, and local anesthetic effects) are confined to one area of the body. Systemic effects occur when the drug is absorbed and delivered to body tissues by way of the circulatory system.

Depending on how a drug is formulated (e.g., tablet or liquid), the means of drug delivery can target a site of action. Some drug formulations (dosage forms) deliver the drug into the gastrointestinal (GI) tract quickly (immediate release), whereas others release the drug slowly. This strategy for extending the activity of drugs in the body dampens the high and low swings of drug concentrations, thereby yielding a more constant blood level. Many medications are available in these controlled- or sustained-release dosage forms. The aim of sustained-release dosage forms is to administer them as infrequently as possible, improving compliance and minimize hour-to-hour or day-to-day blood level fluctuations. The various release systems available are subject to physiologic and pathophysiologic changes in patient

conditions.

Blood Flow

Blood flow ensures that the concentration across a gradient is continually in favor of passive diffusion—that is, as blood flows through an area, it continually removes the drug from the area, thereby maintaining a positive concentration gradient. Many hydrophobic–lipophilic drugs can readily pass through membranes and be absorbed. However, if the blood flow to that area is limited, the extent of absorption is limited. Because of the minimal vascularization in the subcutaneous layer compared with the greater vascularity of the musculature, drugs injected subcutaneously may undergo less absorption compared with drugs delivered by IM injection.

Gastrointestinal Motility

High-fat meals and solid foods affect GI transit time by delaying gastric emptying, which in turn delays initial drug delivery to intestinal absorption surfaces. The administration of agents that delay or slow intestinal motility (e.g., anticholinergic agents) prolongs the contact time. This increased intestinal contact time secondary to prolonged intestinal transit time may increase total drug absorption. Conversely, laxatives or diarrhea can shorten an agent's contact time with the small intestine, which may decrease drug absorption.

Enteral Absorption

Enteral absorption, with the oral route of administration being the most common and probably the most preferred, occurs anywhere throughout the GI tract by passive or active transport of the drug through the cells of the GI tract.

Following Fick's law, low molecular weight, nonionized drugs diffuse passively down a concentration gradient from the higher concentration (in the GI tract) to the lower concentration (in the blood). Active transport across the GI tract occurs more frequently with larger, usually ionized, molecules. These active mechanisms include binding of the drug to carrier molecules in the cell membrane. The molecules carry the drug across the lipid bilayer of the cells. However, most drugs are absorbed passively.

Oral Administration

The oral route of administration refers to any medication that is taken by mouth (per os or PO). The ability to swallow is implicit in oral administration; however, many practitioners consider local action, in which absorption does not occur, also to be "oral" (e.g., troches for fungal infections of the mouth). Common dosage forms administered by mouth include tablets, capsules, caplets, solutions, suspensions, troches, lozenges, and powders.

Absorption after oral administration usually occurs in the lower GI tract (small or large intestine), is slow, and depends on the patient's gastric-emptying time, the presence or

absence of food, and the gastric or intestinal pH. Variations in one or more of these factors can affect the stability of the drug, the contact time with the intestinal walls, or the blood flow to the GI tract. Most of the absorption occurs in the small intestine, where the large surface area enhances and controls drug entry into the body.

Drugs administered orally must be relatively lipid soluble to cross the GI mucosa into the bloodstream. The diffusion rate, a function of the lipid solubility of a drug across the GI mucosa, is a major factor in determining the rate of absorption of a drug. The acid pH of the stomach and the nearly neutral pH of the intestines can degrade some medications before they are absorbed. In addition, bacteria in various parts of the intestines secrete enzymes that also can break down drugs before absorption.

Although the GI tract is generally resistant to a variety of noxious agents, considerable irritation and discomfort can arise from certain medications in some people. Nausea, vomiting, diarrhea, and less often mucosal damage are common side effects of medications, and the practitioner should monitor all patients for these effects.

Sublingual Administration

Sublingual (SL, *under the tongue*) drug administration relies on absorption through the oral mucosa into the veins that drain those vascular beds. These veins carry the drug to the superior vena cava and eventually the heart. Drugs administered this way are not subject to the first-pass effect (see Box 2.2). This method of administration is limited by the amount of drug that can be placed sublingually and the drug's ability to pass through the oral mucosa into the venous system. Buccal administration, in which the drug is absorbed through the mucous membranes of the mouth, is similar to SL administration.

Rectal Administration

Drugs administered rectally (PR, per rectum) include suppositories and enemas. Primarily used in the treatment of local conditions (e.g., hemorrhoids) and inflammatory bowel disease, this method is less effective than other enteral routes because of the erratic absorption of most agents. Bowel irritation, early evacuation, and minimal surface area contribute to erratic absorption and poor tolerability of this route. Advantages, however, include the ability to administer a medication to an unconscious or nauseated patient.

Parenteral Absorption

All routes of administration not involving the GI tract are considered parenteral. Parenteral routes include inhalation, all forms of injection, and topical and transdermal administration.

Inhalation

Drugs that are gaseous or sprayable in small particles may be delivered by inhalation. The lungs provide a large surface area for absorption and quick entry into the bloodstream.

Inhaled medications bypass the first-pass effect and therefore may have a high bioavailability. Examples of inhalants are anesthetic gases and beta-adrenergic agonists (e.g., albuterol) used in treating asthma. Conversely, agents such as inhaled corticosteroids are intended for local action in the lung tissue. Regardless of the intent of inhaled medications, the disadvantages include irritation to the alveolar space and the need for good coordination during self-administration, such as with metered-dose inhalers.

Intravenous Administration

The intravenous (IV) route provides rapid access to the circulatory system with a known quantity of drug. Bypassing the first-pass effect and any GI metabolism or degradation, drug absorption by this route is considered the gold standard with regard to bioavailability. IV bolus injections allow for large amounts of medication to be administered quickly for a high peak drug level and a rapid effect. However, adverse effects from these high levels of medications also occur with this form of administration. Repeated bolus doses of medications, at designated intervals, can produce large fluctuations in peak and trough (lowest concentration before next dose) levels. Although over time these peaks and troughs produce average desired concentrations, significant peak and trough fluctuations may not be desirable in some patients. Continuous administration by an infusion can minimize or eliminate these fluctuations and produce a consistent, steady-state concentration.

Like IV administration, intra-arterial administration produces a rapid effect. However, because the drug is directly instilled in an organ, this route is considered more dangerous than the IV route. Therefore, intra-arterial administration is usually reserved for a time when injection into a specific tissue is indicated (e.g., anticancer treatment for a specific tumor).

Subcutaneous Administration

Subcutaneous (SC or SQ) administration produces a slower, more prolonged release of medication into the bloodstream. Injected directly beneath the skin, a drug must diffuse through layers of fat and muscle to encounter sufficient blood vessels for entry into the systemic circulation. This route is limited by the quantity of the liquid suitable for administration (usually 2 to 3 mL). Caution must also be taken because dermal irritation, or even necrosis, may occur. More recent technological advances allow the practitioner to implant drug-releasing mechanisms under the skin, providing a reservoir of drug for long-term absorption. Levonorgestrel (Norplant), a hormonal contraceptive, is administered in this manner.

Intramuscular Administration

Injecting medications into the highly vascularized skeletal muscle is a way of administering drugs quickly and avoiding the relatively large changes in plasma levels seen with IV administration. Local pain and muscle soreness are drawbacks to this method, as is the wide

variability in the rate of absorption resulting from injections given in different muscles and in different patients. Blood flow to the area is the major factor in determining the rate of absorption. This is considered a safe way to administer irritating drugs, although not all IM injections are truly IM: in grossly obese patients, presumed IM injections may actually be intralipomatous, which decreases the rate of absorption because of the lower vascularity of fatty tissue.

Topical Administration

Topical drug administration involves applying drugs, in various vehicles (e.g., liquids, powders), to the site of action, primarily the skin. Topical ointments, creams, drops, and gels typically produce a local effect. Ointments are occlusive, preventing water absorption or evaporation, and therefore have a hydrating effect and typically produce greater local effects than their cream counterparts. Creams are water soluble and therefore can be washed from the skin more readily than ointments. In hairy areas, creams are preferred over ointments because creams are hydrophilic and hence easier to apply and wash off. Gels, the most water-soluble topical dosage form, allow medication to be spread more easily over a larger area.

Transdermal Administration

Transdermal (*across the skin*) administration refers to the systemic delivery of medication through the skin. Several transdermal drug delivery systems are available for a wide range of medications, including estrogens (Estraderm) and fentanyl (Duragesic). In general, this method continuously delivers medication to achieve a constant blood level. The consistent delivery of drug throughout the dosing interval minimizes the peak-to-trough fluctuations seen with other forms of drug administration, thereby minimizing the toxicity associated with high blood levels while maintaining therapeutic concentrations.

Distribution

A discussion of the routes of administration offers the opportunity to consider the factors affecting drug absorption and bioavailability; once the medication is in the body, however, it must distribute to the site of action to be effective.

Distribution of an absorbed drug in the body depends on several factors: blood flow to an area, lipid or water solubility, and protein binding. For an absorbed drug to distribute from the blood to a specific site of action, there must be adequate blood flow to that area. In patients with compromised blood flow (e.g., from shock), relying on the blood to deliver a drug to a site of action, such as the kidney, may be risky.

In addition, drug distribution may be affected by obesity, both immediately after absorption and after achieving an equilibrium or steady state in the body. Lipid-soluble drugs readily distribute into the fatty tissues, where they may be stored and even concentrated. Water-soluble drugs, however, tend to remain in the highly vascularized spaces of the skeletal muscle. Ideal body weight is usually considered the standard for determining drug dosage, which is often adjusted for obese or cachectic patients.

Protein Binding

After absorption into the blood (and lymph), a drug may circulate throughout the body unbound (*free drug*) or bound to carrier proteins such as albumin. The extent of drug binding to carrier proteins depends on the affinity of the drug for the carrier protein and the concentrations of both the drug and the protein. Acidic drugs commonly bind to albumin and basic drugs commonly bind to alpha$_1$-acid glycoprotein or lipoproteins.

Plasma protein binding is typically a reversible phenomenon, with binding and unbinding occurring within milliseconds. Therefore, the bound and unbound forms of the drug can be assumed to be at equilibrium at all times. As such, the degree of binding to plasma proteins can be expressed as a percentage of bound drug to total concentration (bound plus unbound). It is only the unbound or free drug that can exert a pharmacologic effect. If the drug becomes bound, it becomes inactive because it cannot leave the bloodstream or bind to an enzyme or receptor and exert its therapeutic action (Figure 2.3).

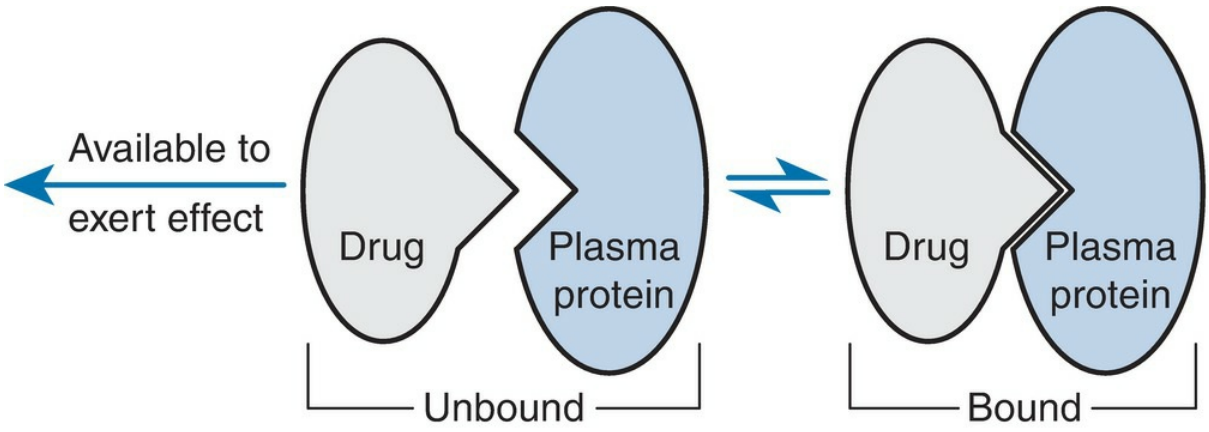

FIGURE 2.3 Relationship between bound and unbound drugs and plasma proteins.

Once the free drug is eliminated from the body through metabolism or excretion, the bound drug can be released from the protein to become active. In essence, the bound drug may serve as a storage site or reservoir of the drug. The percentage of the free drug usually is constant for a single drug but varies among drugs. Patient-specific factors, such as nutritional status, renal function, and levels of circulating protein or albumin, can change the percentage of the free drug.

Volume of Distribution

The amount of drug in the human body can never be directly measured. Observations are made of the concentration of drug in plasma or sometimes in blood. Over time, the concentration of drug in the plasma depends on the rate and extent of drug distribution to the tissues and on how rapidly the drug is eliminated. For most drugs, distribution occurs more rapidly than elimination. The resultant plasma concentration after distribution depends on the dose and the extent of distribution into the tissues. This extent of distribution can be determined by relating the concentration obtained with a known amount of administered drug.

For example, if 100 mg of an IV drug is administered to a person and remains only in the plasma, and if that person's total plasma volume measures 5 L, the resulting measured concentration of drug would be 20 mg/L [concentration = dose/volume: 100 mg/5 L]. However, in reality, few drugs distribute solely in the plasma, and many bind to plasma proteins. Drugs commonly bind not only to plasma proteins but also to tissue-binding sites on fat and muscle. In addition, drugs translocate into other "compartments" or spaces throughout the body. The volume into which a drug distributes in the body at equilibrium is called the (apparent) volume of distribution (V_d). This volume does not refer to a real volume; rather, it is a mathematically calculated volume (Box 2.3). The V_d is a direct measure of the extent of distribution of a drug in the body and represents the apparent volume that a drug must distribute to contain the amount of drug homogenously.

BOX 2.3 Calculating the Apparent Volume of Distribution (V_d)

$$V_d = \frac{\text{Amount in body}}{\text{Plasma drug concentration}}$$

V_d is usually measured in liters (L); *amount in body* is usually measured in milligrams (mg); and *plasma drug concentration* is usually measured in milligrams per liter (mg/L).

The apparent volume of distribution is a theoretical parameter calculated by determining the amount of drug in the body (usually the dose administered) divided by the concentration of drug in the plasma taken at an appropriate time interval after administration.

Drugs that are highly water soluble or highly bound to plasma proteins remain in the blood compartment and do not distribute or bind to fatty tissue. These drugs have a low V_d, usually less than the volume of total body water (approximately 50 L, or 0.7 L/kg). Drugs with a low V_d usually circulate at high levels in the blood. In contrast, drugs that are not highly protein bound and are highly lipophilic have a high V_d (greater than 150 L, which is greater than the volume of total body water). These drugs distribute widely throughout the body and may even cross the blood–brain barrier.

Elimination

All drugs must eventually be eliminated from the body to terminate their effect. Drugs can be eliminated through metabolism (or biotransformation) of the drug from an active form to an inactive form. Drugs can also be eliminated by excretion from the body. Therefore, elimination is a combination of the metabolism and excretion of drugs from the body. Important concepts in understanding drug elimination are half-life, steady state, and clearance. Knowledge of these phenomena in any given patient helps practitioners understand how long a drug will last in the body and how much should be given to maintain therapeutic levels and therefore helps in determining the appropriate dose and dosing intervals.

Metabolism

Metabolism is a function of the body designed to change substances into water soluble, more readily excreted forms. The liver primarily performs the body's metabolic functions because of its high concentration of metabolic enzymes. This is why the first-pass effect is significant to the bioavailability of a drug administered orally.

Other organs, such as the kidneys and intestines, as well as circulating enzyme systems, also contribute to the metabolism of drugs. Metabolic processes are used to detoxify drugs and other foreign substances as well as endogenous substances. Drugs may be metabolized from active components into inactive or less active ones. Some drugs, however, may be biologically transformed from an inactive parent drug into an active metabolite. This type of drug is called a prodrug because it is a precursor to the active drug (Table 2.1). Not all drugs are metabolized to the same extent or by the same means. In fact, some drugs, such as the aminoglycosides (e.g., gentamicin [Garamycin]), are not metabolized at all.

TABLE 2.1 Selected Prodrugs and Metabolites

Parent Drug (Prodrug)	Active Metabolite
allopurinol	oxypurinol
codeine	morphine
enalapril	enalaprilat
prednisone	prednisolone
valacyclovir	acyclovir

Enzyme actions are the primary means for metabolizing drugs, and these actions are broadly classified as phase 1 and phase 2 enzymatic processes. Phase 1 enzymatic processes

involve oxidation or reduction, by which a drug is changed to form a more polar or water-soluble compound. Phase 2 processes involve adding a conjugate (e.g., a glucuronide) to the parent drug or the phase 1–metabolized drug to further increase water solubility and enhance excretion.

The oxidative process of phase 1 metabolism is catalyzed by the flavin-containing monooxygenases (FMO), the epoxide hydrolases (EH), and the cytochrome P-450 system (CYP). The FMOs and CYP are composed of superfamilies of more than 100 enzymes each. Three families (about 15 total enzymes) of the CYP enzymes are important contributors to drug metabolism. The common feature of these enzymes is their lipid solubility. Most lipophilic drugs are substrates for one or more of the CYP enzymes (Table 2.2). FMOs are not considered major contributors to drug metabolism at this time.

TABLE 2.2 Key Cytochrome P-450 Families and Isoforms in Drug Metabolism

Family	Isoform	Example of Drugs Metabolized
CYP1	CYP1A2	theophylline
CYP2	CYP2C	omeprazole
	CYP2D6	dextromethorphan
	CYP2E1	acetaminophen
CYP3	CYP3A4	atorvastatin

Some drugs can induce or stimulate the production of one or more isoforms of the enzymes by a process called enzyme induction, which increases the amount of enzyme available to metabolize drugs. The result of enzyme induction is an increased metabolism of other drugs, thereby decreasing the amount of drug circulating throughout the body.

Conversely, some drugs inhibit the production of CYP enzymes and thereby decrease the metabolism of drugs and increase circulating levels. This is known as enzyme inhibition. Both enzyme induction and inhibition are the basis of metabolically mediated drug–drug interactions. See Chapter 3 for further discussion of induction and inhibition and their role in drug–drug interactions.

Although the liver is regarded as the primary site of drug metabolism, other tissues also possess the enzymes necessary for metabolism. The kidneys, for example, have several enzymes needed for drug metabolism and can serve as the site of drug inactivation. The GI tract is also known to possess several of the CYP isoforms, contributing to the extrahepatic metabolism of drugs.

The nature, function, and amount of any drug-metabolizing enzyme can be different, resulting in differing drug disposition among patients. Disease-induced changes can affect drug metabolism as well. For example, alterations in liver function induced by long-standing cirrhotic changes can reduce the production of necessary enzymes, resulting in increased concentrations of drugs typically metabolized in the liver. Also, decreased blood flow to the liver, as occurring in congestive heart failure, can decrease the delivery of drug to metabolic sites in the liver. Cigarette smoking on the other hand, can increase the levels of enzymes responsible for drug metabolism, resulting in increased metabolic rates and the need for higher doses of drugs (e.g., theophylline) in smokers than in nonsmokers.

Drug Excretion

Metabolism eliminates a drug from the body by changing the drug molecule into something else, but drugs also can be eliminated from the body by excretion. Excretory organs include the kidneys, lower GI tract, lungs, and skin. Other structures, such as the sweat, salivary, and mammary glands, are active in excretion as well. Drugs may also be removed forcibly by dialysis.

The primary route of excretion is the kidney. After the drug is metabolized, the resultant metabolite may be filtered by the glomerulus. As the drug continues through the proximal tubule, loop of Henle, and distal tubule, several things may occur: the drug may exert action (as in the case of diuretics), be reabsorbed into the bloodstream, or remain in the nephron, eventually reaching the collecting ducts, from which it ultimately leaves the body in the patient's urine. This filtration works well for hydrophilic, ionized compounds and is a common route of elimination. Conversely, active secretion of drugs occurs in the proximal tubule. Two different systems exist, one for organic acids (e.g., uric acid) and one for organic bases (e.g., histamine). Once ionized by the acidic pH of the urine, organic bases are not reabsorbed back into the bloodstream. If the pH rises, then more of the organic base becomes nonionized and thus more readily reabsorbed. Similarly, changes in urine pH can alter the reabsorption of organic acids, increasing or decreasing the circulating levels as the pH changes. Drugs such as penicillin are excreted by the organic acid system.

Drugs are excreted by the liver into the gallbladder, resulting in biliary elimination. Biliary elimination can sometimes result in drug reabsorption. For example, if a drug is excreted in the bile, it goes into the GI tract, where it may be reabsorbed and returned to the general circulation. This is called *enterohepatic recirculation* (Figure 2.4). The result of significant enterohepatic recirculation is a measurable increase in the plasma concentration of a drug and a delay in its elimination from the body.

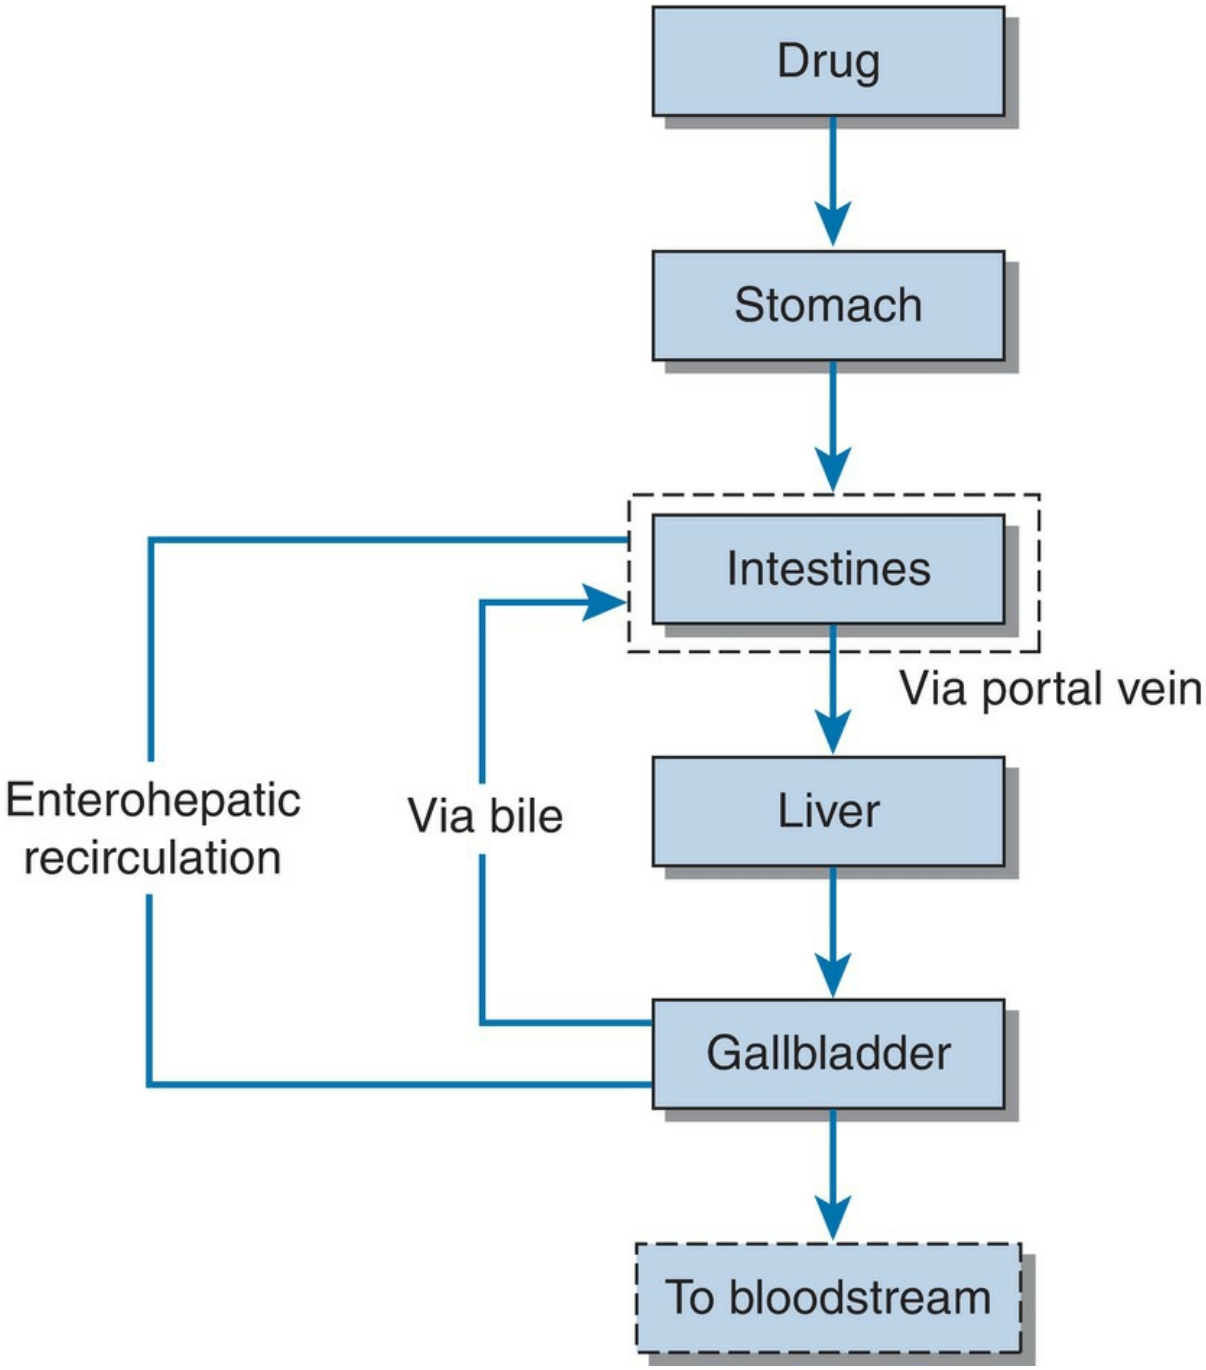

FIGURE 2.4 Enterohepatic recirculation. When a drug is absorbed from the intestine, travels to the liver and gallbladder, and into the bile unchanged, it has the potential for being reintroduced into the intestine and therefore reabsorbed. This is known as enterohepatic recirculation.

Half-Life

The time required for a drug to be eliminated from the body varies according to the drug and the individual. However, useful generalizations can be made that help practitioners estimate how long a drug will remain in the body. The first generalization has to do with

the elimination half-life ($t_{1/2}$), which is the time required for half of the total drug amount to be eliminated from the body. Assuming 100% of a drug exists in the body at time X, then one half-life later, 50% of the original amount would remain in the body. An additional half-life later, 25% would remain and so on. For example, theophylline has a $t_{1/2}$ of approximately 8 hours. If the theophylline concentration in a patient's body is 15 mg/L, then it would take 8 hours to decline to 7.5 mg/L, another 8 hours (16 hours total) to fall to 3.75 mg/L, and another 8 hours (24 hours total) to fall to 1.875 mg/L. The actual rate of elimination of a drug remains constant, but as can be seen in Figure 2.5, the actual amount of drug eliminated is proportional to the concentration of the drug—that is, the more drug there is, the faster it is eliminated. This phenomenon, known as first-order kinetics, applies to most drugs. Rate processes can also be independent of concentration, and fixed amounts of drugs, rather than a fractional proportion, are eliminated at a constant rate. This phenomenon is called zero-order kinetics. Alcohol undergoes zero-order elimination.

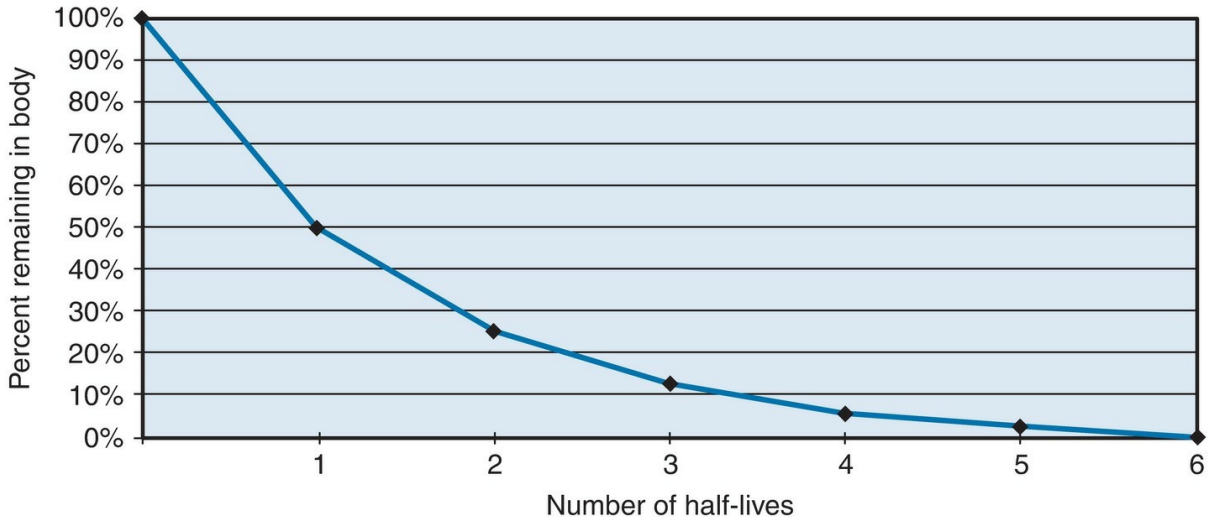

FIGURE 2.5 Drug elimination based on half-life ($t_{1/2}$).

After five half-lives, according to first-order kinetics, approximately 97% (96.875%) of the drug is eliminated from the body. Even after three half-lives, nearly 90% (87.5%) of the drug is eliminated. In most cases, after three to five half-lives, the amount of drug remaining is too low to exert any pharmacologic effect, and the drug is considered essentially eliminated. Understanding this concept is useful for practitioners in many situations. For example, if a drug reaches a toxic level, the practitioner knows that it will take three to five half-lives for the drug to be essentially eliminated from the body. The practitioner also can estimate when the drug level will approach a minimally effective concentration and can then calculate when to administer another dose of medication to reach a therapeutic drug level.

Steady State

In reality, patients take medications on a consistent basis, usually somewhere between one and four times daily. By doing so, they are absorbing and eliminating the drug throughout the day. Because the rate of elimination is proportional to the concentration, at some point, equilibrium is reached. Figure 2.6 demonstrates how doses of a drug with a half-life of 8 hours produce this equilibrium. Note that after approximately three to five half-lives, the curve levels off. This demonstrates equilibrium between the amount of drug entering the body and the amount leaving the body. This point, which is called *steady state*, reflects a constant mean concentration of drug in the body. At steady state, even though the blood levels of a drug fluctuate above and below this mean concentration and the drug level tends to have peaks and troughs during dosing intervals, the fluctuations remain within a constant range.

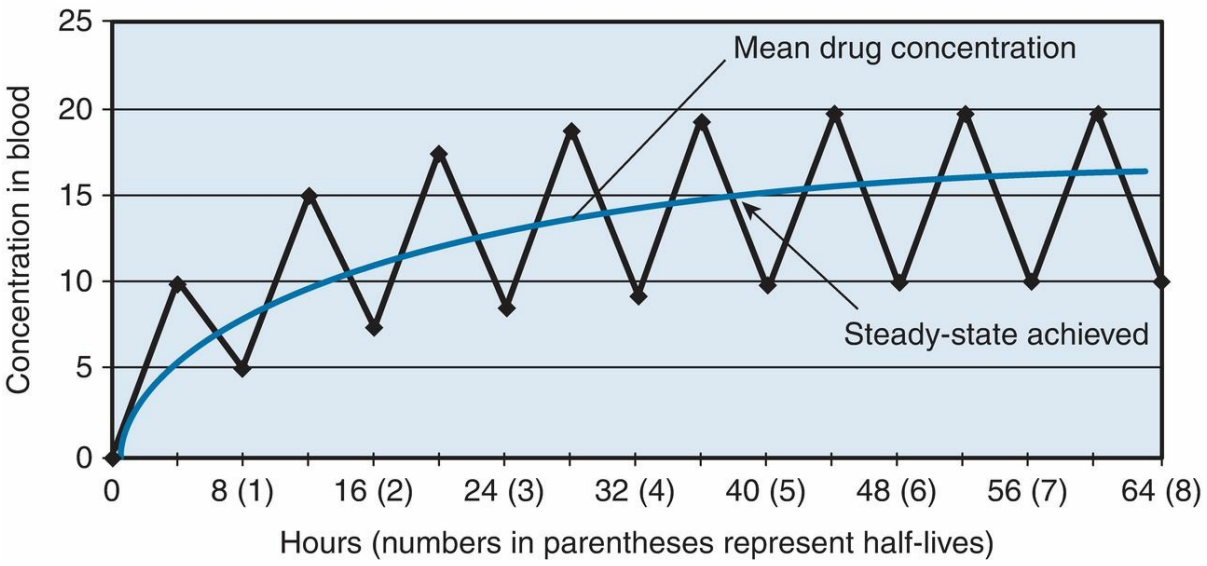

FIGURE 2.6 Steady state achieved with regular dosing (half-life = 8 hours).

For some drugs, the time required to achieve steady state may be very long. For example, digoxin (Lanoxin) has a half-life of 39 hours (1.6 days), meaning that between 4.8 and 8 days are needed to achieve steady state. Clearly, when it is imperative to gain a therapeutic level quickly, waiting this long is unacceptable. Therefore, an initial loading dose of a drug is needed to reach the desired blood concentration quickly. The loading dose is based on the volume of distribution of the drug, independent of the half-life. The maintenance dose, however, is based on the half-life of the drug. Maintenance doses of the drug are given at scheduled intervals to replace the amount of drug eliminated.

Clearance

The concept of clearance, which refers to the removal of a drug from the plasma or organ, is the final element in the process of elimination. Drugs with high clearances are removed

rapidly; those with low clearances are removed slowly. Drugs can be cleared by biliary, hepatic, and renal means. The following discussion highlights renal clearance.

Clearance is related to the volume of distribution and the half-life (Box 2.4). Clearance of a drug from the body depends directly on the apparent volume of distribution and is inversely related to the elimination half-life: the greater the volume of distribution and the shorter the half-life, the faster the clearance.

BOX 2.4 Relationship between Apparent Volume of Distribution, Clearance, and Half-Life

$$\text{Clearance} = \frac{0.693 \times V_d}{t_{1/2}}$$

Clearance is usually expressed as L/hour; V_d is in L; $t_{1/2}$ is usually in hours.

Clearance of a drug is directly dependent on the apparent volume of distribution and inversely related to the elimination half-life. The larger the V_d, the faster the clearance. Also, the smaller the $t_{1/2}$, the faster the clearance.

Because most drugs are "cleared" through the kidney, estimating the renal elimination rate or clearance can help the practitioner to understand how fast a drug is being eliminated in an individual patient. The kidney's ability to clear drugs is estimated through a surrogate substrate: creatinine. Creatinine, which is produced through the continual breakdown of muscle tissue and eliminated largely by glomerular filtration, is not significantly secreted or reabsorbed. Therefore, in estimating the creatinine clearance, the practitioner can also estimate the glomerular filtration rate (GFR). The level of creatinine is usually measured through a blood test (serum creatinine), with normal values ranging from 0.8 to 1.2 mg/dL. By combining this information with a patient's ideal body weight and age, the practitioner can use the formula of Cockroft and Gault to evaluate creatinine clearance and evaluate the kidney's ability to function and eliminate drugs (Box 2.5). For example, for a 40-year-old man of average height weighing 70 kg (154 lb) and having a serum creatinine level of 1 mg/dL, the estimated creatinine clearance is 97 mL/min. (This is only an estimate of this patient's creatinine clearance. The best method of determining the actual value is by a 24-hour urine specimen collection and measurement of excreted creatinine.)

BOX 2.5 Estimating Creatinine Clearance or Glomerular Filtration Rate (GFR)—the Cockroft and Gault Formula and the Modification of Diet in Renal Disease (MDRD) Study Equation

$$\text{Cockroft and Gault}: \text{CrCl}_{\text{est}} = \frac{[140 - \text{age(y)}] \times \text{IBW}}{S_{cr} \times 72}$$

$$\text{MDRD}: \text{GFR} = 175 \times (\text{Standarized } S_{cr})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American})$$

Note: GFR is expressed in mL/min per 1.73 m^2, S_{cr} is serum creatinine expressed in mg/dL, and age is expressed in years.

Multiply $CrCl_{est}$ by 0.85 for women.

$CrCl_{est}$ = estimated creatinine clearance

S_{cr} = serum creatinine (mg/dL)

IBW = ideal body weight in kilograms (kg; 2.2 lb = 1 kg)

Alternatively, the Modification of Diet in Renal Disease (MDRD) equation can also be employed to estimate the GFR of a patient. This equation, also shown in Box 2.5, should be used in adults only. This equation estimates the GFR adjusting for body surface area. There are several studies that show that the MDRD equation is useful in patients with chronic kidney disease, but in patients with a true GFR greater than 90 mL/min, the MDRD equation underestimates the true GFR (National Kidney Disease Education Program, 2012).

In either case, creatinine clearance or GFR values below 50 mL/min suggest significant impairment of renal function and thus possible impairment of renal drug elimination. This may result in administered drugs having longer half-lives and higher steady-state concentrations, which may result in toxicity if the dose is not decreased or the length of time between doses is not increased.

Not every patient needs to have creatinine clearance estimated. Two rules of thumb are useful for the practitioner: patients older than age 65 or those with a serum creatinine value greater than 1.5 mg/dL may be at risk for accumulating drug (and therefore toxicity)

because of decreased renal function. In patients with either of these characteristics, a baseline and routine evaluation of renal function (e.g., serum creatinine determination) should be performed.

Pharmacodynamics

Pharmacodynamics refers to the set of processes by which drugs produce specific biochemical or physiologic changes in the body. Most often, pharmacodynamic effects occur because a drug interacts with a receptor. Receptors may be cell membrane proteins, extracellular enzymes, cytoplasmic enzymes, or intracellular proteins. A receptor is the component of the cell (or an enzyme) to which an endogenous substance binds, or attaches, initiating a chain of biochemical events. This chain of biochemical events culminates in a change in the physiologic function of the cell or activity of the enzyme. Like endogenous substances, drugs can initiate the biochemical chain of events. For example, a drug stimulating a receptor on the surface of an artery may ultimately cause vasoconstriction or vasodilation; or the drug's binding to a receptor may produce a change in cell wall permeability, thus allowing other substances to enter or leave a cell, such as occurs in nerve cells; or the drug attached to a receptor may initiate an increase or decrease in the production of an enzyme, thereby changing the amount of enzymatic activity for a given process.

Any chemical, endogenous or exogenous, that interacts with a receptor is called a *ligand*. Regardless of the ligand, or the actual interaction type, a substance can only alter or modify a cell or process, not impart a new function.

Drug Receptors

The capacity of a drug to bind to a receptor depends on the size and shape of the drug and the receptor. The drug acts as a "key" that fits into only a certain receptor or receptor type (Figure 2.7). Once the drug fits into the receptor, it may act to "unlock" the activity of the receptor, thus initiating the biochemical chain of events, much like an ignition key initiates the chain of events that starts a car.

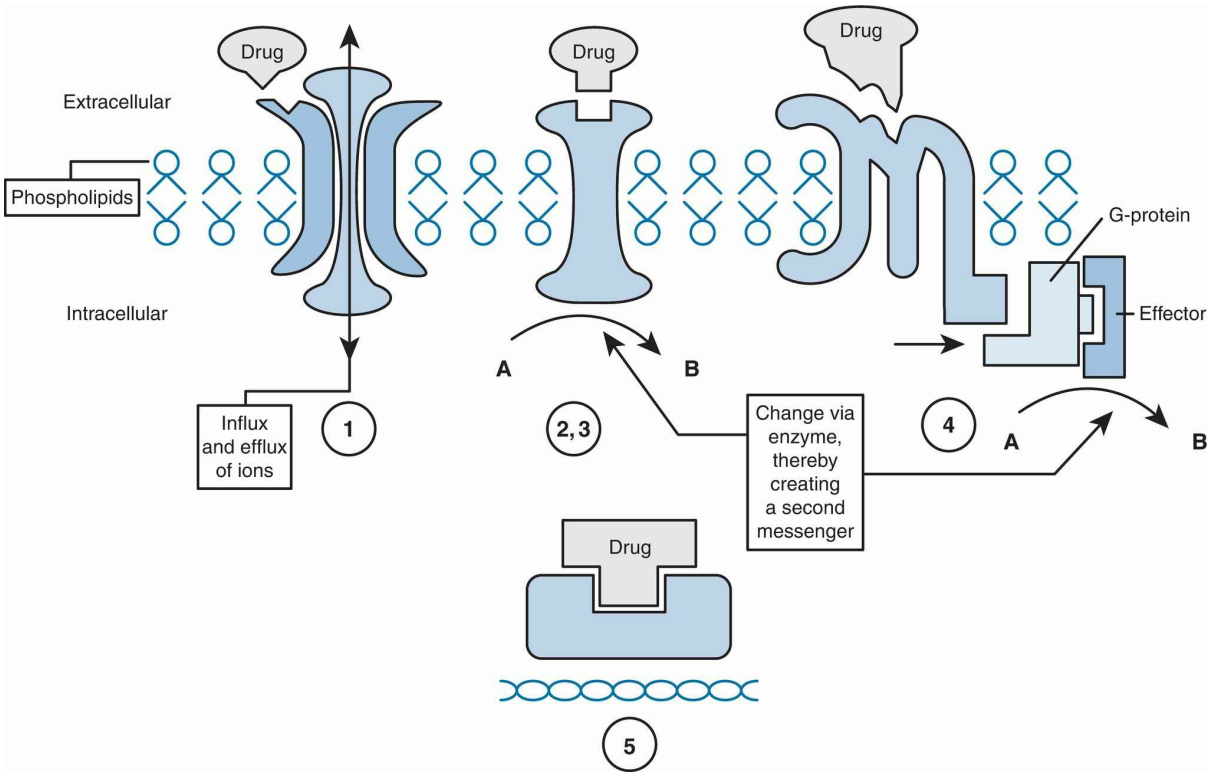

FIGURE 2.7 Drug and drug–receptor interaction and signal transduction. The five primary receptors and their mechanisms of signal transduction include (1) gated ion channels; (2 and 3) transmembranous receptors—cytoplasmic enzyme and tyrosine kinase activated; (4) G protein–coupled receptors; and (5) intracellular receptors.

Drug receptors are commonly classified by the effect they produce. Some drugs interact with several receptors, causing multiple effects, whereas others interact with only a specific receptor, eliciting a single response. Epinephrine, for example, interacts with the alpha and beta receptors of the sympathetic nervous system. As a result, epinephrine produces vasoconstriction (alpha receptor action) and an increase in heart rate (beta receptor action). Various molecules or enzymes can serve as drug receptors, such as ion channels (calcium channels), enzymes (angiotensin-converting enzyme [ACE]), and even receptors that generate intracellular second messengers (substances that interact with other intracellular components).

There are four known types of receptors: gated ion channels, transmembranous receptors, G protein–coupled receptors, and intracellular receptors (see Figure 2.7). Understanding these receptors and the signals they generate is central to understanding the actions of many drugs.

Gated Ion Channels

The function of gated ion channel receptors is to open or close channels to allow certain ions to pass through the cell membrane. Binding of ligands to these receptors produces a conformational change that widens or narrows the channel, thereby regulating the access of

soluble ions (Figure 2.7). The nicotinic acetylcholine receptor is a good example of a gated ion channel receptor. Its function is to translate the signal from acetylcholine into an electrical signal at the neuromuscular endplate. As such, when acetylcholine binds to this receptor, the channel opens, allowing sodium or potassium to enter the cell and cause cellular depolarization.

Other types of gated ion channel receptors are associated with the neurotransmitters. Gamma-aminobutyric acid ($GABA_A$), the primary inhibitory neurotransmitter, opens a chloride channel in the cell, which minimizes the depolarization potential. Certain drugs, such as the benzodiazepines, bind to an allosteric site and enhance the activity of $GABA_A$ by increasing the opening of the chloride channel. There is no intrinsic activity at the allosteric site, and it serves only to enhance the primary action of the endogenous ligand. Other excitatory neurotransmitters, such as L-glutamate and L-aspartate, operate by this mechanism, called signal transduction, which transfers the signal quickly.

Transmembranous Receptors: Cytoplasmic Enzyme or Tyrosine Kinase Activated

A transmembranous receptor has its ligand-binding domain, the specific region to which ligands bind, on the cell's surface. The enzymatic portion of the receptor is in the cell cytoplasm. When a ligand binds to a transmembranous receptor, several things may occur. The receptor–ligand complex produces a conformational change in the receptor and triggers a response. Alternatively, the ligand–receptor complex can pass through the cell membrane and trigger an intracellular response directly. This intracellular response often is a change in enzymatic activity. A key feature of the transmembranous receptor response is the downregulation of the receptors or a decrease in the number of receptors available for response. The opposite of this is upregulation, which does not occur as frequently. The nature of the signal depends on the specific ligand–receptor interaction, but it commonly results in the generation of second messengers. A second messenger is an intracellular chemical that interacts with other intracellular components. Ions such as calcium and potassium, along with cyclic adenosine monophosphate, are common second messengers. Hormones and other endogenous substances, such as growth factors and insulin, often operate with this signaling mechanism.

The receptor tyrosine kinase signaling pathway can bind with a polypeptide hormone or growth factor at the receptor's extracellular domain. This results in enzymatically active tyrosine kinase domains that phosphorylate each other, allowing a single receptor to activate multiple biochemical processes. For example, insulin works by stimulating the uptake of glucose as well as amino acids, resulting in changes in glycogen content within the cell. Alternatively, inhibition of tyrosine kinase processes through blockage of the external receptor can result in a decrease in stimulation of growth factors within the cell. This is particularly important in cancer treatments, when inhibiting the growth of the cell is key to treatment success.

A drawback of this system is the potential for downregulation of the receptors. Activation of these receptors leads to an endocytosis of the receptor and subsequent receptor degradation. When this activity exceeds the production of new receptors, there is a reduction in the number of receptors available for stimulation, thus a decrease in the cell's activity.

G Protein–Coupled Receptors

G protein–coupled receptors are another family of receptors that generate intracellular second messengers. These receptors also exist as transmembranous receptors composed of an extracellular protein receptor and an intracellular type G protein. The interaction of a ligand and the receptor produces a conformational change in the receptor, bringing it in contact with the G protein. This contact results in activation of an enzyme or opening of an ion channel in the cell and, in turn, increased levels of the second messenger. It is the second messenger that triggers a change in the function of the cell. Alpha- and beta-adrenergic receptors, along with several hormone receptors, use G proteins to affect cell function.

Intracellular Receptors

Lipid-soluble drugs can traverse the lipid bilayer of the cell and enter the cytoplasm. Once inside, these drugs attach to intracellular receptors and initiate direct changes in the cell by affecting DNA transcription. Glucocorticoids and sex hormones are known to act by way of this signaling mechanism.

Drug–Receptor Interactions

The ability of a drug to bind to any receptor is dictated by factors such as the size and shape of the drug relative to the configuration of the binding site on the receptor. The electrostatic attraction between the drug and the receptor may also be important in determining the extent to which the drug binds to the receptor.

Affinity

A drug attracted to a receptor displays an *affinity* for that receptor. This affinity, the degree to which a drug is attracted to a receptor, is related to the concentration of drug required to occupy a receptor site. Drugs displaying a high affinity for a given receptor require only a small concentration in the circulation to elicit a response, whereas those with a low affinity require higher circulating concentrations. There exists equilibrium between the blood concentration of a drug, the concentration of drug at the site of action (i.e., near the receptor), and the amount of drug bound to a receptor. The magnitude of a drug's effect can be explained by the receptor occupancy theory—that is, a response from a cell (or group of cells) depends on the fraction of receptors occupied by a drug or endogenous substance. Therefore, one can infer a relationship between the minimally and maximally effective concentrations needed at the site of action and the minimum and maximum blood concentrations.

Chirality

The shape of a drug can influence its interaction with a receptor. Most drugs display chirality—that is, they exist in two forms with mirror-image spatial arrangements called enantiomers, or isomers. Each enantiomer is distinguished from the other through its ability to rotate polarized light in pure solution to the right or left. This results in a dextrorotary, or D-enantiomer, and a levorotary, or L-companion.

A pair of enantiomers is like a left and a right hand. As such, enantiomeric pairs may not fit into a receptor equally well, just as a right hand does not fit well into a left-hand glove. This is called stereoselectivity; one enantiomer may fit better into a receptor than the other and, hence, be more active. For example, the drug dextromethorphan (Robitussin DM) is the D-isomer of a compound. This D-isomer is a common cough suppressant found in most over-the-counter medications. Its L-isomer counterpart, levorphanol (Levo-Dromoran), is an extremely potent narcotic analgesic. Although the L-isomer also possesses cough suppressant activity, the D-isomer is essentially devoid of analgesic activity at commonly used doses. This similarity coincident with dissimilarity illustrates the importance of isomers in pharmacodynamics.

Agonists and Antagonists

Not all drugs with an affinity for a receptor elicit a response. Drugs that display a degree of

affinity for a receptor and stimulate a response are considered agonists. Others that display an affinity and do not elicit a response are called antagonists. Antagonists do not have intrinsic activity; they can only block the activity of the endogenous agonist. An antagonist may be viewed as a key that fits into the lock but, because of its different configuration, cannot be turned. Because an antagonist can occupy, or fit into, a receptor, it competes with agonists for that receptor, thereby blocking the effect of the agonist. Antagonists with a high affinity for a receptor may be able to "bump" an agonist off the receptor and reverse the agonist activity. Antagonists usually are used to block the activity of an endogenous substance, but they also can be used to block the activity of exogenously administered drugs. For example, when naloxone (Narcan) is given to a patient taking opioid drugs, the analgesic (and adverse) effects of the opioid are reversed within 1 to 2 minutes. In most cases, naloxone has a higher affinity for the opioid receptor than the opioid itself. This rough explanation of drug–receptor interactions serves only as a basis for understanding the complexity of this interplay.

Dose–Response Relationships

For many drugs, the relationship between the dose and the response is obvious: lower doses produce smaller responses, whereas higher doses increase the response. This correlation is based on the amount of drug occupying specific receptors. As the amount of drug exceeds the number of available receptors, the response reaches a plateau, so that further increases in dose do not increase response. However, dose–response relationships such as these clearly depend on the affinity of a drug for a receptor: a drug with a high affinity for a receptor needs a significantly lower concentration to achieve the same effect compared with a drug with a lower affinity.

This difference in affinity accounts for the varying "potency" of drugs. For example, drugs such as hydromorphone (Dilaudid) and morphine produce the same effect: analgesia. However, hydromorphone is more potent than morphine and therefore requires a smaller concentration to elicit a similar level of analgesia. Figure 2.8 demonstrates a typical dose–response relationship.

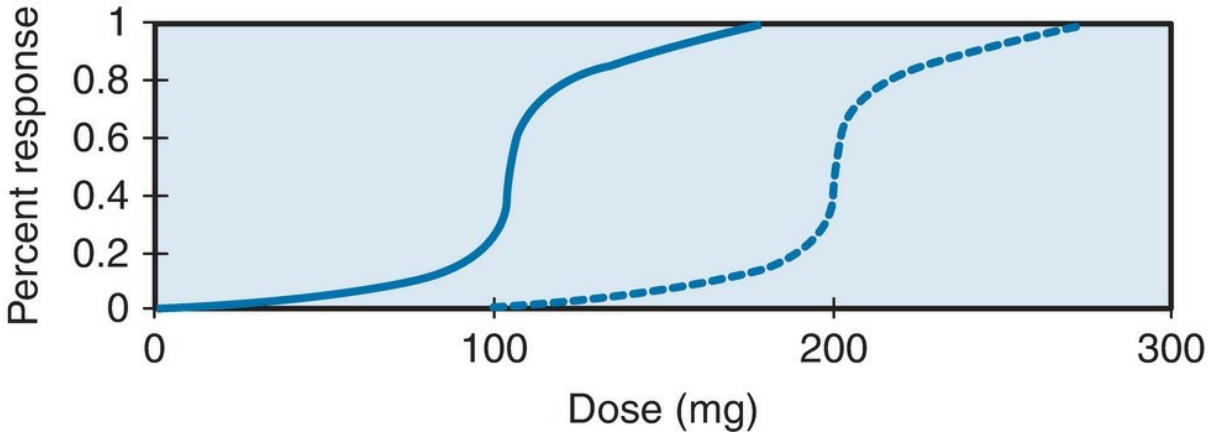

FIGURE 2.8 Two drugs with differing receptor affinities produce similar effects at different dosage ranges. The drug with the greater affinity (*solid line*) requires less drug to produce the same effect as a drug with less affinity (*dotted line*). This demonstrates the relationship between receptor affinity and drug potency.

Factors Affecting Pharmacokinetics and Pharmacodynamics

The goal of pharmacotherapeutics is to achieve a desired beneficial effect with minimal adverse effects. Once a medication has been selected for a patient, the practitioner must determine the dose that most closely achieves this goal. A rational approach to this objective combines the principles of pharmacokinetics with pharmacodynamics to clarify the dose–response relationship. Knowing the relationship between drug concentration and response allows the practitioner to take into account the various pathologic and physiologic features of a particular patient that make his or her response different from the average person's response to a drug.

Patient Variables

A host of variables affect the disposition of a drug in the body and the reaction the body has to the drug. People vary in their body type, weight, diet, ethnicity, and genetic makeup. These factors, individually and combined, contribute to significant variation in the response to drug therapy. For example, the genetic makeup of the people of Japan is known to affect the expression of certain hepatic enzymes involved in the metabolism of drugs. This suggests that, at least pharmacokinetically, some people of Japanese heritage respond differently to certain drugs. The same logic applies to people who are overweight and underweight, people of varying ages, people with various pathophysiologic problems, and even people with different diets and nutritional habits.

Pathophysiology

Structural or functional damage to an organ or tissue responsible for drug metabolism or excretion presents an obvious problem in pharmacology. Diseases that initiate changes in tissue function or blood flow to specific organs can dramatically affect the elimination of various drugs. Certain diseases may also impair the absorption and distribution of the drug, complicating the problem of individualized response. The role of disease in affecting the patient's response is crucial because the response to the medication may be affected by the same pathologic process that the drug is being used to treat. For instance, renal excretion of antibiotics, such as aminoglycosides, is altered radically in many types of bacterial infection, but these drugs are typically administered to treat the same infections that alter their own excretion. Consequently, great care must be taken to adjust the dosage accordingly when administering medications to patients with conditions in which drug elimination may be altered.

Genetics

Genetic differences are a major factor in determining the way that people metabolize specific compounds. Genetic variations may result in abnormal or absent drug-metabolizing enzymes. The anomaly can be harmful or even fatal if the drug cannot be metabolized and therefore exerts a toxic effect from accumulation or prolonged pharmacologic activity. Some people, for example, lack the enzyme that breaks down acetylcholine. In these people, a drug such as succinylcholine (Anectine, an acetylcholine-like drug) is not degraded and therefore accumulates. The result is respiratory paralysis because the undegraded, accumulated succinylcholine has an increased half-life, causing it to remain active longer.

Age

The influence of age on pharmacokinetics and pharmacodynamics is well known. Developmental differences in the neonate, toddler, and young child, for instance, influence how drugs are handled by the GI tract, liver, and kidneys. Of equal importance is how these children respond to drugs in light of the presence or absence of receptors at different stages of development. For example, drug-metabolizing enzymes are deficient in the fetus and premature infant. The fetus can metabolize drugs early in its development, but its expression of drug-metabolizing enzymes differs from that of the adult and is usually less efficient.

Children can metabolize many drugs more rapidly than adults, and as children approach puberty, the rate of drug metabolism approaches that of adults. Similarly, older adults undergo physiologic changes that affect the absorption, distribution, and elimination of many agents. The pharmacodynamic changes imparted by age as well as accompanying diseases pose a greater challenge for the practitioner in understanding the impact a single agent has on a patient's health and well-being. Chapter 4 discusses pediatric considerations, and Chapter 6 discusses geriatric considerations in more depth.

Sex

The role of sex as a distinct patient variable is recognized by some but poorly understood by most. Most of the published clinical drug studies use male subjects as the primary study population, and clinicians then extrapolate the data to women. However, women in general have a higher percentage of body fat, which could ultimately alter the pharmacokinetic disposition of certain drugs. Similarly, the pharmacodynamic response of women may be different because of the presence or absence of hormones such as estrogen and testosterone.

Ethnicity

Ethnicity is a significant factor in both the pharmacokinetic and pharmacodynamic responses of patients. The genetic makeup of various ethnic populations governs the levels of hepatic enzymes expressed in these groups. Equally important are the habits and traditions of certain groups, such as diet or the use of home remedies.

Pharmacodynamically, ethnically based differences exist in the responses to agents. An example is the minimal response of African American patients to monotherapy with some drugs, such as ACE inhibitors. African Americans produce a low level of renin, a key component in the renin–angiotensin–aldosterone system by which the ACE inhibitors work. This low level of renin makes this system unaffected by the ACE inhibitor, thereby negating its effect.

Diet and Nutrition

Diet affects the metabolism of and response to many drugs. Animal and human studies indicate that total caloric intake and the percentage of calories obtained from different sources (carbohydrates, proteins, and fats) influence drug pharmacokinetics. Specific dietary constituents, such as cruciferous vegetables and charcoal-broiled beef, can also alter drug metabolism. Fortunately, most food–drug interactions are not serious and do not alter the clinical effects of the drug. However, a few well-known food and drug combinations should be avoided because of their potentially serious interactions. For instance, certain tyramine-containing foods, such as fermented cheese and wine, should not be ingested with drugs that inhibit the monoamine oxidase enzyme (MAO) inhibitors. Tyramine-rich foods stimulate the body to release catecholamines (norepinephrine, epinephrine). MAO-inhibiting drugs work by suppressing the destruction of catecholamines, thereby allowing higher levels of norepinephrine and epinephrine to accumulate. Consequently, when MAO inhibitors are taken with tyramine-containing foods, excessive catecholamine levels may develop and lead to a dangerous increase in blood pressure (hypertensive crisis). Practitioners should be aware of this and should be on the alert for other such interactions as new drugs arrive on the market.

Case Study*

M.T., a 75-year-old, white 60-kg IBW woman with a serum creatinine of 1.8 mg/dL, has atrial fibrillation. A decision has been made to use digoxin for heart failure. The target concentration of digoxin for the treatment of atrial fibrillation is 0.5 ng/mL to less than 1 ng/mL, but her current level is high at 2 ng/mL.

1. What is her estimated creatinine clearance using the Cockcroft/Gault method? GFR using the MDRD Method?

2. Assuming a 4-day half-life, how long will it take for MT to achieve a 1 ng/mL level? A 0.5 ng/mL level?

3 Impact of Drug Interactions and Adverse Events on Therapeutics

Tep Kang ■ Andrew M. Peterson

As the quantity and types of pharmacologic agents continue to expand, the likelihood of drug interactions and adverse reactions increases. Currently, more than 8,000 drugs are available to treat various conditions. Each agent is designed to alter the homeostasis of the human body to some degree, and individual responses to these agents can be unpredictable.

In a prospective study, Benard-Laribiere et al. (2014) found that 3.6% (97/2,692) of hospital admissions were due to serious adverse drug reactions (ADRs). Thirty percent of which were preventable and 16.5% of which were potentially preventable. Drug interactions caused 29.9% of ADR-related hospital admissions. According to the Institute for Safe Medicine Practices (ISMP) QuarterWatch (2014), psychiatric adverse drug events, notably suicidal behaviors, represent the major adverse effects reported in children under age 18. In a meta-analysis of observational studies, Martins et al. (2014) reported a 21.3% incidence of adverse drug events among adult inpatients. These data were captured during prospective monitoring whereby the events are detected during the hospital stay and can include interviews of the patient and/or care team and reviews of clinical and laboratory records.

ADRs present an alarming problem that warrants significant attention from health care practitioners. Not only do ADRs affect morbidity and mortality, they also dramatically increase health care costs. In the United States, the impact of ADRs may cost up to $30.1 billion per year. Most of the cost is attributed to increased hospitalization, increased length of stay, and increased cost of performing additional tests (Sultana et al., 2013).

Similarly, drug interactions are potentially preventable ADRs posing a significant problem to the health care community. It has been reported that approximately 10% to 20% of hospital admissions are drug related and about 1% of these are secondary to drug interactions. Others have reported that drug interactions are responsible for up to 3% of hospital admissions (Bjerrum et al., 2008). In addition, the prevalence of a first dispensing of drug–drug interactions in people older than age 70 has been reported to have increased from 10.5% in 1992 to 19.2% in 2005 (Becker et al., 2008). Therefore, a thorough understanding of how drug–drug interactions occur and how they relate to ADRs should help decrease the rate of occurrence and the associated morbidity/mortality. This chapter discusses the mechanisms of drug interactions and their potential consequences. For the purpose of this chapter, these interactions are broken down into four major categories: drug–drug interactions, drug–food interactions, drug–herb interactions, and drug–disease

interactions. Each of the interaction categories can affect the drug's pharmacokinetic or pharmacodynamic profile. The definition, identification, and management of ADRs are discussed at the end of the chapter.

Drug–Drug Interactions

When a person takes two or more medications concomitantly, the potential exists for one or more drugs to change the effect of other drugs. The drug whose effect is altered by another drug is termed the *object* or *target* drug. Although minor interactions between drugs probably occur frequently, these interactions may not be significant enough to alter the effect of either drug. However, it is important for the practitioner to understand the mechanisms behind these interactions to predict more accurately when clinically significant (and potentially fatal) drug interactions may occur.

Pharmacokinetic Interactions

Absorption

Because most medications in the ambulatory care setting are administered orally, this route is the focus of discussion. For a drug to exert its effect, it must reach its site of action. Normally, this requires access to the bloodstream. As discussed in Chapter 2, drugs administered orally must be absorbed into the portal vein, through the intestinal wall, to reach the systemic circulation. The oral tablet must dissolve in the gastrointestinal (GI) tract before it can penetrate the intestinal wall.

Acidity (pH)

For some drugs, this process depends on the acidity in the GI tract. Therefore, if a drug that alters the gastric pH is administered concomitantly with a drug that depends on a normal gastric pH for dissolution, the absorption of the object drug will be affected. An example of this type of interaction is the concurrent administration of a histamine-2 (H_2) receptor antagonist (e.g., ranitidine) and ketoconazole, an imidazole antifungal agent. Ketoconazole is the object drug that requires an acidic pH for absorption. When ranitidine is administered along with ketoconazole, the increase in gastric pH hinders the dissolution of ketoconazole and, therefore, decreases its absorption. Similarly, this change in pH can increase the absorption of other drugs that require a more alkaline environment for absorption.

Adsorption

Another mechanism of absorptive drug–drug interactions is adsorption. Adsorption occurs when one agent binds the other to its surface to form a complex. The most common agents associated with this type of interaction are divalent and trivalent cations (Mg^{2+}, Ca^{2+}, Al^{3+}, found in antacids and some vitamin preparations) and anionic-binding resins (colestipol, cholestyramine). This type of interaction occurs when certain medications such as tetracyclines or fluoroquinolones are given with antacids. The metal ions in the antacid chelate (form a complex with) the antibiotic, preventing absorption of both components (ion and antibiotic). Adsorbents can interact with a variety of drugs; therefore, appropriate intervals between doses of the interacting medications are warranted. In general, with agents known to interact in this manner, the object drug should be administered at least 2 hours before or 4 to 6 hours after the interacting agent.

Gastrointestinal Motility and Rate of Absorption

Drugs that affect the motility of the GI tract produce a less common absorption-altering mechanism. These agents tend to affect the rate of absorption and not the amount of drug absorbed. Any agent—for example, metoclopramide—that stimulates peristalsis and

increases gastric-emptying time can affect the rate of absorption of other medications. In most cases, an increase in the rate of absorption occurs because the target drug reaches the duodenum faster, allowing absorption to occur sooner. However, in some cases such as with metoclopramide and digoxin, a decrease in digoxin concentrations may occur (American Society of Health-System Pharmacists, 2008).

Conversely, anticholinergic agents and opiates decrease gastric motility, thereby decreasing the rate of absorption of object drugs. Because this type of interaction does not usually affect the amount of drug absorbed, it is usually clinically insignificant.

GI Flora and Absorption

The bacteria present in the GI tract are also responsible for a portion of the metabolism of some agents. An example of this is digoxin; concomitant administration with antibiotics (such as erythromycin or tetracycline) may alter the normal bacterial flora and reduce digoxin metabolism, thereby increasing bioavailability and serum concentrations in some patients (Susla, 2005). To the contrary, GI bacteria produce enzymes that deconjugate inactive unabsorbable ethinyl estradiol metabolites of oral contraceptives that have been excreted into the GI tract via the bile. Deconjugation allows reabsorption of active ethinyl estradiol back into the bloodstream. By disrupting the GI flora, anti-infectives may decrease or eliminate reabsorption of active ethinyl estradiol, thereby decreasing plasma concentrations and the effectiveness of oral contraceptives (Weaver & Glasier, 1999). However, in a case-crossover study of 1,330 failure cases, Toh et al. (2011) did not find an association between concomitant antibiotic use and the risk of breakthrough pregnancy among combined oral contraceptive users.

Table 3.1 summarizes some of the major drug interactions that occur in the absorptive process.

TABLE 3.1 Drugs Affecting Absorption

	Mechanism of Action	Object Drug	Results
Absorption Inhibitors			
activated charcoal	Binding agent	digoxin	Decreased absorption
aluminum hydroxide	Unknown	allopurinol	Decreased absorption
antacids (Mg^{2+}, Ca^{2+}, Al^{3+})	Chelating agent	quinolones, tetracyclines, levodopa, levothyroxine	Decreased absorption
aluminum and Mg hydroxide	Binding agent	digoxin	Decreased absorption
bismuth (Pepto-Bismol)	Binding agent	tetracycline, doxycycline	Decreased absorption
antibiotics (i.e., erythromycin, tetracycline)	Altered GI flora	digoxin	Increased absorption
	Altered GI flora	oral contraceptives	Decreased reabsorption, decreased enterohepatic recycling
anticholinergics	Decreases gastric emptying	acetaminophen, atenolol, levodopa	Decreased absorption
cholestyramine	Binding agent	acetaminophen, diclofenac, digoxin, glipizide, furosemide, iron, levothyroxine, lorazepam, methotrexate, metronidazole, piroxicam	Decreased absorption
colestipol	Binding agent	carbamazepine, diclofenac, furosemide, tetracycline, thiazides	Decreased absorption
desipramine	Decreases GI motility	phenylbutazone	Decreased absorption
didanosine	Binding agent	ciprofloxacin	Decreased absorption
	Increases gastric pH	imidazole, antifungals	Decreased absorption
ferrous sulfate	Chelating agent	quinolones, tetracyclines, levodopa, levothyroxine	Decreased absorption
histamine-2 receptor antagonists/proton pump inhibitors	Increases gastric pH	imidazole, antifungals, enoxacin	Decreased absorption
phenytoin	Unknown	furosemide	Decreased absorption
sucralfate	Binding agent	quinolones, tetracyclines, phenytoin, levothyroxine	Decreased absorption
sulfasalazine	Unknown	digoxin	Decreased absorption
Absorption Enhancers			
cisapride	Increases gastric emptying	disopyramide	Increased absorption
histamine-2 receptor antagonists	Increases gastric pH	pravastatin, glipizide, dihydropyridine, calcium antagonists	Increased absorption
metoclopramide	Increases gastric motility	cyclosporine	Increased absorption
	Increases GI motility	acetaminophen, cefprozil, ethanol	Increased absorption

GI, gastrointestinal.

Distribution

After drugs are absorbed into the bloodstream, most of them, to some degree, are bound to plasma protein such as albumin or α_1-acid glycoprotein. As described in Chapter 2, only an unbound drug is free to interact with its target receptor site and is therefore active. The percentage of drug that binds to plasma proteins depends on the affinity of that drug for the protein-binding site. If two drugs with high affinity for circulating proteins are administered together, they may compete for a single binding site on the protein. In fact, one drug may displace the other from the binding site with the result being an increase in the unbound (free) fraction of the displaced drug. This increase in free drug may trigger an exaggerated pharmacodynamic response or toxic reaction. However, because the excess unbound drug is now subject to elimination processes, the increases in both free drug fraction and the effects produced are usually transient.

Clinically significant drug displacement interactions normally occur only when drugs are more than 90% protein bound and have a narrow therapeutic index. For example, warfarin is 99% protein bound, and therefore, only 1% of the drug in the bloodstream is

free to induce a pharmacodynamic response (inhibition of clotting factors). If a second drug is administered that displaces even 1% of the warfarin bound to albumin, the amount of free warfarin is doubled, to 2% free. This can result in a significant increase in its pharmacodynamic action, leading to excessive bleeding. Table 3.2 lists examples of several displacement interactions.

TABLE 3.2 Distribution Drug Interactions

Displacing Agent	Object Drug
aspirin	meclofenamate, tolmetin
salicylates	methotrexate
TMP-SMZ	
sulfaphenazole	phenytoin
tolbutamide	
valproic acid	
halofenate	sulfonylureas
quinidine	digoxin
aspirin	warfarin
chloral hydrate	
diazoxide	
etodolac	
fenoprofen	
lovastatin	
nalidixic acid	
phenylbutazone	
phenytoin	
sulfinpyrazone	

TMP-SMZ, trimethoprim–sulfamethoxazole.

Metabolism

Lipophilicity (fat solubility) enables drug molecules to be absorbed and reach their site of action. However, lipophilic drugs are difficult for the body to excrete. Therefore, they must be transformed by the body to more hydrophilic (water-soluble) molecules. This is accomplished primarily through phase I, or oxidation, reactions. The main sites of metabolism in the body are the liver (hepatocytes) and small intestine (enterocytes). Other tissues, such as the kidneys, lungs, and brain, play a minor role in the metabolism of drug molecules (Michalets, 1998). These sites of metabolism contain enzymes called cytochrome P-450 isoenzymes. This group of isoenzymes has been identified as the major catalyst of phase I metabolic reactions in humans.

The nomenclature of the cytochrome P-450 system classifies the isoenzymes (designated CYP) according to family (greater than 36% homology in amino acid

sequence), subfamily (77% homology), and individual gene (Brosen, 1990; Guengerich, 1994; Nebert et al., 1987). For example, the isoenzyme CYP3A4 belongs to family 3, subfamily A, and gene 4. As one moves down the classification system from family to gene, the structures of the isoenzymes become more similar.

This enzyme system has evolved to form new isoenzymes that metabolize foreign substrates (i.e., drugs) that are presented to the body. These enzymes are structured to recognize and bind to molecular entities on substrates. Many different substrates may have molecular structures that differ only slightly; therefore, an isoenzyme can bind to any one of these substrates. Although several different substrates may compete for the same enzyme receptor, the substrate with the highest affinity binds most often. The converse of this is also true. Two isoenzymes can bind to the same substrate (Figure 3.1), but the substrate binds more often to the isoenzyme to which it has the most affinity. However, not every drug molecule ("substrate") can be metabolized by every enzyme with which it binds; therefore, it is not a true substrate. These concepts form the backbone for the drug interactions that are expanded on later.

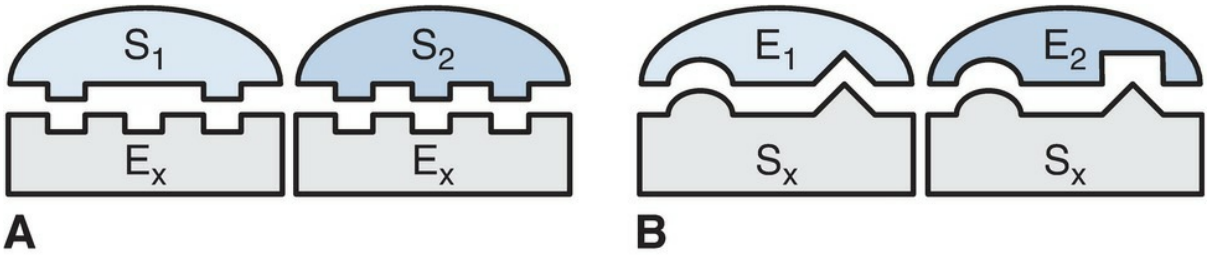

FIGURE 3.1 Substrate binding. A. Different substrates. Although Enzyme X (E_x) can bind to both Substrate 1 (S_1) and Substrate 2 (S_2), S_2 has greater affinity for E_x than S_1. Therefore E_x will bind to S_2 most often. B. Different enzymes. Although Substrate X (S_x) can bind to both Enzyme 1 (E_1) and Enzyme 2 (E_2), E_1 has a greater affinity for S_x than E_2. Therefore, S_x will bind to E_1 most often.

Six isoenzymes have been determined to be responsible for most metabolism-related drug interactions. They are the isoforms CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. The CYP3A4 isoform is responsible for 40% to 45% of drug metabolism, the CYP2D6 for the next 20% to 30%, CYP2C9 about 10%, and CYP2E1 and CYP1A2 each responsible for about 5% (Ingelman-Sundberg, 2004). The remaining 5% to 20% is accounted for by several lesser important isoforms. Because there are so few enzymes that transform a multitude of substrates, it is easy to see how there would be a great potential for interactions.

There are some genetic variations with respect to the distribution of the enzymes. For example, about 10% of Europeans lack the CYP2D6 enzyme and are therefore considered poor metabolizers of drugs using this pathway for biotransformation. These individuals are

at greater risk for ADRs related to drugs metabolized by CYP2D6. In addition, prodrugs requiring this enzyme for activation (e.g., codeine, tamoxifen) may be less effective or have no effect. In contrast, about 5% of this population are considered ultrametabolizers, have too rapid metabolism, and may show little to no response related to drugs metabolized by the CYP2D6 pathway (Ingelman-Sundberg, 2004). Similarly, there is variability within the CYP2C19 isoform, with about 14% of Chinese, 2% of Whites, and 4% of Blacks being poor metabolizers (Scott et al., 2011). The effectiveness of certain prodrugs (e.g., clopidogrel) that require metabolic activation by this enzyme system may be reduced (Holmes et al., 2010).

There has been increasing interest in genetic testing to identify strategies to reduce the risk of ADRs and to optimize therapy for individuals. Pharmacogenomic information has been incorporated into about 10% of labels for drugs approved by the U.S. Food and Drug Administration (FDA) in an effort to identify responders and nonresponders, avoid toxicity, and adjust doses of medications to optimize efficacy and ensure safety (FDA Table of Pharmacogenomic Biomarkers in Drug Labeling accessed July 16, 2015). In addition, regulatory authorities have recently recommended genetic testing to aid the clinician in determining if an agent is safe and effective in certain individuals (e.g., abacavir) (Highlights of Prescribing Information: Ziagen (abacavir sulfate) Tablets and Oral Solution accessed July 16, 2015). While commercial assays are available for genetic testing, turnaround time for the results varies, testing can be expensive, data on the validation of techniques used and reliability and reproducibility are limited, and, to date, there is limited evidence-based data on which to develop specific recommendations on the role of genetic testing in routine care (Holmes et al., 2010).

There are two types of metabolic drug interactions: drugs that inhibit the action of an enzyme and those that induce the activity of the enzyme.

Inhibition

Inhibition of drug metabolism occurs through competitive and noncompetitive inhibition. When two drugs, administered concurrently, are metabolized by the same isoenzyme, they are defined as competitive inhibitors of each other. In essence, they compete for the same binding site on an enzyme to be metabolized.

Noncompetitive inhibition also occurs when both drugs compete for the same binding site, but one drug is metabolized by that isoenzyme and the other drug is not. The best known example of a noncompetitive inhibitor is quinidine. Quinidine is metabolized by the CYP3A4 isoenzyme but can also bind to the CYP2D6 enzyme. Therefore, although quinidine does not compete for metabolism by the CYP2D6 isoenzyme, it does compete for the CYP2D6 isoenzyme binding site.

In both competitive and noncompetitive inhibition, the drug with the greatest affinity for the isoenzyme receptor is usually the inhibiting drug because it binds in the receptor site, preventing the other drug from being bound and metabolized (Figure 3.2). The

significance of the drug interaction depends on several characteristics of the inhibiting drug.

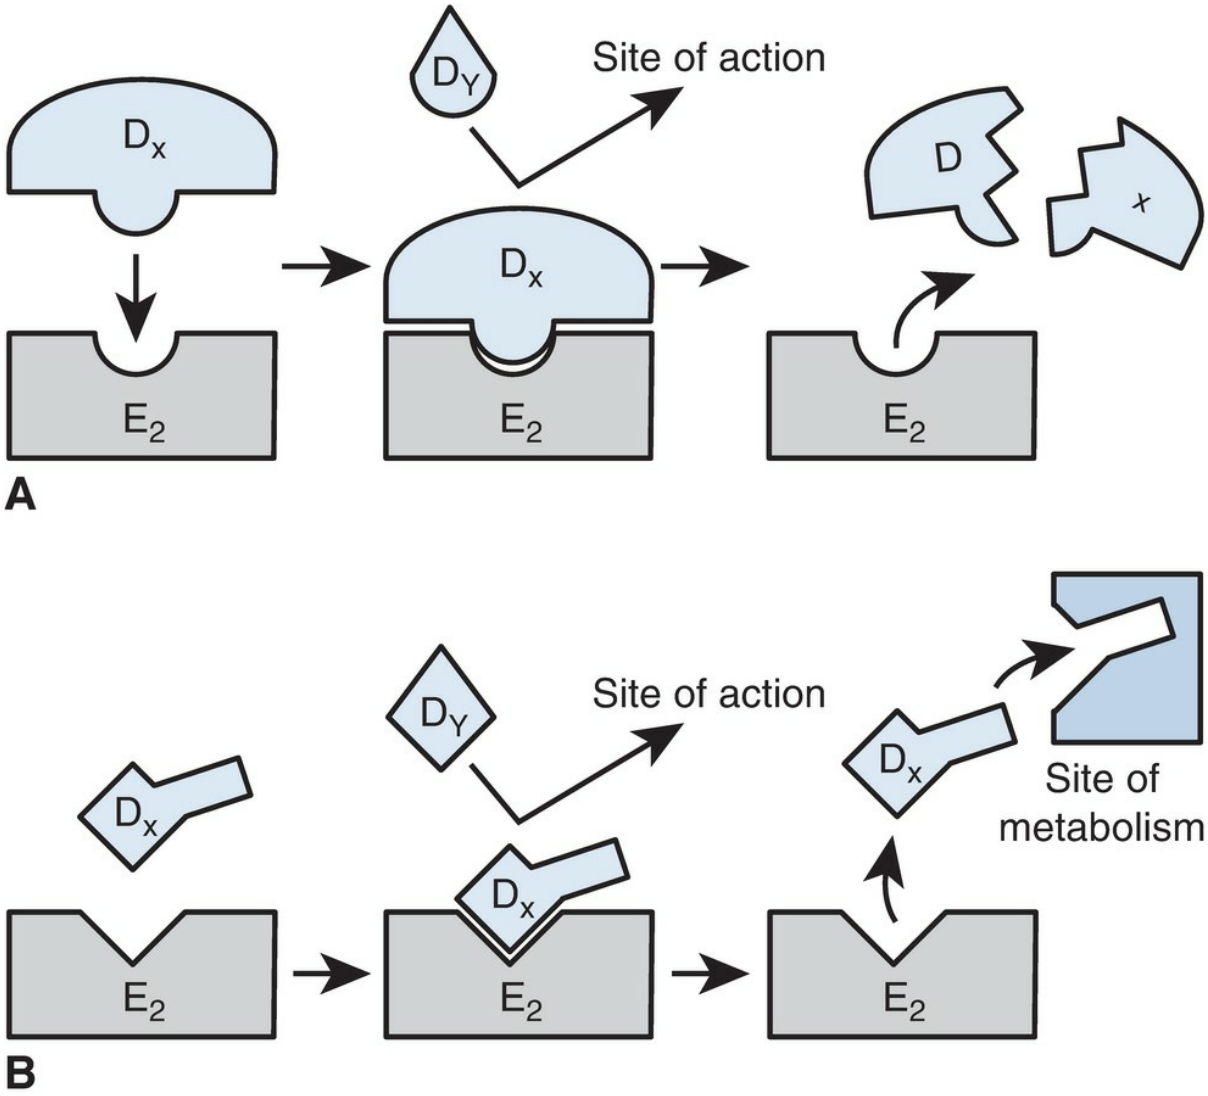

FIGURE 3.2 Inhibition. A. Competitive inhibition. Drug X (D_X) and Drug Y (D_Y) are both metabolized by Enzyme 2 (E_2). B. Noncompetitive inhibition. Although D_X and D_Y compete for the binding site on E_2, only D_Y is metabolized by E_2. Therefore, D_X noncompetitively inhibits D_Y.

Affinity

The first characteristic, affinity, has already been mentioned. Many drugs may inhibit the same isoenzyme but not to the same extent. The greater the affinity of an inhibiting drug for an enzyme, the more it blocks binding of other drug molecules.

Half-Life

Along with affinity, the half-life ($t_{½}$) of the inhibiting drug determines the duration of the

interaction. The longer the half-life of the inhibiting drug, the longer the drug interaction lasts. For example, after a regimen of ketoconazole ($t_{½}$ = 8 hours) is discontinued, its ability to inhibit the CYP3A4 enzyme lasts until it is eliminated, in three to five half-lives or approximately 1 day. However, the inhibiting effect of amiodarone, with a $t_{½}$ of approximately 53 days, lasts for weeks to months after its discontinuation.

Concentration

The third major factor contributing to a drug's ability to inhibit hepatic enzymes is the concentration of the inhibiting drug. A threshold concentration must be reached or exceeded to inhibit an enzyme. This is similar to the threshold concentration discussed in Chapter 2 regarding minimally effective concentrations and therapeutic responses. This minimally effective threshold concentration, or concentration-dependent inhibition, is exhibited by a variety of drugs. The dose yielding this concentration-dependent inhibition varies based on volume of distribution, drug and receptor affinity, and characteristics of the individual patient. An example of a dose- or concentration-dependent inhibitor is cimetidine. In most patients, a dose of 400 mg/d results in only weak enzyme inhibition. However, at higher doses, it interacts significantly with both the CYP2D6 and CYP1A2 isoenzymes (Shinn, 1992).

Some enzyme inhibitors may affect one enzyme at a smaller concentration and more than one isoenzyme at higher concentrations. These enzyme inhibitors demonstrate that some isoenzymes have differing thresholds. For example, fluconazole at a dose of 200 mg/d significantly inhibits only the 2C9 isoenzyme, but as the dose increases above 400 mg/d, it also inhibits the 3A4 isoenzyme (Hansten & Horn, 2015; Kivisto et al., 1994).

Toxic Potential

Another consideration with regard to inhibition interactions is the toxic potential of the object drug. For example, nonsedating antihistamines (i.e., terfenadine and astemizole) are metabolized by the CYP3A4 isoenzyme to a nontoxic metabolite. The parent compound of both drugs is cardiotoxic. If a potent CYP3A4 inhibitor (e.g., erythromycin) is administered concurrently with these agents, the parent compound accumulates in the body and causes a potentially fatal arrhythmia, such as torsades de pointes (Mathews et al., 1991; Woosley, 1996). Because of their serious toxic potential, both terfenadine and astemizole have been removed from the market.

Efficacy

An additional consideration related to inhibition interactions is the effectiveness of the object drug. This is particularly important for prodrugs that require cytochrome P-450 metabolism to the active metabolite in order for the drug to be effective. An example of this is clopidogrel, an antiplatelet agent, which requires CYP2C19 enzymes to be metabolized to the active form. When administered with omeprazole, a CYP2C19 inhibitor, a reduction

in plasma concentrations of the active metabolite of clopidogrel as well as reduced platelet function occur (clopidogrel [Plavix] prescribing information). In addition, tamoxifen, an agent used for breast cancer, is converted to its active metabolite by CYP2D6. Women may have a higher risk of breast cancer recurrence if they take tamoxifen in combination with CYP2D6 inhibitors such as the serotonin reuptake inhibitors paroxetine, fluoxetine, or sertraline (The Medical Letter, 2009).

Not all inhibition reactions result in harmful effects, however. Some interactions may be inconsequential or even beneficial. For example, ketoconazole (a potent inhibitor of the CYP3A4 isoenzyme) can be given with cyclosporine. The consequent interaction enables practitioners to give less cyclosporine to achieve the same immunosuppressive response (Hansten & Horn, 2015).

The cytochrome P-450 system is complex, but an understanding of the basic concepts of inhibitory interactions leads to the ability to anticipate which agents are likely to interact. The affinity, half-life, and drug concentration determine the potency of the inhibiting drug. A potent enzyme inhibitor inhibits most drugs metabolized by that enzyme. A clinically significant drug interaction also depends on the toxic potential of the drug being inhibited. Table 3.3 lists several enzyme inhibitors.

TABLE 3.3 Drugs Affecting Metabolism through Cytochrome P-450 Isoenzymes

Inhibitors	Inducers	Substrates	Inhibitors	Inducers	Substrates
Isoenzyme 1A2			***Isoenzyme 3A4***		
cimetidine	carbamazepine	theophylline	amiodarone	carbamazepine	alprazolam
ciprofloxacin	phenobarbital		azole antifungals	dexamethasone	atorvastatin
clarithromycin	phenytoin	tricyclic antidepressants	clarithromycin	ethosuximide	calcium channel blockers
enoxacin	rifampin	benzodiazepines	erythromycin	phenobarbital	carbamazepine
erythromycin	ritonavir	warfarin	fluoxetine	phenytoin	clindamycin
norfloxacin	smoking		fluvoxamine	rifabutin	clomipramine
oral contraceptives	polycyclic		imidazole	rifampin	clonazepam
SSRIs	aromatic		nefazodone		cyclosporine
zileuton	hydrocarbons		norfloxacin		dapsone
			protease inhibitors		dexamethasone
			quinine		dextromethorphan
Isoenzyme 2C (primarily 2C9, 2C19)					
amiodarone	carbamazepine	amitriptyline	telithromycin		disopyramide
cimetidine	phenobarbital	clomipramine	verapamil		erythromycin
fluconazole	phenytoin	diazepam	zafirlukast		oral contraceptives (estrogens)
fluoxetine	rifampin	imipramine			
fluvastatin		losartan			ethosuximide
fluvoxamine		omeprazole			fexofenadine
isoniazid		phenytoin			imipramine
metronidazole		tricyclic antidepressants			ketoconazole
omeprazole		warfarin			lidocaine
sertraline					lovastatin
zafirlukast					miconazole
					midazolam
Isoenzyme 2D6					nefazodone
amiodarone	carbamazepine				ondansetron
					oxycodone
cimetidine	phenobarbital				pravastatin
clomipramine	phenytoin				prednisone
codeine	rifampin				protease inhibitors
desipramine					quinidine
haloperidol					quinine
perphenazine					rifampin
propafenone					sertraline
quinidine					tacrolimus
SSRIs					tamoxifen
thioridazine					temazepam
venlafaxine					triazolam
					verapamil
Isoenzyme 2E1					warfarin
disulfiram	ethanol	acetaminophen			zileuton
ritonavir	isoniazid	chloral hydrate			
		ethanol			
		isoniazid			
		ondansetron			
		tamoxifen			

SSRIs, selective serotonin reuptake inhibitors.

Induction

Drug–drug interactions can also result from the action of one drug (inducer) stimulating the metabolism of an object drug (substrate). This enhanced metabolism is thought to be produced by an increase in hepatic blood flow or an increase in the formation of hepatic enzymes. This process, known as *enzyme induction*, increases the amount of enzymes available to metabolize drug molecules, thereby decreasing the concentration and

pharmacodynamic effect of the object drug.

Some of the more common enzyme inducers are rifampin, phenobarbital, phenytoin, and carbamazepine. Enzyme induction, like enzyme inhibition, is substrate dependent. Therefore, any drug that is a potent inducer of a cytochrome P-450 system increases the metabolism of most drugs metabolized by that enzyme. Also, in a manner similar to that of enzyme inhibitors, inducers may affect more than one cytochrome P-450 isoform; for example, phenobarbital is a potent inducer of the CYP3A4, CYP1A2, and CYP2C isoforms.

Some enzyme inducers, such as carbamazepine, also increase their own metabolism. Over time, carbamazepine stimulates its own metabolism, thereby decreasing its half-life and frequently resulting in an increased dose requirement to maintain the same therapeutic drug level. This process is termed *autoinduction*.

The onset and duration/cessation of enzyme induction depend on both the half-life of the inducer and the half-life of the isoenzyme that is being stimulated. For example, rifampin ($t_{½}$ = 3 to 4 hours) results in enzyme induction within 24 hours, whereas the enzyme induction capacity of phenobarbital ($t_{½}$ = 53 to 140 hours) is not evident for approximately 7 days. The level of induction remains constant while the drugs are being administered. However, on discontinuation of the respective inducers, the inducing action of rifampin ends more rapidly because of its shorter half-life. This occurs because rifampin is removed from the body at a faster rate than phenobarbital and therefore is not available to inhibit hepatic enzymes for as long.

The initiation and duration of enzyme induction also depend on the half-life of the induced isoenzyme. It takes anywhere from 1 to 6 days for a cytochrome P-450 enzyme to be degraded or produced. Therefore, even if a drug achieves a high enough concentration to produce induction of liver enzymes, the increase in metabolism of an object drug may not be evident until more liver enzymes have formed. The effect of rifampin on warfarin metabolism is a good example of this. Although induction begins within 24 hours of rifampin administration, its effect on warfarin metabolism is not evident for approximately 4 days. On discontinuation of rifampin, the remaining drug is metabolized to negligible levels before the effect on warfarin metabolism dissipates. This occurs because the half-life of the liver enzymes is greater than the half-life of rifampin, and therefore, the enzymes remain to metabolize warfarin after rifampin is eliminated from the body.

These concepts are important to remember when monitoring laboratory values that demonstrate the effectiveness of the object medication. For example, the international normalized ratio (INR), which is a surrogate marker of warfarin levels, fluctuates significantly within a couple of days of the initiation or discontinuation of rifampin. However, no change in the INR is evident for approximately 1 week after administration of phenobarbital. This is also true when measuring levels of certain antibiotics and other agents that may be affected by inducers. Table 3.3 lists several enzyme inducers and the drugs they affect.

Excretion

Although most drugs are metabolized by the liver, the primary modes of elimination from the body are biliary and renal excretion. Drugs are removed from the bloodstream by the kidneys by filtration or by urinary secretion. However, reabsorption from the urine into the bloodstream may also occur.

Changes in these processes become important when they affect drugs that are unchanged or still active. Excretion of drug molecules can be affected in a number of ways; these include, but are not limited to, acidification or alkalinization of the urine and alteration of secretory or active transport pathways. For example, amphetamine is excreted predominantly via the urine. Thirty percent of the drug can be recovered from the urine after 24 hours of administration. Acidic urine increases while alkaline urine slows down the renal excretion of amphetamine (Jones & Karlsson, 2005). Although they are not discussed here for various reasons, there are a select number of other mechanisms of renal drug interactions.

The ionization state of drug molecules plays a key role in the excretion process. The urine pH determines the ionization state of the excreted molecule. Because lipophilic membranes are less permeable to ionized molecules (hydrophilic), ionized molecules become "trapped" in the urine and are subsequently excreted. Drugs that are nonionized in the urine may be reabsorbed and then recirculated, effectively decreasing their elimination and increasing their half-lives.

Acidic drugs remain in their nonionized state in an acidic urine and become ionized in an alkaline urine. The opposite is true for basic drug molecules, which remain nonionized in an alkaline urine and are ionized in an acidic urine. When a drug is administered that alters the urine pH, it may promote an increased reabsorption or excretion of another drug. For example, the administration of bicarbonate can potentially increase the urine pH. This leads to the increased excretion of acidic drugs (e.g., aspirin) and the increased reabsorption of basic drugs (e.g., pseudoephedrine).

Although most drugs cross the membrane of the renal tubule by simple diffusion, some drugs are also secreted into the urine through active transport pathways. These pathways, however, have a limited capacity and can accommodate only a set amount of drug molecules. Therefore, if two different drugs using the same pathway are coadministered, the transport pathway may become saturated. This causes a "traffic jam" and the excretion of one or both of the drugs is inhibited.

These interactions can be beneficial or detrimental, depending on the agents that are administered. For example, when probenecid and penicillin are given together, they compete for secretion through an organic acid pathway in the renal tubule. The probenecid blocks the secretion of the penicillin, thereby increasing the therapeutic concentration of penicillin in the bloodstream. This is a prime example of drug interactions benefiting the patient. In contrast, digoxin and verapamil also share an active transport pathway. When they are administered concomitantly, their interaction leads to an increase in digoxin levels

resulting in potential cardiotoxicity (e.g., arrhythmia). Table 3.4 lists some other clinically important excretion interactions.

TABLE 3.4 Drugs Affecting Excretion

Renal Elimination	Mechanism	Object Drug	Results
acetazol-amide	Increases urine pH	salicylates	Increased elimination
losartan	Unknown	lithium	Decreased elimination
salicylates	Unknown	acetazolamide	Decreased elimination
cetazolamide	Increases urine pH	quinidine	Decreased elimination
triamterene	Unknown	amantadine	Decreased elimination
amiodarone	Unknown	digoxin	Decreased elimination
	Unknown	procainamide	Decreased renal and hepatic elimination
antacids	Increase urine pH	dextroam-phetamine, quinidine, pseudo-ephedrine	Decreased elimination
diuretics	Inhibit sodium reabsorption with subsequent renal tubular reabsorption of lithium	lithium	Decreased elimination
salicylates	Inhibit renal tubu-lar secretion of methotrexate	methotrexate	Decreased elimination

The other common pathway of excretion, the biliary tract, allows for the elimination of drugs and their metabolites into the feces. This route of excretion is involved in interactions with drugs that undergo enterohepatic recirculation. Drugs subject to this process are excreted into the GI tract through the biliary ducts and have the potential to be reabsorbed through the intestinal wall into the bloodstream. Some of these drugs depend on enterohepatic recirculation to achieve therapeutic concentrations. An example of a drug class that undergoes enterohepatic recirculation is the oral contraceptive. As previously described, antibiotics can adversely affect reabsorption of the estrogen components of oral contraceptives, potentially rendering them ineffective. In addition, drugs that undergo enterohepatic recirculation may also be affected by binding agents. An example of this is warfarin in combination with the bile acid sequestrants colestipol and cholestyramine. Warfarin undergoes enterohepatic recirculation. Once warfarin has been excreted in the bile, the bile acid sequestrant binds with warfarin, preventing its reabsorption and increasing its clearance, decreasing its efficacy. This has been shown to occur even when warfarin is administered intravenously (Jahnchen et al., 1978). Therefore, it is not only important to administer warfarin 2 hours before or 6 hours after cholestyramine, but consistency in the administration time of these agents is important as well (Mancano, 2005).

Pharmacokinetic interactions make up a large part of the interactions that practitioners must contend with every day. These interactions are the most studied because they have an objective measurable outcome (e.g., drug concentrations, enzyme concentrations). However, a drug's pharmacodynamic profile must also be considered when it is administered with other agents.

P-Glycoprotein Interactions

Inhibition or induction of P-glycoprotein (P-gp), an energy-dependent efflux transporter, can result in interactions involving absorption or excretion (biliary or renal). P-gp pumps drug molecules out of cells and is found in the epithelial cells of the intestine (enterocytes), liver, and kidney. As a drug passes through the enterocyte in the intestine to be absorbed into the systemic circulation, P-gp can pick up the molecule and carry it back to the intestinal lumen, preventing absorption. P-gp in the liver and kidney act to increase the excretion of drugs by transporting the molecules into the bile and urine, respectively (Hansten & Horn, 2015).

If P-gp is inhibited, more drugs will be absorbed through the enterocytes. This will result in an increase in plasma concentrations of the object drug. An example of this interaction is when quinidine is administered with digoxin. Quinidine inhibits intestinal P-gp, which results in increased absorption of digoxin. In addition, quinidine inhibition of renal P-gp results in reduced elimination of digoxin by the kidney. The end result is increased concentrations of serum digoxin (Horn & Hansten, 2004).

If P-gp is induced, less drug will be absorbed through the enterocytes. An example of an induction interaction of P-gp is when rifampin is given with digoxin. Rifampin induces intestinal P-gp, resulting in reduced absorption and reduced serum digoxin concentrations (Hansten & Horn, 2015).

Table 3.5 provides examples of common substrates, inhibitors, and inducers of P-gp (Hansten & Horn, 2015; Kim, 2002).

TABLE 3.5 Examples of Substrates, Inhibitors, and Inducers of P-Glycoprotein*

Substrates	Inhibitors	Inducers
aldosterone	amiodarone	indinavir
cimetidine	atorvastatin	morphine
colchicine	clarithromycin	nelfinavir
cyclosporine	cyclosporine	phenothiazine
digoxin	diltiazem	rifampin
diltiazem	erythromycin	ritonavir
erythromycin	felodipine	saquinavir
fexofenadine	indinavir	St. John's wort
indinavir	itraconazole	
itraconazole	ketoconazole	
morphine	methadone	
nelfinavir	nelfinavir	
quinidine	nicardipine	
ranitidine	quinidine	
saquinavir	ritonavir	
tetracycline	sirolimus	
verapamil	tacrolimus	
	verapamil

Retrieved from http://www.hanstenandhorn.com/hh-article10-04.pdf and Kim, R. B. (2002). Drugs as P-glycoprotein substrates, inhibitors, and inducers. *Drug Metabolism Reviews*, 34, 47–54.

Pharmacodynamic Interactions

The responses or effects produced by a drug's actions are referred to as the drug's *pharmacodynamic profile*. Although drugs are administered to elicit a specific response or change in dynamics, an agent usually causes several changes in the body. When one or more drugs are coadministered, the entire pharmacodynamic profile of each drug must be considered because of the potential for each to interact. Drugs that have a similar characteristic in their pharmacodynamic profile may produce an exaggerated response. For example, when a benzodiazepine (e.g., alprazolam) is administered with a muscle relaxant (e.g., cyclobenzaprine), the sedative effects of both drugs combine to produce excessive drowsiness. A less obvious pharmacodynamic interaction occurs with the coadministration of angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril) and potassium-sparing diuretics (e.g., triamterene). These agents individually can both produce an increase in the potassium (K^+) level. Unless the prescriber is aware of the pharmacodynamic profile of both drugs, the potential for an excessive increase in the potassium level may go unnoticed and arrhythmia may ensue.

In contrast, drugs may also produce opposing pharmacodynamic effects. This type of interaction may cause the expected drug response to be diminished or even abolished. Unfortunately, these interactions are often overlooked. Instead of the lack of response being interpreted as a pharmacodynamic drug interaction, it is suspected to be due to an ineffective dose or drug. This often leads to an increase in the amount of drug administered and consequent unwanted side effects or interactions. This type of interaction is illustrated by the concomitant administration of an antihypertensive agent (e.g., a diuretic) and a nonsteroidal anti-inflammatory drug (NSAID). Thiazide diuretics produce their hypotensive effects by blocking sodium reabsorption in the distal tubule of the kidney, which leads to increased sodium and water excretion. If NSAIDs are administered concomitantly, the sodium and water retention effects of the NSAIDs may reduce or nullify the hypotensive action of the diuretic.

Drug–Food Interactions

The interaction between food and drugs can affect both pharmacokinetic and pharmacodynamic parameters. The mechanism of these pharmacokinetic interactions is mediated by alteration of drug bioavailability, distribution, metabolism, or excretion, as seen with drug–drug interactions. The potential for pharmacodynamic drug–food interactions warrants concern about proper diet for patients on certain drugs. Although practicing clinicians often overlook drug–food interactions, these interactions can significantly affect efficacy of drug therapy. Awareness of significant drug–food interactions can reduce the incidence of these effects and optimize drug therapy.

Effect of Food on Drug Pharmacokinetics

Absorption

Food can affect the absorption of drugs in two ways: first, by altering the extent of drug absorption and second, by changing the rate of drug absorption. Usually, changes in the rate of drug absorption have less significance if only the rate of absorption is delayed without affecting bioavailability. The underlying mechanisms that mediate these interactions are highly variable and depend on both the content of food and the properties of the drug involved.

Food can either increase or decrease the amount (extent) of drug absorption, potentially altering the bioavailability of a drug. One mechanism, similar to drug–drug interactions, is adsorption. For example, tetracycline and fluoroquinolone antibiotics (e.g., ciprofloxacin, ofloxacin) can chelate with calcium cations found in milk or milk products, thus significantly limiting the drug's bioavailability.

A second type of drug–food interaction occurs when food serves as a physical barrier and prevents the absorption of orally administered drugs. The absorptive capacity of the small intestine is related to the accessibility of a drug to the GI mucosal surfaces, the site where absorption occurs. When food is coadministered with a drug, access to the mucosa is reduced, resulting in delayed or decreased drug absorption. For example, the bioavailability of azithromycin is reduced by 43% when the drug is taken with food (Zithromax (Pfizer Pharmaceuticals) Package Insert, 2013). Similar types of interactions can be seen when erythromycin, isoniazid, penicillins, and zidovudine are given orally. To avoid such interactions, these drugs can be administered 2 hours apart from mealtime. Box 3.1 identifies some commonly prescribed drugs that should be taken on an empty stomach. Note, however, if patients cannot tolerate these medications on an empty stomach (because of GI side effects like diarrhea), coadministration with food may be advisable.

BOX 3.1 Drugs to Be Taken on an Empty Stomach

azithromycin
captopril
erythromycin
fluoroquinolones (e.g., ciprofloxacin, ofloxacin)
griseofulvin
isoniazid
oral penicillins
sucralfate
tetracycline

theophylline, timed release (e.g., Theo-Dur Sprinkle, Theo-24, Uniphyl)
zidovudine

In contrast, food can also decrease the absorption of some drugs. For example, phenytoin is known to bind to protein source, heavy metals such as calcium carbonate, and enteral feeding formulas (Sacks, 2004). Doses of phenytoin may have to be increased up to 1,000 mg/d compared to 300 mg/d when it is given without food. To avoid the drug–food interaction, phenytoin doses can be given 1 hour before or 2 hours after eating.

Metabolism

Food can also affect drug metabolism. Grapefruit juice, for example, can affect the metabolism of many drugs. Grapefruit juice specifically inhibits the 3A4 subset of intestinal cytochrome P-450 enzymes and thus increases the serum concentration of drugs dependent on these enzymes for metabolism (Ameer & Weintraub, 1997; Huang et al., 2004).

The extrahepatic cytochrome enzymes are found in highest concentrations in the proximal two thirds of the small intestine. These enzymes are located at the distal portion of the villi that line the small intestine and are responsible for the extrahepatic metabolism of more than 20 drugs (Ameer & Weintraub, 1997; Huang et al., 2004). The component in grapefruit juice that is responsible for this interaction remains undetermined; however, the flavonoid naringin, found in high concentrations in grapefruit juice, is suspected. Increases in the bioavailability of verapamil and dihydropyridine calcium channel blockers such as felodipine, nisoldipine, nitrendipine, nifedipine, and amlodipine have been documented with the coadministration of grapefruit juice (Bailey et al., 1991, 1992, 1993; Rashid et al., 1993). The bioavailability of carbamazepine and midazolam is markedly increased when taken with grapefruit juice (Sacks, 2004). However, unlike verapamil and dihydropyridine calcium channel blockers, diltiazem does not demonstrate an increase in bioavailability with grapefruit juice.

The amount of grapefruit juice required to increase plasma concentrations can vary between agents. A single glass of grapefruit juice can increase the area under the curve and maximum concentration (C_{max}) of felodipine by several fold (Bailey et al., 1998) while the warnings in the product labeling for some HMG CoA reductase inhibitors metabolized by CYP3A4 say to avoid quantities greater than 1 quart per day (Zocor Package Insert, 2015). The extent of the increase in felodipine plasma concentrations is maximal between simultaneous and 4 hours before administration of grapefruit juice. However, higher C_{max} concentrations were evident even when grapefruit juice is consumed 24 hours before felodipine. Therefore, separating doses may reduce but does not eliminate the potential for the interaction (Bailey et al., 1998). Because grapefruit juice appears to inhibit mostly intestinal CYP3A4 and not hepatic CYP3A4 enzymes, the metabolism of drugs administered intravenously is unlikely to be altered. Further, the data suggest that only those agents given at doses higher than usual or if the patients' livers are severely damaged

result in the intestinal CYP3A4 as the primary metabolic pathway (Huang et al., 2004). Box 3.2 identifies some drugs that may interact with grapefruit juice.

BOX 3.2 Drugs That Interact with Grapefruit Juice

benzodiazepines
midazolam
triazolam
cyclosporine
dihydropyridine calcium channel blockers
  amlodipine
  felodipine
  nifedipine
  nisoldipine
nitrendipine
lovastatin
simvastatin
theophylline
verapamil
17 β-estradiol

In contrast to the ability of grapefruit juice to inhibit drug metabolism, other components of food may induce drug metabolism and therefore decrease drug efficacy. For example, in the treatment of Parkinson disease, dopamine in the brain needs to be replenished. However, exogenous dopamine does not cross the blood–brain barrier, but its precursor, levodopa, does. Unfortunately, much of the levodopa is lost to metabolism when given orally and only approximately 1% of the administered amount enters the brain to be converted to dopamine (Trovato et al., 1991). Concomitant administration with food containing pyridoxine (or vitamin B_6) can potentially further enhance the peripheral metabolism of levodopa, thus decreasing drug efficacy (Trovato et al., 1991). Patients taking levodopa should therefore be educated about moderate intake of pyridoxine-rich foods, such as avocados, beans, bacon, beef, liver, peas, pork, sweet potatoes, and tuna. Similarly, charcoal-broiled meats can induce the activity of the CYP1A2 isoenzymes, thus increasing the metabolism of drugs such as theophylline.

Excretion

Ingestion of certain fruit juices can alter the urinary pH and affect the elimination and reabsorption of drugs such as quinidine and amphetamine. Orange, tomato, and grapefruit

juices are metabolized to an alkaline residue, which can increase the urinary pH. For drugs that are weak bases, making the urine more alkaline by raising the pH increases the proportion of nonionized drug and enhances the reabsorption of the drug systemically. (Recall that the ionization of drugs helps promote water solubility and ultimately enhances drug elimination into the urine.)

Effect of Food on Pharmacodynamics

Food affects the pharmacodynamics of drugs either by opposing or potentiating a drug's pharmacologic action. For example, warfarin exerts its anticoagulant effects by inhibiting synthesis of vitamin K–dependent clotting factors. Vitamin K is required for activation by several protein factors of the clotting cascade, namely, factors II, VII, IX, and X. When foods rich in vitamin K are ingested, they can significantly oppose the anticoagulatory efficacy of warfarin. Leafy green vegetables, such as collard greens, kale, lettuce, spinach, mustard greens, and broccoli, are generally recognized to contain large quantities of vitamin K. Health care providers should educate patients who are taking warfarin about this interaction. More importantly, however, practitioners should stress maintaining a balanced diet without abruptly changing the intake of foods rich in vitamin K.

Another significant drug–food interaction occurs between monoamine oxidase (MAO) inhibitors and foods containing tyramine, an amino acid that is contained in many types of food. Tyramine can precipitate a hypertensive reaction in patients taking MAO inhibitors, such as phenelzine, tranylcypromine, or isocarboxazid. MAOs are enzymes located in the GI tract that inactivate tyramine in food. When patients are taking MAO inhibitors, the breakdown of tyramine is prevented and therefore allows for more tyramine to be absorbed systemically. Because of the indirect sympathomimetic property of tyramine, this amino acid provokes the release of norepinephrine from sympathetic nerve endings and epinephrine from the adrenal glands, resulting in an excessive pressor effect. Clinically, patients may complain of diaphoresis, mydriasis, occipital or temporal headache, nuchal rigidity, palpitations, and elevated blood pressure. Examples of foods that contain tyramine are listed in Box 3.3.

BOX 3.3 Foods High in Tyramine

Bean pods
Beer (draft)
Cheese (aged)
Cured meats (i.e., salami, pepperoni, sausage)
Fruits (overripe, such as figs, avocados, prunes, and raisins)
Herring (pickled)
Liver
Sauerkraut
Soy sauce
Wine

Effect of Drugs on Food and Nutrients

Many of the aforementioned examples indicate that food can precipitate an interaction with a drug, but in some cases, a reciprocal relationship also holds true. First, some drugs can cause a depletion of nutrients or minerals found in food through various mechanisms. For example, drugs such as cholestyramine and colestipol, which were designed to bind bile acid in the GI tract, could also potentially bind to fat-soluble vitamins (i.e., vitamins A, D, E, and K) and folic acid when taken with food, resulting in the decreased absorption of these vitamins. Orlistat, an over-the-counter and prescription medication used for weight loss, reduces fat absorption. In addition to reducing fat absorption, it can also decrease the absorption of fat-soluble vitamins and beta-carotene. Similarly, the chronic use of mineral oil as a laxative reduces the absorption of fat-soluble vitamins. Careful monitoring of the INR in patients taking warfarin and drugs that affect vitamin K absorption is warranted to avoid changes in bleeding times.

Second, drug-induced malabsorption can occur in patients with pre-existing poor nutritional status. For example, long-term use of isoniazid can cause pyridoxine (vitamin B_6) deficiency. Pyridoxine supplementation is recommended for patients who are malnourished or predisposed to neuropathy (e.g., patients with diabetes or alcoholism) when treated with isoniazid. Metformin is associated with vitamin B_{12} deficiency in about 7% of patients, which may lead to anemia. In general, the clinical significance of these interactions may depend on the baseline nutritional status of the patient. Patients with poor nutrition or inadequate dietary intake (e.g., elderly or alcoholic patients) are potentially at greater risk for drug-induced vitamin and mineral depletion.

Third, drugs can change nutrient excretion as well. Both thiazide and loop diuretics can enhance the excretion of potassium, possibly leading to hypokalemia. Digoxin, in the presence of diuretic-induced hypokalemia, can lead to digoxin-induced arrhythmias. Spironolactone, an aldosterone antagonist and potassium-sparing diuretic, can increase potassium levels, especially in the presence of an ACE inhibitor or angiotensin receptor blocker. Loop diuretics can increase urinary excretion of calcium, whereas thiazide diuretics can decrease it. In addition, ascorbic acid and potassium depletion can occur with high doses of long-term aspirin therapy (Trovato et al., 1991). Lithium, a drug used in the treatment of bipolar disorder, depends on renal tubular transport for clearance. Sodium can compete with this process. A diet low in sodium can enhance the renal tubular reabsorption of lithium, which could lead to lithium toxicity (Chan, 2013).

Continuous enteral feeding impairs the dissolution of levothyroxine tablets. The drug could also be bound to the enteral feeding tubes. All of which could lead to further hypothyroidism due to inadequate levothyroxine reaching the systemic circulation.

Drug–Herb Interactions

In today's society, the search for a "natural way" to treat and prevent diseases has become commonplace. This potentially stems from the misconception that "natural" means "safer." Among U.S. adults aged 18 years and older, 33.2% of the population has used some form of herbal products in 2012 (Clarke et al., 2015). For the most part, these herbal supplements are not regulated by the FDA. In many cases, little research has been conducted to assess the efficacy and safety of these agents or the potential for pharmacokinetic or pharmacodynamic interactions. Some clinical trials have been conducted to evaluate the safety and efficacy of certain herbal medications; however, much of available data are based on animal studies, case reports, and the potential for interactions derived from what is known about the chemical characteristics and pharmacokinetic parameters of the herbs.

Pharmacokinetic Interactions

Absorption

As discussed earlier in the chapter, certain agents can interact with other medications in the GI tract to prevent absorption. Likewise, some herbs can prevent absorption of medications and reduce the effectiveness of those medications. For example, acacia, marketed as a fiber supplement, has been shown to impair the absorption of amoxicillin. This may be secondary to the fiber content of acacia. Doses of acacia and amoxicillin should be separated by 4 hours. Dandelion has a high mineral content and has been shown to reduce the effectiveness of quinolones in animals (Ulbricht et al., 2008). Table 3.6 summarizes some of the potential herb–drug interactions that can occur in the absorptive process.

TABLE 3.6 Herb–Drug Interactions Affecting Absorption

Herbal Medication	Mechanism of Action	Object D	Results
Acacia	Fiber content may slow or reduce absorption of medications	Amoxicillin	Decreased absorption (separate doses by at least 4 h)
Carob	Decreased bowel transit time	Oral medications	Decreased absorption (separate doses by several hours)
Citrus pectin	Fiber content may slow or reduce absorption of medications	Oral medications	Take 1 h before or 2 h after intake of other oral medications
Dandelion	High mineral content (chelation)	Ciprofloxacin and potentially other medications affected by chelation	Decreased absorption; dandelion and quinolone coadministration should be avoided
Flaxseed	Fiber content may decrease absorption of oral agents	Oral agents/vitamins/minerals	Decreased absorption; oral agents should be taken 1 h before or 2 h after flaxseed
Psyllium	Fiber content may decrease absorption of oral agents	Carbamazepine, digoxin, lithium	Decreased absorption

Data from Ulbricht, C., Chao, W., Costa, D., et al. (2008). Clinical evidence of herb–drug interactions: A systematic review by the Natural Standard Research Collaboration. *Current Drug Metabolism*, 9, 1063–1120.

Distribution

Meadowsweet and black willow contain salicylates that have the potential to displace highly protein-bound drugs. To avoid toxicity, coadministration of these products with highly protein-bound drugs with a narrow therapeutic index, such as warfarin and carbamazepine, should be avoided.

Metabolism

Certain herbs can be inducers or inhibitors of the cytochrome P-450 enzyme system. St. John's wort, an herbal medication often used to treat depression, has consistently been shown to induce CYP3A4, CYP2E1, and CYP2C19. In addition, St. John's wort induces intestinal P-gp and has been shown to lower plasma concentrations of common P-gp substrates such as digoxin and fexofenadine. Induction of these enzymes is secondary to hyperforin, an ingredient in St. John's wort. St. John's wort has been shown to clinically

interact with a number of drugs, including immunosuppressants, hypoglycemics, anti-inflammatory agents, antimicrobial agents, antimigraine medications, oral contraceptives, cardiovascular agents, and antiretroviral and anticancer drugs as well as drugs affecting the central nervous, GI, and respiratory systems (Izzo & Ernst, 2009).

In contrast, kava, used as an anxiolytic, and garlic, used to treat dyslipidemia, have both been shown in pharmacokinetic studies to inhibit the cytochrome P-450 enzyme system, specifically CYP2E1 (Izzo & Ernst, 2009). Table 3.7 shows some common herb–drug interactions affecting metabolism.

TABLE 3.7 Drug–Herb Metabolism Interactions

Herbal Medication	Mechanism of Action	Object Drug	Results
Garlic	Inhibitor of CYP2E1	Chlorzoxazone	Increased chlorzoxazone levels and potentially other 2E1 substrates
Ginkgo	Inducer of CYP2C19	Antiseizure medications, omeprazole	Decreased levels of valproic acid, phenytoin, and omeprazole possible
Goldenseal (berberine)	Inhibitor of CYP3A4	Cyclosporine	Increase in cyclosporine levels
Kava	Inhibitor of CYP2E1	Chlorzoxazone	Increased chlorzoxazone levels and potentially other 2E1 substrates
Licorice	Inhibitor or inducer of CYP3A4	CYP3A4 substrates	Potential increase or decrease in CYP3A4 substrate levels
Red yeast rice	CYP3A4 inhibitors can increase plasma concentrations of Monacolin K	Monacolin K	Increased plasma concentrations of Monacolin K can result in muscle toxicity
Scotch broom	Haloperidol (CYP2D6 inhibitor) has been shown to increase levels of sparteine	Sparteine	Increased levels of sparteine, which may be potentially cardiotoxic
St. John's wort	Inhibitor of CYP3A4	Alprazolam, amitriptyline, atorvastatin, erythromycin, imatinib, indinavir, irinotecan, ivabradine, methadone, midazolam, nevirapine, nifedipine, oral contraceptives, quazepam, simvastatin, tacrolimus, verapamil, warfarin	May result in decreased efficacy and/or effectiveness of the object drugs listed
	Inducer of CYP2C19	Omeprazole	Decreased levels of omeprazole possible
	Inducer of CYP2E1	Chlorzoxazone	Decreased chlorzoxazone levels and potentially other 2E1 substrates

Pharmacodynamic Interactions

Herbs may contain ingredients that potentiate the pharmacodynamic effects of certain medications, which may lead to adverse effects. The causative mechanism of these effects may not be well understood in many cases.

Several herbal medications have been shown to inhibit platelet activity and/or have an effect on increasing the INR. Case reports of increased bleeding in patients taking herbal medications with nonsteroidal anti-inflammatory agents, antiplatelet agents, and anticoagulants have been reported (Ulbricht et al., 2008). Box 3.4 shows herbal medications that may increase the potential for bleeding when given concomitantly with medications that inhibit platelets or alter coagulation.

BOX 3.4 Herbal Supplements That Potentially Increase Bleeding When Taken with Antiplatelets/Anticoagulants*

Borage seed oil
Clove

Policosanol
Pycnogenol
Saw palmetto
Turmeric

*Data from Ulbricht, C., Chao, W., Costa, D., et al. (2008a). Clinical evidence of herb–drug interactions: A systematic review by the Natural Standard Research Collaboration. *Current Drug Metabolism*, 9, 1063–1120.

Some herbal medications have been shown to potentiate the central nervous system (CNS) depressant effects of some medications. Kava, lavender, and valerian may potentiate the effects of CNS depressants, such as barbiturates, benzodiazepines, and narcotics. In addition, kava may interfere with the effects of dopamine or dopamine antagonists and it is potentially hepatotoxic (Kuhn, 2002; Ulbricht et al., 2008).

Aloe has been associated with hypoglycemia in patients taking glibenclamide (glyburide). Bitter orange contains MAO inhibitor substrates such as tyramine and octopamine, and concomitant use with an MAO inhibitor may increase the potential for hypertensive effects (Ulbricht et al., 2008).

While many patients may believe herbal medications are safe because they are "natural" and are available over the counter, the potential for herb–drug interactions still exists. Clinicians must be aware of the potential for these interactions and encourage patients to disclose all medications they are taking, including herbal remedies.

Drug–Disease Interactions

Certain drug–disease interactions can change drug pharmacokinetic and pharmacodynamic parameters, leading to less-than-optimal drug therapeutic outcomes and greater risk of toxicity. In addition, certain drugs can exacerbate a patient's coexisting disease.

Effect of Disease on Pharmacokinetics of Drugs

Absorption

As already discussed, the absorption of drugs may be affected by the presence of other drugs and food in the GI tract. However, drug absorption also depends on the physiologic processes that maintain normal GI function. These processes can include enzyme secretion, acidity, gastric emptying, bile production, and transit time. Thus, any disease that alters the normal physiologic function of the GI system potentially alters drug absorption.

Vitamin B_{12} deficiency is common in patients undergoing stomach surgery. Stomach acid and intrinsic factor play a critical role in the absorption of vitamin B_{12}. Without acid, vitamin B_{12} is not able to be cleaved and released from proteins in food. Vitamin B_{12} and intrinsic factor form a complex and are absorbed in the duodenum. Without intrinsic factor, vitamin B_{12} absorption is impaired (Goldenberg, 2008).

As an example, the gastric-emptying rate can be reduced in patients with duodenal or pyloric ulcers and hypothyroidism. In addition, long-term diabetes can result in diabetic gastroparesis, which delays gastric emptying. This results in later or fluctuating maximal serum concentrations and has been documented with oral hypoglycemic agents. This may become particularly important when a rapid acting drug is required. However, drugs with longer half-lives may be less likely to be affected (Jing et al., 2009). Another example includes bowel edema and intestinal hypoperfusion from advancing heart failure, which can delay the absorption of diuretics prescribed to control edema (Hunt et al., 2009). Finally, diarrhea, a manifestation of many diseases, can pose a problem for oral absorption of drugs as well as food and nutrients.

Distribution

The distribution of drugs can be affected by certain disease states. Of significance are conditions that change plasma albumin levels and therefore can increase or decrease the concentration of drugs usually bound to albumin. Examples of conditions that may decrease plasma albumin levels include burns, bone fractures, acute infections, inflammatory disease, liver disease, malnutrition, and renal disease. Examples of conditions that may increase plasma albumin levels include benign tumors, gynecologic disorders, myalgia, and surgical procedures.

Metabolism

The metabolism of drugs can often be altered by diseases that affect the functions of the liver, such as cirrhosis. Failure of the liver (the primary organ responsible for drug metabolism) not only impairs drug metabolism but can cause a reduction in albumin synthesis. Therefore, the clinical impact of liver failure includes a strong potential for

interactions with drugs. Heart failure is another disease that can cause direct reduction in the ability of the liver to metabolize drugs. In patients with heart failure, however, decreased metabolic capacity of the liver is also caused by a decrease in blood flow to the liver owing to changes in cardiac output.

In some cases, normal liver function is needed to activate a drug rather than to inactivate it. Certain drugs like enalapril are called *prodrugs*, meaning the drug needs to be converted by the liver to its active form (enalaprilat) to achieve maximal therapeutic effect. Therefore, use of a prodrug in patients with liver dysfunction can potentially reduce the efficacy of the drug.

Excretion

Renal function can influence serum drug concentrations because most drugs are eliminated by the kidneys either as unchanged drug or as metabolites. Chronic renal diseases that compromise the function of the kidney to clear drugs can result in drug accumulation. Glomerulonephritis, interstitial nephritis, long-term and uncontrolled diabetes, and hypertension are primary causes of declining renal function. In clinical practice, once the patient's estimated creatinine clearance has declined to less than 50 mL/min, dose adjustments usually are required for drugs that are primarily renally cleared. For example, drugs such as H_2 receptor antagonists and fluoroquinolone antibiotics commonly require dose adjustments for patients with renal insufficiency. In particular, the drug regimen of elderly patients or those with an elevated serum creatinine level above 1.5 mg/dL should be evaluated to detect any ADRs from possible drug accumulation secondary to declining renal clearance.

Effects of Drugs on Coexisting Disease

Drugs used to treat one medical condition can sometimes exacerbate the status of another comorbid disease. Practitioners, therefore, should be aware of potential drug–disease interactions. This is of particular importance in elderly individuals who have multiple concomitant diseases and often take multiple medications. Detected rates of drug–disease interactions range from 6% to 30% in older adults (Lindblad et al., 2006). A complete discussion of this topic is beyond the scope of this chapter. However, a consensus statement has been published from a multidisciplinary panel of health care providers whose members specialize in geriatric medicine. The statement identifies several drug–disease interactions that are common in older individuals and are considered to have a deleterious impact on coexisting disease in older individuals. Table 3.8 lists these common and clinically significant drug–disease interactions in the elderly (American Geriatrics Society, 2012).

TABLE 3.8 Drug–Disease Interactions Common in the Elderly*

Disease/Condition	Drug/Drug Class
Benign prostatic hyperplasia	Anticholinergics
	Tricyclic antidepressants
Chronic renal failure	Nonaspirin NSAIDs
Heart failure (systolic dysfunction)	First-generation calcium channel blockers
Constipation	Anticholinergics
	Opioid analgesics
	Tricyclic antidepressants
Dementia	Anticholinergics
	Barbiturates
	Benzodiazepines
	Tricyclic antidepressants
Diabetes	Corticosteroids
Falls	Antipsychotics (thioridazine/haloperidol)
	Benzodiazepines
	Sedative hypnotics
	Tricyclic antidepressants
Heart block	Digoxin
	Tricyclic antidepressants
Narrow-angle glaucoma	Anticholinergics
Parkinson disease	Metoclopramide
Peptic ulcer disease	Aspirin
	Nonaspirin NSAIDs
Postural hypotension	Thioridazine
	Tricyclic antidepressants
Seizures	Bupropion
Syncope	Alpha-blockers (e.g., doxazosin, terazosin, methyldopa)

*Data from Lindblad, C. I., Hanlon, J. T., Gross, C. R., et al. (2006). Clinically important drug–disease interactions

and their prevalence in older adults. *Clinical Therapeutics*, 28, 1133–1143.

Patient Factors Influencing Drug Interactions

The outcomes of drug interactions are highly variable from one person to another. Many patient factors can influence the propensity for an interaction to occur, such as genetics, diseases, environment, smoking, diet/nutrition, and alcohol. An understanding of these factors can help to identify potential sources of drug interactions.

Heredity

As discussed previously, the cytochrome P-450 system can display genetic polymorphism. That is, the variable metabolism of drugs by cytochrome P-450 enzymes from one person to another in the population can be partly explained by genetic differences. For example, approximately 8% of Americans lack the gene to form the isoenzyme CYP2D6 and therefore are at greater risk for toxicity from psychotropic drugs and, potentially, other drugs that are metabolized by these isoenzymes. The metabolism of isoniazid also demonstrates variation among different people; some acetylate isoniazid very rapidly, whereas others acetylate it slowly.

Warfarin is a widely used oral anticoagulant. Its dose depends on age and CYP2C9 genotype. It works by depleting the supply of vitamin K. The formation of vitamin K depends on a protein known as vitamin K epoxide reductase complex subunit 1 gene (VKORC1). Mutations of this particular gene have been associated with a decrease in formation of clotting factors and warfarin resistance (Sconce et al., 2005).

Disease

Another important factor that influences drug interactions is the patient's existing disease state. Any disease affecting liver or kidney function can potentially predispose the patient to drug interactions and ADRs because these organs are primary sites of drug metabolism and elimination, respectively. Significant deterioration in drug metabolism or elimination can lead to increased serum drug concentrations and therefore increase the likelihood for drugs to interact. Consequently, elderly patients and those with a history of liver disease or renal insufficiency should be evaluated for dose adjustments of drugs significantly cleared by the liver and kidneys. For example, enoxaparin is a drug used to treat various clotting disorders. It is renally cleared from the body. Poor kidney function could lead to its accumulation. If the dose is not lowered in these patients, they could be exposed to too much enoxaparin resulting in excessive bleeding (Nutescu et al., 2009).

Environment

Environmental factors, such as DDT and other pesticides, can increase the activity of liver enzymes, potentially causing an increase in drug metabolism. Although the general significance of the effect of environmental exposure on the clinical outcome of drug therapy has not been well studied, people working in occupations with prolonged exposure to toxins and chemicals should be more closely observed.

Smoking

Studies show that smoking can increase the liver's metabolism of certain drugs, including diazepam, propoxyphene, chlorpromazine, and amitriptyline. For example, the polycyclic aromatic hydrocarbons in cigarettes can induce CYP1A2 metabolism, resulting in decreased theophylline serum concentrations (Schein, 1995).

Diet and Nutrition

The nutritional status and dietary intake of the patient can influence the importance of a drug–nutrient interaction. Drugs can deplete valuable vitamins and minerals from food; however, these interactions are often difficult to recognize and may go undetected. Patients with poor baseline nutrition (e.g., alcoholics) may experience more pronounced effects mainly because of underlying nutritional deficiency. Practitioners should be aware of potential drug–nutrient interactions by identifying patients who have poor dietary intake and who concurrently take medications that can deplete vitamins and minerals.

Alcohol Intake

Alcohol can complicate drug therapy on many different levels. Alcohol has a variable effect on drug metabolism depending on acute or chronic intake. Acute alcohol ingestion can inhibit drug metabolism, thus increasing serum drug concentrations; it also can enhance the pharmacodynamic effect of drugs with properties of CNS depression. Patients concurrently taking narcotics, antihistamines, antidepressants, antipsychotics, and muscle relaxants with alcohol are at greatest risk for CNS depression and should be warned of this interaction (Trovato et al., 1991). In addition, acute ingestion of alcohol can increase the potential for hypoglycemia in diabetic patients taking insulin or insulin secretagogues (e.g., sulfonylureas). Metronidazole is an antibiotic used to treat intra-abdominal infections. When taken with alcohol, it inhibits the enzyme, aldehyde dehydrogenase, which is responsible for metabolizing alcohol. This results in an accumulation of the intermediate metabolite, acetaldehyde, causing a disulfiram-like reaction such as facial flushing, headache, nausea and vomiting, weakness, dizziness, blurred vision, confusion, and hypotension.

In contrast, chronic alcohol intake tends to increase the synthesis of drug-metabolizing enzymes, leading to induction. Enzyme induction causes decreases in serum drug levels. Enzyme induction secondary to chronic alcohol use increases conversion of acetaminophen to hepatotoxic metabolites. Chronic use of alcohol in combination with high doses of acetaminophen (often from several sources) above that recommended in the labeling may result in liver damage (Jang & Harris, 2007). In addition, chronic use of alcohol in combination with NSAIDs or aspirin increases the risk of GI bleeding. Long-term abuse of alcohol leads to liver cirrhosis, which ultimately impairs drug metabolism by destruction of functional hepatocytes.

Adverse Drug Reactions

An ADR can be defined as an undesirable clinical manifestation that is consequent to and caused by the administration of a particular drug. ADRs are basically drug-induced toxic reactions. The World Health Organization defines an ADR as "a response to a medicine which is noxious and unintended, and which occurs at doses normally used in man" (Nebeker et al., 2004).

There are two general types to consider. The first type of ADR is an exaggeration of the principal pharmacologic action of the drug. The ADR is simply a more pronounced drug response than normal. These reactions usually are dose dependent and predictable. These are often referred to as type A reactions.

In the second type, type B reactions, the ADR is unrelated to the principal pharmacologic action of the drug itself. These reactions are precipitated by the secondary pharmacologic actions of the drug, may be unpredictable, and may or may not be dose dependent. In either type, the ADR can result from overdosage of drug or administration of therapeutic doses to a patient hyperreactive to the drug or as an indirect consequence of the primary action.

ADRs are sometimes referred to as side effects. A side effect is also recognized as an undesirable pharmacologic effect that accompanies the primary drug action and usually occurs within the therapeutic dosing range. ADRs or side effects can have varying levels of intensity. For example, the dry mouth and blurred vision that occur from drugs with anticholinergic properties are considered routine side effects of that class of medication. In contrast, drug-induced liver damage would be an uncommon and severe ADR or side effect not routinely associated with that class of medication. Patients experiencing ADRs or side effects from drugs do not necessarily require discontinuation of therapy; however, proper drug selection emphasizing agents with minimal side effect profiles may help improve patient acceptance of and compliance with the drug.

Medication Errors

Medication errors are also a potential cause of ADRs. These errors could range from switching from one dosage form to another to using foreign drugs. Table 3.9 lists some potential causes of ADRs. Some drugs may look-alike and soundalike. The Institute for Safe Medication Practices (2015) provides a list of drugs with confused drug names. For example, Figure 3.3 shows two look-alike vials of drugs were mixed-up and a patient inadvertently received phenylephrine instead of metoclopramide. Phenylephrine is a potent blood vessel vasoconstrictor often used to manage hypotension. Metoclopramide is a drug often used to treat nausea and vomiting. The event can lead to pulmonary edema and cardiac arrest.

TABLE 3.9 Potential Causes of Medication Errors

Potential Causes of Medication Errors	Example
Dosage conversion	When converting from oral to IV medications and vice versa, it is often not a 1 to 1 conversion. Levothyroxine 100 mcg oral dose is equal to ~50 mcg IV dose.
Foreign drugs	Dilacor is the brand name drug for diltiazem in the United States. In Serbia, it is the brand name drug for digoxin.
Illegible handwriting	Isordil was mistakenly filled with Plendil.
Look-alike and soundalike	Phenylephrine vial mistaken for metoclopramide vial.
Unacceptable abbreviations	Insulin 5.0 units was mistaken for 50 units.

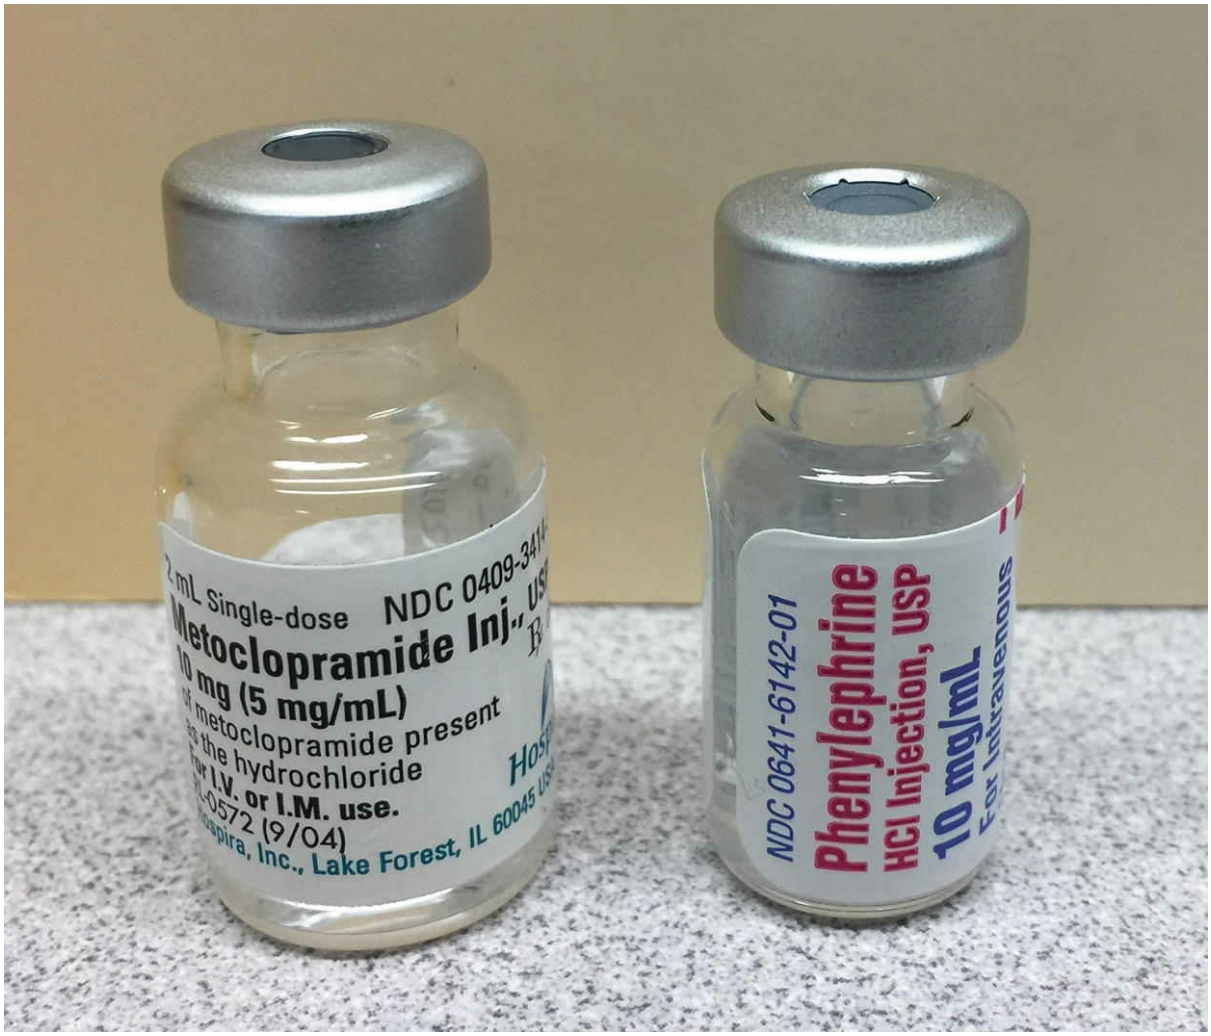

FIGURE 3.3 Look-alike drugs: Phenylephrine vial was mistaken for a metoclopramide vial.

Tracking Drug Interactions and Adverse Drug Reactions

The initial source of documented ADRs comes primarily from the experience gained while using a drug during clinical trials. Usually, the number of people taking the drug in clinical trials, on the order of hundreds to several thousands, is too few to detect all the possible adverse reactions from the drug. However, after a drug is approved by the FDA, it becomes readily available for public use in hundreds of thousands to millions of people. The potential for drug interactions and ADRs then becomes much greater than during clinical trials. Therefore, practitioners should have a basic understanding of drug interactions and ADRs and report these events to the FDA when they occur.

MedWatch is a medical product reporting program conducted by the FDA (Figure 3.4). The purpose of the MedWatch program is to enhance the effectiveness of surveillance of drugs and medical products after they are marketed and as they are used in clinical practice. The benefit to health care providers for reporting drug interactions and ADRs is to ensure that drug safety information is rapidly communicated to health care professionals, thus improving patient care. Health care providers should also be aware of programs in their own institutions that collect and report ADRs or drug interactions.

Case Study*

A.C. is a 60-year-old Caucasian woman with newly diagnosed peptic ulcer disease, generalized anxiety disorder, and iron deficiency anemia. She also has a long history of asthma and depression. She is a strong believer of herbal medicine. She takes St. John's wort for her depression, iron pills for her anemia, and alprazolam (Xanax) as needed for her anxiety. During her asthma exacerbation, she is instructed to take prednisone for at least 5 days. She also takes esomeprazole (Nexium) for her peptic ulcer disease. Three months later, she experienced severe fatigue, shortness of breath, dizziness, and swelling/soreness in the tongue. Her asthma is well controlled with the occasional use of albuterol (Proventil) inhaler. During her physical exam, her physician suspected that she had bacterial vaginosis and gave her a prescription for a 1-week course of metronidazole (Flagyl). She drinks at least two to three cans of beer per day.

Diagnosis: Drug–Drug Interactions

1. St. John's wort is known to inhibit which of her medication that is known to be metabolized by cytochrome P-450 (CYP3A4) and could potentially cause her to experience significant fatigue?

2. Which of her medication could interfere with the absorption of her iron pills?

3. Which of her medication could potentially cause her to develop vitamin B_{12} deficiency?

4. How does metronidazole interfere with alcohol?

5. If she was given a prescription for ketoconazole, which of her medication could interfere with its absorption?

4 Principles of Pharmacotherapy in Pediatrics

Anita Siu ■ James C. Thigpen Jr

When treating pediatric patients, many health care practitioners use the terms *infant*, *child*, or even *kid* interchangeably. However, there are currently accepted terms that define the different age categories of pediatric patients (Table 4.1). These terms should be used for accuracy when describing young patients and especially when determining drug dosages. Safe and effective drug therapy in pediatric patients is based on a firm understanding of three concepts:

TABLE 4.1 Age Groups of Pediatric Population

Group	Age
Preterm or premature	<36 wk gestational age
Neonate	<30 d old
Infant	Age 1 mo until 1 y old
Child	Age 1 until 12 y old
Adolescent	Age 12 until 18 y old

- Ongoing maturation and development in pediatric patients and their effect on a drug's absorption, distribution, metabolism, and excretion. Interpatient variabilities may be attributed to physiologic changes throughout childhood.
- Short- and long-term effects that the prescribed drug will have on a pediatric patient's growth and development
- Effects of underlying congenital, chronic, or current diseases on the prescribed drug, and vice versa

The popular concept that the pediatric patient is merely a "little or small adult," and therefore, pediatric pharmacokinetics, drug dosing, and even adverse effects can be extrapolated from the results of adult clinical drug trials is a serious misconception. Although many drugs do exhibit similarities between the adult and pediatric populations, the assumption of resemblance should not be applied to all drugs. Several tragic drug

misadventures in the 1960s and 1970s illustrate this. Extrapolated data from adult responses to chloramphenicol (Chloromycetin) led to its use in neonates in the 1960s. When given chloramphenicol, these neonates developed gray baby syndrome, hypotension, and hypoxemia, leading eventually to shock and death (Haile, 1977). This occurred because neonates, unlike adults, lack the enzyme needed to metabolize chloramphenicol. Another tragedy in the 1970s involved the topical antimicrobial cleanser hexachlorophene. Used routinely and safely in adults, hexachlorophene caused vacuolar encephalopathy of the brain stem in premature neonates after they were repeatedly bathed in a 3% solution (Anonymous, 1972).

Several barriers exist for pharmaceutical manufacturers in conducting pediatric clinical trials, such as fears of unforeseen adverse events affecting growth or development or difficulties in obtaining informed consent or blood samples. In turn, the lack of clinical trials in pediatric patients prevents the U.S. Food and Drug Administration (FDA) from approving drugs for use in the pediatric population. As such, the prescribing information commonly states "Pediatric Use: Safety and effectiveness in pediatric patients has not been established."

Without FDA approval or adequate documented information, many practitioners are uncertain how to use drugs in pediatrics. This leaves prescribers little choice but to use drugs in pediatric patients in an off-label capacity, based on adult data, uncontrolled pediatric studies, or personal experience. In 1997, the FDA took the initiative to increase the quantity and quality of clinical drug trials in the pediatric population by proposing alternate ways to obtain FDA approval. The FDA would waive the need for well-controlled clinical drug trials if drug manufacturers provided other satisfactory data for drugs already approved for the same use in adults. These data could include the results of controlled or uncontrolled pediatric studies, pharmacodynamic studies, safety reports, and premarketing or postmarketing studies. Alternatively, the drug manufacturer could provide evidence demonstrating that the disease course and drug effects are sufficiently similar in adult and pediatric patients in order to support extrapolation of data from adult clinical trials. In addition, pediatric pharmacokinetic studies are necessary to provide data for an appropriate pediatric dosage recommendation, especially age-dependent dosing. An FDA regulation issued in December 1998 required manufacturers to provide additional information about the use of their drug products in pediatric patients. The nature of the studies required to support pediatric labeling will depend on the type of application, the condition being treated, and existing data about the product's safety and efficacy in pediatric patients. Manufacturers will be required to study the drug in all relevant pediatric age groups (U.S. FDA, 1998a). Over the years, the FDA has encouraged more well-controlled trials on drug efficacy and safety in pediatrics. The FDA Modernization Act of 1997 and the Best Pharmaceuticals for Children Act of 2002 offered support for the pharmaceutical industries to conduct and submit pediatric clinical trials. Companies that conduct appropriate clinical trials are eligible to receive a 6-month patent extension on their product. The Pediatric Research Equity Act of 2003 mandated that drugs used in pediatrics require literature or

clinical trials supporting their use, even if the original patent did not have a pediatric indication. As a result, pediatric pharmacotherapy will evolve with additional clinical trials.

Pediatric Pharmacokinetics

Pediatric patients differ from adults, anatomically and physiologically. For safe use of drugs in pediatrics, prescribers and other caregivers need to recognize the potential for very different pharmacokinetics in pediatric patients as opposed to adults. The differences are based on developing body tissues and organs, which affect a drug's absorption, distribution, metabolism, and excretion.

Changes in a pediatric patient's body proportions and composition and the relative size of the liver and kidneys can alter the pharmacokinetics of a drug. During the first several years of life, a child undergoes rapid changes in growth and development, most rapid during infancy. Growth is a quantitative change in the size of the body or any of its parts, and development is a qualitative change in skills or functions. Maturation, a genetically controlled development independent of the environment, is a slower process, lasting until late childhood. Table 4.2 summarizes pharmacokinetic differences in pediatric patients.

TABLE 4.2 Age-Related Pharmacokinetic Differences in Children Compared with Adults

	Premature Neonate	Neonate	Infant	Child	Adolescent
Absorption					
Gastric acidity	↓	↓	↓	=	=
Gastric emptying time	↓	↓	=	=	=
GI motility	↓	↓	↓	=	=
Pancreatic enzyme activity	↓↓	↓	↓	=	=
GI surface area	↑	↑	↑	↑	=
Skin permeability	↑↑	↑	=	=	=
Distribution					
Blood–brain barrier	↓	↓	=	=	=
Plasma proteins	↓↓	↓	=	=	=
Metabolism					
Liver	↓	↓	↓	=/↑	=
Elimination					
Renal blood flow	↓	↓	↓	=	=
Glomerular filtration	↓	↓	↓	=	=
Tubular function	↓	↓	↓	=	=

By the end of the first year of life, an infant's weight triples, whereas body surface area (BSA) and length double. Accompanying these changes in growth and development are changes in body composition, intracellular and extracellular body water, fat, and protein. Approximately 75% to 80% of a full-term neonate's body weight is total body water (Friis-Hansen, 1957). By age 3 months, total body water constitutes approximately 65% of the patient's body weight. Extracellular water progressively declines and intracellular water increases faster than total body water, exceeding extracellular water (Friis-Hansen, 1957). The decreasing percentage of body weight from total body water is replaced by an increase in body fat during the first 5 months of life. In fact, the percentage of body weight from fat doubles in these 5 months. The protein percentage increases during the second year of life

as fat is lost, primarily because of ambulation. The liver and kidney reach their maximum size relative to body weight by age 2, producing a "peak" in the child's metabolism and elimination. After age 2, the child's liver and kidney size/body weight ratios steadily decrease until adult liver and kidney ratios are reached by adolescence.

Oral Absorption

The extent of a drug's absorption in a pediatric patient depends on a variety of factors: gastric pH, gastric and intestinal transit time, gastrointestinal surface area, enzymes, and microorganism flora or any combination thereof.

Gastric pH

Basal and stimulated secretion of gastric acid controls the pH of the stomach. The stomach pH is alkaline at birth (greater than 4) because of residual amniotic fluid and the immaturity of parietal cells. As gastric acid is produced, the pH falls. By the end of the first day of life, the basal and stimulated rates are equal, although lower than the rates in adults. An increased stomach pH (alkaline) adversely affects the absorption of weakly acidic drugs and improves the absorption of weakly basic drugs. This phenomenon results from increased ionization of the weakly acidic drug, producing more ionized (polar) drug, which moves poorly across the nonpolar gastric membrane, and vice versa for weakly basic drug. For example, the bioavailability of phenobarbital (a weak acid) is decreased in neonates, infants, and young children because their alkaline gastric pH produces more ionized phenobarbital, which crosses the gastric membrane poorly.

For weakly basic drugs, the alkaline stomach pH increases the nonionized form of the drug, which then easily moves across the gastric membrane. By the second year of life, the child's gastric acid output on a per kilogram body weight basis is similar to that observed in the adult (Deren, 1971). As a result, gastric pH affects the degree of drug ionization, thus changing the amount of drug absorbed.

Gastric Emptying Time and Surface Area

The gastric emptying time is delayed in both preterm and full-term neonates during the first 24 hours of life. No studies have been conducted beyond the immediate neonatal period. The combination of delayed gastric emptying time and gastroesophageal reflux can result in the regurgitation of orally administered drugs, producing irregular drug absorption. In general, gastric emptying is more prolonged in neonates and infants than in children.

The characteristics of a drug's movement through the intestines can drastically affect the rate and extent of drug absorption because most drugs are absorbed in the duodenum. Both neonates and infants have irregular peristalsis, which can lead to enhanced absorption. In addition, the type of feeding an infant receives can affect intestinal transit time. For instance, the intestinal transit time in breast-fed infants is greater than in formula-fed infants (Cavell, 1981).

The relative size of the absorptive surface area in the duodenum can significantly influence the rate and extent of drug absorption. In the young, the greater relative size of the duodenum compared with adults enhances drug absorption.

Gastrointestinal Enzymes and Microorganisms

The absorption of drugs that are fat soluble or carried in fat vehicles depends on lipase. Premature neonates have low lipase concentrations and no alpha amylase. The reduced activity of bile acids, lipase, alpha amylase, and protease continues until approximately age 4 months. Vitamin E absorption is decreased in neonates because of the diminished bile acid pool and biliary function; therefore, supplementation of this vitamin may be necessary.

The development of the intestinal microorganism flora depends more on diet than on age (Yaffe & Juchau, 1974), which may account for the more rapid development of flora in breast-fed infants than in formula-fed infants. The reduction of digoxin (Lanoxin) to inactive metabolites by anaerobic intestinal bacteria can be used as a marker for the development or changes in intestinal flora (Lindenbaum et al., 1981). Digoxin metabolites are not detected in children until 16 months, and an adult-like reduction of digoxin does not occur until age 9 (Linday et al., 1987).

Rectal Absorption

The rectal route of administration is seldom used; it usually is reserved for patients who cannot tolerate oral drugs or who lack intravenous access. In rectal administration, the drug is absorbed by the hemorrhoidal veins, which are not part of the portal circulation, therefore avoiding first-pass hepatic elimination. Unfortunately, most drugs administered by this route are erratically and incompletely absorbed. Feces in the rectum, frequent bowel movements in neonates and infants, and lack of anal sphincter muscle contribute to the poor absorption profile of drugs administered rectally.

Although rectal administration may not be appropriate for routine dosing of drugs, the rectal administration of diazepam (Valium), valproic acid (Depakote), or midazolam (Versed) has been used to control seizures when intravenous access could not be quickly established in infants or children with status epilepticus (Brigo et al., 2015; Graves & Kriel, 1987).

Intramuscular and Subcutaneous Absorption

Both the characteristics of the patient and the properties of the drug influence the absorption of intramuscularly or subcutaneously administered drugs. Patient characteristics include blood flow to the muscle, muscle mass, tone, and activity. Important properties of the drug are its solubility, the pH of extracellular fluid, its ease in crossing capillary membranes, and the amount of drug administered at the injection site.

In pediatric patients, all the patient characteristics are highly variable. Neonates have decreased muscle mass, and their limited muscle activity decreases blood flow to and from the muscle. Collectively, these factors produce erratic and poor intramuscular drug absorption. On the contrary, infants possess a greater density of skeletal muscle capillaries than older children, allowing for more efficient drug absorption. Some drugs, such as erythromycin, can cause pain at the injection site and should not be administered intramuscularly. However, many drugs, such as the penicillins, reach concentrations in the serum with intramuscular administration that are comparable with those achieved after intravenous administration, with minimal adverse effects.

Percutaneous Absorption

Adverse effects resulting from the inadvertent systemic absorption of percutaneously administered hexachlorophene emulsion, salicylic acid ointment, and hydrocortisone creams in neonates have limited the use of this route of drug administration. The absorption of compounds is inversely related to the thickness of the stratum corneum and directly related to hydration of the skin (Morselli et al., 1980). Relative to body mass, the BSA is greatest in the infant and young child compared with older children and adults. The decreased thickness of the skin with increased skin surface hydration relative to body weight produces much greater percutaneous drug absorption in neonates than in adults. The percutaneous administration of drugs in neonates does pose some risks of toxic effects. Neonatal skin is structurally immature, resulting in less subcutaneous fat and a thinner stratum corneum and epidermis (Rutter, 1987). Since a greater skin surface area/body weight ratio is observed during the neonatal period, percutaneous drug absorption is also superior. Both the advantages and subsequent disadvantages of enhanced percutaneous absorption disappear after infancy, however.

Mucosal Absorption

Mucosal administration of medications, whether via the nasal or buccal route, has become a viable method for use in children. Some medications, such as nasal corticosteroids, are intended for a local effect and have almost no systemic absorption or effects. However, some medications, such as midazolam (Versed) and ketamine (Ketalar), have been administered by nasal aerosolization with good absorption and systemic effect (Hosseini Jahromi et al., 2012; Klein et al., 2011). Administration by these routes avoids the trauma of placing an intravenous line and the associated costs. Also, in urgent situations where there may be considerable difficulty placing an intravenous line (i.e., status epilepticus), nasal administration can be utilized with great effectiveness (Thakker & Shanbag, 2013).

Pulmonary Absorption

Aerosolized drug delivery to the lungs continues to be a favorite technique in many respiratory disorders, such as asthma. Factors affecting drug deposition in the lungs include particle size, lipid solubility, protein binding, drug metabolism in the lungs, and mucociliary transport (American Academy of Pediatrics, 1997). Aerosol particle size and lipid solubility are factors in determining whether the drug is deposited in the upper or lower airways; smaller particle size and lipid-soluble drugs are more likely to be absorbed and deposited in the lower airways (Bond, 1993).

Besides drug considerations, pediatric characteristics also affect aerosol drug delivery. Infants and children have lower tidal volumes and increased respiratory rates (especially while crying), reducing drug delivery and absorption in the lungs. Studies have shown that less than 2% of aerosolized drugs are deposited in young infants and toddlers (Fok et al., 1996; Salmon et al., 1990). Therefore, adult dosing may be necessary to counteract these effects.

Distribution

Six factors affect drug distribution in the pediatric population: vascular perfusion, body composition, tissue-binding characteristics, physicochemical properties of the drug, plasma protein binding, and route of administration (Stewart & Hampton, 1987). During the neonatal period, most of these factors are significantly different from those in the adult population, while children and adolescents are very similar to or the same as adults.

Vascular Perfusion

Changes in vascular perfusion are common in neonates. For example, in neonatal respiratory distress syndrome and postasphyxia, a right-to-left vascular shunt may occur and divert blood from the lungs to the tissues and organs, potentially changing the Vd of some drugs.

Body Composition

Neonates have increased total body water (75% to 80%) with decreased fat compared with adults, resulting in a higher water-to-lipid ratio. After the neonatal period, fat increases and total body water decreases steadily until puberty, especially in girls. For instance, neonates and infants have increased total body and extracellular water, creating a larger volume of distribution and affecting the pharmacokinetics of some drugs, such as aminoglycoside. The larger volume, in turn, requires administering a larger milligram-per-kilogram dose of aminoglycosides to neonates and infants than to adults.

Tissue-Binding Characteristics

The mass of tissue available for binding can affect drug distribution. Drugs extensively bound to tissues exhibit increased "free" blood levels when the mass of tissue is reduced by disease or degeneration or immaturity, as in pediatrics.

Physicochemical Properties

The physicochemical properties of a drug include lipid solubility (ionized vs. nonionized) and molecular configuration. These properties affect the ability of a drug to move across membranes into target cells or tissues. Drugs that display favorable properties for absorption may pose a greater risk for toxicity in neonates, who have enhanced percutaneous drug absorption.

Plasma Protein Binding

Preterm neonates have lower circulating amounts of $alpha_1$ acid glycoprotein, which binds alkaline drugs, than full-term neonates, who have lower $alpha_1$ acid glycoprotein levels than adults. Neonates also have a reduced amount of circulating albumin compared with adults.

Albumin is responsible for binding acidic drugs, fatty acids, and bilirubin. While the affinity of drugs for either of these plasma proteins is harder to determine, theoretically a neonate's affinity for protein binding is reduced, resulting in the likelihood of displacing drugs or bilirubin bound to albumin and leading to increased serum concentrations. All these factors produce a larger volume of distribution and increased free drug concentrations (e.g., phenytoin [Dilantin]) in neonates than in adults.

Route of Administration

The route by which a drug is administered has a primary influence on the drug's distribution. If the drug is administered orally, the liver becomes the primary distribution site. However, if a drug is administered intravenously, the heart and lungs act as the primary distribution sites. This is important because when a drug passes through the liver before reaching its site of activity, it is subject to the first-pass effect of extensive hepatic metabolism, which typically reduces the amount of circulating active drug and thus limits its effects. Therefore, to achieve an equal effect, the dosage of a drug administered by the oral route usually needs to be higher than the dosage of a drug administered intravenously.

Metabolism

Clearance of many drugs is mainly reliant on hepatic metabolism. The two phases of drug metabolism in the liver are the oxidation, reduction, and hydrolysis reactions (phase I) and conjugation reactions (phase II). Age-related changes in metabolism affect how drugs are broken down or transformed in pediatric patients and how certain metabolic enzymes are activated (Table 4.3 summarizes developmental patterns in phase I oxidation reactions). Phase I and II reactions are delayed in neonates, infants, and young children, with consequential drug toxicities.

TABLE 4.3 Summary of Age-Related Changes in Metabolism

P-450 Cytochromes	Reduced Activity versus Adults	Increased Activity versus Adults	Age at Which Adult Activity Is Reached
CYP1A2	Until age 4 mo	1–2 y old	End of puberty
CYP2C19			
CYP2C9	First week of life	3–4 y old	End of puberty
CYP2D6	Until age 3–5	3–5 y old	
CYP2E1	Unknown	Unknown	Unknown
CYP3A4	First month of life	1–4 y old	End of puberty

Based on data from Leader, J. S., & Kearns, G. L. (1997). Pharmacogenetics in pediatrics: Implications for practice. *Pediatric Clinics of North American,* 44, 55–77.

The P-450 cytochrome (CYP) is the most important component of phase I drug metabolism. Cytochromes in the CYP1, CYP2, and CYP3 families have been identified as important in human drug metabolism. Additional information suggests there is substantial genetic variability in the quantity and quality of CYP in the human body (Kearns, 1995). For example, codeine is metabolized to morphine via the CYP2D6 and can result in high levels of morphine in ultrarapid metabolizers to the enzyme. Deaths in children who are ultrarapid metabolizers have been reported after receiving codeine postoperatively from tonsillectomy and/or adenoidectomy. These reports led to the FDA to create a boxed warning avoiding the use of codeine in children undergoing these procedures.

The metabolism of caffeine and theophylline, the prototypic substrate for CYP1A2, is reduced at birth; the drug concentration increases linearly over the first year of life and exceeds adult levels in older infants and children. To maintain therapeutic serum theophylline concentrations, smaller doses are prescribed and administered less frequently in neonates than in older infants and children.

In pediatrics, phase II reactions are less well studied than phase I reactions. In adults, acetaminophen (Tylenol) (a substrate for glucuronosyltransferase 1A6 and 1A9) is metabolized by a phase II glucuronidation reaction. In neonates and infants, however, this metabolic pathway is deficient. As a result, acetaminophen metabolism is shifted to sulfate conjugation, which results in a half-life for acetaminophen that is similar to its half-life in adults.

Elimination

Almost all drugs and their metabolites are excreted through the kidneys. The kidney eliminates drugs by glomerular filtration (passive diffusion) or tubular secretion (energy-dependent channels or pumps). The glomerular filtration rate (GFR) increases quickly during the first 2 weeks of postnatal life and does not approach adult rates until age 2 (Rubin et al., 1949); tubular secretion and reabsorption rates do not reach adult values until age 5 to 7 months. The proximal tubules are characterized by an inability to concentrate urine or reabsorb various filtered compounds and a reduced ability to secrete organic acids. This immaturity of the renal system in neonates and infants results from restricted blood flow and a resultant decrease in cardiac output to the kidneys, combined with incomplete glomerular and tubular development. As a result, plasma clearance of many drugs via the kidneys is altered. For example, during infancy, the response to thiazide diuretics, which require a GFR greater than 30 mL/minute to be effective, is diminished. Often, a larger dosage of a thiazide diuretic or substitution by a loop diuretic is required to produce adequate diuresis. Because the elimination of aminoglycosides is directly related to the GFR, aminoglycosides have a longer half-life in neonates and infants, thus requiring a longer dosing interval than in adults. In addition, decreased tubular secretion in neonates and infants can lengthen the elimination half-life of other antibiotics, such as the penicillins and sulfonamides. Selecting the appropriate dosing regimen based on age, weight, and kidney maturation and identifying concomitant agents renally eliminated are important factors to prevent toxicity. In general, renal excretion of many drugs is directly proportional to age.

Drug Selection

Various factors are considered when prescribing a drug for a pediatric patient. Among them are the benefits of the drug in relation to the risks of administration, the long-term effects, the dosage form, and the route and frequency of administration (Figure 4.1).

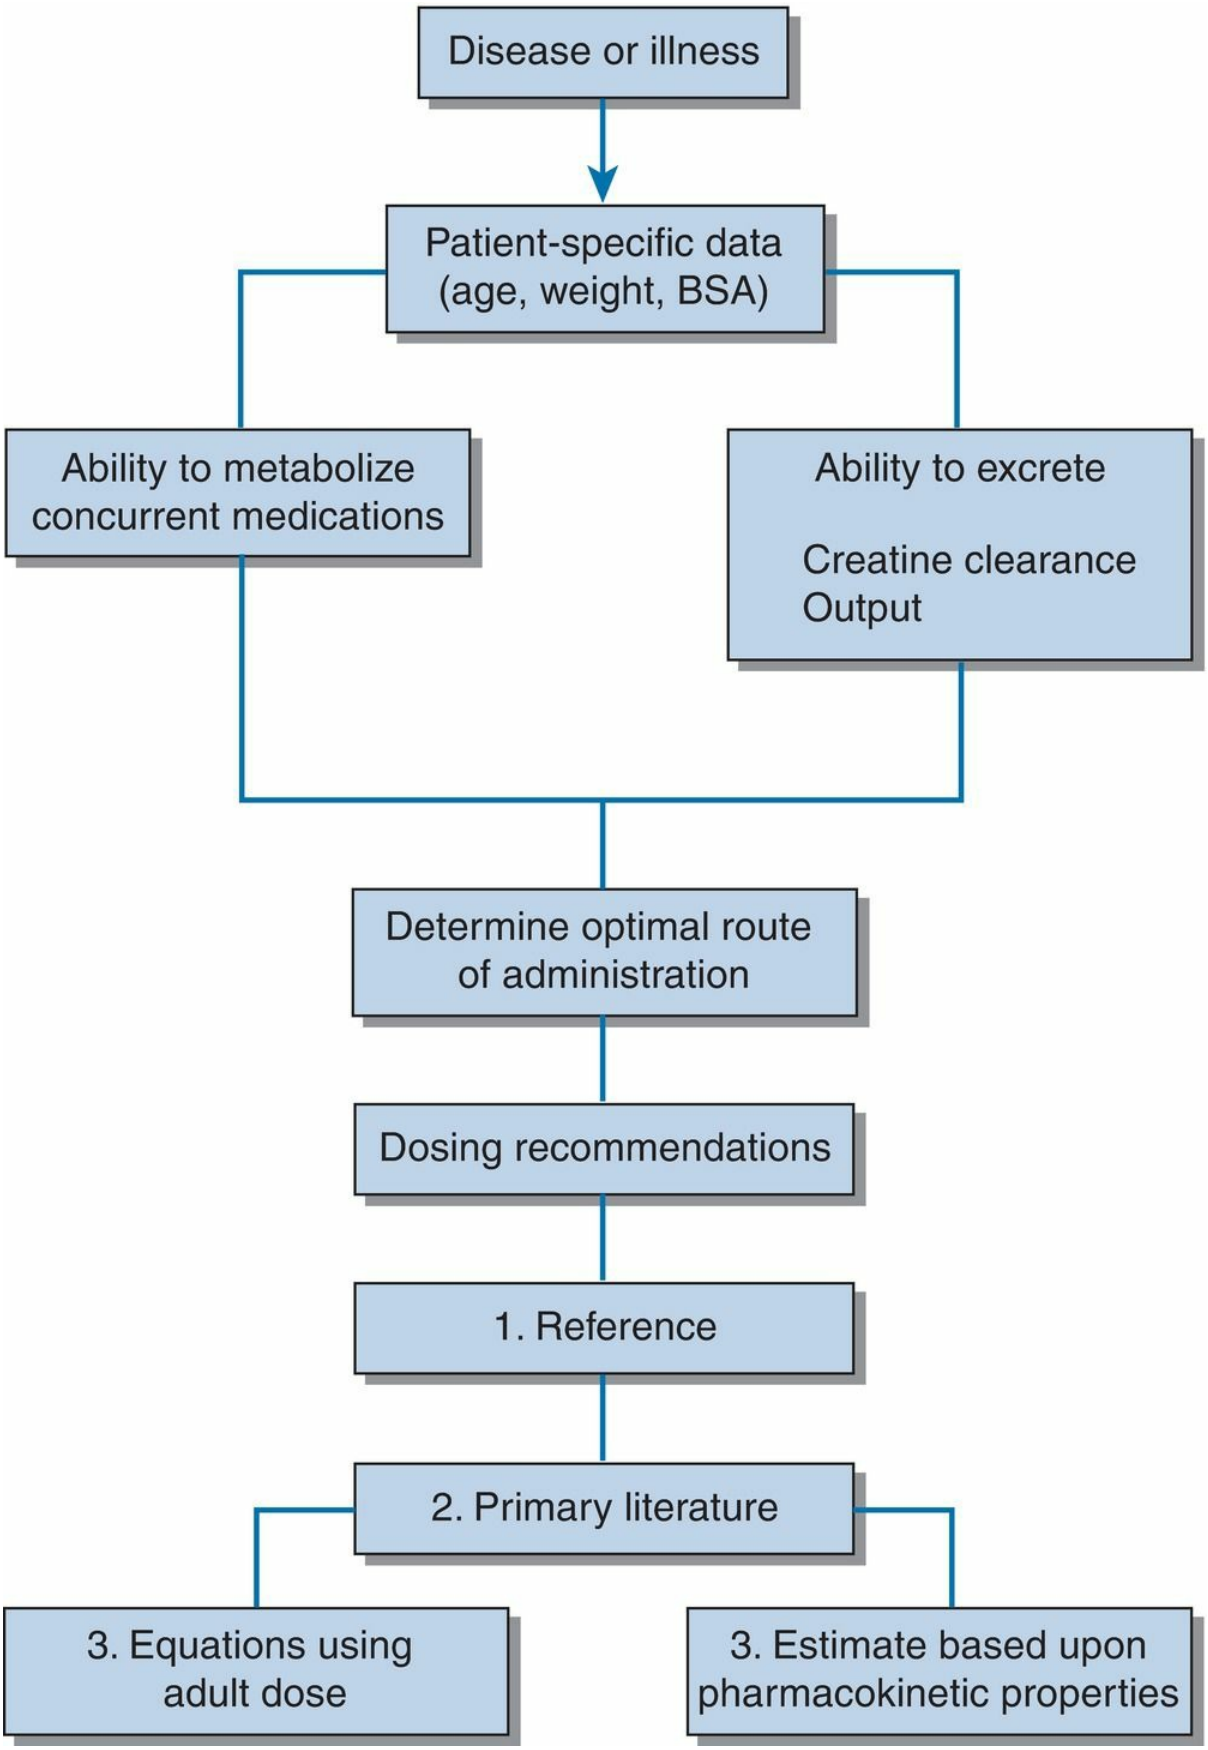

FIGURE 4.1 Approach to prescribing drug therapy for the pediatric patient.

Risks and Benefits

The classic medication when discussing risks and benefits in the pediatric population is ciprofloxacin (Cipro), a fluoroquinolone. Ciprofloxacin was brought to market in 1987 and carried a risk of severe degenerative arthropathy. This effect was seen in juvenile study animals during drug development. The potential for this problem led to these drugs being contraindicated in all pediatric populations. Numerous studies over the past 20 years disputing this risk has led to over 500,000 prescriptions for the drug being written annually for children younger than age 18. The American Academy of Pediatrics developed a policy statement that provides an outline for the use of fluoroquinolones in children (American Academy of Pediatrics, 2011). The use of the drug class in children is driven more by resistance patterns in pathogens covered by the class than the potential risk of arthropathy to the patient.

Cardiovascular safety and adverse psychiatric effects are a concern with the use of psychostimulants in the treatment of attention deficit hyperactivity disorder (ADHD). A very small number of case reports of sudden cardiac death have been reported in children prescribed psychostimulants for ADHD. The risk has been found to be greater in patients with underlying cardiac structural abnormalities. However, the risk is similar to that of strenuous exercise in this population, and the use in the general population does not necessitate additional testing beyond normal screening. There is also a small risk of psychosis and mania-type reactions in children. As a result, the FDA requires the pharmaceutical industry to provide medication guides to patients and prescribers explaining the risks of ADHD drug treatments and information on their potential side effects.

Another widely used drug class with specific safety concerns in the pediatric population is antidepressants. There is a very slight increase in suicide risk in patients started on antidepressants, which likely reflects the current depressed state and other comorbidities. The FDA has included a black box warning for increased suicidality for children and adolescents initiating all classes of antidepressants. Although this is a statistically significant increased risk compared to the normal population, the risk of suicide in untreated depressed patients is much higher.

Long-Term Effects

Drugs administered to pediatric patients may take a longer time to produce adverse effects than in adults. Certain adverse effects may not be detected until decades after treatment. For example, secondary cancers, growth retardation, hypogonadism, and sterility have all been reported as late adverse effects associated with certain antineoplastic therapies. Inhaled and intranasal corticosteroids may decrease growth velocity, which is a means of comparing growth rates among children of the same age. Studies with inhaled steroids showed approximately a 1-cm/year reduction in growth velocity. The FDA suggests that the reduction is related to dose and how long the child takes the drug (U.S. FDA, 1998b). Lone and Pederson (2000) evaluated the long-term effect on growth of inhaled or intranasal budesonide in pediatric asthma patients. At the end of this 10-year study, the researchers concluded that normal adult height was achieved in patients receiving these corticosteroids. More recently, the Children Asthma Management Program (CAMP) Research Group showed a reduction of 1.2 cm in adult height in the inhaled budesonide versus placebo group (Kelly et al., 2012).

Potential long-term effects of medications used in children create a concern. The 5-year survival rates of most pediatric malignancies are approaching 80%. This has led to a focus on the late effects of therapy and the quality of life in this growing population of childhood cancer survivors (Shankar et al., 2008). Nearly two thirds of all childhood cancer survivors will experience some physical or psychological outcome that develops or persists beyond 5 years from the initial diagnosis (Shankar et al., 2008). Other medications used in pediatrics may also carry risks for long-term effects. Unfortunately, these effects may not be seen for years after the medication is stopped, and there are likely other factors that could cause or at least contribute to the effect. Studies that evaluate the long-term effect of a medication are very difficult to perform and often yield conflicting results.

Dosage Formulation

Commercially available dosage formulations often limit the drugs that can be prescribed to children and are not always child friendly. Many drugs are available only as an oral tablet, capsule, or intravenous dilution in adult dosage strengths. Prescribing a drug as a tablet or capsule for a pediatric patient has several drawbacks. He or she may have difficulty swallowing a whole or intact tablet or capsule, and attempting to break a tablet into smaller pieces or emptying part of a capsule to provide an appropriate dose leads to questionable accuracy of the administered dose. It is important to provide a dosage form that can be administered easily, accurately, and safely to a pediatric patient. A method to improve administration is via extemporaneous formulations, especially if a product is not commercially available as an elixir, solution, suspension, or syrup. However, these oral liquid formulations also have drawbacks such as an unfavorable taste. Other alternatives to oral liquid formulations include tablet dispersion, powdered papers, and repacked capsules. Combination products are available to reduce pill burden and improve medication adherence. However, these agents contain fixed dosage forms in tablets or capsules, making it difficult for a child less than age 5 to swallow.

Ideally, a practitioner who is prescribing a dosage formulation not commercially available for a pediatric patient ought to work with a pharmacist who is willing and able to compound accurate pediatric drug dosages and formulas. Practitioners can familiarize themselves with additional drugs that can be extemporaneously compounded for use in pediatrics by a pharmacist in such publications as *Pediatric Drug Formulations* (Nahata & Hipple, 2010); *Teddy Bear Book: Pediatric Injectable Drugs* (Phelps, 2013); *Pediatric Dosage Handbook* (Taketomo et al., 2014); *Extemporaneous Formulations for Pediatric, Geriatric, and Special Needs Patients* (Jew et al., 2010); or *Trissel's Stability of Compounding Formulations* (Trissel, 2012). A Medline search should be conducted for drugs not contained in these publications.

Dosage

In adult drug therapy, one standard dose of a drug can be used for almost all adults, but the opposite is true in pediatric drug therapy: a pediatric drug dose changes for different illnesses or as the patient grows or develops and requires age-dependent adjustments.

When writing or assessing a pediatric medication order, the following process is recommended to ensure safe and effective pharmaceutical care:

1. Determine the patient type (i.e., neonate, pediatric, adolescent).
2. Assess the appropriateness of the drug therapy selected in this patient type, patient population, and/or disease state.
3. Establish the appropriate dose, route, formulation, and frequency based on the recommended references mentioned below.
4. If all resources have been exhausted or further information is needed regarding the pediatric dosage, contact a pharmacist. It is important to ensure that the dose is appropriate or reasonable based on his or her knowledge of pediatric pharmacokinetics and available resources.

Many drugs currently in use in pediatrics have established dosing recommendations based on body weight, BSA, concurrent drug therapy, and stage of development or physiologic function (age). Body weight–based dosing is the most common method for pediatric dosing. A total daily dose, milligrams per kilogram per day (mg/kg/day), is divided by the dosing interval to calculate each individual dose. Analgesics, antipyretics, and emergency drugs are often administered on a dose-by-dose method; as such, the recommended pediatric dose is reported as milligrams per kilogram per dose (mg/kg/dose). The starting or maximum doses for pediatric intravenous infusions are usually reported as micrograms per kilogram per minute (mcg/kg/minute) or micrograms per kilogram per hour (mcg/kg/hour). Drug dosages based on a patient's BSA are usually reserved for antineoplastic agents or critically ill patients. BSA correlates closely with many factors that influence drug elimination, including cardiac output, respiratory metabolism, blood volume, extracellular water volume, GFR, and renal blood flow. Dosages of several drugs, including docusate (Colace) and montelukast (Singulair), are based on age.

General pediatric drug references such as the *Pediatric Dosage Handbook* (Taketomo et al., 2014) and Micromedex (MICROMEDEX Solutions, 2015) provide comprehensive drug monographs, including dosage formulations, adverse events, pharmacology, and pharmacokinetics. *The Harriet Lane Handbook* (Engorn & Flerlage, 2014) provides drug monographs based on the Johns Hopkins Hospital formulary and special drug topics. A specialty pediatric reference such as the *Red Book* (Pickering et al., 2012) covers only antimicrobial agents and vaccines; *Neofax* (Neofax, 2015) provides information about drug dosing in neonates.

Obesity

Obesity, defined in children as a body mass index (BMI) at or above the 95th percentile for age, is considered a public health crisis in the United States (Ogden et al., 2010). Since 1980, the percentage of school-age children and adolescents that are considered obese has tripled and is approximately 17% (Ogden et al., 2010). Children with a BMI at or above the 85th percentile are considered "at risk for overweight," and nearly 32% of U.S. children ages 2 to 19 fall into this category (Ogden et al., 2010). While it is known that there is an overall lack of information on dosing most medications in children, there is far less information on proper medication dosing in the overweight child. Obesity can affect the pharmacokinetics, dosing, half-life, and metabolism of a medication. Medications originally intended for adult use are now being utilized to treat hypertension, hyperlipidemia, and type 2 diabetes as these diseases are on the rise secondary to the increase in obesity (Kennedy et al., 2013). There is a greater risk of dosing errors in overweight children, specifically for underdosing and overdosing of antimicrobials (Pediatric Pharmacy Advocacy Group, 2010). The Pediatric Pharmacy Advocacy Group recommends that weight-based dosing be utilized for all children less than age 18 and weighing less than 88 lb (40 kg). For children who weigh over 40 kg, weight-based dosing should be used, unless the patient's dose or dose/day exceeds the recommended adult dose for the specific indication (Johnson et al., 2010).

Routes of Administration

Oral

When prescribing or administering oral drugs for pediatric patients, the caregiver needs to consider not only the drug's flavor and ease of delivery but the frequency of administration, dosage form, and "inactive" ingredients, such as alcohol and sugar. A liquid dosage form is preferred for most pediatric patients.

To ensure the accuracy of each dose administered, the drug should be measured and then administered with an oral syringe or a calibrated drug cup, with the base of the meniscus viewed at eye level. If the drug is available only in tablet form, and the tablet can be broken, the tablet may be crushed and mixed in compatible syrup. However, mixing a crushed or whole tablet with food should be done cautiously because many foods interfere with drug absorption.

If the patient is an infant, the head should be raised to prevent aspiration of the drug. Applying gentle downward pressure on the chin with a thumb helps open the patient's mouth. If a syringe is used, the tip of the syringe should be placed in the pocket between the patient's cheek and gum and the drug administered slowly and steadily to reduce the risk of aspiration.

For bottle-fed infants, the drug can be placed in a nipple and the infant allowed to suck the contents. However, a drug should never be mixed with the contents of a baby's bottle because the correct dose will not be received if the infant does not consume the full contents of the bottle. In addition, a drug–nutrient interaction may occur if a drug is mixed with formula. A classic example of a drug–nutrient interaction is the significant reduction of oral phenytoin absorption after concurrent administration with an enteral feeding formula (Sacks & Brown, 1994).

Rectal

Toddlers being toilet trained, especially children experiencing stress or difficulty, often resist the rectal administration of drugs. Older children may perceive the procedure as an invasion of privacy and may react with embarrassment or anger and hostility. The best approach to reducing anxiety and increasing cooperation is to spend time explaining the procedure and to reassure the child that giving drugs by this route will not hurt. It may be necessary, after placing a suppository, to hold the child's buttocks together for a few minutes to prevent expulsion of the drug.

Parenteral

Establishing venous access, venipuncture for blood samples, and intramuscular injections are a great source of distress and pain for children. Several local anesthetic agents have been

developed to help manage the pain and anxiety brought on by these procedures. The ideal product would have needle-free or topical administration, a rapid onset of anesthetic, and no dermal or systemic adverse effects, and the product would have no impact on the success rate of the procedure. No commercially available product has all these qualities. The three general delivery methods used to bypass the stratum corneum layer include direct injection of local anesthetics, passive diffusion from topically applied gels or creams, and several needle-free methods that hasten the rate of drug passage through the skin and speed the time to onset of action. Table 4.4 lists the methods of drug delivery, the available agents, and the advantages and disadvantages of each (Zempsky, 2008).

TABLE 4.4 Topical Anesthetics

Method	Product(s)	Medication(s)	Onset of Topical Anesthesia	Adverse Reactions
Injection of local anesthetics	Lidocaine Lidocaine buffered with sodium bicarbonate	Lidocaine	<1 min	Pain associated with initial needle stick for injection of medication
Lidocaine needle-free injection	J-Tip	Lidocaine	<1 min	"Popping noise" with administration (may frighten some children)
Passive diffusion with topical creams or gels	EMLA, generic	Lidocaine 2.5%, prilocaine 2.5%	30 min (minimum), 60 min for more complete effect	Skin blanching, rare methemoglobinemia in infants
	LMX4	Liposomal lidocaine 4%	30 min	Erythema, blanching
Needle-free strategies to accelerate onset	Synera	Lidocaine/tetracaine	10 min	Local reactions (erythema, 71%; blanching; and edema)
Lidocaine iontophoresis	Numby Stuff	Lidocaine	10–15 min	Intolerable tingling, itching, burning sensation, and discomfort, potential for burn
Lidocaine HCl monohydrate powder intradermal injection system	Zingo	Lidocaine HCl monohydrate	1–3 min	Local reactions (erythema, 62%; petechiae, 52.8%) and edema
Vapocoolant sprays	Pain Ease	Liquid refrigerant (ethyl chloride)	Immediate (may require two providers as effect lasts <1 min)	Some skin pigmentation changes (temporary)

Pulmonary

Nebulizers, metered-dose inhalers (MDIs), and dry powder inhalers (DPIs) can be used to deliver bronchodilators, aminoglycosides, and corticosteroids in the treatment of asthma or cystic fibrosis. Nebulized drugs require connecting an air or oxygen tube to the nebulizer machine and are often used in infants and young children. MDIs require coordination between actuation and inhalation; this is difficult in any age group, so a tube spacer is recommended for children less than age 5 (National Heart, Lung, and Blood Institute, 2007). Spacer devices have expanded the use of MDIs even to the neonatal population. A DPI such as budesonide powder (Pulmicort Turbuhaler) involves coordination with the patient's inspiratory flow; therefore, the delivery mechanism is not recommended in children less than age 4. Table 4.5 summarizes the recommended population for aerosol delivery devices (National Heart, Lung, and Blood Institute, 2007).

TABLE 4.5 Recommended Age Groups of Aerosol Delivery Devices

Device	Age
Metered-dose inhaler (MDI)	• ≥5 y old • <5 y old (+ spacer or valved holding chamber)
Breath-actuated MDI	• ≥5 y old
Dry powder inhaler	• ≥4 y old
Spacer or valved holding chamber (VHC)	• ≥4 y old • <4 y old (VHC + face mask)
Nebulizer	• Any age

Topical

The topical delivery of medications is common in the pediatric population with diseases such as eczema and acne as well as other skin disorders that appear during childhood. Caution is warranted in this population due to several factors that may lead to a higher rate of drug absorption. When compared to adults, infants and children have a higher ratio of skin surface to body weight. This increases the risk of accumulating significant serum drug levels (Metry & Herbert, 2000). It is especially true in the newborn and infant because the barrier function of their skin is immature. Parents must be cautioned to follow the directions for administration of all topical medications to prevent toxic drug levels. A fatal case of diphenhydramine toxicity was reported in the literature, largely due to excessive application following a bath in a child with eczema (Turner, 2009).

Medication Adherence

The term "medication adherence" is used to describe the extent to which patients take medication as prescribed by their health care providers (Osterberg & Blaschke, 2005). Adherence (or nonadherence) to prescribed therapy is multifactorial and includes simply forgetting, busy lifestyle, complexity of the regimen, taste, education, and motivation, among others. Practitioners must consider these factors when prescribing therapy and must strive to find the balance that will help the patient and family achieve necessary adherence to the prescribed therapy. It is practical to select medications that can be administered once or twice daily because adherence falls dramatically when medications are to be administered more than twice per day (Richter et al., 2003). Establishing a good relationship with honest communication between the prescriber and the patient/family is an important factor in medication adherence and positive outcomes. Practitioners should always look for poor adherence as a cause of less-than-optimal outcomes. Better adherence can often be achieved by additional education, simplifying the regimen, and customizing the regimen to the

patient's/family's lifestyle (Osterberg & Blaschke, 2005).

Conclusion

In summary, pediatric pharmacotherapy poses a unique challenge. The lack of medications approved by the FDA, insufficient literature resources, pharmacokinetic parameters compared to adults, individual drug dosing calculations, lack of dosage forms, and inappropriate drug delivery systems are a few examples (Levine et al., 2001). Ensuring effective and safe delivery of drugs in pediatrics involves understanding the physiologic changes that occur throughout childhood. Since the start of the Institute for Safe Medication Practices in 1994, pediatric medication safety movements have progressed over time. In 2004, the Institute of Healthcare Improvement (IHI) introduced the 100K Lives Campaign to protect patients from medical harm. Two years later, the IHI launched the 5 Million Lives Campaign with a pediatric initiative to reduce adverse drug events and decrease harm from high-alert medications (i.e., anticoagulants, sedatives, opioids, insulin) (IHI, 2006). The Joint Commission Sentinel Event Alert stated that harm caused by medication errors is three times greater in pediatric patients than adults (The Joint Commission, 2008). As a result, the Joint Commission Issue 39 recommends initiatives to prevent medication errors and suggests risk reduction strategies. Box 4.1 gives some recommendations to assist health care professionals in reducing medication errors (American Academy of Pediatrics, 2003; The Joint Commission, 2008). In the future, pediatric pharmacotherapy will evolve with additional legislation and safety movements.

BOX 4.1 Preventing Pediatric Medication Errors

American Academy of Pediatrics

- Maintain an up-to-date patient allergy profile.
- Confirm the validity of a patient's weight for medications that are dosed by body weight (or body surface area [BSA] for medications dosed by BSA).
- State specific dosage strengths or formulation.
- Do not use abbreviations for drug names or patient instructions.
- Avoid using abbreviations for dosage units.
- Use a zero before a decimal point.
- Avoid a zero after a decimal point.

The Joint Commission

- Standardize concentrations of high-alert medications (i.e., heparin, insulin, or narcotics).
- Utilize oral syringes to administer liquid formulations.
- Create drug order pathways for protocols.
- Collaborate and educate all health care members involved with the patients' care.
- Use technology such as automated dispensing cabinets, smart infusion pumps, bar coding.

Case Study*

M.T. is an 18-month-old, 20-kg male who presents to the emergency department in status epilepticus, which has continued for approximately 20 minutes. He was brought to the emergency department from a small community via a family vehicle. He has not received any care at this point. The nursing staffs has attempted several intravenous line insertions but were unable to gain access. M.T. continues to convulse without interruption.

1. Which of the following would be the most appropriate route of administration for an anticonvulsant to consider for M.T.?
   a. Intramuscular
   b. Percutaneous
   c. Subcutaneous
   d. Rectal

2. Midazolam is a benzodiazepine that can be used effectively for status epilepticus. Which of the following routes of administration has been used effectively for the delivery of midazolam when intravenous access is unobtainable?
   a. Percutaneous
   b. Mucosal
   c. Oral
   d. Subcutaneous

3. Which of the following is true regarding the percutaneous absorption of medications?
   a. The absorption of compounds is inversely related to the thickness of the skin.
   b. The absorption of compounds is inversely related to the hydration of the skin.
   c. Body surface area (BSA) is decreased, relative to body mass, in the infant and young child when compared with older children and adults.

d. The percutaneous administration of medications is reliable and safe in the infant and young child.

4. What are the advantages of utilizing the mucosal route of administration?
   a. Some medications have very good absorption and systemic effect when administered by nasal spray.
   b. Nasal (mucosal) administration avoids the trauma of intravenous line placement.
   c. Nasal administration of medication is typically less expensive than intravenous administration.
   d. All of the above are advantages of the mucosal route of administration.

5 Principles of Pharmacotherapy in Pregnancy and Lactation

Andrew M. Peterson ■ Lauren M. Czosnowski

Although very little is known about the effects of medications on the fetus, many women ingest drugs during their pregnancy. The World Health Organization states "there can be no doubt that at present some drugs are more widely used in pregnancy than is justified by the knowledge available" (Collaborative Group on Drug Use in Pregnancy, 1991). Although considerable attention has been given recently to complementary and alternative medicine use during pregnancy, the use of these ubiquitous substances continues and poses significant challenges to today's health care practitioner (Briggs et al., 2014).

Issues in Medication Use During Pregnancy

Studies have determined that about 90% of women will use one medication during pregnancy, and about 70% will use one or more prescription medications (CDC, 2014). As the number of medications being prescribed during pregnancy increases, the practitioner needs a solid understanding of the physiologic changes that occur during pregnancy and the effects that these changes have on medication use. The practitioner must also balance the need to treat the mother against the potential risk to the fetus. Because there are few studies available discussing the pharmacokinetic changes that occur during pregnancy, appropriate dosing of medications may be difficult. Understanding these changes will assist the practitioner in making recommendations during drug therapy. The maternal and fetal response to medications ingested during pregnancy may be influenced by two factors:

- Changes in the absorption, distribution, and elimination of the drug in the mother, which are altered by physiologic changes.
- The placental–fetal unit, which affects the amount of drug that crosses the placental membrane, the amount of drug metabolized by the placenta, and the distribution and elimination of the drug by the fetus.

Pregnancy-Induced Maternal Physiologic Changes

Women undergo many physiologic changes during pregnancy (Table 5.1). These changes affect the way a medication exerts its effects on both the mother and fetus.

TABLE 5.1 Physiologic Changes in Pregnancy

Organ System Dynamic	Change during Pregnancy
Cardiovascular	
Blood volume	Increased by 30%–50%
Cardiac output	Increased by 30%–50%
Systemic vascular resistance	Decreased
Gastrointestinal	
pH of intestinal secretions	Increased
Gastric emptying time	Increased
Gastric acid secretions	Decreased
Intestinal motility	Decreased
Kidney	
Renal blood flow rate	Increased
Glomerular filtration rate	Increased
Gynecologic	
Uterine blood flow	Increased

Adapted with permission from Kraemer, K., et al. (1997). Placental transfer of drugs. *Neonatal Network*, 16(2), 65–67. Copyright 1997 Springer Publishing Company, Inc., with permission.

Absorption

Drug absorption into the maternal bloodstream can occur by different processes, including the gastrointestinal (GI) tract, skin, or lungs, or the drug may be directly placed into the bloodstream via intravenous administration.

Gastrointestinal Absorption

Pregnancy-induced maternal physiologic changes may affect GI function, and therefore, the absorption of some drugs may be altered. Of the many factors that can affect GI absorption

of drugs, one is the decrease in GI tract motility, especially during labor. It is believed that an increase in plasma progesterone levels causes this decrease in motility, which may delay the absorption of orally administered drugs.

In addition, pregnant women experience a reduction in gastric acid secretions (up to 40% less than in nonpregnant women) as well as an increase in gastric mucus secretion (Fredericksen, 2001; Loebstein et al., 1997). Together, this may lead to an increase in gastric pH and a decrease in the absorption of medications that need an acidic pH for appropriate absorption.

Another reason for decreased GI absorption may be the nausea and vomiting that is common during the first trimester of pregnancy and that is thought to be associated with increased progesterone levels. Therefore, pregnant women may be well advised to take their medications at times when nausea is minimal.

Lung Absorption

Physiologic changes in pregnancy favor the absorption of medications administered through the inhalation route. Both cardiac and tidal volumes are increased by approximately 50% in pregnancy; this results in hyperventilation and increased pulmonary blood flow (Loebstein et al., 1997). These alterations aid in the transfer of medications through the alveoli into the maternal bloodstream (Loebstein et al., 1997).

Transdermal Absorption

An increase in the absorption of medications through the skin is evident during pregnancy. The increase in peripheral vasodilation and increase in blood flow to the skin (Kraemer et al., 1997) enhance this increase in absorption. Because of an increase in total body water, there is increased water content in the skin, therefore favoring an increased rate and extent of absorption to water-soluble medications like lidocaine, which is used as a topical anesthetic during pregnancy (Yankowitz & Niebyl, 2001).

Distribution

Maternal blood volume increases significantly during pregnancy. The 30% to 50% increase in blood volume (Guyton & Hall, 1996; Loebstein et al., 1997) is characteristically distributed to various organ systems serving the needs of the growing fetus. The full increase in total body water during pregnancy is 8 L, with 60% distributed to the placenta, fetus, and amniotic fluid and 40% going to maternal tissues (Loebstein et al., 1997). It is these increases that cause the volume of distribution of medications to increase, resulting in a decrease (dilutional effect) in drug concentrations. Studies show that serum levels of water-soluble drugs decrease because of the increased volume of distribution (Simone et al., 1994). Conversely, drug distribution is affected by an increase in maternal fat deposits. Medications that are highly lipophilic distribute to maternal fat deposits, also resulting in decreased serum drug levels. Body fat increases during pregnancy by 3 to 4 kg and may act

as a reservoir for medications that favor a fat-soluble environment (Yankowitz & Niebyl, 2001). Another factor that may affect medication distribution is the concentration of albumin in the maternal blood. The concentration of plasma albumin decreases during pregnancy. This decrease is believed to be caused by a reduction in the rate of albumin in synthesis or an increase in its rate of catabolism (Fredericksen, 2001). Medications that are highly bound to plasma albumin (e.g., anticonvulsants) may have an increased free drug concentration due to decreased albumin binding.

Elimination

Hormonal changes that normally occur during pregnancy can affect the elimination of various medications. The normal increase in progesterone levels can stimulate hepatic microsomal enzyme systems, thereby increasing the elimination of some hepatically eliminated medications (e.g., phenytoin [Dilantin]). Progesterone may also decrease the elimination of some medications (e.g., theophylline [Theo-Dur]) by inhibiting specific microsomal enzyme systems. Therefore, depending on the elimination pathway of a specific medication, the elimination rate may not be predictable. The extent of these physiologic changes is difficult to quantify, and it is unknown whether changes in dosages are required.

As plasma volumes increase, so does renal blood flow (Fredericksen, 2001; Guyton & Hall, 1996; Loebstein et al., 1997). With the increase in renal blood flow by 50% (Loebstein et al., 1997) and increased glomerular filtration rate, drugs excreted primarily by the kidney show increased elimination. Again, the magnitude of these increases in elimination is not known, and therefore, dosage adjustment may not be required.

Factors in Placental–Fetal Physiology

Until the 1960s, it was widely believed that the uterus provided a secure and protected environment for the developing fetus. Very little thought was given to the potential harm posed to the fetus from maternal drug use. After the thalidomide tragedy in the 1960s, the government required testing of drugs before human use. It is now known that by the fifth week of fetal development, virtually every drug has the ability to cross the placenta (Kraemer et al., 1997).

The treatment of medical conditions is complicated during pregnancy by various factors that must be considered before initiating drug therapy. A key factor is whether the drug will cross the placenta and potentially cause fetal harm.

Placental Transfer of Medications

The following factors affect a drug's ability to cross the placenta:

- Lipid-soluble drugs can cross the placenta more freely than water-soluble drugs because the outer layers of most cell membranes are made up of lipids. Many antibiotics and opiate compounds are highly soluble in lipids and can therefore easily cross the placental membrane.
- The ionization status of the drug affects placental transfer. Drugs with high lipid solubility tend to remain in a nonionized state; therefore, placental transfer is increased. Heparin, for example, is a highly ionized drug, and therefore, it does not readily cross the placental membrane.
- The molecular weight of the drug can determine the ease of placental transfer. The lower the molecular weight or the smaller the drug molecule, the more readily the drug crosses the placenta (Table 5.2).
- Only drugs that are not bound to a protein (e.g., albumin) can cross the placenta. Albumin is the most abundant protein in the human body. During pregnancy, the concentration of albumin decreases, and therefore, fewer proteins are present, allowing for more unbound or "free" drug to cross the placental membrane.

TABLE 5.2 Effect of Molecular Weight on Placental Transfer of Drugs

Molecular Weight	Drug Example	Rate of Placental Transfer
<500 g/mol	acetaminophen, caffeine, cocaine, labetalol, morphine, penicillins, theophylline	Readily crosses the placenta
600–1,000 g/mol	digoxin	Crosses the placenta at a slower rate
>1,000 g/mol	heparin, insulins	Transfer across the placenta severely impeded

Placental and Fetal Metabolism

Evidence exists to support the theory that the human placenta and fetus are capable of metabolizing medications. Research findings suggest that liver enzyme systems are present in fetal livers as early as 7 to 8 weeks' gestation (Juchau & Choa, 1983). Although these enzyme systems are present, they are immature, and any drug elimination that occurs is a result of drug diffusing back into maternal blood.

Fetal Physiology

Not all drugs that cross the placental barrier cause fetal harm. Therefore, the practitioner needs to ask whether a specific drug will cross the placenta and cause fetal harm. Fetal factors to be considered in answering the question include the gestational age at the time of exposure to the drug, which is important because some drugs can exert their effects on the fetus throughout gestation. On the other hand, some drugs exert their effects on the fetus at different stages of gestation. For example, angiotensin-converting enzyme inhibitors, such as captopril (Capoten), quinapril (Accupril), and enalapril (Vasotec), vary in their fetal risk during pregnancy, being a lesser risk in the second trimester and higher risk in the third trimester. In other words, they become less safe as the pregnancy advances.

Within the first 14 days after conception, the embryo is protected from exogenous toxicity (Kraemer et al., 1997; Rayburn, 1997). The cells at this time are totipotential, meaning that if one cell is damaged or killed, another cell can perform the dead cell's function, and the embryo remains unharmed (Dicke, 1989). After this point, the developing fetus is susceptible to the effects of drugs. The first 3 months of gestation are the most crucial in terms of abnormalities and malformations (Briggs et al., 2014). Some

medications that may be relatively safe during the middle trimester of pregnancy may not be safe in the last trimester or during delivery. For example, aspirin use late in pregnancy is associated with increased bleeding at the time of delivery. Moreover, the effect that aspirin has on prostaglandins may delay labor.

Fetal total body water and fat deposition are associated with gestational age, and they affect the absorption and distribution of drugs. As the fetus matures, total body water decreases and fat deposition increases, and the fetus is more likely to be affected by medications that are highly lipophilic (e.g., opiates) than by medications that are water soluble (e.g., ampicillin [Principen]).

Fetal circulatory patterns can alter the amount of drug distributed to the fetus. In early gestation, a disproportionately large percentage of the fetal cardiac output is presented to the brain, and consequently, the concentration of drug in the fetal circulation is increased (Kraemer et al., 1997).

Teratogenicity of Medications

The word *teratogenicity* is derived from the Greek root *teras*, meaning "monster." Teratogenicity is the ability of an exogenous agent to cause the dysgenesis of fetal organs as evidenced either structurally or functionally (Koren et al., 1998; Kraemer et al., 1997).

The risk of fetal abnormality depends on many factors, including not only the gestational age of the fetus at the time of exposure but the agent or medications the fetus is exposed to and the length of exposure.

The health care provider must therefore balance the risk of exposing the fetus to the drug with the benefit of treatment to the mother. If it is determined that the drug is necessary, the drug with the safest profile should be used at the lowest effective dose. The practitioner always keeps in mind that the mother is not the only recipient of the drug—the fetus is as well. It is estimated that approximately 2% or 3% of all malformations and abnormalities in the developing fetus result from drug ingestion (Oakley, 1986). In addition, it is important to remember that any illnesses or chronic medical conditions that go untreated during pregnancy could potentially cause harm to the mother and fetus, even though treating the illness or condition may be potentially harmful to the fetus. Therefore, weighing the benefit of drug therapy to the mother with the risk of drug therapy to the fetus needs to be as balanced as possible.

To help prevent drug-induced abnormalities in the fetus, starting in 1979, the U.S. Food and Drug Administration (FDA) categorized drugs according to fetal risks. The categories were based on the presence or absence of controlled studies in women to determine the level of fetal risk (Table 5.3). Health care providers have used these categories to determine the appropriate drug therapy that will effectively treat the mother but carries the least potential for fetal harm, but the pregnancy categories had inherent flaws. Because the drug categories were based on animal data and controlled trials in pregnant women, which are scarce, these drug categories often oversimplified a complex

medical decision and did not inform the provider or patient about the risk–benefit profile of the drug. The new FDA rule, entitled the Pregnancy and Lactation Labeling Rule (PLLR), was passed in December 2014 and took effect in June 2015. The new rule includes three separate sections that are required in package labeling: pregnancy, lactation, and females and males of reproductive age. The third section was not required previously.

TABLE 5.3 FDA Pregnancy Risk Categories

Category	Risk Summary	Example
A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.	folic acid, thyroid hormone
B	Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).	erythromycin, penicillin
C	Either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk.	labetalol, nifedipine, angiotensin-converting enzyme (ACE) inhibitors
D	There is positive evidence of human fetal risk, but benefits from the use in pregnancy may be acceptable despite the risk.	glyburide, diazepam, aspirin, ACE inhibitors
X	Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.	oral contraceptives, lovastatin, isotretinoin

The updated requirements for these new sections in the package labeling are summarized in Table 5.4. All new drugs will have to include the current labeling requirements and will not be assigned a pregnancy category. Pregnancy risk categories should be removed from existing drugs by 2018. It will still be important to understand the pregnancy categories until the new changes are completely adopted and may take some extra effort from practitioners to interpret the data for clinical decision making. All drugs approved after June 2001 will be required to submit new labeling information within a minimum of 3 years, and manufacturers are also required to update labeling when new information is available under the new rule. It is important to note that OTC products were not affected by this new legislation. Drugs approved before 2001 must remove pregnancy categories, but are not required to conform to the new labeling requirements. The manufacturers of these drugs are encouraged to voluntarily use the new labeling sections.

TABLE 5.4 Pregnancy and Lactation Labeling Rule

Labeling Section	Requirements
8.1 Pregnancy (Includes Labor and Delivery)	Includes risk summary, clinical considerations, and data (to support the risk summary) Must include information for a pregnancy exposure registry if one is available
8.2 Lactation	Also includes risk summary, clinical consideration, and data, including the amount of drug appearing in breast milk and potential effects on the infant
8.3 Females and Males of Reproductive Potential	Includes information about need for pregnancy testing, contraception recommendations, and infertility information when applicable

Drug Therapy in the Breast-Feeding Mother

With the number of women who choose to breast-feed their infants increasing yearly, the number of questions presented to health care practitioners concerning the safety of medication use while breast-feeding is also increasing. Recommendations to discontinue or interrupt breast-feeding while taking a medication are far too common. Health care practitioners are reluctant to recommend medication use while the mother is breast-feeding because of the potential adverse effects on the infant. Most research on lactation has been conducted in small groups or on animal models. The American Academy of Pediatrics has previously published lists of medications that are safe for use while breast-feeding (Boxes 5.1 and 5.2), although recently they have placed less emphasis on these lists, last updated in 2001, and published that the benefits of breast-feeding usually outweigh the risks of many drugs (Sachs, 2013).

BOX 5.1 Potentially Safe Medications to Use in Breast-Feeding—Selected Agents

Analgesics
- acetaminophen

Narcotic analgesics
- codeine
- morphine
- fentanyl
- methadone

Anticoagulants
- warfarin

Anticonvulsants
- carbamazepine
- ethosuximide
- phenytoin

Antihistamines
- brompheniramine
- diphenhydramine
- triprolidine

Antihypertensives
- diltiazem
- enalapril
- metoprolol

- hydralazine
- hydrochlorothiazide

Anti-infectives
- cephalosporins
- penicillins
- macrolides
- tetracyclines
- trimethoprim/sulfamethoxazole
- nitrofurantoin

Nonsteroidal anti-inflammatory drugs
- ibuprofen
- indomethacin
- naproxen

Sedatives–hypnotics
- zolpidem

Vitamins

BOX 5.2 Medications Contraindicated or Cautioned in Breast-Feeding

Anticonvulsants
- phenobarbital
- primidone

Antidepressant
- lithium (use with caution)

Chemotherapeutic agents
- cyclosporine
- cyclophosphamide
- methotrexate
- doxorubicin

Radioactive isotopes

Recreational drugs
- alcohol (in large amounts)
- amphetamines
- cocaine
- heroin, methadone
- lysergic acid diethylamide (LSD)
- marijuana

Human Breast Milk as a Drug Delivery System

Human breast milk is complex, nutrient-enriched fluid. Containing approximately 80% water, breast milk also has immunologic properties and proteins, fats, carbohydrates, minerals, and vitamins needed for normal development. The availability of the drug to be distributed into breast milk depends on many factors. For a drug to be distributed into breast milk, it must first be absorbed into the maternal circulation. The concentration or level of the drug in the mother's plasma influences the amount and degree of drug distributed into breast milk. Once drug is available for distribution into breast milk, several other factors need to be considered. These factors are similar to those determining whether a drug will cross the placental membrane and include (Dillon et al., 1997):

- Blood flow to the breast—the greater the blood flow to the breast, the greater the drug level in breast milk.
- Plasma pH (7.45) and milk pH (7.08)—the medication will stay in the maternal plasma if the medication favors a higher pH.
- Mammary tissue composition—high adipose or fat content of the breast tissue causes lipophilic medications to be distributed into the breast tissue and then into breast milk.
- Breast milk composition—breast milk contains proteins, fat, water, and vitamins. Any medication that has a high affinity for any component will have an increased distribution into breast milk.
- Physicochemical properties (i.e., lipophilicity, molecular weight, ionization of medication in plasma and breast milk) of the drug—drug characteristics that favor transfer of medication into breast milk are low molecular weight, low ionization in plasma, low protein binding, and high lipophilicity.
- Extent of drug protein binding in plasma and breast milk—medications that are highly protein bound in the plasma are less likely to be distributed into the breast milk.
- The rate of breast milk production—the more breast milk produced, the more diluted the medication will be in the breast milk.

When considering these factors, it can easily be appreciated that different medications distribute into breast milk at different rates and to different extents. That is one factor that makes prescribing medications to the breast-feeding woman problematic at best. Health care providers need to ask themselves many questions before selecting a drug therapy.

First, is there a need to treat the maternal condition? Many prescriptions are written for conditions that do not need to be treated. Second, what medication can be prescribed that is least likely to be secreted into the breast milk, and for which there is the greatest information about its use in breast-feeding mothers? Third, would it be possible to treat the condition with a different route of therapy that is not systemic?

Answers to these questions are often difficult or elusive. Referring to the FDA guidelines for medication use in pregnancy and lactation is helpful. A database called LactMed is available to all practitioners that has comprehensive and up-to-date information regarding the known concentrations of drug reaching the infant through breast milk, possible adverse reaction, and potential alternatives. This is an excellent resource that is powered by the National Library of Medicine. Consulting the known pharmacokinetic parameters of medications can also be helpful in prescribing medications. Selected drugs should have short half-lives, and the use of sustained-release products should be discouraged. Dosing schedules also help in minimizing the amount of drug reaching the infant. Scheduling the mother to take the medication immediately after breast-feeding minimizes the dose to the infant by circumventing peak breast milk levels (Dillon et al., 1997).

Patients with chronic conditions, such as hypertension, epilepsy, or diabetes, need to consult their health care practitioners about continuing treatment and minimizing risk to the infant. If a medication is for short-term use, the clinician can also consider if the medication could be postponed until the mother is finished breast-feeding and limiting the medication to the shortest possible duration. Without other options, patients with short-term illnesses can temporarily interrupt breast-feeding for the duration of treatment and resume breast-feeding a few days after therapy is completed if the risk of the drug to the infant is thought to outweigh the benefits. By this time, no residual drug should be concentrated in the breast milk. During the interruption, however, the mother must pump the breast and discard the milk. Doing so relieves engorgement and promotes continued milk production and flow.

Balancing Benefits and Risks

Although the health benefits of breast-feeding are established, there remain a few medications that are unsafe to use during breast-feeding. As with medication use during pregnancy, the risk–benefit ratio needs to be assessed. Choice of the best medication to treat the maternal condition needs to be balanced against the risk of adverse effects to the infant.

Case Study*

K.F. is a 23-year-old female with a history of acne and bipolar disorder. She currently takes lithium to treat her bipolar disorder and isotretinoin (Accutane) for her acne. She also occasionally takes famotidine for reflux.

1. Should K.F. become pregnant, which of the following would be considered safe for her to continue taking?
   a. Accutane
   b. Lithium
   c. Famotidine

2. One year later, K.F. is seen again in your clinic. Her acne and bipolar medications have been discontinued, and she now presents 4 months pregnant with a complaint of pain and rising fever since the last 5 days. Lab tests show gram-negative bacilli and Widal test comes out positive. Which one of the following drugs will most likely be administered?
   a. Ampicillin
   b. Ciprofloxacin
   c. Levofloxacin
   d. Tetracycline

6 Pharmacotherapy Principles in Older Adults

Richard G. Stefanacci

Older adults are the most pharmacotherapeutically challenging population because of the requirement to take into consideration their unique physiology and other factors in the face of the need to treat multiple chronic comorbid conditions. This warrants an understanding of aging and its effects on the body. Some of the other factors impacting this population include changes such as cognitive and social issues affecting proper adherence resulting in suboptimal outcomes. In addition, part of this challenge is the fact that many pharmaceuticals have not been testing in this population. As a result, practitioners need to rely on their knowledge of basic principles of pharmacotherapy in the older and monitor on an individual patient basis.

This expertise of managing pharmacotherapy in the older adults is crucial given that the older population is the fastest growing of any age group. By the year 2050, the "oldest old," those aged 85 and older, will approach 19 million and 4.3% of the U.S. population (Vincent & Velhoff, 2010). The latest numbers available from the Centers for Disease Control and Prevention (CDC) reveal that 14.1% of the U.S. population is over the age of 65. Specifically, that population breaks down as shown in Table 6.1.

TABLE 6.1 Population by Age and Sex: 2012

	Both Sexes		Male		Female	
Age	Number	Percent	Number	Percent	Number	Percent
All ages	308,827	100.0	151,175	100.0	157,653	100.0
55–59 y	20,470	6.6	9,879	6.5	10,592	6.7
60–64 y	17,501	5.7	8,278	5.5	9,223	5.8
65–69 y	13,599	4.4	6,461	4.3	7,139	4.5
70–74 y	9,784	3.2	4,519	3.0	5,265	3.3
75–79 y	7,331	2.4	3,122	2.1	4,209	2.7
80–84 y	5,786	1.9	2,421	1.6	3,365	2.1
85 y and over	5,006	1.6	1,809	1.2	3,196	2.0

Numbers in thousands. Civilian noninstitutionalized population.

A report from National Center for Health Statistics, Division of Vital Statistics at the Centers for Disease Control and Prevention, finds an increase in overall life expectancy from 78.7 years in 2011 to 78.8 years in 2012. This is the longest life expectancy ever recorded, which they attribute to a reduction in many major causes of death, such as cancer, heart disease, and stroke. While decreasing in frequency, these remain significant

health issues for older adults, which is a concern given the rise in obesity. Specifically, the CDC has identified certain overall health issues for older adults as described in Box 6.1.

BOX 6.1 Summary of Pharmacokinetic Changes Caused by Aging

Absorptive Changes
- Decreased blood flow
- Increased gastric pH
- Delayed gastric emptying

Distribution Changes
- Decreased albumin
- Decreased lean body mass
- Increased total body fat
- Decreased total body water

Metabolic Changes
- Decreased liver blood flow
- Decreased liver mass
- Decreased enzymatic activity

Excretion Changes
- Decreased glomerular filtration
- Decreased secretion

The consequences of longevity are evidenced by the rising number of older adults living with multiple chronic diseases, contributing to disability, frailty, and decline in function and presenting significant challenges for medical management (Norris et al., 2008). This has led to an increased use of health care utilization, which the CDC reports as described in Box 6.2.

BOX 6.2 Drugs with Reduced Hepatic Metabolism in Older Adults

amlodipine
codeine
diltiazem
ibuprofen
meperidine
morphine
naproxen

nifedipine
phenytoin
propranolol
quinidine
theophylline
verapamil

Treating multiple problems with prescription as well as over-the-counter (OTC) medications can result in adverse drug reactions (ADRs) and interactions related to changes produced by aging. Problems of polypharmacy (the use of an inappropriate amount of medications to treat a host of medical conditions), improper dosing for an older adult, and a lack of understanding by adults about medications can lead to significant but preventable adverse effects, such as falls, fractures, and delirium. This chapter discusses basic physiologic changes of aging, proper prescribing principles, and social concepts pertaining to safe medication use for the older adult.

Body Changes and Aging

Every body system is affected by the aging process, although homeostasis is often maintained despite less-than-optimal functioning of organ systems. Certain systems are more vitally affected by aging and play significant roles in the pharmacokinetic and pharmacodynamic changes in drug effects. Box 6.3 summarizes the impact of aging on the pharmacokinetics of drugs.

BOX 6.3 Guidelines for Safe Prescribing for Older Adults

Initiation of Therapy

- Review the risks and benefits of adding a medication. Explore nonpharmacologic options first.
- If possible, choose one medication that treats two coexisting problems.
- Always start with the lowest dose possible and titrate up slowly. "Start low; go slow."
- Choose a drug with the fewest daily required doses (i.e., daily vs. twice daily).
- Remember to consider the cost of the brand name drug and consider generic equivalents if cost issues will deter compliance.

Ongoing Pharmacotherapy Assessment

- Schedule routine follow-up examinations for the patient who has multiple chronic illnesses and who takes multiple medications.
- Reduce dosages or discontinue medications if possible to avoid polypharmacy.
- Advise adults to bring all medications (prescription or OTC) to each office visit for review.
- Document accurately all current medications and dosages.
- Review medications added by other practitioners and specialists. Inform these professionals of changes made by the primary health care provider.
- Schedule blood tests regularly to monitor levels of such medications as diuretics, ACE inhibitors, antiseizure medications, anticoagulants, antiarrhythmics, and digitalis.

Patient Support

- Give a written list and instructions to the patient after each office visit of the

medications to be taken.

- Provide the written medication instructions and changes in large print in terms easily understood by older adults.
- Explain and document both the generic and brand name of the prescribed drug to avoid confusing the patient as well as the important reason for each medication.
- Review medications and changes in the regimen with family/caregivers especially for those caring for loved ones with cognitive impairments.
- Recommend or provide medication planners or weekly/daily dosage containers to improve compliance and promote safe medication administration.

Absorption

Older individuals frequently have oropharyngeal muscle dysmotility and altered swallowing of food. Reductions in esophageal peristalsis and lower esophageal sphincter (LES) pressures are also more common in the aged. Delayed motility and gastric emptying have been reported in some cases as well as the propulsive motility of the colon is also decreased, which may impact absorption. Decreased gastric secretions (acid, pepsin) and impairment of the mucous–bicarbonate barrier are frequently described in the older and may impact absorption. The prolonged transit time in the GI tract still allows for adequate drug absorption.

Distribution

Muscle that makes up lean body tissue decreases in the older adult, shifting to increased fat stores, and body water content decreases by 10% to 15% by age 80. Aging results in some reduction in serum albumin (by approximately 20%), leading to an increase in free drug concentration of drugs such as warfarin (Coumadin) and phenytoin (Dilantin).

There are two important plasma-binding proteins in drug metabolism: albumin and α-acid glycoprotein. Albumin has an affinity for acid compounds or drugs such as warfarin, whereas α_1-acid glycoprotein binds more readily with lipophilic and alkaline drugs such as propranolol (Inderal). The effects of chronic disease, nutritional deficits, immobility, and age-related liver changes contribute to the changes in serum proteins. The significance of decreased serum proteins is realized when highly protein-bound drugs compete for decreased protein-binding sites. The result can be greater levels of free or unbound circulating drug and, therefore, potential toxicity.

Body mass changes may lead to changes in total body content of drugs in older adults. A water-soluble drug (low volume of distribution [V_d]) is taken up more readily by lean tissue or muscle and attains higher serum concentrations in adults with less body water or lean tissue. Conversely, a lipid-soluble drug is retained in body fat, resulting in a higher V_d for some drugs. Coupled with a decrease or no change in total body clearance, this increase in V_d can lead to increased half-lives and drug accumulation in older adults. For example, diazepam (Valium) has a half-life ($t_{½}$) of approximately 20 hours in a young adult, but the $t_{½}$ can exceed 70 hours in the older adult. In addition, some drugs, such as tricyclic antidepressants (TCAs) and long-acting benzodiazepines, pass more readily through the blood–brain barrier, causing more pronounced central nervous system (CNS) effects. Older adults who are treated for depression and anxiety may experience fatigue and confusion from drug therapy because antidepressant and antianxiety agents more readily cross their blood–brain barrier.

Elimination

The liver is the major organ of drug metabolism in the body. With aging comes a decrease in blood flow and liver size. However, in the absence of disease, function is maintained. Decreased size and hepatic blood flow may slow the clearance of certain drugs, and reduced dosages may be required. This is particularly important for drugs with high hepatic extraction ratios. Phase I metabolism, particularly oxidation, is affected by aging. The result is decreased oxidation of drugs, which in turn results in a decreased total body clearance (Box 6.3). The phase II metabolism of drugs by conjugation, which promotes drug elimination by breaking the drug into water-soluble components, is not affected by age.

After the liver, the kidneys are the most important organs for drug metabolism and excretion. After age 40, renal blood flow declines and the glomerular filtration rate (GFR) drops approximately 1% a year and accelerates with advancing age. Function is usually maintained despite decreased filtration unless illness or disease overstresses the kidney (Kelleher & Lindeman, 2003). In older adults, drugs excreted primarily by the kidney are given in smaller doses, or the time between doses is extended.

A serum creatinine level alone cannot be used to estimate renal function in the aging person because reductions in lean body mass result in decreased rates of keratinase formation. This, coupled with the decreased GFR, makes the serum keratinase appear normal. It cannot be assumed that the GFR is normal from a normal serum creatinine value. The most accurate means of measuring renal function is a 24-hour urine test for creatinine clearance; however, this is not standard procedure before ordering a medication. When there is a need to determine a drug choice in the setting of a potential reduction in creatinine clearance, the Cockcroft and Gault or the MDR formula (see Chapter 2) provides an estimate based on age, weight, and serum creatinine level with an adjustment for sex. Table 6.2 lists drugs eliminated by the kidney and recommended dosage adjustments based on estimated creatinine clearance.

TABLE 6.2 Examples of Dose Adjustments Based on Estimated Creatinine Clearance

Drug	Usual Oral Dose (Nonrenally Impaired)	Dose Based on Estimated CrCl*		
		CrCl >50 mL/min	CrCl 10–50 mL/min	CrCL <10 mL/min
amantadine	100 mg q12h	Usual dose	Increase interval to q24–72h	Increase interval to q7 days
amoxicillin	250–500 mg q8h	Usual dose	Increase interval to q12h	Increase interval to q24h
cefaclor	250 mg tid	Usual dose	Decrease dose to 50%–100% of usual	Decrease dose to 50% of usual
ciprofloxacin	250–750 mg q12h	Usual dose	Reduce dose to 50% of usual	Reduce dose to 33% of usual or extend to q24h
codeine	30–60 mg q4–6h	Usual dose	Reduce dose to 75% of usual	Reduce dose to 50% of usual
digoxin†	0.125–0.5 mg q24h	Usual dose	Reduce dose to 25%–75% of usual OR increase interval to q48h	Reduce dose to 10%–25% of usual
enalapril	5–10 mg q12h	Usual dose	Reduce dose to 75% of usual 300 mg daily (for CrCl 15–30 mL/min)	Reduce dose to 50% of usual 300 mg every other day (for CrCl 15 mL/min)
gabapentin†	400 mg tid (for CrCl >60)	300 mg bid (for CrCl 30–60 mL/min)		
nadolol	80–120 mg/d	Usual dose	Reduce dose to 50% of usual	Reduce dose to 25% of usual
procainamide‡	350–400 mg q3–4h	Usual dose	Increase interval to 6–12h	Increase interval to q8–24h
ranitidine	150 mg q12h or 300 mg qhs	Usual dose	Decrease dose to 50% of usual OR increase interval to q24h	Decrease dose to 25% of usual OR increase interval to q48h

*Dose adjustments based on actual creatinine clearance or creatinine clearance estimated by the Cockroft and Gault formula (see Chapter 2).

†These drugs are best monitored using actual drug levels, and dose adjustments should be made based on these results.

‡Based on manufacturer's information.

Pharmacodynamic Changes in the Older Adult

Many of the changes that occur due to aging affect major organ systems and therefore affect the pharmacokinetic disposition of the drug. However, the clinician also must consider the impact drugs have on the aging body, the pharmacodynamic effect. Although few data are available regarding age-related pharmacodynamic changes in older adults, it is known that the older adult may be more sensitive to drug–receptor interactions, because of either increased sensitivity of the receptor to the drug or decreased capacity to respond to drug-induced innervation of receptors. In addition, the number or affinity of receptors may be reduced. Nevertheless, it is commonly accepted that the CNS effects of drugs appear to be exaggerated in the older patient. Particularly egregious are the agents with anticholinergic effects, such as the TCAs, antihistamines, and antispasmodics. The anticholinergic effect induced by these agents can lead to excessive dry mouth, blurred vision, constipation, and even an exacerbation of benign prostatic hyperplasia in men. Caution should be used if these agents are prescribed at all.

Similarly, the sedative effects of agents may be intensified in older adults. The benzodiazepines and potent analgesic agents are examples of drugs for which older adults are particularly susceptible to this adverse effect. Overprescribing, or typical prescribing without considering the potential for exaggerated effect, can lead to oversedation and a greater risk of falls and fractures.

The cardiovascular system also can be affected by changes due to aging. Orthostatic hypotension is more common in the older adult because of a loss of the baroreceptor reflex and changes in cerebral blood flow. Moreover, drugs that lower blood pressure or decrease cardiac output put the older patient at risk for a syncopal episode.

Polypharmacy

Polypharmacy is a significant factor in the morbidity and mortality of older adults. Increasing age puts the person at risk for multiple chronic illnesses, many of which require drug therapy For example, the most common chronic disease in the United States, osteoarthritis, affects 40 million people, the majority being older adults. The costs in terms of morbidity are staggering. Chronic stiffness and pain from arthritis have an impact on function, prompting the routine use of nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin products. Long-term use of NSAIDs lowers the prostaglandin level in the GI tract, which may result in esophagitis, peptic ulcerations, GI hemorrhage, and GI perforation. In an older adult, treatment with histamine-2 blockers or proton pump inhibitors to relieve the side effects of aspirin or other NSAIDs may cause additional side effects, such as confusion and mental status changes, in turn requiring more treatment. This demonstrates how easily adverse events occur and snowball in an older patient. ADRs account for 30% of hospital admissions for persons older than age 65; approximately 106,000 deaths are attributed to medication problems. Sadly, 15% to 65% of these events are preventable (Shiyanbola & Farris, 2010) by avoiding potentially inappropriate medications, effective communication, and patient education.

Several factors contribute to polypharmacy. Among them are the varied symptoms and complaints associated with multiple chronic illnesses. In addition, adults often believe that a "pill will fix what ails them," and the health care provider feels pressured to "prescribe something" to satisfy the adults' expectations of a prescription for medication. When a particular medication regimen is unsuccessful, the health care provider typically prescribes another drug, this is referred to as the prescribing cascade. Dr. Jerry Gurwitz, a noted geriatrician, has attributed the caveat that "Any symptom in an elderly patient should be considered a drug side effect until proved otherwise," although his wife, Leslie Fine, a pharmacist, is actually believed to have first described this approach (Smith, 2013).

Polypharmacy is also the effect from many older adults stockpiling their discontinued medications in case they may be needed again—primarily because of the cost of prescription drugs. Many providers who visit older adults in their homes have seen evidence of stockpiled medications. Some older adults keep a drawer or cabinet full of old prescription drug bottles. Some contain the same medication, differing only in brand name. Some adults may place a current medication (prescription or OTC) in a labeled prescription bottle that was used for another drug. In addition, the stockpile may reveal prescription bottles for other family members. Adults may be sharing medications or may have received medications from others who believed that the drug that helped them would help the patient.

Other sources of polypharmacy are "polyproviders." Many older adults see multiple specialists for various chronic diseases. Medications prescribed without the provider carefully reviewing the patient's other medications can lead to drug overuse and

complications. Without a primary care provider overseeing the care of the older adult seeing multiple specialists, ADRs are sure to occur.

The health care provider sometimes creates a polypharmacy situation because multiple drugs are used to treat several chronic illnesses. The provider who is not astute in the principles of safe geriatric prescribing practices may create avoidable side effects and complications. In addition, the patient, who may be a great consumer of OTC medications or home remedies, often self-prescribes without knowing the consequences of mixing these treatments with current prescription drugs.

Drug Interactions in the Older Adult

Because of normal, age-related physiologic changes, the older adult is at greater risk for complications from medications. Complications related to drug–disease, drug–drug, and drug–food interaction are all commonly encountered. (For more information on drug–drug interactions, see Chapter 3.)

Adverse Drug Reactions

ADRs often result in significant negative health outcomes, such as falls and fractures, costing billions of dollars in hospital and nursing home care (Shiyanbola & Farris, 2010). Although age itself creates a risk for ADRs, polypharmacy and the multiplicity of drugs taken by older adults present the greater risk. The older adult with multiple chronic illnesses and medications must be identified as a potential candidate for ADRs (Fick et al., 2003). Older women in particular are at great risk for ADRs because they often receive more prescription drugs and have a more significant loss of muscle mass than older men.

There is a paucity of information on safety and efficacy of drugs for the older patient. Most research and clinical trials are performed with younger subjects. It often is difficult or impossible to predict the consequences of a medication for its intended use on an older adult because few data may be available. In an effort to better understand the effects of drugs on older adults, the U.S. Food and Drug Administration published guidelines in 1997 recommending older adults be included in clinical trials of drugs specifically being developed to treat prevalent diseases affecting older adults (Murray & Callahan, 2003).

Contributing Lifestyle Factors

Preventing adverse events or failed treatments begins with being unaware of potential drug interactions resulting from older adults commonly taking OTC medications and prescription drugs without alerting their health care providers. Additional combinations of foods or nutritional supplements can slow absorption, prolonging the time for medications to reach peak levels (see Chapter 3). Fatty foods, in particular, can increase intestinal drug absorption because of the longer time required to digest a fatty meal. This, in turn, potentially leads to increased drug levels or toxicity.

Alcohol and Other Drugs

The ingestion of alcohol and other drugs can alter the metabolism of many medications in older adults. The combination of comorbid conditions, physiological changes with age, and concomitant medications is often potentiated with alcohol usage. CNS effects such as lethargy and confusion occur, as does hypotension, when alcohol is combined with nitrates and some cardiovascular drugs. Alcohol can be found in many OTC products such as cough and cold syrups and mouthwashes.

Alcohol abuse may be overlooked as a potential problem in the older adult, but abuse among community-dwelling (noninstitutionalized) people age 65 and older has a prevalence of 14% for men and 1.5% for women. High numbers of older alcoholics are treated in emergency departments and medical offices or are hospitalized for medical or psychiatric admissions. Depression, which is more prevalent in the older, often coexists with alcohol abuse. Moderate-to-heavy drinkers older than 65 are 16 times more likely to die of suicide. Practitioners need to be more aware of the potential for alcohol abuse in

older adults. Although alcohol use and abuse decline with age, approximately 40% of older adults use alcohol, with between 2% and 4% meeting the criteria for alcohol abuse/dependency. The use of alcohol is anticipated to increase as baby boomers age. The baby boomer cohort has a history of greater alcohol, tobacco, and nonmedical substance usage than previous generations. Life stressors such as retirement, loss of loved ones, dependency, and chronic illness are contributors to potential alcohol abuse. Also, as more and more states follow Washington and Colorado's lead in legalizing the recreational use of marijuana, it should be expected that older adults will also be among the users. So the inclusion of this potential drug–drug interaction needs to be taken into account as well.

Caffeine and Nicotine Use

Caffeine and nicotine are among some of the most commonly used products that have the potential to interact with certain drugs, thereby altering efficacy and therapeutic drug levels. Besides its presence in coffee, tea, and some sodas, caffeine is found in many OTC drug products. The interaction of caffeine and certain medications may alter drug absorption, cause CNS effects, or decrease drug effectiveness. Table 6.3 summarizes selected caffeine–medication interactions.

TABLE 6.3 Medication–Caffeine Interactions

Type of Interaction	Example of Interaction Effect
Caffeine-induced increase in gastric acid secretion	Decreased absorption of iron
Caffeine-induced gastrointestinal irritation	Decreased effectiveness of cimetidine; increased gastrointestinal irritation from corticosteroids, alcohol, and analgesics
Altered caffeine metabolism	Prolonged effect of caffeine when combined with ciprofloxacin, estrogen, or cimetidine
Caffeine-induced cardiac arrhythmic effect	Decreased effectiveness of antiarrhythmic medications
Caffeine-induced hypokalemia	Exacerbated hypokalemic effect of diuretics
Caffeine-induced stimulation of CNS	Increased stimulation effects from amantadine, decongestants, fluoxetine, and theophylline
Caffeine-induced increase in excretion of lithium	Decreased effectiveness of lithium

Many older adults have lifelong smoking addictions and are unsuccessful in stopping. Adults and providers alike are frequently unaware of the effects of nicotine and medications. Nicotine alters the metabolism of many drugs, causes CNS effects, and interferes with platelet activity. Table 6.4 reviews nicotine–medication effects and interactions.

TABLE 6.4 Medication–Nicotine Interactions

Type of Interaction	Example of Interaction Effect
Nicotine-induced alteration in metabolism	Decreased efficacy of analgesics, lorazepam, theophylline, aminophylline, β-blockers, and calcium channel blockers
Nicotine-induced vasoconstriction	Increased peripheral ischemic effect of β-blockers
Nicotine-induced CNS stimulation	Decreased drowsiness from benzodiazepines and phenothiazines
Nicotine-induced stimulation of antidiuretic hormone secretion	Fluid retention and decreased effectiveness of diuretics
Nicotine-induced increase in platelet activity	Decreased anticoagulant effectiveness (heparin, warfarin); increased risk of thrombosis with estrogen use
Nicotine-induced increase in gastric acid	Decreased or negated effects of H_2 antagonists (cimetidine, famotidine, nizatidine, ranitidine)

Adherence Issues

One reason older adults, similar to all patients, do not achieve the optimum outcome from their treatments is their failure to adhere to the medication regimen. In many cases, prescription drugs are not taken as prescribed: up to 40% of older adults take their medications improperly. More than 40% of ambulatory adults age 65 and older take at least 5 medications per week, with 12% taking at least 10 per week. Studies have shown that as the complexity of the medication regime increases, improper drug usage rises proportionately. In some cases, they may not take enough of the medication, either because they think that they will save money by making the prescription last longer or because they believe that the medicine is not needed at the prescribed dose. In other situations, a medication may not be taken if it interferes with the patient's lifestyle, for example, not taking a diuretic for fear of incontinence on certain days.

Cost Factors

Cost is actually becoming less of an issue for some of the more commonly used medications while it is still an issue especially for older adults requiring innovative biologics. For the more commonly used medications today, many are available in a generic formulation such as those needed for hypertension, diabetes, and hypercholesterolemia. The addition of the Medicare Part D prescription drug benefit provides older adults drug coverage. When this Medicare benefit was first introduced in 2006, there was a coverage gap or as it is more commonly referred to as "the doughnut hole." During this gap period in the Medicare Part D benefit, beneficiaries were responsible for 100% of the cost of their medication. As a result, this sudden increase in cost from 25% during the initial benefit period to 100%, many older adults abandoned their medication at the pharmacy counter (Tseng et al., 2009). Follow on legislation has moved to close the coverage gap, so by 2020, it will no longer exist and older adults will continue to only be responsible for a maximum of 25% through their benefit until they reach the catastrophic period where they are only responsible for 5% of the cost of their medication (Stefanacci & Spivack, 2010). The savings on prescription drugs is even greater for older adults with low income who qualify for extra help. These individuals only pay a little over $2 per prescription for generic medications and $6 for branded products. This exact co-payment is adjusted annually.

Side Effects

Other reasons for nonadherence to drug treatments include the unpleasant or inconvenient side effects accompanying some medications. Dry mouth, change in taste sensations, fatigue, or frequent urination are reported as reasons for stopping a medication. The form of the medication and ease of administration are reasons as well. Large tablets and capsules may be difficult to swallow. Swallowing problems may be compounded by insufficient fluid being taken with medications. Taking several oral medications at one dosing time with too little fluid may result in the medications "getting stuck," leading to chronic esophageal irritation. Presbyesophagus (the slowing of esophageal motility with advancing age) makes it difficult and frustrating to swallow multiple medications, and it can also lead to choking or aspiration.

Many times, perceived side effects are not truly related to the medications resulting in an inappropriate discontinuation of a needed therapy. Critical in the management of side effects are education and communication. Education requires that health care providers inform patients of the expected side effects of their medications. Communication is required to assure that patients openly describe their concerns regarding any and all real and perceived side effects. It is only through effective education and communication that side effects are appropriately managed.

Physical and Mental Changes

Functional deficits, especially those affecting the senses, can also challenge adherence to the medication regimen. Poor vision leads to difficulty reading labels and consequently taking the wrong pills or too many of the same pills. Arthritic hands and safety caps can make opening prescription bottles difficult and frustrating for an older adult.

The prevalence of dementia, which manifests in symptoms of cognitive impairment and poor short-term memory and recall, slowly progresses with age, affecting a substantial percentage of those residing in the community. The condition may be unrecognized by the family because the patient may remain seemingly independent and functional despite mental deficits. The family may be fooled into believing the loved one is fine until the condition affects the person's ability to manage basic, daily routines. Unfortunately, the affected older adult is often responsible for taking his or her own medications. Poor memory results in not taking medication properly, forgetting doses, or taking too many doses of the same drug. Approximately 30% of hospital admissions in the older adult are attributed to toxicity from medications or ADRs. Of prescription medications, almost one third are for those age 65 and older. While technology including personal mechanical medication management systems is providing a wide range of solutions to assist in overcoming these challenges, having engaged caregivers is often required to overcome these issues in assuring adherence to therapy.

Self-Medication Issues

The use of OTC drugs and home remedies is another significant issue. Noninstitutionalized older adults consume between 40% and 50% of all OTC medications sold. Of more concern is the fact that 70% of those OTC medications were consumed without the patient consulting the health care provider. Approximately 20% of ADRs in the older are due to OTC medications. On average, the older take two OTC medications with 3.8 to 6.7 prescription drugs. Many OTC medications are taken without the medical provider's awareness in order to treat symptoms they do not want to report. Family members and friends often borrow medications believed to treat a particular ailment, again without consultation with their medical provider.

The use of herbal preparations contributes to ADRs, especially when taken with prescription medications. Of those over age 65 taking herbal preparations, 49% do not divulge this information to their medical providers, compounding the risk of drug interactions and toxicity.

Many OTC medications are products that were once available only by prescription. Now, despite their decreased strength, these medications that once required medical supervision and monitoring present a potential hazard for side effects.

The most common OTC medications used by the older adult include analgesics, vitamins and minerals, antacids, and laxatives. Cough and cold products and sleeping aids such as Tylenol PM are frequently used by older adults. Combining these products may result in confusion, change in mental status, fluid and electrolyte imbalances, dysrhythmias, and nervousness. Cold medications may worsen hypertension without the patient's knowledge or worsen glucose control in a patient with diabetes.

The older adult must be educated to use OTC drugs safely and to do so only after consulting with the health care provider. If an alternative to drug use is feasible, such as initiating sleep hygiene practices versus taking a sleeping pill, the patient should be encouraged to try these measures first because of their limited negative side effects.

Life Expectancy and Goals of Care

Appreciating an older adult's life expectancy and goals of care is critical for determination of when discontinuation of treatments would be appropriate. To aid in the determination of prognosis, there is a calculator available to health care providers through www.ePrognosis.org.

The information on ePrognosis is intended as a rough guide to inform health care providers about possible mortality outcomes. This information can assist in making a determination when a medication such as a statin may no longer be appropriate because of a limited life expectancy. This situation is unique to older adults, for in the care of younger adults, discontinuation because of limited effectiveness secondary to a shortened life expectancy is typically not an issue. Understanding this dynamic such that recommendations can be made for discontinuation is essential to prevent unnecessary adverse events from occurring as well as a waste of health care resources.

Special Considerations in Long-Term Care

Advanced age and years of multiple illnesses and mental decline result in frailty and disability. Transitioning to a long-term care (LTC) facility occurs when an older adult requires assistance with daily functions, such as bathing and dressing, shows cognitive impairment, or has a significant nursing need such as wound care. The national percentage of older adults in nursing homes is about 5%, rising to 20% for age 85 and older. With a wide array of physical, psychiatric, neurologic, and behavioral problems, the LTC resident is the most complex of all older adults. Consequently, the complexity of prescribing medications for the nursing home resident can be challenging. As a result, there is a federal requirement that all residents of skilled nursing facilities receive a drug regimen review by a consultant pharmacist on a monthly basis. All of these practices described for older adult residents of skilled nursing facilities apply to those living in the community as well. This is especially true given that LTC needs are increasing being served in the community. Programs such as the Program of All-Inclusive Care for the Elderly (PACE) service nursing home eligible older adults in the community. Additionally, states are using home and community waivers to provide LTC services outside of the nursing home. This has forced clinicians to be able to apply LTC practices outside of the nursing home to serve this increasingly community-based frail older adults.

Falls and Medication

One of the most serious problems in LTC facilities are traumatic falls. Approximately half of nursing home residents fall annually, sustaining fractures and soft tissue and other injuries. Among the multiple causes of falls are medications, in particular psychotropic agents (e.g., sedatives, hypnotics, antidepressants, and neuroleptics). These medications are useful for treating the depression, anxiety, and behavioral problems that are not unusual in the LTC resident. However, their use presents an ongoing treatment challenge. Medication-related falls are often caused by orthostatic hypotension, sedation, extrapyramidal side effects, myopathy, and pupil constriction. Table 6.5 lists drug classes leading to instability (Hile & Studenski, 2007).

TABLE 6.5 Medications That Contribute to Instability

Mechanism	Classes of Medications
Orthostatic hypotension	Antihypertensives, antianginals, Parkinsonian drugs, TCAs, and antipsychotics
Sedation, decreased attention	Benzodiazepines, sedating antihistamines, narcotic analgesics, TCAs, SSRIs, antipsychotics, anticonvulsants, and ethanol
Extrapyramidal side effects	Antipsychotics, metoclopramide, phenothiazines for nausea such as prochlorperazine, and SSRIs
Myopathy	Corticosteroids; colchicine; high-dose statins, especially in combination with fibrates; ethanol; and interferon
Miosis (pupil constriction)	Glaucoma medications, especially pilocarpine

Antipsychotics

Significant reduction of antipsychotic use in nursing home residents suffering from dementia is a high priority of legislators, regulators, and LTC providers (Smith, 2013). Currently, the Food and Drug Administration (FDA) has approved the use of certain antipsychotic drugs only for schizophrenia, bipolar disorder, and major depressive disorder

(in the latter case, when used as adjunctive treatment). Yet, almost 40% of people with dementia living in nursing homes receive antipsychotic medications for management of a wide variety of behavioral/neuropsychiatric symptoms, many of which fall outside the indications approved by the FDA.

Since the launch of the National Partnership to Improve Dementia Care in early 2012, the Centers for Medicare and Medicaid Services (CMS) set an ongoing goal of reducing the use of antipsychotics in LTC facilities by 15%. The overall goal of the partnership is to improve the quality of life for the 1.5 million nursing home residents in the United States by improving the quality of care. Disruptive behavior by LTC residents is problematic beyond the resident themselves. Disruptive behavior is troubling to family, caregivers, providers, and the LTC community as a whole—disruptive behavior is truly disruptive. All too often in the past, this behavior has been addressed with antipsychotic medications but studies show that there will be 1 premature death for every 53 frail elderly patients with dementia who are treated with antipsychotics. To improve the management of disruptive behavior and reduce antipsychotic medication in LTC, several regulations and guidance have been developed. This included a bill entitled Improving Dementia Care Treatment for Older Adults Act of 2012 (Act), which was enacted to establish requirements relating to antipsychotic administration to residents of skilled nursing facilities under Medicare and Medicaid and for the implementation of prescriber education programs.

These risks were previously noted when the Food and Drug Administration (FDA) issued black box warnings in 2005 (for "atypical" antipsychotics) and 2008 (for "conventional" antipsychotics), stating that elderly patients with dementia-related psychosis who are administered antipsychotics face a 1.6 to 1.7 times greater risk of death than patients treated with placebo. However, antipsychotic prescription rates in LTC facilities for patients with dementia and no diagnosis of psychosis remained high despite these significant warnings. A study in 1999 showed that within a 1-week period, 39% of elderly nursing home residents with dementia and aggressive behavioral symptoms received antipsychotics.[1] By 2006, some facilities had more than 50% of nursing home residents with dementia using antipsychotics, which was an increase of approximately 33%. Despite the FDA black box warning, the State Operations Manual tag F329, and consultant pharmacist medication regimen review (MRR) requirements, inappropriate use of antipsychotics continues to be an issue.

According to the CMS Online Survey, Certification and Reporting (OSCAR) data from 2012, the national average utilization rate of antipsychotics was more than 25% among all long-stay residents (Table 6.6) (CMS, 2012).

TABLE 6.6 National Average Utilization Rate of Antipsychotics among All Long-Stay Residents, Reported February 1, 2012 (CMS, 2012)

Category	Value
Antipsychotic medications	25.2%
Antianxiety medications	22.0%
Antidepressant medications	48.5%
Hypnotic medications	7.6%
All psychoactive medications	65.6%
Total residents	1,388,058
Total facilities	15,712

In May 2012, CMS set a goal to reduce the use of antipsychotic drugs in LTC facilities by 15% by the end of that year. A 15% reduction in that rate would have meant a national prevalence of 20.3%. This does not mean that each facility across the country should have a prevalence of 20.3% but that the national average should not be higher. This initial target was to ensure that rapid progress was made and that systems and infrastructure were put in place to continue to work toward lower rates of antipsychotic medication use. It does not mean that a rate of 20.3% is acceptable, since tag F329 requires the lowest dose possible to improve the targeted symptoms. Thus, it is believed by CMS, the Department of Health and Human Services (HHS) Office of Inspector General (OIG), and others that a much lower percentage is achievable and more appropriate. In addition, although the goal was a reduction in the use nationally, facilities with use higher than the national or state norm will be more closely scrutinized during routine surveys.

This goal of reducing psychotropic drug use was followed by reporting requirements tied to the Nursing Home Five-Star Quality Rating System. Specifically, new quality measures related to antipsychotic medications for both the short- and long-stay residents will be posted on the Nursing Home Compare (NHC) Web site. For short-stay residents, the measure covers those who are given an antipsychotic medication after admission to the nursing home; the focus therefore is on new starts. A separate prevalence measure assesses the percentage of long-stay residents who are receiving an antipsychotic medication without regard to when it was initially ordered. The Pharmacy Quality Alliance (PQA) has endorsed a similar measure—Antipsychotic Use in Persons with Dementia—which measures the percentage of older individuals with dementia (age ≥65 years) who are taking an antipsychotic medication and who show no evidence of a psychotic disorder or related condition.

The Interdisciplinary Team (IDT) approach to caring for patients includes many professionals performing a variety of specialized functions designed to meet the physical, emotional, and psychological needs of the patient. The collaborative efforts of the members are focused on delivering patient-centered coordinated care. A number of experts have said

that IDT collaboration improves safety and quality of care. This approach can be used to optimize individual resident management assuring appropriate use of antipsychotic medications, which should result in the CMS goal of a 15% reduction.

The goals for this team are as follows:

1. Prevent initiation of inappropriate use of psychotropic medications in residents.
2. Taper and discontinue inappropriate psychotropic medications, to ensure that use of the medications is appropriate and that monitoring and documentation are properly conducted.
3. Improve disruptive behaviors while limiting/diminishing the use of psychotropic medications, by educating and encouraging prescribers and nursing facility staff to adopt a more structured and broader approach to management of behavioral symptoms.

The team approach to management of older adults with disruptive behaviors should emphasize certain key principles:

- Individuals who exhibit disruptive symptoms should be thoroughly assessed by a qualified health professional.
- The assessment should seek to identify possible underlying causes that may contribute to disruptive symptoms, so that treatment can target the underlying cause.
- Disruptive symptoms should be objectively and quantitatively monitored by caregivers or facility staff and documented on an ongoing basis.
- If the behaviors do not present an immediate and serious threat to the patient or others, the initial approach to management should focus on environmental modifications, behavioral interventions, psychotherapy, or other nonpharmacologic interventions.
- When medications are indicated, an appropriate agent should be selected only after consideration of the underlying diagnosis or condition, effectiveness of the medication, and risk of side effects.

While developed for antipsychotic medications, these practices should be applied to all classes of medications when managing pharmacotherapy in older adults.

Anxiolytics

Anxiety is a problem frequently confronted in the nursing home setting. It may be precipitated by physical causes such as pain, infection, or chronic illness. Other stressors that contribute to anxiety include fatigue or change, such as a change in a daily routine or change of caregiver. An overly stimulating environment or expectations of staff members hurrying the older resident through daily routines may evoke anxiety. Initially, nonpharmacologic measures should be used to assess and ameliorate anxiety; prescribing a medication to relieve anxiety should be a last choice.

Several nonpharmacologic antianxiety treatments may be beneficial. They include

establishing daily routines in a structured environment, consistently providing the same caregiver for bathing and hygiene assistance, avoiding overstimulation from activities, limiting social visits, and scheduling quiet time with rest or naps.

When anxiolytic drugs are prescribed, the benzodiazepines are often chosen for adults age 65 and older. Unfortunately, side effects are prevalent, among which are the discomforts of discontinuing the therapy. Benzodiazepines can impact cognitive function and psychomotor performance in older adults. The patient may experience increased agitation, anxiety, and insomnia. More serious symptoms include tremors, tachycardia, diaphoresis, nausea, vomiting, and alterations in perception, anterograde amnesia, and seizures. The benzodiazepines have a propensity for dependence by accumulating in the older body. For this reason, they should be prescribed for short courses of up to 2 weeks at most.

The older patient receiving benzodiazepine therapy often experiences significant daytime sedation, dizziness, and subsequent falls. Studies indicate the "oldest old," those older than age 85, have a 15-fold increased risk of falls with benzodiazepine use. When a benzodiazepine with a long half-life is prescribed, the fall rate is 10-fold greater than when a benzodiazepine with a short to moderate half-life is prescribed. Benzodiazepines with a long half-life include diazepam and flurazepam (Dalmane); benzodiazepines with a shorter half-life include lorazepam (Ativan), alprazolam (Xanax), and oxazepam (Serax). When a benzodiazepine is prescribed, it should have a short half-life, be for short-term use, and be given in the lowest dose possible.

The selective serotonin reuptake inhibitors (SSRIs), which treat depression, general anxiety, and panic and obsessive–compulsive disorders, are now considered the better choice for treating anxiety in the frail older adult due to their favorable side effect profile (Sheikh & Cassidy, 2003). There is often comorbid depression with anxiety, so an SSRI may treat both conditions, such as sertraline (Zoloft) for panic and depression.

An alternative anxiolytic is buspirone (BuSpar). It is nonsedating and has minimal drug interactions and a slow onset of action, 2 to 3 weeks. For that reason, it is not indicated for acute anxiety but works well as an add-on drug. Caution must be used with buspirone in adults with Parkinson disease because EPSs can occur. For anxiety with underlying depression and insomnia, trazodone (Desyrel) is an alternative. Because of its sedating properties, it promotes sleep and treats underlying depression that may exacerbate anxiety.

Antidepressants

The prevalence of depression increases with age, as evidenced by 25% of those with chronic illness and a 15% to 25% rate of depression among nursing home residents (Bergman et al., 2009). Older adults with late life depression exhibit more psychotic symptoms, delusions, insomnia, and somatic complaints. In such settings, older adults with depression should be treated because antidepressant treatment usually improves nutrition and function and decreases symptoms of pain and insomnia. Better choices for antidepressants include

SSRIs (e.g., paroxetine, fluoxetine [Prozac], sertraline [Zoloft], citalopram [Celexa], and escitalopram [Lexapro]). SSRIs have the advantage of daily dosing and fewer side effects than TCAs, which were used frequently before the advent of SSRIs. Although the TCAs are still used, they are associated with many side effects that can lead to cognitive impairment and falls. Cardiovascular effects include hypotension, arrhythmias, and sudden death. Other troublesome side effects include sedation, dry mouth, urinary retention, and dizziness from anticholinergic properties.

Significant drug interactions and toxicity may occur with SSRI use because these drugs inhibit oxidative metabolism. Drugs that may be affected by SSRIs include warfarin, phenytoin, and class 1C antiarrhythmics. Studies indicate that older adults taking SSRIs have a greater risk of falls than older adults not taking antidepressants (Leipzig et al., 1999) and suggest higher doses of combined CNS medications, such as SSRIs, benzodiazepines, and antipsychotics, can lead to cognitive decline in older adults (Wright et al., 2009). Common side effects of SSRIs in the older include headache, nausea, dry mouth, dizziness, constipation, dyspepsia, diarrhea, asthenia, insomnia, decreased appetite, tachycardia, and abnormal taste. Hyponatremia has been increasingly noted to occur in older adults on SSRIs. On withdrawal of the SSRI, sodium levels return to normal within days to weeks (Kirby & Ames, 2001). The prescriber needs to be aware of early signs of hyponatremia: lethargy, fatigue, muscle cramps, anorexia, and nausea.

Other Disorders and Drug Therapies

Studies have shown that, in general, older adults are more vulnerable to severe or persistent pain and that the inability to tolerate severe pain increases with age. Further, older adults are far more likely to experience pain associated with surgical procedures, such as knee and hip replacements, arthritis, cancer, and end-of-life symptoms. Compounding the problem of pain in the elderly is the well-documented fact that pain in the institutionalized older adult population, particularly among minorities and those with dementia, is far more likely to be undertreated. According to the IOM report, "a study of more than 13,000 people with cancer aged 65 and older discharged from the hospital to nursing homes found that, among the 4,000 who were in daily pain, those aged 85 and older were more than 1.5 times as likely to receive no analgesia than those aged 65-74; only 13 percent of those aged 85 and older received opioid medications, compared with 38 percent of those aged 65-74".

While many drug precautions have been in effect since the passage of the Comprehensive Drug Abuse Prevention and Control Act of 1970, they have now taken the form of forced restrictions. Some of these new restrictions are resulting in issues in managing pain for SNF residents. For example, in 2011, the U.S. Food and Drug Administration (FDA) asked drug manufacturers to limit the strength of acetaminophen in combination prescription drugs to 325 mg per tablet by January, 2014, in an attempt to reduce incidences of potentially fatal liver damage. Even though acetaminophen has been commercially available since 1953, it was not until 2009 that the FDA required manufacturers of OTC Tylenol and its generic equivalents to post a warning label for liver damage, due in large part to deaths attributable to acetaminophen use and heavy alcohol consumption. According to the FDA, more than half of manufacturers have voluntarily complied with this request. However, some prescription combination drug products containing more than 325 mg of acetaminophen per dosage unit remain available, prompting the FDA to eventually withdraw approval of any prescription combination drug products containing more than 325 mg of acetaminophen that remain on the market. The result of all of this focus is a limitation on access of higher dose acetaminophen preparations, and as a result, appropriate adjustments for patients receiving these treatments may need to occur. To avoid hepatotoxicity, caution should be taken not to exceed 4,000 mg in 24 hours, especially with known liver disease, alcoholism, or malnutrition.

The chronic pain of degenerative joint disease unrelieved by acetaminophen can be treated with an NSAID. Long-term treatment with NSAIDs can result in GI bleeding, anemia, and renal insufficiency. Caution should be taken when on highly bound drugs, such as warfarin, digoxin, and anticonvulsants, because increased bioavailability occurs due to NSAIDs being highly protein bound. The cyclooxygenase 2 (COX-2) inhibitor celecoxib (Celebrex) is a nontraditional anti-inflammatory drug developed to prevent GI bleeding by not affecting platelet aggregation and bleeding. Although the risk of bleeding with COX-2 inhibitors may be lower than traditional NSAIDs, such as naproxen or ibuprofen, it can still occur. Cardiovascular safety issues led to the withdrawal of rofecoxib

and valdecoxib from the market in the United States.

Neuropathic pain from postherpetic neuralgia or diabetic neuropathy can be treated with mixed serotonin and norepinephrine uptake inhibitors, such as duloxetine (Cymbalta) and venlafaxine (Effexor), with a better side effect profile than older TCAs. The anticonvulsant agents gabapentin (Neurontin) and carbamazepine (Tegretol) are also effective in treating neuropathic pain. Pregabalin (Lyrica) is indicated for diabetic peripheral neuropathy; however, it can cause somnolence and dizziness.

Topical analgesics can be effective in pain management in the LTC setting. The 5% lidocaine patch may help with neuralgia pain, although it is often used off label for localized back pain or arthritis. A newer topical NSAID diclofenac (Flector) is indicated for chronic pain management with less systemic absorption than oral NSAIDs (American Geriatrics Society [AGS] Panel on Pharmacological Management of Persistent Pain in Older Persons, 2009).

Other commonly encountered drug-related problems in LTC are urinary incontinence and recurrent urinary tract infections (UTIs), evidenced by confusion and mental status changes. Respiratory infections such as bronchitis and pneumonia quickly spread through a facility because of the compromised immune state of frail residents. Thus, antibiotic use is called on more frequently than for the community-residing adult. The frail older patient with pneumonia may not have typical signs of illness. For example, the patient may not have a cough or fever. Moreover, the frail older patient becomes ill more quickly and decompensates rapidly if untreated. Dehydration, sepsis, or even death may result.

Constipation is another concern, and sometimes an obsession, of older adults. In many instances, they think they need medications to promote bowel movements. However, alternate methods of treating this problem may be judicious, including increasing physical activity and consumption of fluids, fiber, and fruit. One or two tablespoons of a mixture of prune juice, unprocessed bran, and applesauce taken daily is an alternative to stool softeners and laxatives. When assessing constipation, a review of current medications may yield clues to drug use that contributes to the constipation. For example, anticholinergics, such as oxybutynin (Ditropan) used for urinary incontinence; antidepressants, such as the TCAs; and calcium channel blockers may all cause constipation in the frail older patient.

In summary, the older resident in LTC is usually the frailest and at greatest risk for complications related to improper drug administration. The health care provider should attempt to keep medications at a minimum with the lowest dosage possible. A monthly or bimonthly review of all medications should be done to review medical necessity. A pharmacist from within the facility or from the company supplying the facility with medications should routinely review charts and write recommendations to decrease or stop medications. The suggestions should be evaluated by the health care provider and acted on if appropriate to reduce polypharmacy, side effects, and costs for the resident.

Guidelines for Safe Prescribing

Guidelines for safe prescribing apply not only to residents of LTC facilities but all older adults. The goal of prescribing for adults in LTC should be to prevent adverse events, falls, and injuries that will further degrade the patient's function, both physical and mental. The provider must prescribe cautiously and keep the patient's safety in mind while promoting his or her comfort and dignity. Providers in LTC need to familiarize themselves with the Beers Criteria, a consensus-based document listing potentially inappropriate medications for use in older adults and guidelines for safe-prescribing practices. This extensive list of medication guidelines was created by a consensus panel of nationally recognized experts in geriatrics and updated in 2015 (AGS, 2015).

In addition to the Beers Criteria, an additional opportunity to improve outcomes comes from the Choosing Wisely initiative. In response to the challenge of improving health care, national organizations representing medical specialists have asked their members to "choose wisely" through the identification of tests or procedures commonly used in their field, whose necessity should be questioned and discussed. The resulting list of "Things Providers and Patients Should Question" is meant to discuss about the need—or lack thereof—for many frequently ordered tests or treatments.

The AMDA–The Society for Post-Acute and LTC Medicine developed 5 things to question, while the AGS developed 10. Taking these 15, one can identify five common themes that clinicians should focus their attention. These five center on the following critical areas for management of pharmacotherapy in older adults:

1. Dementia and behavioral and psychological symptoms of dementia (BPSD)
2. Screening and medication management
3. Antibiotic use
4. Diabetes management
5. Nutritional management

These five areas come from extensive work done by both AMDA and AGS and are refined here with a special focus toward the care of older adults. The result is five Choosing Wise initiatives that when followed will serve clinicians caring for older adults well. Choosing wisely starts and often ends with a "wise" clinician; one that understands these five initiatives is a step in that direction.

Dementia and Behavioral and Psychological Symptoms of Dementia

A starting point is the management of dementia and BPSD for perhaps nothing is more critical given the increasing prevalence of dementia. Several of the AMDA and AGS Choosing Wise directives are focused in this area. These include appropriate management of dementia through not prescribing cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects. In randomized controlled trials, some patients with mild-to-moderate and moderate-to-severe Alzheimer disease (AD) achieve modest benefits in delaying cognitive and functional decline and decreasing neuropsychiatric symptoms. The impact of cholinesterase inhibitors on institutionalization, quality of life, and caregiver burden is less well established. Clinicians, caregivers, and patients should discuss cognitive, functional, and behavioral goals of treatment prior to beginning a trial of cholinesterase inhibitors. Advance care planning, patient and caregiver education about dementia, diet and exercise, and nonpharmacologic approaches to behavioral issues are integral to the care of patients with dementia and should be included in the treatment plan in addition to any consideration of a trial of cholinesterase inhibitors. If goals of treatment are not attained after a reasonable trial (e.g., 12 weeks), then consider discontinuing the medication. Benefits beyond a year have not been investigated and the risks and benefits of long-term therapy have not been well established resulting in a need for ongoing assessment.

Regarding other treatments for agitation and delirium, two items were raised regarding the use of chemical and physical restraints. Both the AGS and AMDA called out the use of antipsychotic medications because of their adverse effects and consideration as chemical restraints, specifically not to use antipsychotic medications for BPSD in individuals with dementia as first choice or without an assessment for an underlying cause of the behavior. People with dementia often exhibit aggression, resistance to care, and other challenging or disruptive behaviors. In such instances, antipsychotic medicines are often prescribed, but they often provide limited benefit and can cause serious harm, including stroke and premature death. Use of these drugs should be limited to cases where nonpharmacologic measures have failed and patients pose an imminent threat to themselves or others. Identifying and addressing causes of behavior change can make drug treatment unnecessary.

Careful differentiation of cause of the symptoms (physical or neurological vs. psychiatric, psychological) may help better define appropriate treatment options. The therapeutic goal of the use of antipsychotic medications is to treat patients who present an imminent threat of harm to self or others or are in extreme distress—not to treat nonspecific agitation or other forms of lesser distress. Treatment of BPSD in association with the likelihood of imminent harm to self or others includes assessing for and identifying and treating underlying causes (including pain, constipation, and environmental factors such as noise, being too cold or warm, etc.), ensuring safety,

reducing distress, and supporting the patient's functioning. If treatment of other potential causes of the BPSD is unsuccessful, antipsychotic medications can be considered, taking into account their significant risks compared to potential benefits. When an antipsychotic is used for BPSD, it is advisable to obtain informed consent.

Also regarding chemical restraints in older adults, using benzodiazepines or other sedative–hypnotics as first choice for insomnia, agitation, or delirium is discouraged. Large-scale studies consistently show that the risk of falls and hip fractures leading to hospitalization and death can more than double in older adults taking benzodiazepines and other sedative–hypnotics. Older patients, their caregivers, and their providers should recognize these potential harms when considering treatment strategies for insomnia, agitation, or delirium. Use of benzodiazepines should be reserved for alcohol withdrawal symptoms/delirium tremens or severe generalized anxiety disorder unresponsive to other therapies.

And lastly, avoiding physical restraints to manage behavioral symptoms of hospitalized older adults with delirium was called out. Persons with delirium may display behaviors that risk injury or interference with treatment. There is little evidence to support the effectiveness of physical restraints in these situations. Physical restraints can lead to serious injury or death and may worsen agitation and delirium. Effective alternatives include strategies to prevent and treat delirium, identification and management of conditions causing patient discomfort, environmental modifications to promote orientation and effective sleep–wake cycles, frequent family contact, and supportive interaction with staff. Educational initiatives and innovative models of practice have been shown to be effective in implementing a restraint-free approach to patients with delirium. This approach includes continuous observation; trying reorientation once, and if not effective, not continuing; observing behavior to obtain clues about patients' needs; discontinuing and/or hiding unnecessary medical monitoring devices or IVs; and avoiding short-term memory questions to limit patient agitation. Pharmacological interventions are occasionally utilized after evaluation by a medical provider at the bedside, if a patient presents harm to him or herself or others. Physical restraints should only be used as a very last resort and should be discontinued at the earliest possible time (Box 6.4).

BOX 6.4 Guidelines for Safe Prescribing

1. Assure that dementia and BPSD are properly managed through use of physical and chemical restraints such as antipsychotics and benzodiazepines as well as cholinesterase inhibitors.
2. Assist in the reduction of inappropriate screening and medications that are not beneficial because of limited effectiveness and dangerous adverse effects.
3. Do not request a urine analysis or order for an antibiotic unless there is clear indication of a bacterial infection.
4. Assure appropriate diabetes management through a reasonable HgbA1c target and

use of regularly scheduled antidiabetic medications thus avoiding SSI.

5. Assist in the promotion of oral feeding such that percutaneous feeding tube and appetite stimulants are only used in rare situations.

Screening and Medication Management

Consider the true benefits for each and every individual resident before recommending a screening test or medication. All too often, treatments are ordered based on an overestimate of the benefits and under valuation of the risks. This includes such actions as not recommending screening for breast or colorectal cancer or prostate cancer (with the PSA test) without considering life expectancy and the risks of testing, overdiagnosis, and overtreatment. Cancer screening is associated with short-term risks, including complications from testing, overdiagnosis, and treatment of tumors that would not have led to symptoms. For prostate cancer, 1,055 men would need to be screened and 37 would need to be treated to avoid one death in 11 years. For breast and colorectal cancer, 1,000 patients would need to be screened to prevent one death in 10 years. For patients with a life expectancy under 10 years, screening for these three cancers exposes them to immediate harms with little chance of benefit.

In addition, a resident's life expectancy should be taken into account such that there is not routine use of lipid-lowering medications in individuals with a limited life expectancy. There is no evidence that hypercholesterolemia, or low HDL-C, is an important risk factor for all-cause mortality, coronary heart disease mortality, or hospitalization for myocardial infarction or unstable angina in persons older than 70 years. In fact, studies show that elderly patients with the lowest cholesterol have the highest mortality after adjusting other risk factors. In addition, a less favorable risk–benefit ratio may be seen for patients older than 85, where benefits may be more diminished and risks from statin drugs more increased (cognitive impairment, falls, neuropathy, and muscle damage).

Drug regimen reviews are done monthly by consultant pharmacist within the nursing home and these assessments are critical in assuring appropriate medication use. Older patients disproportionately use more prescription and nonprescription drugs than other populations, increasing the risk for side effects and inappropriate prescribing. Polypharmacy may lead to diminished adherence, ADRs, and increased risk of cognitive impairment, falls, and functional decline. Medication review identifies high-risk medications, drug interactions, and those continued beyond their indication. Additionally, medication review elucidates unnecessary medications and underuse of medications and may reduce medication burden (Box 6.4).

Antibiotic Use

The CDC and others are increasingly sensitive to the overuse of antibiotics. This overuse has led to dangerous drug-resistant organisms. As a result, both the AGS and AMDA made recommendations to not use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present. Cohort studies have found no adverse outcomes for older men or women associated with asymptomatic bacteriuria. Antimicrobial treatment studies for asymptomatic bacteriuria in older adults demonstrate no benefits and show increased adverse antimicrobial effects. Consensus criteria have been developed to characterize the specific clinical symptoms that, when associated with bacteriuria, define UTI.

The inappropriate treatment of positive urine cultures starts with an inappropriate urine analysis; as such, it is recommended not to obtain a urine culture unless there are clear signs and symptoms that localize to the urinary tract. Chronic asymptomatic bacteriuria is frequent in the LTC setting, with prevalence as high as 50%. A positive urine culture in the absence of localized UTI symptoms (i.e., dysuria, frequency, urgency) is of limited value in identifying whether a patient's symptoms are caused by a UTI. Colonization (a positive bacterial culture without signs or symptoms of a localized UTI) is a common problem in LTC facilities that contributes to the overuse of antibiotic therapy, leading to an increased risk of diarrhea, resistant organisms, and infection due to *Clostridium difficile*. An additional concern is that the finding of asymptomatic bacteriuria may lead to an erroneous assumption that a UTI is the cause of an acute change of status, hence failing to detect or delaying the more timely detection of the patient's more serious underlying problem. A patient with advanced dementia may be unable to report urinary symptoms. In this situation, it is reasonable to obtain a urine culture if there are signs of systemic infection such as fever (increase in temperature of equal to or greater than 2°F [1.1°C] from baseline), leukocytosis, or a left shift or chills in the absence of additional symptoms (e.g., new cough) to suggest an alternative source of infection. Remember it often starts with clinicians believing a patient's change in condition and requesting a urine analysis despite their not being any signs of a urinary infection. Thoughtful recommendations in this area can go a long way in assuring appropriate antibiotic use (Box 6.4).

Diabetes Management

Diabetes management was another area where both the AGS and AMDA found common ground. The inappropriate treatment of residents with diabetes can result in falls from hypoglycemia as well as painful frequent fingersticks and injections from the overuse of sliding scale insulin (SSI). As a result, it is recommended to avoid using medications to achieve hemoglobin A1c less than 7.5% in most adults age 65 and older; moderate control is generally better. There is no evidence that using medications to achieve tight glycemic control in older adults with type 2 diabetes is beneficial. Among nonolder adults, except for long-term reductions in myocardial infarction and mortality with metformin, using medications to achieve glycated hemoglobin levels less than 7% is associated with harms, including higher mortality rates. Tight control has been consistently shown to produce higher rates of hypoglycemia in older adults. Given the long time frame to achieve theorized microvascular benefits of tight control, glycemic targets should reflect patient goals, health status, and life expectancy. Reasonable glycemic targets would be 7% to 7.5% in healthy older adults with long life expectancy, 7.5% to 8% in those with moderate comorbidity and a life expectancy less than 10 years, and 8% to 9% in those with multiple morbidities and shorter life expectancy.

SSI was called out to avoid using for long-term diabetes management for individuals residing in the nursing home. SSI is a reactive way of treating hyperglycemia after it has occurred rather than preventing it. Good evidence exists that neither SSI is effective in meeting the body's insulin needs nor is it efficient in the LTC setting. Use of SSI leads to greater patient discomfort and increased nursing time because patients' blood glucose levels are usually monitored more frequently than may be necessary and more insulin injections may be given. With SSI regimens, patients may be at risk from prolonged periods of hyperglycemia. In addition, the risk of hypoglycemia is a significant concern because insulin may be administered without regard to meal intake. Basal insulin, or basal plus rapid-acting insulin with one or more meals (often called basal/bolus insulin therapy), most closely mimics normal physiologic insulin production and controls blood glucose more effectively. Clinicians can raise awareness of inappropriate SSI with recommendations for changes to scheduled dosing or oral or insulin treatments (Box 6.4).

Nutritional Support

Lastly, appropriate nutritional support is often critical at the end of life. This involves avoiding inappropriate nutritional interventions. One such intervention is percutaneous feeding tubes. As such, it is recommended not to use percutaneous feeding tubes in individuals with advanced dementia. Instead, offer oral-assisted feedings. Strong evidence exists that artificial nutrition does not prolong life or improve quality of life in patients with advanced dementia. Substantial functional decline and recurrent or progressive medical illnesses may indicate that a patient who is not eating is unlikely to obtain any significant or long-term benefit from artificial nutrition. Feeding tubes are often placed after hospitalization, frequently with concerns for aspirations and for those who are not eating. Contrary to what many people think, tube feeding does not ensure the patient's comfort or reduce suffering; it may cause fluid overload, diarrhea, abdominal pain, local complications, and less human interaction and may increase the risk of aspiration. Assistance with oral feeding is an evidence-based approach to provide nutrition for patients with advanced dementia and feeding problems.

Careful hand-feeding for patients with severe dementia is at least as good as tube feeding for the outcomes of death, aspiration pneumonia, functional status, and patient comfort. Food is the preferred nutrient. Tube feeding is associated with agitation, increased use of physical and chemical restraints, and worsening pressure ulcers.

Also called out regarding nutritional support was avoiding the use of prescription appetite stimulants or high-calorie supplements for treatment of anorexia or cachexia in older adults; instead, optimize social supports, provide feeding assistance, and clarify patient goals and expectations. Unintentional weight loss is a common problem for medically ill or frail elderly. Although high-calorie supplements increase weight in older people, there is no evidence that they affect other important clinical outcomes, such as quality of life, mood, functional status, or survival. Use of megestrol acetate results in minimal improvements in appetite and weight gain, no improvement in quality of life or survival, and increased risk of thrombotic events, fluid retention, and death. In patients who take megestrol acetate, one in 12 will have an increase in weight and one in 23 will die. The 2012 AGS Beers Criteria lists megestrol acetate and cyproheptadine as medications to avoid in older adults (AGS, 2012). Systematic reviews of cannabinoids, dietary polyunsaturated fatty acids (DHA and EPA), thalidomide, and anabolic steroids have not identified adequate evidence for the efficacy and safety of these agents for weight gain. Mirtazapine is likely to cause weight gain or increased appetite when used to treat depression, but there is little evidence to support its use to promote appetite and weight gain in the absence of depression. In the end, clinicians can assist by increasing family involvement in feeding and promoting this oral feeding activity to prevent the potential inappropriate use of a pharmacotherapy (Box 6.4).

Executing on These Five

These five areas of dementia and BPSD management, screening and medication management, antibiotic use, diabetes management, and nutritional management are critical to improving outcomes for nursing home residents. A common thread through these "Choosing Wisely" initiatives is that prudent use of services such that on an individual resident's care is based on the benefits that clearly exceed the risks. This requires thoughtful assessments to assure that interventions are not encouraged that are truly not of benefit for that particular patient. In the end, all clinicians can play a key role in assuring each resident receives appropriate care. And it's this care that will assist in improving the quality of life and death for older adults.

Exploring Alternatives to Medication

The health care provider must evaluate new problems and determine if a medication is necessary as part of the treatment plan. If there are alternatives to medications, such as diet, exercise, and weight loss for borderline hypertension or antiembolism stockings instead of a diuretic for pedal edema, these options should be explored. Only after nonpharmacologic treatments fail should a medication be initiated. In knowing the patient's overall situation —physically, mentally, and socially—the provider has a baseline from which to consider the risks and benefits of medication therapy. Table 6.7 lists 20 medications that should not be prescribed to any older patients. All of the drugs in this table are also present in the 2002 Beers Criteria (Fick et al., 2003) except for phenylbutazone, which is no longer marketed.

TABLE 6.7 Twenty Drugs to Avoid in Older Adults

Prescription Drug	Use	Reason for Avoiding
amitriptyline	To treat depression	Other antidepressant medications cause fewer side effects.
carisoprodol	To relieve severe pain caused by sprains and back pain	Minimally effective while causing toxicity. Potential for toxic reaction is greater than potential benefit.
chlordiazepoxide	To tranquilize or to relieve anxiety	Shorter-acting benzodiazepines are safer alternatives.
chlorpropamide	To treat diabetes	Other oral hypoglycemic medications have shorter half-lives and do not cause inappropriate antidiuretic hormone secretion.
cyclandelate	To improve blood circulation	Effectiveness is in doubt. This drug is no longer available in the United States.
cyclobenzaprine	To relieve severe pain caused by sprains and back pain	Minimally effective while causing toxicity. Potential for toxic reaction is greater than potential benefit.
diazepam	To tranquilize or to relieve anxiety	Shorter-acting benzodiazepines are safer alternatives.
dipyridamole	To reduce blood clot formation	Effectiveness at low dosage is in doubt. Toxic reaction is high at higher dosages. Safer alternatives exist.
flurazepam	To induce sleep	Shorter-acting benzodiazepines are safer alternatives.
indomethacin	To relieve the pain and inflammation of rheumatoid arthritis	Other NSAIDs cause fewer toxic reactions.
isoxsuprine	To improve blood circulation	Effectiveness is in doubt.
meprobamate	To tranquilize	Shorter-acting benzodiazepines are safer alternatives.
methocarbamol	To relieve severe pain caused by sprains and back pain	Minimally effective while causing toxicity. Potential for toxic reaction is greater than potential benefit.
orphenadrine	To relieve severe pain caused by sprains and back pain	Minimally effective while causing toxicity. Potential for toxic reaction is greater than potential benefit.
pentazocine	To relieve moderate-to-severe pain	Other narcotic medications are safer and more effective.
pentobarbital	To induce sleep and reduce anxiety	Safer sedative–hypnotics are available.
phenylbutazone	To relieve the pain and inflammation of rheumatoid arthritis	Other NSAIDs cause fewer toxic reactions.
propoxyphene	To relieve mild-to-moderate pain	This drug is no longer available in the United States.
secobarbital	To induce sleep and reduce anxiety	Safer sedative–hypnotics are available.
trimethobenzamide	To relieve nausea and vomiting	Least effective of the available antiemetics

When deciding on a medication for an older adult, assisting with that decision, or evaluating a selection, a drug that treats two coexisting conditions should be considered. For example, a calcium channel blocker might be selected for the patient with angina and hypertension. An older man with hyperplasia of the prostate and hypertension may benefit from an α-adrenergic blocking agent such as terazosin (Hytrin). Treating two conditions with one medication reduces cost, cuts down on dosing schedules, and improves adherence and patient satisfaction.

Simplifying the Regimen

Simplifying the medication plan is a key to therapeutic adherence and safety. Drugs are started at the lowest dose possible and the dosage increased as needed. Lower doses are often effective and reduce the risk of toxicity. Dosing schedules must be easy to follow and remember. If two drugs are equally suitable to treat the same condition, it is desirable to prescribe the one that requires the least frequent dosing.

Another important concern is cost of the drug, especially if the drug is for long-term use. Many older adults are on fixed incomes and find the cost of prescription drugs unaffordable. If the most suitable medication for the condition is expensive, this is explained to the patient before purchase to prevent "sticker shock" or the embarrassment of not having enough money to pay for the prescription. Understanding the impact of a patient's out of pocket on adherence is important, as Dr. C. Everett Koop, former U.S. Surgeon General, has been quoted—"A medication only works if the patient takes it."

Educating Adults and Caregivers

Potential side effects need to be discussed in a nonthreatening way to prevent needless fear or anticipation when starting a new medication. Many older adults forgo starting a medication for fear of potential side effects that may occur. The media are powerful in alarming adults about potentially undesirable or dangerous adverse effects, proven or not. Many older adults stop taking essential medications after reading or hearing something in the media pertaining to that particular drug.

Reviewing Medications

The provider working with a geriatric population should have the patient bring in all of his or her medications to each office visit or review a current medication card if the patient carries one. The current medications taken by the patient are recorded at each office visit as part of the progress note. This review alerts the provider to improper dosing and drug administration, misunderstanding of medications, and changes made by specialists and other professionals. The specialist is not always aware of all the medications or OTC drugs the patient takes and may prescribe a drug that places the patient at risk for interactions. As part of the review, the health care provider should ask about topical creams, vitamins, eye drops, and OTC products that may interact with prescription drugs. Adults do not always view these products as medications.

The provider should review all drugs periodically to determine if the dosage can be reduced or the drug discontinued. The goal should always be to use as little medication as possible to treat the multiple illnesses that challenge the older adult.

At the end of each office visit, the provider needs to give the medication list to the patient. Doses and times to take the medications and any special instructions need to be clearly stated and communicated in writing as appropriate. New medications should be listed by brand and generic name so there is no confusion. Clear writing with large lettering should be used, particularly if the patient has common vision impairments, such as cataracts, glaucoma, or macular degeneration.

The caps of the medication bottles that the patient brings to the office can be labeled with the reason for the drug (e.g., “blood pressure,” “water pill,” or “diabetes”). This helps to ensure that the patient has a basic understanding of the importance of each drug. If the caregiver of an older patient is available, the provider should explain any new medication changes or special instructions, especially for the patient with cognitive impairment or other changes in mental status.

Therapeutic Monitoring

When memory problems are an issue, a medication planner helps. Labeled with the days of the week and four dosing times per day, the planner is a useful device for preparing medications for a week. A patient who fails to take the medications despite visual cues and careful labeling may be sending a signal that the family or other responsible caregivers need to investigate additional interventions, home care services, or future placement in assisted living or LTC facilities.

It is important routinely to schedule and monitor the results of laboratory tests when the patient is taking medications that may result in fluctuating drug blood levels. For example, older adults taking such drugs as warfarin, theophylline (Theo-Dur), digoxin, and quinidine (Quinaglute) need careful monitoring, as do adults taking anticonvulsant medications, such as phenytoin, carbamazepine (Tegretol), and valproic acid (Depakote), for seizure disorders.

Adults taking diuretics or angiotensin-converting enzyme (ACE) inhibitors require periodic evaluation with a renal profile to detect electrolyte imbalances, as well as renal insufficiency (as evidenced by rising blood urea nitrogen [BUN] and creatinine levels). Adults starting ACE inhibitor therapy should have a baseline BUN/creatinine level documented with a follow-up test in 2 weeks to alert for renal artery stenosis (evidenced by a rise in the BUN/creatinine levels). Because of the potential for elevations in serum potassium concentration with ACE inhibitor therapy, the older adult needs routine renal profiles to detect such changes, especially when drug therapy also includes diuretics and digoxin (Lanoxin). (Box 6.3 presents guidelines for prescribing drugs safely for older adults.)

Summary

Three quotes help summarize best practices in pharmacotherapy principles in older adults. It begins with determination of the right treatment in the face of new symptoms or issues. This may not always mean beginning a new medication but rather may mean instead reducing a dose of a current medication, discontinuing a therapy, or starting a nonpharmacologic treatment. The quote from Leslie Fine, RPh, should be remembered and practiced that "Any symptom in an elderly patient should be considered a drug side effect until proved otherwise." This is important to prevent polypharmacy issues in older adults. Also, when determining if a new medication should be started, careful assessment of the benefits versus the costs should be undertaken such that only those treatments that offer benefits over costs should be started. When assessing costs, this includes not only financial but potential side effects, while benefits need to take into account benefits given the life expectancy and other concerns in the older adult.

The second quote deals with starting a new medication. It begins with a standard geriatric quote but with a new addition. The quote is that medications in older adults should "start low and go slow" but, to be complete, should include "but get there." This translates to initiating medications at a low starting dose, titrating slowly but getting to the therapeutic dose. This is not only to prevent adverse events from too quick a titration at too high a dose but also to caution against therapies that are not being used at a therapeutic level.

The final quote comes from C. Evert Koop describing the importance of adherence —"A medication only works if the patient takes it." For after a careful determination and initiation of the "right" medication, at the right dose for the right duration has been made; assurance of adherence is the final step in producing optimum outcomes. Of course, there is no final step; pharmacotherapy management, especially in older adults, requires educated clinicians' ongoing evaluation and support to assure optimum outcomes.

Case Study*

R.S. is an 85-year-old female who has congestive heart failure. Over the past 3 months, she has had four hospitalizations. Like many older adults, R.S. is experiencing difficulty swallowing and psychologic changes affecting her medication absorption.

1. Which of the following would be an appropriate starting point for identifying causes for R.S.'s frequency of hospitalizations?
   a. Simply ask if she is taking her medications as directed.
   b. Assume that her frequent hospitalizations are secondary to expected changes, which are normal parts of aging.

c. Examine all of R.S.'s medication vials to complete an assessment including pill count for adherence.

d. Assume that her frequent hospitalizations are the result of undertreating her conditions.

2. In determining the most appropriate course of treatment for R.S., assessing her life expectancy should never be taken into account. Rather, the same course of treatment should be pursued without regard for life expectancy.
   a. True
   b. False

3. Which of the following best describes a concern that R.S. is taking OTCs, which may impact her cardiac function?
   a. Assume that if R.S. has not discussed her taking OTCs with her health care providers that this is most likely not an issue.
   b. Assume because older adults typically do not take OTCs that this is not an issue with R.S.
   c. Because older adults take a significant number of OTCs without knowledge of their physicians, that R.S.'s use is best assessed through a home visit and the asking of open-ended questions.

7 Principles of Pharmacology in Pain Management

Maria C. Foy

One of the most widely encountered clinical situations is a patient in pain. Treatment of pain is one of the most difficult aspects of patient care. Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey & Bogduk, 1994). Pain is subjective, and its intensity varies from patient to patient, day to day. The clinician has a large array of medications available to assist patients in relieving their pain. Principles of managing various types of pain will be described in this chapter and will introduce the practicing nurse to the many types and classes of drugs available for the therapeutic management of pain.

Analgesics represent one of the most frequently prescribed and administered classes of medications used in the treatment of pain. Managing pain in the acutely or chronically ill patient requires both a sound comprehension of the clinical pharmacology of analgesics and a clear understanding of how pain is perceived. Clinicians caring for chronically ill patients not only find themselves assisting the patient in dealing with the physical component of pain but often are confronted by the patient's psychological, spiritual, and social perceptions of pain and pain medications.

Age is a major consideration in assessing pain. For example, elderly patients are less likely to complain about pain and request fewer analgesics to alleviate pain, secondary to incorrect beliefs and biases. A corollary exists in pediatric patients, whose inability to adequately express suffering leads some clinicians to believe that children cannot feel pain. Clinicians, however, now realize that pediatric patients experience as much pain as adults. Because of the identified communication barrier, clinicians need to evaluate a child in pain by utilizing special pain assessment tools developed for children. Similar assessment tools are utilized for adults who may not be able to verbally communicate their pain.

Types of Pain

Pain can be categorized as nociceptive, neuropathic, or inflammatory based on the presumed underlying cause. Nociceptive pain occurs as a result of nerve receptor stimulation following a mechanical, thermal, or chemical insult. Nociceptive pain is purposeful, where the pain tells you to stop doing whatever is causing the pain. Nociceptive pain can be further classified as somatic or visceral. Somatic pain associated with muscle, skin, or bone injury is often well localized. When pain affects the visceral organs, such as pain seen in pancreatitis, it is referred to as visceral pain. Inflammatory pain is a subtype of nociceptive pain, which results from the release of proinflammatory cytokines at the site of tissue injury. Inflammatory pain may be present in acute pain from bruises or infection and chronically in pain from rheumatoid arthritis or osteoarthritis.

Neuropathic pain is caused by abnormal signal processes in the central nervous system (CNS). Neuropathic pain can be peripheral or central in origin and is no longer protective in nature. Peripheral neuropathies include pain from diabetes and postherpetic neuralgia. Examples of central neuropathic pain syndromes include pain from multiple sclerosis, spinal cord injuries, migraine, and poststroke syndrome. Descriptors of neuropathic pain, such as electric-like, burning, tingling, stabbing, or shooting, can differentiate nerve pain from nociceptive pain and help determine appropriate treatment.

More than one type of pain may occur simultaneously. Failed back surgery syndrome, cancer pain, and chronic regional pain syndrome (CRPS) may have characteristics of a mixed nociceptive/neuropathic pain picture.

New evidence is now leading toward considering pain as a disease of the brain, especially when pain persists long after anticipated healing of the initial injury (Henry et al., 2011). Noxious stimulants are no longer present and no pathology exists that would explain the pain. This type of pain is often referred to as maldynia, Greek for “bad pain,” which results from changes in the pain pathway. Pain resulting from nervous system changes and cortical reorganization is referred to as neuroplasticity. Structural changes consist of increase nerve endings and receptive fields, and a decreased threshold for nerve activation.

Classification of Pain

Pain can be classified into two categories, acute and chronic, which help identify the derivation of the pain and provide a framework for treatment. Pain can subsequently be categorized and treated based on expected chronicity of the pain and whether the pain is nociceptive, neuropathic, or mixed in origin.

Acute Pain

Acute pain has a sudden onset, usually subsides quickly, and is characterized by sharp, localized sensations with an identifiable cause. Acute pain is a natural physiologic response to injury, useful in warning individuals of disease or harmful situations. This process is often seen as a signal that the body is invoking critical immunologic and physiologic responses to cellular or tissue damage. Concomitant physiologic responses include excessive sympathetic nervous system activity, such as tachycardia, diaphoresis, and increased blood pressure and respiratory rate. Acute pain is somewhat instructive and purposeful by signaling danger. Pain is usually brief and resolves within a few months of onset. Surgical intervention and trauma are common sources of acute pain.

When acute pain responses become unremitting, constant, or undertreated, the biologic responses outlive their usefulness and can lead to chronic pain. Patients with chronic pain become tolerant to the physiologic response seen in acute pain. In addition, these patients often do not appear to be suffering from pain. The body becomes tolerant to the autonomic indicators where heart rate, blood pressure, and respiratory rate normalize as pain persists. Undesired consequences, such as anxiety and depression, are often associated with constant, long-term pain. The goal of acute pain management is to avoid progression to a chronic pain state. Early pain control will often prevent the development of chronic pain.

Chronic Pain

Chronic pain is defined by the Institute of Clinical Systems Improvement as "pain without biological value that has persisted beyond the normal time and despite the usual customary efforts to diagnose and treat the original condition and injury" (Hooten et al., 2013). Chronic pain may have a verifiable source, as in patients with arthritis, diabetic peripheral neuropathy, and postherpetic neuralgia. In some patients, however, no evidence of structural or nerve damage exists to explain the reason for pain. In these patients, the pain is most likely from peripheral and central sensitization of the pain pathways, explained later in this chapter.

Evidence is now showing that chronic pain is primarily a biopsychosocial disease, with cognitive factors such as pain catastrophizing and anxiety having a strong correlation to pain and disability. The current biomedical approach focusing only on tissue and tissue injury as the cause for the pain has often been ineffective. Patients are often complicated and need an individualized approach to therapy.

Identifying and differentiating pain through careful history of the location, quality, chronicity, and presence of psychological comorbidities is important because treatment choices are dictated by the cause and type of pain. The primary goal of therapy in chronic pain is to decrease the pain to a tolerable level using a combination of various types of therapies to help improve function and quality of life. Examples of types of chronic pain are shown in Box 7.1.

BOX 7.1 Classification of Chronic Pain

Nociceptive Pain

Postoperative pain
Mechanical low back pain
Arthropathies (e.g., rheumatoid arthritis, osteoarthritis, gout)
Ischemic disorders
Myalgia (e.g., myofascial pain syndromes)
Nonarticular inflammatory disorders (e.g., polymyalgia rheumatica)
Skin and mucosal ulcerations
Superficial pain (sunburn, thermal burns, skin cuts)
Visceral pain (appendicitis, pancreatitis)

Neuropathic Pain

Alcoholic neuropathy
Cancer-related pain and some cancer treatments

Vitamin B_{12} deficiency
Chronic regional pain syndrome
Human immunodeficiency virus (HIV)–related pain and some HIV treatments
Multiple sclerosis-related pain
Diabetic peripheral neuropathy
Phantom limb pain
Postherpetic neuralgia
Poststroke pain
Trigeminal neuralgia

Mixed or Undetermined Pathophysiology

Low back pain with radiculopathy
Carpal tunnel syndrome
Chronic recurrent headaches
Painful vasculitis

Cancer-Related Pain

Cancer-related pain is pain associated with malignancy and can result from the disease itself or damage to secondary tissue. Disease-induced pain includes pain secondary to direct tumor involvement of bone, nerves, viscera, or soft tissue. In addition, muscle spasm, muscle imbalance, or other body structure/function changes secondary to the tumor are considered disease induced. Pain may be associated with treatment of the disease and may be seen with biopsies, surgeries, and/or chemotherapy and radiation treatments. Pain may be present in sites where cancer has metastasized (i.e., bone pain). Cancer and treatment interventions may activate peripheral nociceptors, causing somatic and visceral nociceptive pain. Neuropathic pain involving the sympathetic nervous system may also be seen.

Chronic Noncancer Pain

Chronic noncancer pain (CNCP) is persistent pain seen in patients not affected by cancer. Some examples of CNCP are rheumatoid arthritis, osteoarthritis, fibromyalgia, and peripheral neuropathies. Alternately, chronic pain may be thought of as the disease itself when no cause of pain is identified. CNCP may be nociceptive, neuropathic, or mixed in origin (see Box 7.1). Nociceptive mechanisms usually respond well to traditional approaches to pain management, including common analgesic medications and nonpharmacologic strategies. Neuropathic pain will respond to most traditional approaches including opioid therapy. However, higher doses of opioids are required to control this type of pain. Therefore, adjunctive treatment choices including anticonvulsants, antidepressants, or dual-mechanism medications may be considered to replace or add to traditional treatment modalities.

Breakthrough Pain

Breakthrough pain (BTP) is defined as a transitory pain often seen in conjunction with chronic pain, where moderate to severe pain occurs in patients with otherwise well-controlled pain. True BTP is characterized as brief, lasting minutes to hours, and can interfere with functioning and quality of life. True BTP has historically been associated with cancer pain. BTP can also be seen in many other chronic pain conditions, such as neuropathic pain and chronic lower back pain.

Other types of BTP include pain caused by certain activities (incident pain) or when the duration of analgesia is less than the dosing interval (end-of-dose failure). Giving an analgesic prior to the incident known to cause pain will often allow the activity to be performed with minimal discomfort. Shortening the dosing interval is recommended in patients with end-of-dose failure.

Pain Pathophysiology

Several theories exist as to how information resultant from tissue damage is perceived by the brain as pain. Noxious stimuli from the point of the initial injury move through specialized nerve fibers within the spinal cord where the signal reaches the brain and is interpreted by the brain as pain. This transmission of the pain signal through the CNS is termed nociception. Free nerve endings of small myelinated A-delta fibers and larger unmyelinated C fibers are called nociceptors and are responsible for delivering pain signals to the brain. In the past, the "Gate Control Theory" proposed that "closing of the gate" to pain signals was accomplished primarily through stopping the transmission of the pain signal to the brain. However, recent studies theorize that changes in the brain and CNS have a much larger role in the perception of pain (Woo et al., 2015). Anxiety, fear, depression, and previous pain experiences may influence an individuals' perception of pain, especially when pain becomes chronic.

Description of nociception can be divided into four main categories: transduction, transmission, perception, and modulation (Figure 7.1).

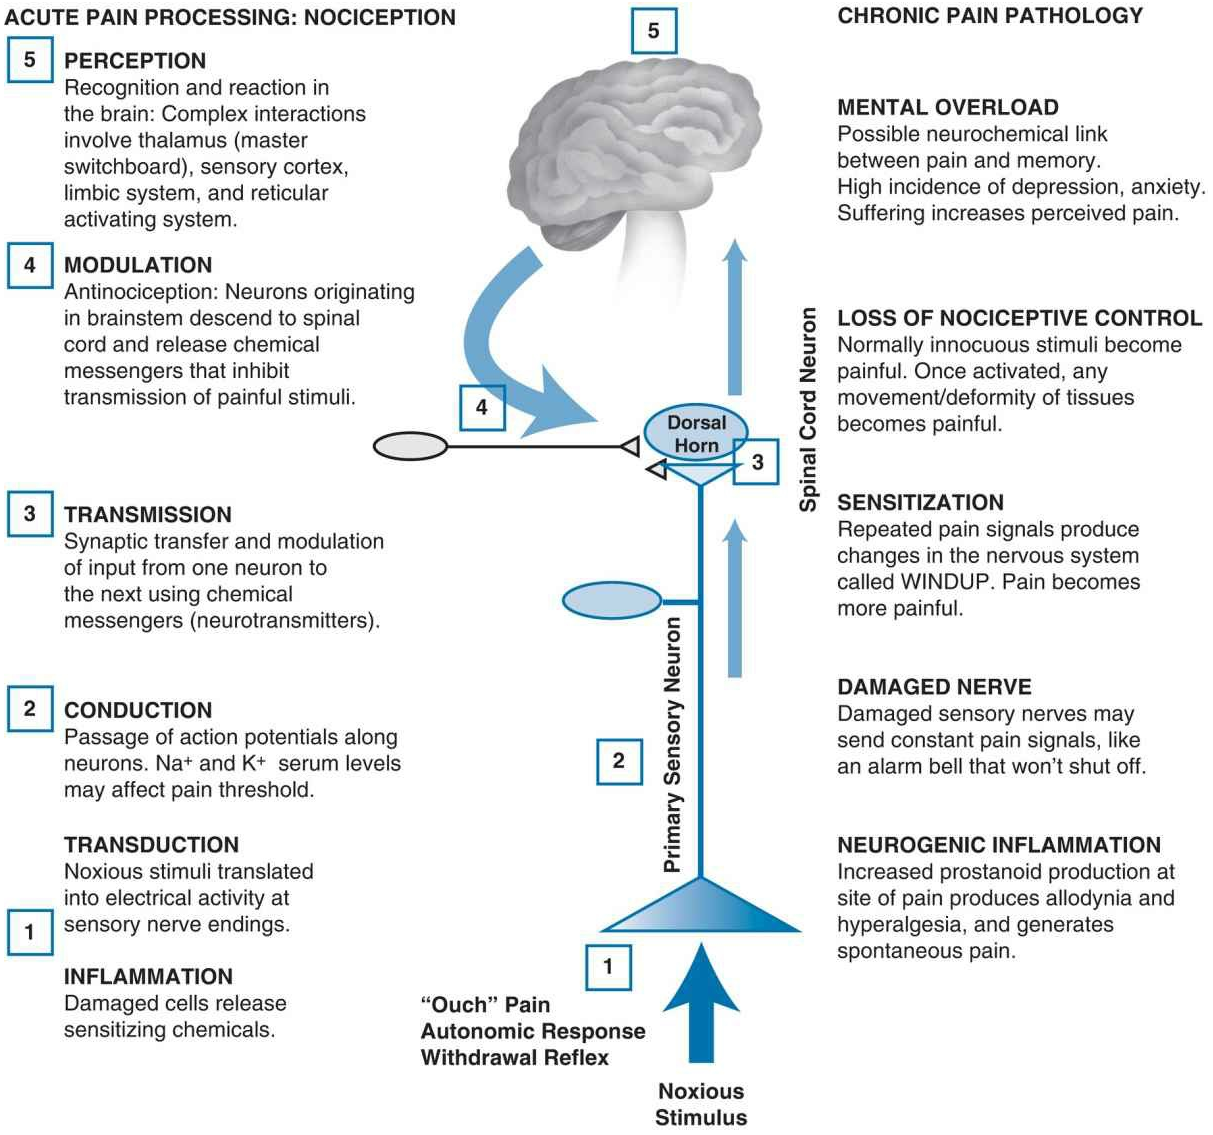

FIGURE 7.1 Acute and chronic pain pathophysiology. (Reprinted with permission from Whitten, C. E., Donovan, M., & Cristobal, K. (2005). Treating chronic pain: New knowledge, more choices. *The Permanente Journal*, 9 (4), 9–18. Retrieved from http://www.thepermanentejournal.org. Copyright 2005 The Permanente Journal.)

Transduction

Transduction refers to a process of nociceptor activation due to mechanical, thermal, or chemical injury. Nerve endings are activated through the release of various excitatory chemical neurotransmitters, such as prostaglandins (PGs), substance P, histamine, bradykinin, and serotonin.

Transmission

Transduction results in an action potential transmitted via the myelinated A-delta and unmyelinated C fibers, by way of the dorsal root ganglia, synapsing in the dorsal horn of the spinal cord. Second-order neurons are then activated and convey pain signals to the higher centers of the CNS. Neurotransmitters in the dorsal horn directly or indirectly depolarize the second-order neurons, facilitating transmission of information to the brain leading to the perception of pain. Inhibitory substances are also released in the dorsal horn (see section on modulation) and may decrease the number of signals reaching the brain, thereby lessening transmission.

Perception

Nociceptive information travels through different areas of the CNS to the brain where the pain is perceived. Perception is the end result of the pain transmission to the brain; at this point, we become consciously aware of the pain. Pain perception is not just a manifestation of physical injury but is affected by psychosocial factors and previous experiences of pain. In a chronic pain state, the perception of pain is no longer influenced by the initial noxious stimuli. The presence of psychological comorbidities in many patients with chronic pain may result in fear of the pain and pain catastrophizing, thereby increasing pain perception.

Modulation

Pain modulation occurs at various levels of the CNS. Endogenous opioids work through binding of opioid receptors in both the periphery and CNS. The main central inhibitory neurotransmitters involved in modulation of pain include serotonin and norepinephrine. These neurotransmitters fight pain by increasing their concentration in the spinal cord and brainstem.

Peripheral and Central Sensitization

Often, pain persists despite healing, and no reason for the pain can be found. Pain pathways become "broken," and pain is seen without an obvious cause. Modifications occurring in the pain conduction pathways of the peripheral nervous system and CNS where hypersensitivity to pain stimulus and neuronal structural changes result in chronic pain syndromes are referred to as *peripheral* and *central sensitization*.

Peripheral Sensitization

When pain receptors in the periphery are continually stimulated (i.e., untreated acute pain), the threshold for stimulation becomes lowered and increased nerve firing occurs. Increased frequency of nerve impulses results in more pain signals reaching the dorsal horn of the spinal cord. These processes contribute to the development of central sensitization.

Central Sensitization

Central sensitization is defined as "an amplification of neural signaling within the CNS that elicits pain hypersensitivity" (Woolf, 2011). When nociceptive information repeatedly stimulates nerve fibers, increased dorsal horn neuronal activity is seen. With actual or potential nerve damage as in many cases of uncontrolled pain, the increase in firing causes increased excitability and responsiveness, termed central sensitization. The end result is a decrease of central pain inhibition, increased spontaneous neuronal activity in the dorsal horn, formation of neuromas causing an increase in receptive fields, and a decreased threshold for neuronal firing. Sensitization of the NMDA (*N*-methyl-D-aspartic acid) receptor in the area of the dorsal horn also contributes to central sensitization. Allodynia (pain response to something painless), hyperalgesia (increased response to pain), persistent pain, or referred pain may result.

Central sensitization can occur in many chronic pain states, especially when associated with nerve injury or dysfunction. Alternately, inadequate treatment of acute pain, concomitant psychological comorbidities, and poor coping skills may lead to the development of chronic pain through the sensitization of the CNS. Pain associated with central sensitization often responds poorly to traditional pain therapies. The addition of coanalgesics, reviewed later in this chapter, should be used for the treatment of chronic pain associated with central sensitization.

Chemical Mediators

Coupled with the neuronal component of pain is the release of chemical mediators initiating or continuing the stimulation of pain-conducting fibers. Peripheral chemical mediators include the neurotransmitters norepinephrine, serotonin, and histamine and polypeptides such as bradykinin, PGs, and substance P. Their role in the pain pathway is activating and sensitizing nociceptors and increasing neuronal excitability. Blocking the production of these mediators, particularly inhibiting the production of PGs with anti-inflammatory medications or similar compounds, minimizes nociceptor activation and neuronal firing, thereby lessening the transmission of pain through the CNS. Because of their role in initiating the pain pathway, these chemicals are targets for many of the medications currently available to treat pain.

Both excitatory and inhibitory neurotransmitters can be found in the dorsal horn of the spinal cord. Excitatory amino acids, glutamate and aspartate, along with substance P facilitate activation of second-order neurons in the dorsal horn primarily through activation of the NMDA receptors.

Pain-Modulating Receptors

Historically, pain modulation was thought to be primarily due to descending inhibitory information from the brain. Pain experts now theorize that both descending inhibitory pain pathways and inhibitory neurotransmitters decrease the perception of pain. Inhibitory substances, such as endogenous opioids, norepinephrine, and serotonin are released in various areas of the CNS and attenuate the transmission of pain by modulating the pain signals in the dorsal horn (Pasero & McCaffrey, 2011). Endogenous opioid substances, primarily β-endorphins, stimulate inhibitory neuronal receptors known as the opioid receptors. Stimulation of these receptors, particularly the *mu* opioid receptor, inhibits the transmission of pain signals to and from the higher brain centers. These receptors are stimulated by morphine-like drugs (opioids) and account for a great deal of the pain relief associated with this class of analgesics.

In contrast, neuropathic pain syndromes do not respond as well to conventional analgesic therapy. Neuropathic pain is often the result of peripheral and central sensitization. Sensitization of the NMDA receptors by various mechanisms is primarily responsible for this type of pain. Use of coanalgesic agents, such as antidepressants, anticonvulsants, and antiarrhythmic agents are recommended for neuropathic pain treatment. Details on the use of coanalgesics are found later in this chapter.

General Principles of Pain Management

Treatment of pain in today's society rests on two major principles: appropriate assessment of the severity and intensity of the pain and selection of the most appropriate agent to relieve pain with minimal side effects. Pain relief often requires a multimodal approach, using multiple agents that target different receptors and neurotransmitters in the CNS. Additional mind body approaches such as cognitive–behavioral therapy, massage, acupuncture, and mindful meditation are often recommended to be used in addition to pharmacologic therapy in patients suffering from chronic nonmalignant pain.

Pain Assessment

The individual assessment of pain is extremely important for determining proper treatments as well as monitoring effectiveness over time. According to the National Institutes of Health (NIH), self-reporting by patients is "the most reliable indicator of the existence and intensity of pain" (Herr & Garand, 2001). Along with self-reporting, involving the caregiver's assessment of pain, especially in the very young or noncommunicating older patient, may be helpful. The self-report should include a description of the pain, location, intensity/severity, aggravating and relieving factors, and effect of pain on quality of life. Assessment tools are recommended to be brief and easy to use in order to reliably document pain intensity and pain relief. These tools will also evaluate other factors effecting pain, such as the presence of psychological comorbidities. One routine clinical approach to pain assessment and management is summarized by the mnemonic PQRSTU (Box 7.2). Assessment tools should be used initially to obtain a baseline level of pain and impaired function. Follow-up assessments should be performed to measure the progress toward acceptable pain relief based on the individual functional goals of the patient.

BOX 7.2 P-Q-R-S-T-U Mnemonic for Assessing Pain

P—Presenting, precipitating, palliating. When and how did the pain start? What makes the pain better? What have you used for pain in the past that wasn't effective?

Q—Quality of the pain. What does the pain feel like? (descriptors such as sharp, stabbing, burning)

R—Region, radiation. Where is the pain? Does the pain stay in one location or does the pain radiate?

S—Severity. On a scale of 0 to 10, 0 being no pain, 10 being the worst pain imaginable, what is your pain now? In the last 24 hours? After a pain medication?

T—Temporal pattern. Is the pain constant, intermittent, associated with movement?

U—How does the pain affect *you*? Quality-of-life indicator.

Because pain is subjective and is not easily quantifiable, several tools are available to determine the quantity and quality of a patients' pain. The various pain scales can be classified as single or multidimensional and self-report or observational. Common single-dimension tools include the visual analog scale (VAS), numerical rating scale (NRS), and verbal description scale (Figure 7.2). The single-dimension scales evaluate the intensity of pain. However, single-dimensional scales alone do not take into account function, which

may be a more reliable indicator of pain control, especially chronic pain. Multidimensional scales consider location, pattern, and affective responses in addition to a severity score alone. Examples of multidimensional scales include the Brief Pain Inventory and the Initial Pain Assessment Tool (Pasero & McCaffrey, 2011).

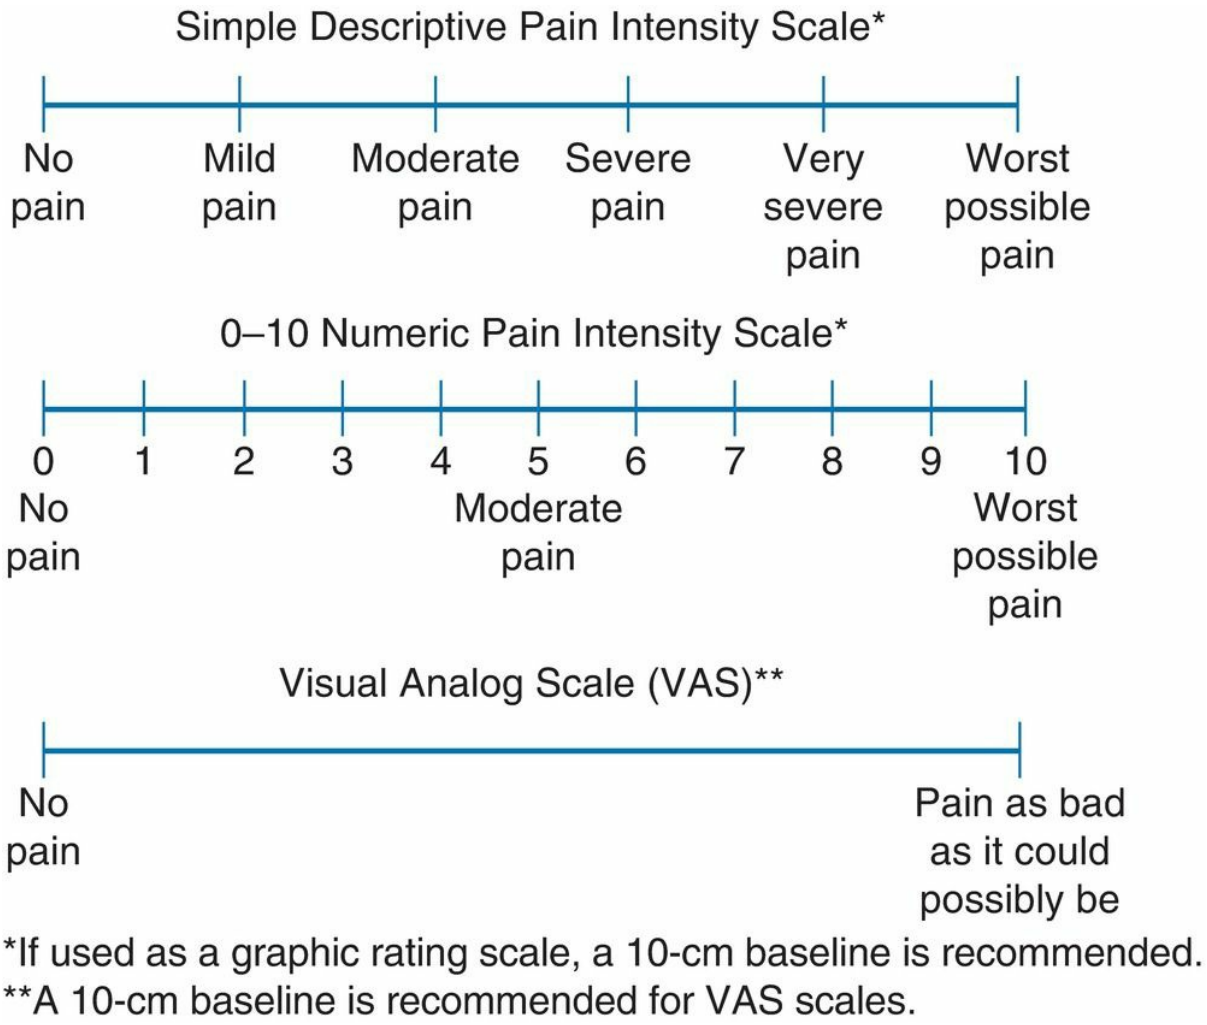

FIGURE 7.2 Visual analog scales used for ranking pain.

The information assessed, particularly from the NRS and VAS, is helpful in determining appropriate treatment and drug selection. The Institute for Clinical Systems Improvement (ICSI) and the NIH have published guidelines on the appropriate evaluation and treatment of acute and chronic pain. Pain is recommended to be assessed with a 0-to-10 scale to assess a patient's current level of pain. Zero defines a pain-free state, and a 10 describes the most severe pain imaginable by the patient. Pain rated at 1 to 3 is classified as mild; 4 to 7, moderate; and 8 to 10, severe. Other validated scales are available for use in special populations, such as in children and adults unable to self-report.

Subsequent assessments should evaluate the effectiveness of the treatment plan. First, determine if the cause of increased pain is related to the progression of disease, disease

treatments, or a new cause of pain, as in cancer that has metastasized. Unrelieved pain may also be due to the development of opioid tolerance where the same amount of pain requires increasing doses of opioids in order to provide relief. The assessment of the patient's pain and the efficacy of the treatment plan should be ongoing, and the pain reports should be documented. Continued use of the same pain scale is crucial to the continued assessment of treatment progress and communication between health care providers.

Pain Management

Treatment options for pain control include nonpharmacologic and pharmacologic therapies. Box 7.3 lists treatments that complement medication management of pain. Often, a multimodal, multidisciplinary approach using a combination of both pharmacologic and nonpharmacologic treatments is necessary to reduce pain to an acceptable level and provide an improvement in function, especially when opioid therapies are used. Maximizing the patient's quality of life and function, while minimizing adverse effects of treatments, is the goal of the pain management treatment plan. Individualization of drug regimens according to the type and severity of pain is essential principles when using medications to manage both acute and chronic pain states.

BOX 7.3 Adjunctive Pain Control Options

Physical methods (stretching, exercise, gait training, immobilization, hot or cold applications)
Patient education (Therapeutic Neuroscience Education)
Coping skills training
Cognitive–behavioral therapy
Massage
Transcutaneous electrical nerve stimulation
Acupuncture
Mindful meditation

For mild to moderate pain, acetaminophen, aspirin, or a nonsteroidal anti-inflammatory drug (NSAID) is usually considered initial therapy. Acetaminophen is used for mild pain across all age groups, mainly due to its favorable side effect profile. NSAIDs are very effective in pain associated with inflammation. However, patients may be at risk for gastrointestinal (GI), cardiac, or renal toxicities. Discussion of risk versus benefits of NSAID therapies will be discussed later in this chapter.

For pain assessed as moderate to severe, combination opioids, such as oxycodone, hydrocodone, or codeine in combination with acetaminophen or ibuprofen, can be used. More potent opioids, such as morphine, hydromorphone, or fentanyl, are used for the treatment of severe pain. Moderate to severe pain can also be treated with low-dose opioids when a patient has contraindications to NSAIDs or acetaminophen. Opioids may be combined with other coanalgesic medications based on severity, description, and type of pain. The combination of an opioid with a coanalgesic medication may provide more pain control than either of the drug classes alone.

When developing a treatment plan, members of the health care team should take into

account the preferences and needs of patients whose education or cultural traditions may impede effective treatment. Certain cultures have strong beliefs about pain and its management. Members of these cultures may hesitate to report unrelieved pain or may have alternative methods of treating pain. Clinicians should be aware of the unique needs and circumstances of patients from different age groups or various ethnic and cultural backgrounds. In addition, many biases to opioids continue to exist in some patients and prescribers. Patient and provider education may be effective in addressing cultural concerns and alleviating biases associated with pain treatments.

Pharmacologic treatment is the most common modality in pain control. However, nonpharmacologic options and therapies have been shown to be effective, especially in patients with chronic pain. Nonpharmacologic approaches include the use of therapies such as heat, cold, exercise, and physical therapy. Complementary therapies such as acupuncture, meditation, and massage may also be effective.

More data is emerging on how CNCP needs to be seen as a biopsychosocial and not a purely biological condition especially when pain has no obvious cause. Behavioral therapies, including systematic coping approaches and relaxation strategies, have been shown to be essential in these patients in order to improve function and quality of life. Transcutaneous electrical nerve stimulation therapy can be used to help control certain types of nerve-related pain. Treatment of difficult pain conditions that cannot be managed by noninvasive and/or pharmacologic treatments may require a consultation with a pain specialist or a pain psychologist to evaluate other options or interventions.

Drug Therapy by Type of Pain

Assessment of pain intensity is important when determining initial analgesic therapies. Mild to moderate pain can be treated with lower-potency medications such as acetaminophen and NSAIDs. These agents can also be part of a multimodal therapy plan in combination with opioids for severe pain. Historically, aspirin had been used as a pain modality for short-term pain treatment. However, increased adverse effects limit its chronic use. Aspirin is mostly used today to prevent cardiac events and is not routinely used as first-line pain management therapy.

Combination opioids, ketorolac, and tramadol are commonly used to treat moderate pain. The combination opioids contain the addition of a "nonopioid," such as acetaminophen or ibuprofen, creating a treatment ceiling dose (maximum dose). Low doses of strong opioids may also be utilized for moderate pain in patients who have contraindications for NSAIDs or tramadol.

Opioids are the most common therapy recommended for severe pain. Morphine is the gold standard and the most studied opioid. When used in equivalent doses, most pure opioids (*mu* receptor agonists) are equally effective in controlling pain, but individual variation may exist among patients. Morphine, oxycodone, hydromorphone, oxymorphone, and fentanyl are pure *mu* opioid agonists indicated for the treatment of severe pain. Morphine is considered the opioid of first choice unless a contraindication exists or the patient has failed prior morphine therapy. Meperidine is another opioid that has historically been utilized for the treatment of severe pain. Use of this agent is no longer recommended due to neurotoxicity associated with accumulation of the active metabolite in patients with renal insufficiency or with chronic use.

In most persistent pain cases, pain medications should be administered around the clock (ATC), with as-needed medications used to treat BTP. This recommendation is based on the finding that regularly scheduled medications maintain a constant level of drug in the body and help prevent a recurrence of pain. BTP medications are indicated when intermittent pain occurs despite ATC therapy.

An essential principle in using medications to manage chronic pain is to individualize medication regimens according to the type and severity of pain. For mild to moderate pain, acetaminophen or an NSAID is usually considered initial therapy. Management of moderate to severe pain may utilize a combination opioid, tramadol, or low doses of opioids. Severe pain is treated with higher-potency opioids, such as morphine, hydromorphone, or oxycodone. Various classes of coanalgesics, such as anticonvulsants and antidepressants, can also be utilized in combination with the opioids (Table 7.1).

TABLE 7.1 Recommended Order of Pain Treatment Based on Initial Pain Assessment

Pain Rating	Classification	NSAID/APAP	Opioids	Coanalgesics
1–3	Mild	✓	Sometimes	✓
4–7	Moderate	✓	Usually	✓
8–10	Severe	✓	Usually	✓

Supplement each level with nonpharmacologic therapy: *psychological*, cognitive–behavioral therapy, biofeedback, relaxation, imagery, psychotherapy; *physical rehabilitation/alternative therapy*, stretching, exercise, reconditioning, thermotherapy, massage, acupuncture.

PAIN ASSESSMENT TOOLS

SINGLE DIMENSIONAL	MULTIDIMENSIONAL
Numerical Rating Scale (NRS)	McGill Pain Questionnaire
Visual Analog Scale (VAS)	Brief Pain Inventory
Thermometer Pain Scale	Behavioral Pain Scales
Faces Pain Scale	Pain/Comfort Journals
Painad Scale	Multidimensional Pain Inventory
FLACC Scale	Pain Disability Index

Acute Pain

Acute pain is often a response to tissue injury or trauma and is usually nociceptive in nature. Treatment includes nonopioids such as NSAIDs and acetaminophen for mild to moderate pain and opioid medications for moderate to severe pain. As acute pain increases and persists, it becomes more difficult to manage. Therefore, it is important to treat acute pain promptly and effectively. Also, untreated acute pain is often the catalyst in the development of chronic pain conditions in which pain persists despite healing of the original injury.

Acetaminophen is the drug of choice for treating minor, noninflammatory pain, especially in patients at risk for GI damage. NSAIDs are also effective as monotherapy in the treatment of mild to moderate pain. Both acetaminophen and NSAIDs are available in combination with opioids for moderate pain. Pure or dual-mechanism opioids are used when pain is severe. The opioids, as a class, generally exhibit equal analgesic effects when given at equipotent doses (adjusted for route of administration and duration of action).

Various strategies are currently implemented in the control of pain. Postoperative pain is often treated with multimodal therapies including opioid medications and various coanalgesics for treatment of severe pain. The use of pre-emptive analgesia, defined as the administration of various analgesics prior to procedures, is often a part of a multimodal treatment plan using two or more medications with different mechanisms to provide benefits to pain control while minimizing adverse effects. Central regional local anesthetic blocks have also been shown to provide additional analgesia when added to opioid therapy. Choice of medications, doses, and use of local interventional techniques should be individualized to the patient (Box 7.4).

BOX 7.4 Interventional Techniques for Chronic Pain

Injections

- Nerve blocks
- Epidural steroid injection
- Facet joint injections
- Nerve root blocks
- Sacroiliac joint injection

Spinal fusion
Percutaneous disc decompression
Radiofrequency rhizotomy
Neuromodulatory therapy

- Intrathecal pump implants
- Spinal cord stimulants

Vertebroplasty
Kyphoplasty

Chronic Pain

Noncancer Pain

NSAIDs and salicylates are effective for chronic inflammatory conditions, such as arthritis and musculoskeletal conditions. Efficacy of NSAID treatment varies greatly among patients. Those who do not respond to an NSAID in one class may respond to an NSAID from the same or a different class. Opioids may be considered as an alternative or an addition to NSAID therapy if pain is moderate to severe in appropriately assessed CNCP. Administration of a lower-potency opioid in conjunction with a coanalgesic may be instituted if treatment failure of NSAIDs or acetaminophen occurs.

Historically, opioids were thought to be ineffective in neuropathic pain. It is now known that opioids may be effective against these types of pain but often require higher than usual doses. Utilizing coanalgesics as monotherapy or in combination with opioids may be effective in chronic pain treatment and may decrease opioid requirements.

Care should be taken when administering opioids to the elderly or in patients with renal failure, liver failure, and respiratory diseases because of the increased chance of respiratory depression and oversedation. Lower doses should be initiated in these patients and titrated slowly based on response.

More evidence is emerging that the use of opioids for chronic pain in patients with psychological comorbidities or risk for addiction and/or abuse may not provide long-term benefits and increase in functionality (Franklin, 2014). Historically, opioids were thought to have no ceiling effect. Studies have shown that prolonged use of high-dose opioids in patients at risk may actually facilitate pain and may become pronociceptive. Opioid

monotherapy in these patients may not provide functional improvements and a better quality of life.

Physical dependence and fear of addiction should not be the overriding considerations when choosing a pain modality for patients. Appropriate assessment tools may provide guidance on which patients may benefit from opioid therapy. A multidisciplinary approach using medications, physical therapy, massage, acupuncture, meditation, and cognitive–behavioral therapy may be needed in patients where medications alone have not provided benefit in function. Research is currently being conducted on long-term opioid use and optimal treatment approaches for CNCP conditions.

Cancer Pain

The National Comprehensive Cancer Network (NCCN) has released guidelines for the management of cancer pain. In the past, the World Health Organization (WHO) utilized three-step analgesic ladder where therapy is started with mild analgesics, moving to stronger therapies when the current therapy fails (Reidenberg, 1996). We now know that cancer pain is much more complex and needs to be individualized for the patient based on type of pain, degree of pain, and comorbidities that may affect pain and suffering. The NCCN provides an algorithm for a treatment approach with recommendations for therapy. Opioids are the mainstay of cancer pain management. The addition of nonopioids and coanalgesics is advocated as part of a multimodal approach to treatment. The goal of therapy is to safely use medications in order to improve function and quality of life.

Morphine, oxycodone, hydromorphone, and fentanyl are the common used opioids in the management of severe pain. Methadone is a long-acting opioid with a dual mechanism, working by activating opioid receptors and as an NMDA receptor antagonist. Both actions help to inhibit pain. Methadone can be difficult to dose and has many drug–drug interactions and adverse reactions. Therefore, for safety reasons, methadone should be reserved for treatment failure to other opioids. Referral to a pain professional trained in the safe dosing of methadone is recommended.

Medications Used in Pain Management

The current pharmacotherapeutic options for pain management include nonopioid and opioid agents. Coanalgesic therapies, such as antidepressants, anticonvulsants, local anesthetics, and topical treatments, are often added especially in neuropathic and/or mixed persistent pain conditions. Selection of the appropriate agent rests on an assessment of the patient's type and source of pain as well as the intensity level of the pain.

Nonopioid Analgesics

The nonopioid analgesics are utilized for mild to moderate pain (Table 7.2). Pain is reduced, and beneficial anti-inflammatory action may also be seen with some agents in this class. Onset of analgesia occurs within 1 hour of oral administration, and drug effects last anywhere from 4 to 12 hours. The agents can be classified by their mechanism of action, chemical class, and anti-inflammatory activity. When choosing a nonopioid, the lowest effective dose should be used to minimize possible adverse reactions.

TABLE 7.2 Pharmacokinetic and Pharmacodynamic Properties of Nonopioid Analgesics

Generic Name	Trade Name	Dosage Forms	Half-Life (h)	Onset (h)	Duration (h)	Route	Usual Starting Dosage	Max Dosage (24 h)
acetaminophen	Tylenol, others	Tablet	2–7	0.5–0.75	4–6	PO	650 mg every 4–6 h	4,000 mg
		Suspension		5–10 min		PR		
		Suppository						
		Intravenous			4–6	IV	1 g every 6 h	
ibuprofen	Motrin, Advil Caldolor	Tablets	1.8–2.4	0.5–1	6–8	PO	200–400 mg every 4–6 h	3,200 mg
		Suspension						
		Injection				IV	400–800 mg every 6 h	
naproxen	Naprosyn	Tablets						
		Suspension	12–15	1	8–12	PO	500 mg × 1, then 250 mg every 8 h	1,250 mg
naproxen sodium	Aleve	Tablets	19	0.5	8–12	PO	550 mg × 1, then 275 mg every 12 h	1,375 mg
diclofenac	Voltaren	Tablets	2	0.5	8–12	PO	25 mg every 12 h	200 mg
		Gel	1–2			Topical		
diclofenac epolamine	Flector	Topical patch	12	1	12	Topical	1 patch every 12 h	2 patches
ketorolac	Toradol	Tablets	5.5–7	0.5	5–6	PO	10 mg every 6 h	120 mg
		Injection			4–6	IV, IM	15–30 mg IV every 6 h	40 mg
tramadol	Ultram	Tablet	6–7	1	5–7	PO	50–100 mg every 6 h	400 mg
diflunisal	Dolobid	Tablet	8–12	1	8–12	PO	1 g × 1, then 500 mg every 8–12 h	1,500 mg

Acetaminophen

Acetaminophen is one of the most commonly prescribed analgesic–antipyretic medications.

The mechanism of analgesic activity is unknown, but it is postulated that pain may be mediated through PG inhibition in the CNS as a COX-3 inhibitor. Lack of peripheral PG inhibition makes acetaminophen a weak anti-inflammatory agent and therefore not considered useful in treating inflammatory disorders such as rheumatoid arthritis. Acetaminophen does not adversely affect platelet aggregation or the gastric mucosa and is generally well tolerated.

Acetaminophen is almost completely absorbed from the GI tract and has a quick onset of action with a time-to-peak effect of 1 to 3 hours. Extensive liver metabolism to inactive substances makes acetaminophen a relatively nontoxic agent. However, a small portion (4%) of the drug is converted to a toxic metabolite, normally inactivated by glutathione pathways. Once glutathione stores are depleted, as seen in cases of chronic ingestion or acute overdosage, the toxic metabolite can cause potentially fatal liver necrosis.

Generally, the maximum daily dose of acetaminophen should not exceed 4,000 mg. Lower maximum doses are recommended when two or more drinks per day are ingested or if liver disease is present. In older adults, some experts are recommending reducing the maximum dose to 3,000 mg/d to reduce risk of overdose and to minimize adverse effects (Byrd, 2013).

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs as a class have anti-inflammatory, analgesic, and antipyretic activity. Cyclooxygenase, consisting of the isoforms COX-1 and COX-2, is the enzyme involved in

the formation of PGs. Aspirin causes irreversible inactivation of COX-1 and COX-2, where nonaspirin NSAIDs cause reversible inactivation. The COX-1 isoform produces PGs that regulate blood flow to the kidneys and GI tract and decrease platelet aggregation. The COX-2 isoenzyme is usually expressed as a result of tissue injury and is the source of inflammatory pain. First-generation NSAIDs inhibit both isoenzymes, thereby reducing inflammation but also decreasing the gastroprotective effects of COX-1. Pain is decreased but gastroprotection is lost from damage to the GI mucosa, increasing the risk of GI bleeding. COX-2 inhibitors were developed in hopes of relieving pain while reducing the chance for GI toxicities. Unfortunately, a subsequent increase in cardiovascular events was seen. All NSAIDs have some degree of COX-2 inhibition. Those that have a greater proportion of COX-2 versus COX-1 inhibition will have a higher risk of thrombus, heart attack, and stroke.

Some NSAIDs, including aspirin, ketoprofen, and indomethacin, inhibit both COX-1 and COX-2 enzymes but are more selective for inhibiting COX-1. Diflunisal and diclofenac may be more selective for COX-2 inhibition and therefore less likely to cause GI toxicity. Celecoxib is the only available COX-2 inhibitor on the market in the United States (Zarchi et al., 2011).

The analgesic effect of NSAIDs is achieved within 1 hour of administration, with maximal effects within 2 or 3 hours. Anti-inflammatory effect has a longer onset, with maximal effects seen in 7 to 10 days. Decreased pain due to reduced tissue swelling is an indirect response to NSAIDs. Lower doses of nonsteroidal therapies should be used in elderly patients to adjust for the decline in renal function.

Long-term use of NSAIDs at high doses (anti-inflammatory doses) can increase the risk serious adverse effects. Indomethacin (Indocin) is associated with more CNS and ocular adverse effects than other NSAIDs. In patients at risk for a GI bleed or who are taking concomitant aspirin and NSAID therapy, acid suppression therapy preferably with a proton pump inhibitor (PPI) is recommended. Misoprostol, a synthetic PG, is also effective for the prevention of bleeding, but GI adverse reactions (nausea, abdominal cramps, and diarrhea) limit its use.

A black box warning on cardiovascular toxicities has been added to all NSAID products. Unlike NSAIDs, acetaminophen and salicylates have minimal GI toxicity and no effect on platelet aggregation at usual doses. See Chapters 36 and 37 for more discussion of NSAIDs and acetaminophen.

Opioids

Opioids bind to opioid receptors in the CNS (*mu (μ), kappa (κ)*, or *delta (δ)*), with analgesic effect primarily associated with *mu* receptor binding. Full agonists include codeine, morphine, hydrocodone, oxycodone, hydromorphone, oxymorphone, fentanyl, and meperidine. Meperidine is associated with significant adverse effects and is no longer recommended as first-line therapy. Meperidine's active metabolite, normeperidine, can

accumulate and induce seizures with high doses or in patients with decreased renal function.

Activation of the *mu* opioid receptor produces effective analgesia as well as undesired effects, including respiratory depression, sedation, confusion, nausea/vomiting, pruritus, miosis, constipation, and urinary retention. With the exception of constipation and possibly pruritus, tolerance to adverse effects develops over time. Morphine and other *mu* opioid receptor agonists provide pain relief over a broad dosage range. Multiple *mu* receptor subtypes exist, which may explain why opioids do not have the same outcomes for everyone. Opioid effects may also differ due to individual differences in hepatic metabolism and genetic factors. For example, an adequate concentration of CYP2D6 is needed to convert codeine to morphine, the active agent. Dependent on if a person is a poor or rapid metabolizer based on CYP2D6 concentrations, codeine may be either ineffective or toxic in 5% to 7% of the Caucasian population (Eckhardt et al., 1998). At equianalgesic doses and appropriate dosing intervals, there is no appreciable difference in potency among opioid agents (Table 7.3) (McPherson, 2010). The described potency is a reflection of the dose needed to achieve a desired level of analgesia. In general, the more potent the agent, the fewer milligrams needed (Table 7.4).

TABLE 7.3 Pharmacokinetic and Pharmacodynamic Properties of Opioid Analgesics

Generic Name	Trade Name(s)	Route	Onset (min)	Half-Life (h)	Duration (h)	Usual Starting Dose
hydrocodone	Vicodin, Lortab, Lorcet, generic	PO	10–20	3.3–4.5	4–8	1 tablet (5 mg hydrocodone) every 4 h
oxycodone	Percocet, Percodan, generic	PO	15	2–3	4–5	1 tablet (5 mg oxycodone) every 4 h
Moderate to severe						
Morphine-immediate release	Various, generic	PO	30–60	2–3	4–6	10–15 mg every 3–4 h
Sustained release	MS Contin, Kadian, Avinza	PO	15–60	15	8–12 (formulation dependent)	15 mg every 12 h *
Injection	Various, generic	IV, SC	5–10	2–3	2–4	5–10 mg every 3–4 h
Hydromorphone	Dilaudid,	PO	15–30	1–3	3–13	2 mg every 4 h
	Exalgo		6	11		Individualize dose
		IV, SC	5–10	1–3	4–5	0.5 mg every 4 h
Oxycodone-immediate release	Oxy IR, Roxicodone	PO	15–60	2–3	3–4	5 mg every 3–4 h
Sustained release	Oxycontin	PO	50–60	5	8–12	Individualize dose
Fentanyl	Duragesic	Transdermal patch	16–24	1.5–6	48–72	Individualize dose
		IV	0–5	2–4	30–60 min	
	Actiq, Fentora	Transmucosal	5–15	17	Related to blood level	†
Oxymorphone	Opana	PO	30	7–9	4–6	5 mg every 4–6 h
	Opana ER	PO	3	10	12	5 mg every 12 h
Hydrocodone	Vicodin	PO	30–60	7.9	4–6	1 tablet ever 4–6 h
Dual mechanism	Zohydro ER			8	24	Individualize
	Hysingla ER			8	24	Individualize
methadone	Dolophine, others	PO	30–60	8–59	2–10 (acute) >12 (chronic)	2.5–5 mg every 8–12 h
		IV	10–20	8–59	>8 (chronic)	1–2 mg every 8 h
tapentadol	Nucynta	PO	30–45	4	4–6	50 mg every 4–6 h

Opioid Pearls

1. Use lower initial opioid doses in elderly and in patients with respiratory comorbidities.
2. **Hydrocodone** for pain is available in combination with acetaminophen or ibuprofen. A long-acting formulation for chronic pain has recently been approved.
3. **Oxycodone** is available in combination with acetaminophen, aspirin, and ibuprofen.
4. **Morphine** is the opioid of choice unless contraindications exist. Morphine is relatively contraindicated in renal failure.
5. **Hydromorphone** is approximately five times the potency of morphine.
6. **Fentanyl** patch is contraindicated for acute pain and/or opioid naive.
   - Fentanyl patch may not be appropriate for patients with fever, diaphoresis, cachexia, morbid obesity, and ascites, all of which affects absorption and clinical effectiveness.
   - Patch may be appropriate for patients who cannot take long-acting oral opioids.
   - Onset of action is 12–16 hours after application. Utilize breakthrough pain (BTP) medications for pain control until onset of analgesia. Full effect takes 72 hours.
   - Application of external heat sources will increase the release of fentanyl from the transdermal system.
   - Titration of the patch should not occur before 3 days after the initial dose or no more frequent than every 7 days thereafter.
7. **Methadone** has a duration of analgesia much shorter than half-life, making the drug difficult to dose.
   - Conservative dose conversions with careful titration are recommended. Use a higher conversion ratio in patients currently on high-dose opioids.
   - *Steady state is not reached for at least 5–7 days. Use BTP medications early in the titration, as analgesic effects are shorter than the half-life of the drug. Observe for accumulation-related side effects during titration (>2 days treatment).
   - Consult a pain management specialist for dosing.

*Not initial therapy for opioid-naive patients.

†Cancer-related BTP only.

TABLE 7.4 Basic Opioid Conversion Table

Opioid	Oral	Parenteral
Morphine	30 mg	10 mg
Oxycodone	20 mg	—
Hydrocodone	30 mg	—
Hydromorphone	7.5 mg	1.5 mg
Oxymorphone	10 mg	1 mg
Codeine	200 mg	120 mg
Fentanyl	—	0.1 mg
Methadone	Refer to a pain management specialist for methadone dosing	2:1 oral to IV

Opioids are primarily metabolized by the liver to active and inactive metabolites. The metabolites of morphine and hydromorphone are eliminated by the kidneys. In renal failure, morphine's active metabolites may accumulate and cause neurotoxicity, such as myoclonus, confusion, and coma. Death may result if this accumulation is not identified.

Hydromorphone has historically been thought to be safe in renal disease. Data is emerging that hydromorphone metabolites may also accumulate causing neurotoxicity. The metabolites of morphine and hydromorphone differ in that hydromorphone's metabolites are eliminated by dialysis, but morphine metabolites are not dialyzable.

Metabolites of oxycodone are inactive, making this a good option in patients with renal failure. Sustained-release formulations, however, are advised to be used with caution in end-stage renal and liver disease. Fentanyl and methadone do not have active metabolites and are considered the drugs of choice in the treatment of chronic pain in patients with renal failure. Fentanyl is the drug of choice in patients with liver failure.

The onset of the analgesic effects of oral opioids is 30 to 60 minutes, and the peak effect is seen within 1 to 2 hours. Fentanyl has a quicker onset and shorter duration and is considered an ultrashort-acting opioid. Moderate-acting opioids, with duration of actions between 4 and 6 hours, include morphine, codeine, hydromorphone, oxycodone, and oxymorphone. Methadone, a dual-mechanism, long-acting opioid, has a variable duration of action and half-life of approximately 24 to 36 hours. Steady state may take 5 to 7 days to be reached; therefore, upward titration should not occur for at least 5 days after therapy initiation.

Morphine and Congeners

Morphine is a low-cost, readily available agent with well-characterized pharmacokinetic and pharmacodynamic properties. It is the opioid to which all others are compared, due to extensive clinical experience and literature available supporting use. Morphine is absorbed erratically from the GI tract and undergoes significant first-pass hepatic metabolism when given by the oral route. Morphine is distributed throughout the body, and sufficient amounts cross the blood–brain barrier to account for most of its pharmacologic effects. Morphine has a plasma half-life of approximately 3 hours, which is due mainly to its nearly complete metabolism in the liver. Morphine crosses the placental barrier and is excreted in maternal milk.

Morphine may be administered by multiple routes. Oral, injectable, rectal, intrathecal, and intraspinal formulations are available. Dosage forms include immediate-release and sustained-release tablets and capsules. Liquid formulations are also available. With chronic dosing, the potency of the intravenous dose is three times that of the equivalent oral dose.

Morphine effectively relieves severe pain, particularly nociceptive pain, regardless of its cause or anatomic source. Analgesia is due to the drug's binding to *mu* receptors in the CNS. Opioids can cause respiratory depression due to both the drug's actions on the brain's medullary respiratory control center and the drug's ability to suppress the medulla's response to blood carbon dioxide levels. Respiratory depression is seen mainly in opioid-naive patients or with upward dose titration in both acute and chronic pain. Tolerance develops relatively quickly to respiratory depressive effects. A person in whom tolerance has developed may experience only moderate respiratory effects when receiving doses that could cause serious or fatal respiratory depression in a nontolerant person.

Opioids also increase smooth muscle tone in various parts of the GI tract. *Mu* receptors are located throughout the GI tract where receptor binding results in reduced peristalsis and increased tone of the rectal sphincter. The overall resultant effect is constipation. Prophylactic bowel regimens consisting of a stimulant laxative and stool softener is recommended with initiation of opioid therapy.

Hydromorphone is considered more potent and more soluble than morphine; however, it has a similar pharmacologic profile. Hydromorphone is available as an oral immediate-release tablet, a suppository, and an injectable formulation. Recently, a long-acting formulation of hydromorphone was released to the U.S. market.

Oxycodone is slightly more potent than morphine. This agent may be used as monotherapy or in combination with nonopioid analgesics, such as ibuprofen or acetaminophen, for the reduction of moderate pain. Oxycodone is available as an immediate-release tablet, an oral liquid formulation, and a sustained-release tablet. No injectable form of oxycodone is currently available.

Hydrocodone is available in combination with nonopioid analgesics. Hydrocodone is equipotent to morphine on a milligram-to-milligram basis. Hydrocodone is available in combination with acetaminophen or ibuprofen and is used for moderate to severe pain. A long-acting formulation indicated for severe pain has been released in 2013. The DEA has

reclassified hydrocodone from Schedule III to Schedule II in 2014.

Oxymorphone, the metabolite of oxycodone, is used to treat moderate to severe pain. Historically, oxymorphone was available as an injectable (Numorphan), but it is now only available as immediate-release and sustained-release tablets. Oxymorphone is approximately twice as strong as oxycodone, with 10 mg of oxymorphone equivalent to 20 mg of oxycodone. Adverse effects and mechanisms of action are similar to other opioids.

Codeine is usually administered orally either alone or in combination with nonopioid analgesics, such as acetaminophen, for moderate pain. Use has fallen out of favor due to increased adverse effects when compared to other opioids. Other more potent and better tolerated pain management modalities are available. At equianalgesic doses, codeine induces greater histamine release than other opioids. This increases the risk of hypotension, cutaneous vasodilation, urticaria, and bronchoconstriction. Currently, codeine is primarily used as an antitussive agent.

Fentanyl and Congeners

Fentanyl is an alternative to morphine and its congeners, with low to no cross-allergenicity in patients with true hypersensitivity to morphine-like drugs. Fentanyl is available for acute pain as injectable and buccal formulations. A long-acting transdermal patch is available for stable chronic pain and is only to be used in opioid-tolerant patients with a chronic pain process. Patients are required to have taken oral morphine 60 mg, oxycodone 30 mg, or hydromorphone 8 mg/d for the previous 7 days or longer to be considered opioid tolerant (Janssen Pharmaceuticals, 2006). Transdermal fentanyl has an onset of effect of 12 to 16 hours after patch placement. Peak systemic concentrations occur between 24 and 72 hours after initial patch application. Duration of effect is approximately 72 hours. However, some patients may require patch changes after 48 hours. Use of the buccal transmucosal formulation is limited to severe BTP associated with cancer. A recent study demonstrated that transmucosal fentanyl formulations (TMF) have better efficacy in cancer BTP when compared to oral short-acting morphine (Maroo et al., 2014). Onset of action is 15 minutes versus 45 to 60 minutes with oral formulations. Practitioners are required to become certified prior to being able to prescribe transmucosal fentanyl as part of a Risk Evaluation Mitigation Strategy (REMS) requirement for safe use.

Other agents, such as sufentanil (Sufenta) and alfentanil (Alfenta), also fall in this class but are used primarily for perioperative and postoperative pain relief and are available only in an injectable formulation.

Meperidine is a synthetic analgesic that binds strongly to both *mu* and *kappa* receptors. Potency is less than that of morphine. Most of the pharmacologic effects of this drug are similar to those of morphine sulfate; however, adverse effects limit its use. Prolonged use of meperidine may cause CNS excitation characterized by tremors and seizures due to the accumulation of its active metabolite, normeperidine. The half-life of normeperidine ranges between 15 and 20 hours and is almost completely renally eliminated. The possibility of

accumulation of this metabolite leading to detrimental CNS effects has limited the use of meperidine in the treatment of pain. Meperidine is still used for treatment of rigors and in procedural sedation.

Dual-Mechanism Analgesics

Tramadol is a centrally acting weak *mu* receptor agonist. Pain is also modulated by norepinephrine reuptake inhibition and serotonin release. Tramadol is used to treat moderate to severe pain and is available alone or in combination with acetaminophen. Tramadol may be useful for pain management in patients where a strong opioid is not an option and an NSAID may introduce undue risk (e.g., GI bleeding). In addition, tramadol may have a place in neuropathic pain management due to the additional norepinephrine reuptake inhibition. Maximum dose of tramadol is 400 mg/d. Dosing should be initiated slowly and titrated to an effective dose. Tramadol may have less abuse potential when compared to other opioids but has recently been changed to a Schedule IV medication. Tramadol is rapidly absorbed. Peak serum levels are obtained within 2 hours and have a 4- to 6-hour duration of effect. Tramadol is metabolized in the liver by the cytochrome P450 enzyme system to an active metabolite (*O*-dimethyl tramadol). Drug–drug interactions are common. Decreased maximum doses are recommended in the elderly and in patients with renal impairment. Increased seizure risk is seen with high doses or in patients with a history of seizure disorders.

Methadone hydrochloride is an effective analgesic alternative when other opioid therapies have failed. Due to different chemical structure, methadone can also be used as an analgesic alternative in patients with a true allergy to morphine-like compounds (anaphylaxis, hives). Methadone is effective both orally and parenterally and has an oral bioavailability exceeding 90%. It is more than 90% bound to plasma tissue proteins and is extensively metabolized by the CYP-450 enzyme system. Patients may be at risk of qTc prolongation and torsades de pointes due to the significant amount of drug–drug interactions seen with methadone. Methadone is most often associated with the treatment of opioid substance abuse but is being used more frequently in the treatment of chronic severe pain. Methadone works as both a *mu* receptor agonist and an NMDA receptor antagonist, making it effective for the treatment of severe neuropathic pain and mixed pain syndromes. The lack of active metabolites makes methadone a viable choice in patients with renal failure. The drug has a long half-life of approximately 24 hours (range between 10 and 60 hours), with an analgesic effect of approximately 4 to 8 hours. Early in methadone titration, pain control may be inadequate until steady state is reached. Aggressive BTP therapies may be required during the first 3 to 5 days of therapy. Tendency to dose methadone aggressively early in titration can lead to serious adverse effects, including fatal respiratory depression. Patients should be monitored carefully for signs of drug accumulation and toxicity. The long biologic half-life also accounts for the mild, but prolonged, withdrawal syndrome if use stops abruptly. Recently, due to a rise in methadone-associated deaths, the *Journal of Pain* released guidelines on methadone safety

(Chou et al., 2014). These guidelines provide direction on the appropriate use of methadone for chronic pain and addiction based on the available evidence. Information on dosing, titration, and ECG monitoring are areas covered in the guidelines.

Tapentadol is a newer combination opioid that works on opioid receptors and as a specific norepinephrine reuptake inhibitor. This medication has been shown to be effective in various pain conditions, such as osteoarthritis and postoperative pain. Tapentadol has recently been approved for the treatment of chronic diabetic peripheral neuropathy. Tapentadol has less affinity for the *mu* receptor than morphine, but the analgesic effect is augmented due to norepinephrine reuptake inhibition. Tapentadol may have fewer GI adverse effects (nausea, vomiting, constipation) when compared with other opioids due to less effect on the *mu* receptor.

Opioid Antagonist—Naloxone

Naloxone is a pure opioid antagonist that competitively binds to opioid receptors without producing an analgesic response. Naloxone is inactivated when given orally and therefore is given mainly by injection. Naloxone is indicated for treating opioid-induced respiratory depression.

The duration of naloxone's drug action is approximately 45 minutes. In most cases, this duration is shorter than the offending opioid, and the overdose effect from the opioid may return, requiring readministration of naloxone. Care must be taken to avoid precipitation of withdrawal in opioid-tolerant patients when administering naloxone. Rare adverse effects of naloxone include tachycardia, ventricular fibrillation, and cardiac arrest due to the release of neurotransmitters when naloxone is administered. Opioid withdrawal syndrome may occur in opioid-tolerant patients when excessive or rapid reversal is used.

Safety of Opioids

Side effects common to all opioids include sedation, confusion, respiratory depression, itching, nausea/vomiting, and constipation. Opioid-induced bowel dysfunction develops due to reduced movement through the lower GI tract due to reduction of bowel tone and motility, increased anal sphincter tone, and increased absorption of fluids. Although considered the most dangerous side effect, severe respiratory depression is seen not only in overdose situations but also in patients who are opioid naive. Patients who are at risk for respiratory depression also include elderly patients, patients who have respiratory comorbidities such as obstructive sleep apnea, and patients with kidney/liver failure. Chronic pain patients on opioids usually develop tolerance to the respiratory depression effects. However, if substantial opioid doses are used in addition to chronic therapy, as in the case of a post-op opioid-tolerant patient, risk of respiratory depression is increased. In patients with closed head injury or recent brain surgery, opioids should be used with caution because hemodynamic effects (e.g., hypotension, orthostasis) may be exaggerated.

Bowel Regimen for the Prevention of Constipation

Tolerance usually develops within a few days to most of the adverse reactions associated with opioids except for constipation. Constipation prevention is needed in patients receiving opioids. The general approach for patients requiring opioids is to institute a prophylactic bowel regimen consisting of a mild stimulant +/– a stool softener. Dose of the stimulant can be titrated based on patient response. Initial dosing would consist of senna 2 tablets daily or twice per day. Docusate sodium 100 mg twice per day is often used when stool softening is needed. Polyethylene glycol (PEG) powder packets used daily is another effective alternative. If there is no bowel movement produced in 48 hours, consider using an additional agent (e.g., bisacodyl suppository, lactulose, additional PEG) to stimulate peristalsis. If interventions continue to be ineffective, assess for impaction. If no impaction is present, utilizing an additional method (e.g., enema) is recommended. Once the patient has a bowel movement, titrate the dosage of senna to an effective dose. (Up to 8 tablets per day or the liquid equivalent has been used in the hospice and palliative care population.) Docusate sodium should not be titrated aggressively because sodium salt may affect sodium levels.

Use of bulk-forming laxatives in patients receiving opioids is not recommended. Due to slower peristalsis in patients receiving opioids and potential inadequate fluid intake, the medication may lodge in the colon, causing bowel obstruction.

New novel agents are now available to treat refractory constipation due to opioids by specifically targeting the *mu* receptors in the gut. These medications were developed by altering the structure of naltrexone and naloxone, making them unable to cross the blood–brain barrier preventing reversal of analgesia. Methylnaltrexone is available as an injectable formulation, with effect seen within minutes to a few hours. Naloxegol is an oral agent with

time to effect of approximately 12 hours.

Opioid Tolerance, Dependence, Pseudoaddiction, and Addiction

Opioid tolerance develops when chronic use of opioids causes the need for upward dose titration to maintain analgesia. Opioid dependence is defined as an emergence of withdrawal symptoms when the drug is abruptly discontinued or when the dose is rapidly decreased. Tolerance and physical dependence of opioids can develop quickly. Apparent dependence and/or tolerance in a patient with chronic pain should not impede titration of therapy to an effective dose.

Patients taking opioids as briefly as 2 or 3 days may become dependent and can experience withdrawal symptoms upon discontinuation. Withdrawal symptoms range from mild tremors to sweating and fever, and mimic flu-like symptoms. Severe withdrawal in opioid-dependent patients may consist of increased respiratory rate, perspiration, lacrimation, mydriasis, hot and cold flashes, and anorexia.

Patients with pain may demonstrate signs of addictive behavior, which may be a result of undertreated pain or worsening pain due to disease progression, rather than drug abuse or addiction. Pseudoaddiction, defined as drug-seeking behaviors due to inadequate pain management, can be differentiated from true addiction because "pseudoaddictive" behaviors will resolve once adequate pain management is achieved.

Addiction is defined as "a primary, chronic, neurobiological disease with genetic, psychosocial and environmental factors influencing its development and manifestations" (Savage et al., 2003). It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and cravings. In 2013, an estimated 24.6 million people aged 12 or older (9.4% of the population) live with substance dependence or abuse (National Survey on Drug Use and Health, 2014). Opioid abuse has been reported in chronic pain patients with psychological comorbidities who use opioids to treat pain resulting from depression or anxiety. The concept of substance abuse with respect to opioids is an important consideration in patients presenting with uncontrolled pain but is beyond the scope of this chapter.

Coanalgesics

Several medications have been evaluated for use either alone or in conjunction with other analgesics to treat many persistent pain conditions. The most benefit is seen in chronic pain, neuropathic pain, and postoperative pain syndromes.

Antidepressants

Antidepressants, including tricyclic antidepressants (TCAs) and selective norepinephrine reuptake inhibitors (SNRIs), exhibit analgesic effects by primarily blocking the reuptake of norepinephrine, thereby increasing pain-modulating pathway activity. TCAs also block peripheral sodium channels, which may also help reduce pain. TCAs and SNRIs have been useful in neuropathic pain resulting from cancer or cancer therapies and chronic noncancer, neuropathic pain syndromes (i.e., diabetic or postherpetic neuropathy, chronic low back pain, and fibromyalgia). Several TCAs have beneficial effects in neuropathic pain, including amitriptyline, desipramine, and nortriptyline. Common adverse reactions include dry mouth, weight gain, dizziness, urinary retention, confusion, and sedation. Dosing of TCAs is initiated at 10 to 25 mg nightly and titrated weekly to an effective dose of 75 to 100 mg each evening. Therapy with TCAs should be initiated with caution in the elderly due to an increased incidence of confusion and sedation due to anticholinergic activity and may lead to falls. TCAs should not be used as a first-line agent in the elderly population and should be reserved for patients with treatment failures to other agents.

Amitriptyline is the most studied TCA. The second-generation agent nortriptyline may be better tolerated than amitriptyline because there is less cholinergic and sedative effects. The SNRIs duloxetine and venlafaxine are newer agents used to treat neuropathic pain conditions. Duloxetine dosing is initiated at 20 to 30 mg/d to a target dose of 60 mg/d. Dosing can be titrated to 120 mg/d if indicated. Venlafaxine dose is initiated at 75 mg/d and titrated to a maximum dose of 225 mg/d either once daily or divided twice daily based on dosage form (SR vs. IR) These medications are better tolerated than the TCAs because no cholinergic side effects are seen. GI disturbances, sedation, insomnia, sweating, and confusion may be seen with SNRI use. Venlafaxine has also been associated with increases in blood pressure.

Anticonvulsants

Another group of agents commonly prescribed for neuropathic pain conditions are the anticonvulsants. The most common agents used are gabapentin, pregabalin, and carbamazepine. Gabapentin is the first-line anticonvulsant agent recommended for pain treatment. Pregabalin is structurally similar to gabapentin and has the same mechanism of action. The mechanism of action is not totally understood, but is postulated to be due to the effects of binding to the α-2-delta subunit of voltage-dependent calcium channels, resulting in a reduction of the influx of calcium into the dorsal horn. This results in a

decreased release of glutamate, causing less activation of second-order neurons responsible for transmission of the pain signal to the brain. Gabapentin and pregabalin are generally well tolerated. Most common side effects include nausea, sedation, dizziness, weight gain, and ataxia. Peripheral edema has been associated with pregabalin use. Gabapentin has been shown to be effective for many neuropathic pain conditions, including diabetic neuropathy, trigeminal neuralgia, restless leg syndrome, phantom limb pain, and pain after a stroke. Generally, doses are started at 100 to 300 mg daily and titrated up to 1,800 to 3,600 mg daily in three to four divided daily doses. A sustained-release formulation is also available with a lower maximum dose of 1,800 mg/d. The sustained-release and immediate-release products are not interchangeable.

Pregabalin is better absorbed than gabapentin, and efficacy is seen in approximately 1 week, compared to 4 to 6 weeks with gabapentin. The dose should be started low and titrated. Initial doses are 50 mg two to three times daily, titrated to an effective dose. The maximum dose of pregabalin is 600 mg/d. Side effects are similar to gabapentin. Dosing of gabapentin and pregabalin should be reduced in patients with renal impairment.

Carbamazepine and oxcarbazepine are primarily used for trigeminal neuralgia pain and are considered drugs of choice for this indication. Other anticonvulsants including topiramate, lamotrigine, and divalproex may be tried for neuropathic pain treatment if other modalities have failed.

Sodium Channel Blockers (Local Anesthetics)

This class of medications exerts its analgesic effects by blocking sodium channels, thereby slowing pain transmission and lowering the firing threshold of the second-order neurons. Several routes of administration exist and are chosen based on the indication for use. Topical applications help control localized neuropathic pain with minimal absorption. Lidocaine patches and EMLA cream (mixture of lidocaine and prilocaine) are available for topical use. Lidocaine patches are indicated for postherpetic neuralgia, but efficacy is reported in painful conditions such as diabetic peripheral neuropathy and osteoarthritis. Patches may be cut and up to three patches may be used. Application is usually 12 hours on and 12 hours off daily. Systemic absorption is minimal. Safety and tolerability of 24-hour administration were demonstrated in a study in the Annuls of Pharmacotherapy in 2002, which compared safety of 24-hour administration to the recommended 12-hour application. Pharmacokinetic data on 24-hour administration reported in the study showed systemic absorption markedly below the level needed for toxicity and was well tolerated.

Local injections of anesthetics can be utilized as regional anesthesia, injected into tissue or the epidural space. Epidural analgesia is commonly utilized in managing obstetric or postoperative pain. Rarely, lidocaine has been administered intravenously to control refractory pain conditions in subanesthetic dosages. Intravenous infusions must be administered in a monitored setting because of the potential for severe ADRs with possible exceptions in the end-of-life population. Evidence has shown that the use of lidocaine as a

palliative measure for refractory pain may be efficacious when other methods have failed.

N-Methyl-d-Aspartate Receptor Antagonists

More evidence is emerging in the use of the NMDA antagonists, specifically ketamine, for both acute and chronic pain. Ketamine, an anesthetic agent, is used as a bolus dose or an intravenous infusion for treatment for a variety of pain conditions, such as postoperative pain, chronic refractory pain, and acute pain in the emergency department. Doses for analgesia are lower than doses used for anesthesia. Cancer and noncancer pain refractory to other treatments may benefit from the addition of ketamine to opioid therapy. Better pain control and an opioid-sparing effect have been demonstrated in studies using this combination. Ketamine reduces firing of the NMDA receptor, thereby decreasing sensitivity to pain impulses. Ketamine, by the oral and topical routes, also shows promise for the treatment of pain. Adverse effects are dose related and increased in patients that have a history of psychiatric comorbidities. The most common side effects with ketamine are vivid dreams and sedation. Delirium, dysphoria, hallucinations, hypotension, hypertension, and increased intracranial pressure have also been associated with its use. Other NMDA antagonists, such as dextromethorphan, memantine, amantadine, and magnesium, have not shown promise for pain reduction in studies related to use as analgesics.

Skeletal Muscle Relaxants

In the past, skeletal muscle relaxants have been one of the most extensively prescribed agents for treatment of musculoskeletal disorders, such as low back pain, muscle sprains, or athletic injury. Currently, muscle relaxants are recommended for the short-term treatment of acute musculoskeletal conditions. Long-term use is not recommended. Two categories of skeletal muscle relaxants exist: antispasmodic agents used for musculoskeletal conditions and antispastic agents for central spasticity in conditions such as multiple sclerosis and cerebral palsy.

Antispasmodic Skeletal Muscle Relaxants

Skeletal muscle relaxants are often used in the treatment of acute low back pain. The most benefit is usually seen within the first few days of treatment. Adverse effects such as drowsiness and dizziness are commonly seen, and some agents in this class have potential for abuse. If a muscle relaxant is indicated, choice should be based on adverse effect profile, drug interaction potential, and identified risk of abuse.

Cyclobenzaprine has been the most studied skeletal muscle relaxant. The manufacturer's recommended dose of cyclobenzaprine is 10 mg. However, a 5-mg dose has been shown to be effective with less toxicity. Its anticholinergic properties must be taken into account if used in the elderly. Tizanidine (Zanaflex) is a centrally acting, α_2-adrenergic agonist, reducing spasticity by increasing presynaptic inhibition of motor neuron

excitation. Tizanidine is very sedating and a useful adjunct in patients with sleep disturbances as a result of musculoskeletal pain. Benzodiazepines, such as diazepam, may be effective for acute pain associated with muscle spasms. The predominance of adverse reactions, especially sedation and risk of abuse limit benzodiazepine use for this indication.

Antispastic Agents

Limited evidence exists for using antispastic agents to treat musculoskeletal conditions. Baclofen is the most utilized agent in this class. Baclofen is indicated for managing signs and symptoms of spasticity resulting from multiple sclerosis and for spinal cord injuries or disease. Some anecdotal evidence exists for the use of baclofen in persistent neuropathic states and is used off label for hiccups. It is available as an oral tablet and an injectable formulation for intrathecal administration. Common side effects of the oral form include drowsiness, hypotension, weakness, nausea/vomiting, and headache. Intrathecal administration results in hypotension, somnolence, dizziness, constipation, and headache. Respiratory depression and difficulty with concentration or coordination are also seen with intrathecal administration. Due to possible precipitation of withdrawal with abrupt discontinuation, tapering baclofen is recommended when discontinuing the drug especially with the intrathecal formulation or prolonged oral use. Seizures and delirium may occur and can progress to rhabdomyolysis, disseminated intravascular coagulation (DIC), and hepatic/renal failure with abrupt discontinuation.

Conclusion

Pain is difficult to manage and often needs a multidisciplinary approach to therapy. Treatment needs to be individualized for each patient, especially when a chronic pain condition exists. A proper assessment must be performed in order to differentiate the type and chronicity of pain. Once the type of pain is determined, patient-specific factors should be evaluated in order to choose the appropriate analgesic for pain treatment. Combination of therapies is often needed to provide a pain management goal of an acceptable level of pain and improvement in function. By utilizing the information provided in this chapter, the nursing practitioner will obtain the knowledge and the tools to effectively assess, treat, and monitor pain. The subsequent development of the individualized treatment plan will then provide improvement in the quality of life of the patient suffering in pain.

Case Study*

J.T. is a 65-year-old male admitted to the hospital with history of chronic cancer pain using Morphine SR 60 mg PO q8h. On admission, morphine 2 mg IV q4h was ordered. The patient reports his pain only went from a 9 to an 8 after the morphine dose and is asking for more pain medication. The staff begins to question the motivation of the patient and if addiction is present. The resident decides to start a PCA for his pain. In a few hours, the patient is comfortable, resting in bed.

1. J.T.'s behavior is best described as:
    a. Tolerance
    b. Addiction
    c. Pseudoaddiction
    d. Dependence

2. During his hospital stay, J.T. went into acute renal failure. He is increasingly lethargic and is experiencing confusion and some hallucinations. The physician believes the morphine metabolites may be responsible and would like to convert to an alternative regimen. What would be your recommendation?
    a. Change opioid to fentanyl patch 50 mcg q72h.
    b. Decrease morphine SR dose to 60 mg PO q8h.
    c. Switch to hydromorphone 8 mg orally q4h as needed.
    d. Add haloperidol 1 mg PO q6h.

3. Tolerance will not develop to which adverse opioid effect?
    a. Respiratory depression
    b. Sedation

c. Constipation
d. Nausea

8 Principles of Antimicrobial Therapy

Steven P. Gelone ■ Staci Pacetti ■ Judith A. O'Donnell

The selection of an appropriate antimicrobial agent to treat an infection is guided by a number of factors. Typically, empiric antimicrobial therapy is based on the epidemiology of the suspected infection, with therapy directed toward the most likely organisms. Laboratory studies, including Gram stain as well as culture and sensitivity testing, help to identify the pathogen and its susceptibility to a variety of antimicrobials. Although there may be several options, efficacy, toxicity, pharmacokinetic profile, and cost ultimately determine the agent of choice. The optimal dose and duration of the antimicrobial therapy are then determined by patient factors such as age, weight, and concurrent disease states as well as the site and severity of infection.

Factors in Selecting an Antimicrobial Regimen

Before initiating antibiotic therapy, a systematic approach to identify the source and site of infection must be undertaken. A complete medical history and physical examination should be conducted to identify signs and symptoms consistent with the presence of infection. Identifying underlying medical or social conditions such as diabetes, immunosuppression (cancer, human immunodeficiency virus [HIV] infection), past medications, or intravenous (IV) drug use may help in identifying a predisposition toward infection or the most likely pathogen causing disease. In addition, determining where the infection was acquired (in the community vs. a nursing home or hospital setting) may also help limit the list of most likely pathogens. Health care–acquired pathogens may necessitate broad-spectrum empiric therapy to cover multidrug-resistant (MDR) pathogens.

Identifying the causative pathogen is the ultimate goal because it allows for optimal antibiotic selection and patient outcome. Specimens from the most likely body sites should be properly collected and sent to the microbiology laboratory. Depending on the body site involved, specimens will be stained (e.g., Gram stain) to determine morphology and cell wall structure (gram positive vs. gram negative and cocci vs. bacilli) and analyzed to detect white blood cells (which indicate inflammation and infection). The gold standard of diagnosis in infectious diseases is to be able to grow the causative organism in culture and perform antibiotic susceptibility testing to determine which agents are most likely to be effective in eradicating the pathogen. Susceptibility results often take 48 to 72 hours after cultures are obtained. Newer methods of testing can help identify specific pathogens (such as methicillin-resistant *Staphylococcus aureus* [MRSA] and *Candida*) more quickly.

Often, antibiotic therapy is initiated before culture and sensitivity testing is complete. Empiric antibiotic therapy is based on the premise of providing coverage for the most likely pathogens (Table 8.1). In general, the most likely organism is based on the suspected site of the infection. Table 8.2 outlines key pathogens and spectra of activity for the most commonly prescribed antibiotics.

TABLE 8.1 Infection and Most Likely Infecting Organism

Body Site (Infection)	Most Likely Organism
Heart (Endocarditis)	
Subacute	*Streptococcus viridans*
Acute	*Staphylococcus aureus*
Injection drug user	*Staphylococcus aureus*, gram-negative aerobic bacilli, *Enterococcus* spp.
Prosthetic valve	*Staphylococcus epidermidis*
Intra-abdominal tissues	*Escherichia coli*, *Enterococcus* spp., anaerobes (especially *Bacteroides fragilis*), other gram-negative aerobic bacilli
Brain (Meningitis)	
Children <age 2 mo	*E. coli*, group B streptococci, *Listeria monocytogenes*
Children age 2 mo to 12 y	*Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae*
Adults (community acquired)	*S. pneumoniae, N. meningitidis*
Adults (hospital acquired)	*S. pneumoniae, N. meningitidis*, gram-negative aerobic bacilli
HIV coinfected	*Cryptococcus neoformans, S. pneumoniae*
Respiratory Tract	
Upper tract, community acquired	*S. pneumoniae, H. influenzae, Moraxella catarrhalis*, group A streptococci
Lower tract, community acquired	*S. pneumoniae, H. influenzae, M. catarrhalis, Klebsiella pneumoniae Mycoplasma pneumoniae, C. pneumoniae*, viruses
Aspiration pneumonia	Mouth flora (anaerobic and aerobic)
Lower tract, hospital acquired	*S. aureus (including MRSA), P. aeruginosa*, other gram-negative aerobic bacilli
HIV coinfected	*Pneumocystis jiroveci, S. pneumoniae*
Skin and Soft Tissue	
Diabetic ulcer	*Staphylococcus* spp., *Streptococcus* spp., gram-negative aerobic bacilli, anaerobes
Urinary Tract	
Community acquired	*E. coli*, other gram-negative aerobic bacilli, *Enterococcus* spp., *Staphylococcus saprophyticus*
Hospital acquired	*E. coli*, other gram-negative aerobic bacilli, *Enterococcus* spp.

*Provides synergistic activity against gram-positive organisms when combined with a cell wall–active agent.

†Applicable only to organisms isolated in urine.

– = No activity or no information available.

+ = Poor to moderate activity; use only when known to be susceptible.

++ = Good activity; resistance in some strains and geographical location may limit use.

+++ = Excellent activity; generally reliable coverage for empiric therapy.

In most patients treated initially with a parenteral antibiotic who are clinically improving, therapy should be switched to the oral route. This does not apply to certain infections, such as osteomyelitis and endocarditis, in which parenteral antibiotics are continued to ensure adequate concentrations at the infection site. This oral conversion should be based on the following criteria:

- The patient is responding to therapy, as evidenced by a return to normal or a trend toward normal values in the patient's temperature and white blood cell count.
- The patient can take oral medications and absorb them adequately.
- An oral equivalent to the parenteral regimen exists. Not all parenteral agents are available orally. In choosing the oral equivalent, the goal is to select an agent (or agents) that provides a similar spectrum of antimicrobial activity and possesses good oral bioavailability. This may necessitate the use of oral agents that are from a different class from the parenteral agent.

The patient's response to therapy should be monitored regularly. This includes monitoring both efficacy and toxicity. If the patient responds to the prescribed antibiotic regimen, the presenting signs and symptoms of the infection should resolve. Parameters to be considered for response regardless of the site of infection include vital signs, white blood cell count, and, if the culture proved positive for bacteria, subsequent negative cultures. Other signs and symptoms are specific to the body site involved. Monitoring for adverse events is specific to the agents prescribed. (Review the drug overview sections for common adverse events.) All patients should be taught how to recognize the most common adverse events, and they should be advised to notify their health care provider if an adverse reaction occurs. The following sections highlight antimicrobials used in practice and include

pharmacokinetics, pharmacodynamics, mechanism of action, spectrum of activity, common clinical uses, adverse events, drug interactions, and antimicrobial resistance.

Penicillins

First isolated in 1928, the penicillins were used successfully to treat streptococcal and staphylococcal infections. Since then, many synthetic penicillins have been developed to address the emerging problem of resistance. Despite resistance, the penicillins remain an important class of antimicrobials. They are classified based on their spectra of activity.

Pharmacokinetics and Pharmacodynamics

Most of the penicillins are unstable in the acid environment of the stomach and must be administered parenterally. Those that are acid stable are given orally. They are widely distributed in the body and penetrate the cerebrospinal fluid (CSF) in the presence of inflammation. Most penicillins are excreted by the kidneys, and renal impairment necessitates dosage adjustment. The half-life of the penicillins in adults with normal renal function is 30 to 90 minutes. The penicillins are removed by hemodialysis, with the exception of nafcillin and oxacillin. The penicillins exhibit time-dependent bactericidal activity and a postantibiotic effect (PAE) against most gram-positive organisms. See Box 8.1 for information on PAE. Also, see Table 8.3 for dosing information.

TABLE 8.3 Penicillin Dosages

Drug	Adult Dosages	Pediatric Dosages
Natural		
penicillin G	2–4 million units IV q4–6h	100,000–400,000 units/kg/d IV divided q4–6h
penicillin G benzathine	1.2–2.4 million units IM at specified intervals	300,000–2.4 million units IM at specified intervals
penicillin G procaine	0.6–4.8 million units IM in divided doses q12–24h at specified intervals	25,000–50,000 units/kg/d IM divided 1–2 times/d
penicillin VK	250–500 mg PO q6h	25–50 mg/kg/d PO divided q6–8h
Aminopenicillins		
ampicillin	1–2 g IV q4–6h	100–400 mg/kg/d IV divided 4–6h
amoxicillin–ampicillin	250–500 mg PO q8h 875–1,000 mg PO q12h	400–100 mg/kg/d PO divided q6–12h
Carboxypenicillins		
ticarcillin sodium	3 g IV q4–6h	200–300 mg/kg/d IV divided q4–6h
Penicillinase Resistant		
cloxacillin	250–500 mg PO q6h	50–100 mg/kg/d PO divided q6h
dicloxacillin	250–500 mg PO q6h	12.5–100 mg/kg/d PO divided q6h
nafcillin	500 mg–1 g IV q4–6h	50–200 mg/kg/d IV divided q4–6h
oxacillin	500–2 g IV q4–6h	100–200 mg/kg/d IV divided q4–6h
Ureidopenicillins		
piperacillin	3–4 g IV q4–6h	200–300 mg/kg/d IV divided q4–6h

Note: Dosage adjustment of all above drugs required in patients with impaired renal function, with the exception of penicillinase-resistant penicillins.

BOX 8.1 Postantibiotic Effect

The PAE is defined as "persistent suppression of bacterial growth after a brief exposure (1 or 2 hours) of bacteria to an antibiotic even in the absence of host defense mechanisms". This delayed growth of bacteria results in an increased efficacy of the drugs and allows for less frequent dosing of medications, potentially lowering toxicity and improving compliance. The duration of the PAE is affected by the class of antibiotic, the relevant exposure time, and the specific bacterial species. Bacteriostatic agents, such as macrolides, clindamycin, streptogramins, tetracyclines, and linezolid, have long PAEs, whereas drugs with relatively slow bactericidal action (e.g., penicillins) have little to no PAE.

Mechanism of Action and Spectrum of Activity

The mechanism of action of the penicillins is the inhibition of bacterial cell growth by interference with cell wall synthesis. Penicillins bind to and inactivate the penicillin-binding proteins (PBPs).

Clinical Uses

Although the use of penicillin itself is limited due to widespread resistance, the penicillin class is effective in many infections, including those of the upper and lower respiratory tract, urinary tract, and central nervous system (CNS) as well as sexually transmitted diseases. They are the agents of choice for treating gram-positive infections such as endocarditis caused by susceptible organisms. Both the carboxypenicillins and ureidopenicillins are useful in treating infections caused by *Pseudomonas aeruginosa*.

Adverse Events

There is a low incidence of adverse reactions with penicillin administration. Hypersensitivity reactions characterized by maculopapular rash and urticaria are most common. Gastrointestinal (GI) side effects are most common with oral administration. In the presence of severe renal dysfunction, high-dose penicillins have been associated with seizures and encephalopathy. Thrombophlebitis has occurred with IV administration. The Jarisch-Herxheimer reaction, characterized by fever, chills, sweating, and flushing, may occur when penicillin is used in treating spirochetes, in particular syphilis. Release of toxic particles from the organism precipitates the reaction. In rare cases, leukopenia, thrombocytopenia, and hemolytic anemia can occur with penicillins.

Drug Interactions

Drug interactions involving penicillins are rare. Probenecid has been shown to increase the half-life of the penicillins by inhibiting renal tubular secretion. Both the carboxypenicillins and ureidopenicillins have been shown to inactivate the aminoglycosides, and these agents should not be mixed in the same IV solution. Also, the parenteral carboxypenicillins have a high sodium content. Caution should be used in patients with fluid or sodium restrictions.

Beta-Lactam/Beta-Lactamase Inhibitor Combinations

Resistance to penicillin develops when the drug is inactivated by the enzymes known as penicillinases or beta-lactamases produced by bacteria. After several attempts over the years to prevent penicillin degradation by this enzyme, clavulanic acid became the first beta-lactamase inhibitor introduced and combined with a beta-lactam. Other beta-lactamase inhibitors, avibactam, sulbactam, and tazobactam, are also available in combination with ampicillin, ceftazidime, ceftolozane, and piperacillin. The role of the beta-lactamase inhibitor is to prevent the breakdown of the beta-lactam by organisms that produce the enzyme, thereby enhancing antibacterial activity. These combinations are suitable alternatives for infections caused by beta-lactamase–producing organisms such as *S. aureus*, *Haemophilus influenzae*, and *Bacteroides fragilis*.

Pharmacokinetics and Pharmacodynamics

The beta-lactam/beta-lactamase inhibitors diffuse into most body tissues, with the exception of the brain and CSF. The half-life of both components in each combination is approximately 1 hour. Because these drugs are eliminated by glomerular filtration, renal dysfunction necessitates dosage changes (Table 8.4). The compounds are removed by hemodialysis and peritoneal dialysis.

TABLE 8.4 Beta-Lactam/Beta-Lactamase Inhibitor Dosages

Drug	Adult Dosages	Pediatric Dosages
amoxicillin–clavulanic acid	250–500 mg PO q8h 500–875 mg PO q12h	20–40 mg/kg/d PO divided q8–12h
	2 g PO q12h*	80–90 mg/kg/d PO divided q12h†
ampicillin–sulbactam	1.5–3 g IV q6h	100–400 mg/kg/d IV divided q6h
piperacillin–tazobactam	4.5 g IV q6–8h or 3.375 g IV q6h	240–300 mg/kg/d IV divided q8h
ticarcillin–clavulanic acid	3.1 g IV q4–6h	200–300 mg/kg/d IV divided q4–6h
ceftazidime–avibactam	2.5 g IV q8h	—
ceftolozane–tazobactam	750 mg IV q8h	—

Note: Dosage adjustment required for all above drugs administered to patients with renal impairment.

** amoxicillin–clavulanic acid (Augmentin XR) extended-release formulation.*

† amoxicillin/clavulanic acid (Augmentin ES-600) formulation.

Mechanism of Action and Spectrum of Activity

The beta-lactam components of the combinations are cell wall–active agents. They interfere with bacterial cell wall synthesis by binding to and inactivating PBPs. The beta-lactamase inhibitors irreversibly bind to most beta-lactamase enzymes, protecting the beta-lactam from degradation and improving their antibacterial activity. The beta-lactamase inhibitors alone lack significant antibacterial activity. The spectrum of activity is similar to the penicillin derivative, with broader coverage against beta-lactamase–producing organisms.

Clinical Uses

Based on their broad spectrum of activity, the beta-lactam/beta-lactamase inhibitors are frequently used in treating polymicrobial infections. They are used extensively to treat intra-abdominal and gynecologic infections, and skin and soft tissue infections, including human and animal bites, as well as foot infections in diabetic patients. Respiratory tract infections, including aspiration pneumonia, sinusitis, and lung abscesses, have been successfully treated with these combinations.

Adverse Events

The addition of the beta-lactamase inhibitor to the penicillins has not resulted in any new or major adverse events. The major effects associated with the beta-lactam/beta-lactamase inhibitor combinations are hypersensitivity reactions and GI side effects such as nausea and diarrhea associated with oral administration. Elevated aminotransferase levels have been documented for all agents.

Drug Interactions

The combinations are physically incompatible with parenteral aminoglycosides. Each of the penicillins in the combinations has been associated with the inactivation of aminoglycosides in vitro. The clinical significance of this interaction is unknown.

Cephalosporins

The cephalosporins, a beta-lactam group, are structurally similar to the penicillins. Substitutions on the parent compound, 7-aminocephalosporanic acid, produce compounds with different pharmacokinetic properties and spectra of activity. The cephalosporins are divided into "generations" based on their antimicrobial spectrum of activity. The progression from first to fourth generation in general reflects an increase in gram-negative coverage and a loss of gram-positive activity.

Pharmacokinetics and Pharmacodynamics

The cephalosporins are well absorbed from the GI tract. In some cases, food enhances absorption. They penetrate well into tissues and body fluids and achieve high concentrations in the urinary tract. Noncephamycin second-generation agents and all third- and fourth-generation agents penetrate the CSF and play a role in treating bacterial meningitis. Most of the oral and parenteral cephalosporins are excreted by the kidney, with the exception of ceftriaxone (Rocephin) and cefoperazone (not available in the United States), which are eliminated by the liver. The cephalosporins exhibit a time-dependent bactericidal effect and a prolonged PAE against staphylococci. Table 8.5 provides dosing information.

TABLE 8.5 Cephalosporin Dosages

Drug	Adult Dosages	Pediatric Dosages
First Generation		
cefazolin	500 mg–1 g IV q8h	50–100 mg/kg/d IV divided q8h
cephalexin	250–1,000 mg PO q6h	25–100 mg/kg/d PO divided q6h
cefadroxil	500 mg–1 g PO q12h	30 mg/kg/d PO divided q12h
Second Generation		
cefotetan	1–2 g IV q12h	40–80 mg/kg/d IV divided q12h
cefoxitin	1–2 g IV q6–8h	80–160 mg/kg/d IV divided q4–8h
cefuroxime	750–1.5 g IV q8h	75–150 mg/kg/d IV divided q8h
cefuroxime axetil	250–500 mg PO q12h	20–30 mg/kg/d PO divided q12h
loracarbef	200–400 mg PO q12–24h	15–30 mg/kg/d PO divided q12h
cefaclor	250–500 mg PO q8h	20–40 mg/kg/d PO divided q8–12h
Third Generation		
cefotaxime	1–2 g IV q8h	100–300 mg/kg/d IV divided q6–8h
ceftazidime	1–2 g IV q8h	90–150 mg/kg/d IV divided q8h
ceftizoxime	1–2 g IV q8h	150–200 mg/kg/d IV divided q6–8h
ceftriaxone*	1–2 g IV q12–24h	50–100 mg/kg/d IV divided q12–24h
ceftibuten	400 mg PO q24h	9 mg/kg/d PO divided q24h
cefpodoxime proxetil	100–400 mg PO q12h	10 mg/kg/d PO divided q12h
cefprozil	250–500 mg PO q12h	15–30 mg/kg/d PO divided q12h
cefdinir	300 mg PO q12h OR 600 mg PO q24h	7–14 mg/kg/d PO divided q12–24h
Fourth Generation		
Cefepime	1–2 g IV q8–12h	50 mg/kg/d IV divided q8h
Ceftaroline	600 mg IV q8h	—

Note: Dosage adjustment necessary for all agents in patients with renal impairment except ceftriaxone.

*Dosage adjustment necessary in patients with liver dysfunction.

Mechanism of Action and Spectrum of Activity

Like other beta-lactams, the cephalosporins interfere with bacterial cell wall synthesis by binding to and inactivating the PBPs.

Clinical Uses

The cephalosporins are used in treating many infections. In general, the first-generation cephalosporins are used in treating gram-positive skin infections, pneumococcal respiratory infections, urinary tract infections, and for surgical prophylaxis. The second-generation cephalosporins are used in treating community-acquired pneumonia, other respiratory tract infections, and skin infections. Mixed aerobic and anaerobic infections may be treated with the second-generation cephamycins (cefotetan and cefoxitin). In addition, treating community-acquired bacterial meningitis typically includes a third-generation cephalosporin such as ceftriaxone or cefotaxime (Claforan). Nosocomial infections are commonly treated with ceftazidime (Fortaz) or cefepime (Maxipime), whose broad spectrum of activity includes gram-negative organisms, especially *P. aeruginosa*. Ceftaroline fosamil (Teflaro), a new IV cephalosporin, has activity similar to ceftriaxone but is the only cephalosporin that covers MRSA.

Adverse Events

The cephalosporins are a safe class of antimicrobials with a favorable toxicity profile. With a few exceptions, the adverse events are similar across the generations. Hypersensitivity reactions, not unlike those with the penicillins, are characterized by maculopapular rash and urticaria. The cross-reactivity between penicillins and cephalosporins is 3% to 10%. Patients who experience allergic reactions to penicillins (other than a type 1 allergy) can often tolerate a cephalosporin. The most common side effects with oral administration are nausea, vomiting, and diarrhea. GI effects are usually transient. Less common reactions include a positive Coombs test and rarely hemolytic reactions.

Drug Interactions

Drug interactions involving cephalosporins are rare. Probenecid has been shown to increase the half-life of some cephalosporins by inhibiting the renal tubular secretion.

Monobactams

The monobactams are a unique class of beta-lactams with a four-membered ring but lacking a fifth or sixth member, like other beta-lactams. Because aztreonam (Azactam) is the only agent of its class commercially available, most of the information relates specifically to that agent. With primary activity against gram-negative organisms, including *Pseudomonas*, aztreonam is considered a safer alternative to the aminoglycosides, with a similar spectrum of activity.

Pharmacokinetics and Pharmacodynamics

Aztreonam distributes well into most tissues, with a volume of distribution of 0.16 L/kg. Penetration into the CSF is increased in the presence of inflamed meninges. Aztreonam is not extensively bound to proteins. The approximate half-life is 2 hours, and dosages are typically calculated according to the severity of disease (Table 8.6). Aztreonam is excreted primarily unchanged by glomerular filtration, so dosage adjustments are necessary in patients with renal insufficiency. Aztreonam is cleared by hemodialysis and peritoneal dialysis.

TABLE 8.6 Aztreonam Dosages

Severity of Infection	Adult Dosages	Pediatric Dosages
Mild	500 mg IV q8–12h	90–120 mg/kg/d IV divided q6–8h
Moderate	1–2 g IV q8–12h	
Severe	2 g IV q6–8h	

Note: Dosage adjustment required in patients with impaired renal function.

Mechanism of Action and Spectrum of Activity

Aztreonam, like other beta-lactams, interferes with bacterial cell wall synthesis by binding to and inactivating PBPs. The principal activity of aztreonam is against most aerobic gram-negative organisms, including *P. aeruginosa*, *Serratia marcescens*, and *Citrobacter* species. It has virtually no activity against gram-positive organisms. Its gram-negative coverage is similar to that of the aminoglycosides and the third-generation cephalosporin ceftazidime. Aztreonam is not active against anaerobic organisms.

Clinical Uses

Aztreonam is commonly used in treating complicated and uncomplicated urinary tract and respiratory tract infections such as pneumonia and bronchitis when aerobic gram-negative coverage is necessary. To broaden coverage, it is usually used in combination with an agent exhibiting gram-positive activity. It is a reasonable substitute for the aminoglycosides in treating gram-negative infections in patients at high risk for toxicity.

Adverse Events

Aztreonam has a relatively safe toxicity profile. Most of the adverse events associated with aztreonam are local reactions and GI symptoms. Elevated aminotransferase levels have also been documented. Despite its beta-lactam structure, patients allergic to penicillins and cephalosporins usually do not manifest an allergic reaction to aztreonam. A cross-allergy specifically with ceftazidime has been reported and linked to an identical side chain on both compounds.

Drug Interactions

No clinically significant drug interactions have been documented with aztreonam.

Carbapenems

The carbapenems, ertapenem (Invanz), doripenem (Doribax), imipenem (Primaxin), and meropenem (Merrem), are bicyclical beta-lactams with a common carbapenem nucleus (Table 8.7). Imipenem is extensively metabolized by renal dehydropeptidases, yielding only limited activity in the urine. Cilastatin, a competitive inhibitor of the dehydropeptidases, was introduced to overcome imipenem degradation and is commercially available in combination with imipenem in a one-to-one ratio. Subsequently, ertapenem, meropenem, and doripenem were developed; they maintain stability against dehydropeptidase metabolism without the addition of a cilastatin-like agent. The carbapenems are the most broad-spectrum agents commercially available.

TABLE 8.7 Carbapenem Dosages

Drug	Adult Dosages	Pediatric Dosages
ertapenem	1 g IV/IM daily	30 mg/kg/d IV divided q12h
doripenem	500 mg IV q8h	Not recommended
imipenem	250–1,000 mg IV q6h	25–100 mg/kg/d IV divided q6h
meropenem	500 mg–1,000 mg IV q8h	30–120 mg/kg/d IV divided q8h

Note: Dosage adjustment required for all above drugs administered to patients with renal impairment.

Pharmacokinetics and Pharmacodynamics

Carbapenems are not absorbed after oral administration. They exhibit linear pharmacokinetics; thus, peak serum levels increase proportionately as the dose is increased. They are widely distributed into most tissues, with an approximate volume of distribution of 0.25 L/kg. With the exception of ertapenem, they are minimally bound to plasma proteins. Penetration into the CSF varies and depends on the degree of meningeal inflammation. The half-life of the carbapenems is approximately 1 hour. They are primarily eliminated by urinary excretion of unchanged drug. Imipenem, meropenem, and doripenem are removed by hemodialysis and hemofiltration.

The carbapenems, like other beta-lactams, exhibit time-dependent bactericidal effects. Unlike other beta-lactams, they exhibit a PAE against gram-negative aerobes lasting at least 1 to 2 hours.

Mechanism of Action and Spectrum of Activity

Similar to the penicillins and cephalosporins, the carbapenems bind to the PBPs on the cell wall and interfere with bacterial cell wall synthesis. They frequently have stability against beta-lactamases and bind to several PBPs.

Imipenem, meropenem, and doripenem possess the broadest spectrum of activity of any of the beta-lactam compounds. They have excellent activity against aerobic gram-positive organisms, including staphylococci and streptococci and gram-negative organisms such as Enterobacteriaceae, *P. aeruginosa*, and *Acinetobacter* species. They are also active against most gram-negative anaerobic organisms, including *B. fragilis*. Ertapenem has a similar spectrum of activity as the other carbapenems, with the noted exceptions of *P. aeruginosa* and *Acinetobacter* species, for which ertapenem has no clinically significant activity.

Clinical Uses

Their broad spectrum of activity and stability to many beta-lactamases make the carbapenems useful as single agents in treating polymicrobial infections. They have been used extensively in treating skin and soft tissue, bone and joint, intra-abdominal, and lower respiratory tract infections. In addition, meropenem is used in treating CNS infections because it has a lower risk than imipenem of causing seizures.

Adverse Events

Neurotoxicity, a well-known effect of the carbapenems, is characterized by seizure activity. Imipenem has been reported to lower the seizure threshold more frequently than meropenem and doripenem. Risk factors for seizures include impaired renal function, improper dosing, age, previous CNS disorder, and concomitant agents that lower the seizure threshold. Meropenem and more recently doripenem are the carbapenems of choice in patients with a seizure disorder or underlying risk factors. Such GI side effects as nausea, vomiting, and diarrhea have also been reported. Decreasing the infusion rate may lessen their severity.

Drug Interactions

Concomitant administration of probenecid and meropenem or doripenem results in decreased clearance of these agents and a substantial increase in half-life; therefore, the concurrent administration of meropenem or doripenem with probenecid is not recommended. A similar interaction with imipenem occurs, but to a lesser degree.

Fluoroquinolones

Since 1990, the fluoroquinolones (FQs) have become a dominant class of antimicrobial agents. No other class of antimicrobial agents has grown so rapidly or been developed with such interest by pharmaceutical research companies. Although multiple medications in this class have been approved by the U.S. Food and Drug Administration (FDA), several FQs have been removed from the U.S. market due to the identification of postmarketing adverse events. This emphasizes the importance of postmarketing research and adverse event reporting. Table 8.8 lists the available FQs. Ciprofloxacin, levofloxacin, and moxifloxacin are most commonly prescribed.

TABLE 8.8 Fluoroquinolone Dosages

Drug	Adult Dosage
ciprofloxacin	250–750 mg PO q12h; 200–400 mg IV q12h; 400 mg IV q8h (severe infections)
gemifloxacin	320 mg PO daily
levofloxacin	250–750 mg PO/IV daily
moxifloxacin	400 mg PO/IV daily
norfloxacin	400 mg PO q12h
ofloxacin	200–400 mg PO q12h

Note: With the exception of ciprofloxacin for the treatment of urinary tract infections and anthrax, these drugs are not recommended for use in children younger than age 18. Dosage adjustment required for all above drugs (except moxifloxacin) administered to patients with renal impairment.

Pharmacokinetics and Pharmacodynamics

The FQs are bactericidal antibiotics. They display a concentration-dependent killing effect. All FQs have excellent bioavailability, making it easy to transition from an IV to an oral formulation. They have a volume of distribution ranging from 1.5 to 6.1 L/kg and distribute well into most tissues and fluids except the CNS. The half-life for the FQs ranges from 4 to 12 hours, with levofloxacin, gemifloxacin, and moxifloxacin having the longest half-lives. These three agents are dosed once daily. All FQs undergo renal elimination with the exception of moxifloxacin. The FQs are removed by hemodialysis and peritoneal dialysis, with percentages varying between products. All FQs also exhibit a PAE, which also appears to be a concentration-dependent parameter. The newer compounds have been reported to have PAEs of 1 to 6 hours, depending on the pathogen and drug.

Mechanism of Action and Spectrum of Activity

The quinolone antibiotics are strong inhibitors of deoxyribonucleic acid (DNA) gyrase and topoisomerase IV. These enzymes are critical to the process of supercoiling DNA. Without such enzymatic activity, bacterial DNA cannot replicate.

All FQs possess activity against aerobic gram-negative organisms. Ciprofloxacin and levofloxacin have activity against *P. aeruginosa*, representing the only oral antibiotics available to treat this pathogen. However, widespread use of the FQs since the late 1990s have led to increased resistance against gram-negative pathogens and limited use in some parts of the United States. Newer FQs, such as levofloxacin, moxifloxacin, and gemifloxacin, have activity against gram-positive organisms including *Streptococcus* species. These agents are sometimes referred to as the "antipneumococcal" or "respiratory" FQs given their activity against *S. pneumoniae* and usefulness in treating community-acquired pneumonia. Moxifloxacin has some activity against anaerobic bacteria.

Clinical Uses

The FQs have been shown to be effective in treating many infections, including urinary tract infections (for which they are one of the agents of choice), pneumonia, sexually transmitted diseases, skin and soft tissue infections, GI infections (in combination with an agent for anaerobic coverage), traveler's diarrhea, and osteomyelitis. For hospital-acquired infections such as nosocomial pneumonia, ciprofloxacin (Cipro) or levofloxacin (Levaquin) are the preferred agents, as part of a drug combination, because they have the best activity against *P. aeruginosa*. Ciprofloxacin is also recommended for meningococcal prophylaxis as a single 500-mg oral dose.

Adverse Events

The FQs have a relatively safe side effect profile. The most common side effects include nausea, diarrhea, dizziness, and confusion. Rare but serious side effects include QTc prolongation, tendon rupture, tendonitis, and peripheral neuropathy.

Drug Interactions

The FQs have several significant drug–drug interactions. Ciprofloxacin is a potent inhibitor of the cytochrome P-450 (CYP) 1A2 isoenzyme and may increase the effect of other medications, including theophylline, warfarin (Coumadin), tizanidine, propranolol, and others. Antacids, sucralfate, and magnesium, calcium, or iron salts will decrease the absorption of the FQs if given concomitantly. These agents should be separated when administered orally. Due to the risk of QTc prolongation and torsades de pointes, medications that prolong the QTc interval should be used cautiously with the FQs. Prolonged administration of FQs in combination with corticosteroids increases the risk of tendonitis and tendon rupture. Hyperglycemic and hypoglycemic events have been reported with FQs when administered with insulin or other antidiabetic agents.

Macrolides and Ketolides

Erythromycin (E-Mycin), the prototypical macrolide, has been used in treating many infections over the years. However, its use has been diminished by its GI side effects. This toxicity has even been used as a means of treating patients with diabetic gastroparesis. Newer agents (clarithromycin and azithromycin) have been developed with improved GI tolerance and longer half-lives. Telithromycin (Ketek) is the only agent in the class known as ketolides. Although separate from macrolides, telithromycin has a similar mechanism of action and antibacterial coverage.

Pharmacokinetics and Pharmacodynamics

The macrolides are usually administered orally and are absorbed from the GI tract if not inactivated by gastric acid. They have good tissue penetration, achieve high intracellular concentrations, and exhibit minimal protein binding. The macrolides are metabolized via the liver and excreted in the urine. Half-lives vary throughout the class, from 2 hours for erythromycin, 4 to 5 hours for clarithromycin (Biaxin), and 50 to 60 hours for azithromycin (Zithromax). The long half-life and high intracellular concentrations of azithromycin permit once-daily dosing and short courses. Dosage adjustment in patients with renal failure is necessary with clarithromycin (Biaxin) and erythromycin (Table 8.9).

TABLE 8.9 Macrolide/Ketolide Antibiotic Dosages

Drug	Adult Dosage	Pediatric Dosages
azithromycin	250–500 mg IV/PO daily	5–12 mg/kg IV/PO daily
	2,000 mg (ER) PO single dose	30 mg/kg PO single dose
clarithromycin*	250–500 mg PO q12h or 1,000 mg (ER) PO daily	15 mg/kg/d PO divided ql2h
erythromycin base*	250 mg–1 g PO q6h	30–50 mg/kg/d PO divided q6–8h
ethyl succinate	400–800 mg PO q6–12h	30–50 mg/kg/d PO divided q6–8h
estolate, stearate		30–50 mg/kg/d PO divided q6–12h
injection	500–1,000 mg IV q6–8h	15–50 mg/kg/d IV divided q6h
telithromycin*	800 mg PO daily	Not recommended

*Dosage adjustment necessary in patients with renal impairment.
ER, extended-release product.

Telithromycin is well absorbed following oral administration and is moderately protein bound. The half-life of telithromycin is approximately 10 hours. Telithromycin is metabolized in the liver and eliminated in the urine and feces. A dosage adjustment is recommended for patients with renal failure. The macrolides and ketolides are minimally cleared via hemodialysis and peritoneal dialysis.

Mechanism of Action and Spectrum of Activity

The mechanism of action of the macrolides is inhibition of bacterial protein synthesis by binding to the 50S ribosomal subunit. The spectrum of activity of the macrolides includes gram-positive and gram-negative aerobes and atypical organisms, including chlamydia, mycoplasma, legionella, rickettsia, mycobacteria, and spirochetes. Telithromycin is classified as a ketolide and also works by binding to the 50S ribosomal subunit; however, it has a higher binding affinity compared to the macrolides. The spectrum of activity is similar to the macrolides, with coverage against most organisms isolated in respiratory tract infections, including some strains of erythromycin-resistant *S. pneumoniae*.

Clinical Uses

The macrolides are used in several settings. Their broad spectrum of activity makes them useful in treating respiratory tract, skin, and soft tissue infections, sexually transmitted diseases, HIV-related *Mycobacterium avium–Mycobacterium intracellulare* complex infection, and other infections caused by atypical organisms such as chlamydia, rickettsiae, and legionella. Telithromycin is approved for the treatment of community-acquired pneumonia; however, its use is limited due to the risk of hepatotoxicity.

Adverse Events

The macrolides are in general considered safe agents. Particularly with erythromycin, GI effects such as abdominal pain, nausea, and vomiting are most common. The newer macrolides cause fewer GI effects. Hepatotoxicity related to the macrolides is rare but serious; it also is less frequent with the newer agents. Extremely high doses of IV erythromycin and oral clarithromycin have been associated with ototoxicity. Phlebitis may occur with IV erythromycin administration. Telithromycin has been linked to cases of acute hepatic failure and severe liver injury. Common adverse effects of telithromycin include nausea, vomiting, diarrhea, dizziness, and blurred vision.

Drug Interactions

Among the macrolides, erythromycin and clarithromycin are potent inhibitors of the CYP3A4 isoenzyme. When administered concomitantly, they have been shown to prolong the half-life of an extensive list of agents, including cyclosporine, tacrolimus, carbamazepine, theophylline, warfarin, and most statins. Azithromycin does not undergo significant cytochrome P-450 metabolism, so the possibility of similar interactions is low. Telithromycin is also a strong inhibitor of CYP3A4 and has similar interactions and precautions to erythromycin and clarithromycin. Macrolides and ketolides have the potential to increase the QTc interval, so caution should be used in patients receiving concomitant medications that can also prolong the QTc interval.

Aminoglycosides

Despite the advent of many new antibiotics over the past several decades, the aminoglycosides remain an important therapeutic drug class. Their major drawback has been their potential for drug-related toxicities (nephrotoxicity and ototoxicity). Because of these, their use or the length of therapy has been restricted. The introduction of a modified dosing regimen that uses once-daily (or extended-interval) dosing of these agents for several infections has provided a way of maximizing their therapeutic effects while minimizing the risk of toxicity.

Pharmacokinetics and Pharmacodynamics

The aminoglycosides are poorly absorbed from the GI tract, and parenteral administration is necessary to treat systemic infections. They are weakly bound to serum proteins (10%) and freely distribute into the extracellular fluid. The approximate volume of distribution is 0.25 L/kg, which may be significantly affected in intensive care patients and in disease states such as malnutrition, obesity, and ascites. The aminoglycosides are excreted unchanged via glomerular filtration. The half-life of aminoglycosides in an adult with normal renal function is approximately 1 to 3 hours. Dosage adjustments are necessary in patients with renal impairment because substantial increases in the half-life are seen. Aminoglycosides can be removed by hemodialysis, peritoneal dialysis, and continuous hemofiltration/dialysis.

Because of a narrow range between efficacy and toxicity, renal function and serum levels are used to monitor therapy with aminoglycosides. Table 8.10 gives dosage guidelines.

TABLE 8.10 Aminoglycoside Dosages

Aminoglycoside	Adult Dosages	Pediatric Dosages
Multiple Daily Dosing		
gentamicin, tobramycin	1–1.7 mg/kg IV q8h	6–7.5 mg/kg/d IV divided q8h
netilmicin*	1.7–2 mg/kg IV q8h	
amikacin, kanamycin*	5 mg/kg IV q8h or 7.5 mg/kg IV q12h	15–22.5 mg/kg/d IV divided q8h
streptomycin	0.5–2 g IV q24h	20–40 mg/kg/d IV divided q6–12h
Once-Daily Dosing†		
gentamicin, tobramycin	5–7 mg/kg IV q24h	5–7.5 mg/kg IV q24h
netilmicin*	4–6 mg/kg IV q24h	
amikacin	15–20 mg/kg IV q24h	20 mg/kg IV q24h

Note: Dosage adjustment required for all above drugs administered to patients with renal impairment.

*Not routinely available for use in the United States.

†Once-daily dosing of aminoglycosides is not recommended for enterococcal infections, during pregnancy, in instances of gram-positive synergy, or for endocarditis, meningitis, or ascites.

Pharmacodynamically, the bactericidal effect of the aminoglycosides depends on drug concentration. The number of organisms decreases more rapidly when a higher peak concentration is achieved. In addition, the aminoglycosides exhibit a PAE for both gram-positive and gram-negative organisms.

Mechanism of Action and Spectrum of Activity

The aminoglycosides are actively taken up by bacteria and subsequently bind to the smaller 30S subunit of the bacterial ribosome, thus inhibiting bacterial protein synthesis.

The principal activity of the aminoglycosides is against aerobic gram-negative bacilli such as *Escherichia coli*, *Klebsiella* species, *Proteus mirabilis*, *Enterobacter* species, *Acinetobacter* species, and *P. aeruginosa*. They are also generally active against gram-positive

cocci, particularly *Staphylococcus*, *Enterococcus*, and *Streptococcus* species, but they must be used in combination (for synergy) with a cell wall–active agent such as ampicillin, nafcillin, or vancomycin. Streptomycin is also active against *Francisella tularensis* and *Mycobacterium tuberculosis*.

Clinical Uses

The aminoglycosides are primarily used in treating gram-negative infections. They have long been used in the empiric treatment of neutropenic fever and nosocomial infections because of their broad coverage of *P. aeruginosa* and Enterobacteriaceae. They are also frequently used with cell wall–active agents such as penicillins, cephalosporins, and vancomycin to achieve synergy in treating gram-positive infections, including staphylococcal and enterococcal infections. They are routinely used in combination with other agents in treating pneumonia, bacteremia, and intra-abdominal and skin and soft tissue infections. Monotherapy usually is not recommended, with the noted exception of patients with urinary tract infections. The aminoglycosides have been used in treating tuberculosis, with streptomycin having the greatest activity against *M. tuberculosis*. Streptomycin is also the treatment of choice for tularemia, a potential agent of bioterrorism.

Adverse Events

In general, the aminoglycosides have been associated with a variety of adverse events (GI and CNS), most of which are mild and transient. They rarely produce hypersensitivity reactions and are well tolerated at the sites of administration. Nephrotoxicity and ototoxicity are also associated with aminoglycoside use.

Nephrotoxicity results from accumulation of the drug in the proximal tubule cells of the kidney, causing nonoliguric renal failure. This renal failure is usually mild and reversible and rarely progresses to the need for dialysis. Factors that increase the risk of toxicity to the kidney include increased age, renal disease, increased trough levels, dehydration, and concomitant administration of nephrotoxic agents such as amphotericin B, cyclosporine, and vancomycin. Blood urea nitrogen and serum creatinine values are monitored in addition to serum levels to ensure safe and effective therapy. Table 8.11 provides optimal serum concentrations for aminoglycosides.

TABLE 8.11 Aminoglycoside Concentration Monitoring

Aminoglycoside	Target Peak	Target Trough
Multiple Daily Dosing*		
gentamicin, tobramycin	4–10 µg/mL	<2 µg/mL
netilmicin	4–10 µg/mL	<2 µg/mL
amikacin, kanamycin	20–30 µg/mL	<8 µg/mL
streptomycin	20–30 µg/mL	<8 µg/mL
***Once-Daily Dosing**†*		
gentamicin, tobramycin	>15 µg/mL	<1 µg/mL
netilmicin	>15 µg/mL	<1 µg/mL
amikacin	>50 µg/mL	<5 µg/mL

*Serum concentrations based upon steady state for multiple daily dosing. Peak concentrations should be obtained 30–60 min after infusion and trough concentrations 30 min before next infusion.

†Random concentrations routinely measured for once-daily dosing in lieu of peak and trough serum concentrations and dosage adjustments based upon dosing nomograms.

Two forms of ototoxicity—auditory and vestibular—may occur alone or simultaneously. Auditory toxicity presents as hearing loss and tinnitus; vestibular toxicity is manifested by nausea, vomiting, and vertigo. Ototoxicity may be irreversible and has been associated with high serum trough levels. The risk of ototoxicity increases when the aminoglycosides are

administered in combination with high-dose loop diuretics, high-dose macrolide antibiotics, or vancomycin. Long courses of aminoglycosides warrant baseline and periodic auditory monitoring.

Drug Interactions

The aminoglycosides have the potential to cause or prolong neuromuscular blockade, although this is uncommon. It is recommended that parenteral aminoglycosides be administered over a 30-minute interval. The risk of neuromuscular blockade increases in patients receiving concurrent neuromuscular blockers, general anesthetics, or calcium channel blockers and in those with myasthenia gravis. Administration of calcium gluconate usually reverses the neuromuscular blockade.

Tetracyclines

The tetracyclines possess activity against gram-positive, gram-negative, and atypical organisms, including rickettsiae, chlamydia, mycobacteria, and spirochetes. They are separated into short-, intermediate-, and long-acting agents. Doxycycline and minocycline are considered long-acting and the most active of the class. The tetracyclines became the first class of antimicrobials to be labeled "broad spectrum," and they remain a frequently used class of antimicrobials.

Pharmacokinetics and Pharmacodynamics

Absorption from the GI tract along with protein binding varies among agents. The long-acting agents have the highest absorption and are bound to protein to the greatest extent. With the exception of the long-acting agents, absorption is improved with administration on an empty stomach. The tetracyclines have excellent tissue distribution. The primary route of elimination is through the kidney by glomerular filtration, with the exception of doxycycline. In general, the short-acting agents have a half-life of 8 hours, and the long-acting agents, 16 to 18 hours. The tetracyclines are removed to a small degree by hemodialysis. Table 8.12 provides dosing information.

TABLE 8.12 Tetracycline Dosages*

Drug	Adult Dosages
demeclocycline	150 mg PO q6h 300 mg PO q12h
doxycycline	100 mg IV/PO q12h
minocycline	100–200 mg PO q12h
tetracycline	250–500 mg PO q6h

Note: Dosage adjustment for all above drugs necessary in patients with renal impairment, with the exception of doxycycline.

*The tetracyclines are not recommended for use in children less than age 8 or during pregnancy and breast-feeding.

Mechanism of Action and Spectrum of Activity

The tetracyclines inhibit bacterial protein synthesis by binding to the 30S subunit of the ribosome. The tetracyclines are active against gram-positive and gram-negative bacteria and atypical organisms, including spirochetes, rickettsiae, chlamydia, mycoplasma, and legionella. They typically are bacteriostatic agents.

Clinical Uses

Because of their broad spectrum of activity, the tetracyclines are used extensively in many settings. They are typically used as alternatives when beta-lactams are not an option. They are frequently used in treating rickettsial, chlamydial, and gram-negative infections, in addition to acne vulgaris and pelvic inflammatory disease (PID). Doxycycline is the drug of choice for the treatment of early Lyme disease and used in treating community-acquired pneumonia. Doxycycline and minocycline are used as sclerosing agents for pleurodesis. Additionally, minocycline and doxycycline have gained popularity as a treatment for community-acquired MRSA infections. Though a tetracycline, demeclocycline (Declomycin) is primarily used to treat the syndrome of inappropriate antidiuretic hormone and not as an antibiotic.

Adverse Events

The most frequent side effects associated with the tetracyclines are anorexia, nausea, vomiting, and epigastric distress. These are typically lessened if the agents are administered with food. Thrombophlebitis is associated with IV administration, and it is recommended that doxycycline be administered in a large volume and infused slowly. Hepatotoxicity is a rare but potentially fatal toxicity. The risk of hepatotoxicity increases if the patient is concurrently receiving other hepatotoxic agents. Gray-brown discoloration of the teeth can be a permanent effect of the tetracyclines. It results from stable tetracycline/calcium complexes in bone and teeth and is related to dose and duration of therapy. Therefore, children younger than age 8 should not receive tetracyclines. Patients receiving tetracyclines are more sensitive to the effects of the sun because of accumulation of the drug in the skin. Minocycline has been associated with dose-related vertigo.

Drug Interactions

There are multiple drug interactions involving the tetracyclines. The absorption of the tetracyclines is affected by several agents. Tetracyclines form chelating complexes with divalent and trivalent cations, decreasing tetracycline absorption. It is recommended that the administration of tetracyclines and antacids, iron, cholestyramine, and sucralfate be separated by at least 1 hour. Likewise, food decreases the absorption of most tetracyclines, with the exception of doxycycline. Milk and dairy products also impair their absorption. Phenytoin and carbamazepine, CYP enzyme inducers, decrease the half-life of doxycycline. Concomitant administration of the tetracyclines and oral contraceptives results in decreased levels of the oral contraceptive, so an additional form of contraception is recommended. The tetracyclines also potentiate the effect of warfarin by impairing vitamin K production by intestinal flora.

Glycylcyclines

Tigecycline (Tygacil) belongs to a new class of agents known as the *glycylcyclines*. It is structurally related to the tetracycline class. Tigecycline is derived from the addition of a glycyl ring to minocycline, which significantly enhances its antimicrobial spectrum.

Pharmacokinetics and Pharmacodynamics

Tigecycline is available only in a parenteral formulation. Following IV administration, tigecycline has a half-life of 27 to 42 hours. It is moderately protein bound with a volume of distribution of 7 to 9 L/kg. Given its large volume of distribution, it does not result in prolonged serum concentrations. The dose in adults is a single 100-mg IV dose followed by 50 mg IV every 12 hours. Tigecycline is not extensively metabolized in the liver and does not require adjustments for renal insufficiency; however, the dose should be adjusted for patients with severe underlying liver disease. Tigecycline is not removed by hemodialysis.

Similar to the tetracyclines, tigecycline is bacteriostatic and has a PAE lasting 2 to 4 hours.

Mechanism of Action and Spectrum of Activity

Tigecycline inhibits bacterial protein synthesis by binding to the 30S subunit of the ribosome. It has a fivefold higher binding affinity to these ribosomes compared to the tetracyclines. Tigecycline is active against many gram-positive, gram-negative, and anaerobic organisms, with the exception of *Pseudomonas* and *Proteus* species. Tigecycline has activity against MRSA and vancomycin-resistant enterococci (VRE).

Clinical Uses

Tigecycline is approved by the FDA for treating complicated skin and skin structure infections, intra-abdominal infections, and community-acquired pneumonia; however, given the spectrum of activity, it is also used for gram-negative organisms resistant to alternative agents.

Adverse Events

Tigecycline is generally well tolerated, with nausea and vomiting being the most common adverse effects. Tigecycline has also been reported to cause asymptomatic hyperbilirubinemia. Given the similarity in chemical structure to minocycline, there is the potential for adverse effects seen with the tetracycline class.

Drug Interactions

Concomitant administration of tigecycline and oral contraceptives results in decreased levels of the oral contraceptive, so an additional form of contraception is recommended.

Sulfonamides

In 1932, the dye prontosil rubrum was found to be effective in treating streptococcal infections. Subsequent studies found that one of its by-products was sulfanilamide. Manipulation of this by-product created the class of antimicrobials known as the sulfonamides.

Pharmacokinetics and Pharmacodynamics

Oral sulfonamides are readily absorbed from the GI tract. They are distributed through all body tissues and enter the CSF, pleural fluid, and synovial fluid. They are eliminated from the body by glomerular filtration and hepatic metabolism. The half-lives of the sulfonamides vary from hours to days; sulfadoxine (Fansidar) (no longer available in the United States), at 5 to 10 days, has the longest half-life. Table 8.13 gives dosing information.

TABLE 8.13 Sulfonamide Dosages

Drug	Adult Dosages	Pediatric Dosages
sulfadiazine	4–8 g PO in divided doses q6–12h	100–150 mg/kg/d PO divided q6h
sulfisoxazole	4–8 g PO in divided doses q4–6h	120–150 mg/kg/d PO divided q4–6h
trimethoprim	100 mg PO q12h or 200 mg PO q24h	4–6 mg/kg/d PO divided q12h
trimethoprim–sulfamethoxazole*	160/800 mg PO q12h 10–20 mg/kg/d IV in divided doses	6–20 mg/kg/d PO/IV divided q6–12h

Note: Dosage adjustment necessary in patients with renal impairment.

*Dosing recommendations are based on the trimethoprim component.

Mechanism of Action and Spectrum of Activity

The sulfonamides work by inhibiting the incorporation of para-aminobenzoic acid, the basic building block used by bacteria to synthesize dihydrofolic acid, the first step leading to folic acid synthesis, required for bacterial cell growth. Sulfamethoxazole (SMX) competitively inhibits the bacterial enzyme dihydropteroate synthetase.

Trimethoprim (TMP), combined with SMX, inhibits the enzyme dihydrofolate reductase, synergistically inhibiting folic acid formation at another step in the pathway. Because bacterial dihydrofolate reductase is inhibited much more than the mammalian enzyme and because humans obtain exogenous dietary folate, inhibition of folate synthesis by SMX-TMP in humans is not a major problem.

The sulfonamides are active against a wide range of gram-positive and gram-negative organisms, with the exception of *Pseudomonas* species and group A streptococci. In combination with other folate antagonists, they also demonstrate activity against *P. jiroveci* and *Toxoplasma gondii*.

Clinical Uses

The sulfonamides are frequently used in treating many infections. Sulfasalazine (Azulfidine), a sulfonamide derivative lacking significant antimicrobial activity, is poorly absorbed and is used in the management of ulcerative colitis. Because of their limited spectrum of activity and increasing resistance, the sulfonamides are typically used in combination with other agents to increase efficacy or expand coverage. Trimethoprim–sulfamethoxazole (Bactrim) is the combination of choice in treating urinary tract infections, *P. jiroveci* pneumonia (PCP), toxoplasmosis, and some resistant gram-negative infections. Mafenide (Sulfamylon) and silver sulfadiazine (Silvadene) are topical agents frequently used in treating burns.

Adverse Events

Several side effects are reported for sulfonamides. The most common are rash, fever, and GI side effects. The rash occurs within 1 to 2 weeks of initiating therapy. Severe dermatologic reactions, such as Stevens-Johnson syndrome and vasculitis, are uncommon and associated more with longer-acting preparations. Hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase deficiency.

Drug Interactions

The sulfonamides potentiate the effects of warfarin, phenytoin, hypoglycemic agents, and methotrexate as a result of drug displacement or decreased liver metabolism.

Glycopeptides

Vancomycin, a glycopeptide antibiotic, was first introduced in 1958. Shortly after its introduction, vancomycin became known as "Mississippi Mud" because of the color and impurities in the manufacturing process. The clinical use of vancomycin was initially limited due to its potential for drug-related toxicities, alternative available agents, and concern for the development of resistance. However, since the early 1980s, vancomycin has been an important agent in treating infections. More recent additions to this class include dalbavancin, oritavancin, and telavancin. All of these agents have a narrow spectrum of activity directed toward gram-positive organisms. The newest agents, dalbavancin and oritavancin, have prolonged half-lives that allow for much less frequent dosing.

Pharmacokinetics and Pharmacodynamics

Vancomycin is poorly absorbed from the GI tract. Because of its poor bioavailability, oral administration of vancomycin provides concentrations in the stool sufficient to treat *Clostridium difficile* colitis. The volume of distribution for vancomycin and telavancin, respectively, is 0.6 to 0.9 L/kg and 0.1 L/kg. Vancomycin is minimally bound to proteins; however, telavancin is highly bound to proteins (greater than 90%). They have relatively good penetration into most body fluids and tissues. Unpredictable levels are attained in the CSF and bone. Telavancin is dosed 10 mg/kg IV once daily. Vancomycin is dosed 15 to 20 mg/kg IV with the interval based on kidney function. Table 8.14 provides an example of a vancomycin-dosing nomogram, and Table 8.15 provides the dosing of dalbavancin and oritavancin. Monitoring renal function is important in determining proper dosing because dosage adjustments are necessary in patients with renal insufficiency. Both vancomycin and telavancin are renally excreted, primarily as unchanged drug. The vancomycin half-life in adults with normal renal function is 5 to 11 hours. The half-life of telavancin is approximately 8 hours. Neither telavancin nor vancomycin is cleared to a significant extent by hemodialysis or peritoneal dialysis.

TABLE 8.14 Vancomycin Dosages

Estimated Creatinine Clearance (mL/min)	Dosing Interval		
	40–55 kg, 500 mg*	55–75 kg, 750 mg*	75–100 kg, 1,000 mg*
>80	q8h	q12h	q12h
54–80	q12h	q18h	q18h
40–53	q18h	q24h	q24h
27–39	q24h	q36h	q36h
21–26	q36h	q48h	q48h
16–20	q48h		

Note: These recommendations represent one of several nomograms used in the empiric dosing of vancomycin. Some prescribers use pharmacokinetic calculations and monitor serum trough levels to evaluate the efficacy and toxicity of a particular regimen. Therapeutic trough levels are typically maintained between 10 and 20 μg/mL.

*Patient's body weight and IV dose of vancomycin.

TABLE 8.15 Glycopeptide Dosages

Drug	Adult Dosages	Pediatric Dosages
dalbavancin	1,000 mg IV followed by 500 mg IV 1 wk later	—
oritavancin	1,200 mg IV as a single injection	—

Serum drug monitoring is used for vancomycin in patients with unpredictable kidney function or severe infections or those receiving therapy for more than 3 to 5 days. In general, the target trough concentration ranges from 15 to 20 mg/mL for pneumonia, osteomyelitis, meningitis, and endocarditis and from 10 to 15 mg/mL for other infections. Peak concentrations are generally not recommended. Serum monitoring is not required for dalbavancin, oritavancin, or telavancin. All of these agents exhibit bactericidal activity and a PAE of 1 to 4 hours.

Mechanism of Action and Spectrum of Activity

Glycopeptides are cell wall–active agent. They work by inhibiting the binding of the D-alanyl-D-alanine portion of the cell wall precursor or by interfering with the polymerization and cross-linking of peptidoglycan. The newer agents have more rapid bactericidal activity than vancomycin.

The principal activity of the glycopeptides is limited to gram-positive aerobic and anaerobic bacteria such as methicillin-sensitive and methicillin-resistant staphylococci, streptococci, enterococci, and *Clostridium* species.

Clinical Uses

Vancomycin is used to treat many infections. It is frequently used to treat serious gram-positive infections in patients allergic to or unable to tolerate beta-lactam antibiotics, and it is the drug of choice for MRSA and other resistant gram-positive infections. Neutropenic fever, endocarditis, and meningitis are commonly treated with vancomycin. Oral vancomycin is used in treating severe cases or *C. difficile* colitis or those that have failed to respond to metronidazole. The newer agents are currently indicated only for the treatment of skin and skin structure infections.

Adverse Events

The most common side effects associated with vancomycin administration are fever and chills, phlebitis, and "red man" syndrome, a histamine-mediated phenomenon associated with the rate of vancomycin infusion. The typical syndrome consists of pruritus; flushing of the head, neck, and face; and hypotension. It usually resolves when the drug is discontinued. This reaction can also occur with telavancin. Vancomycin and telavancin should be infused over at least 1 hour.

Nephrotoxicity as a result of vancomycin alone is uncommon. Typically, a combination of variables and risk factors precipitates renal insufficiency. Risk factors include age, pre-existing renal disease, and the use of other nephrotoxic agents such as aminoglycosides, amphotericin B, acyclovir, and cyclosporine. In clinical trials evaluating telavancin and vancomycin, an increase in serum creatinine was more common with telavancin. Vancomycin has been classified as an ototoxic agent. Although rare, ototoxicity has occurred in patients receiving high-dose therapy or concurrent ototoxic agents (e.g., aminoglycosides). Hematologic effects from vancomycin such as thrombocytopenia and neutropenia are rare. The most common reported adverse effects of telavancin are taste disturbances, nausea, vomiting, and foamy urine. Due to the risk to the fetus, telavancin is contraindicated during pregnancy.

Drug Interactions

Since the glycopeptides do not undergo significant hepatic metabolism, drug–drug interactions with these two agents are unlikely.

Oxazolidinones

The oxazolidinones are a totally synthetic antibiotic class first investigated in the late 1980s as antidepressant agents. Serendipitously, these agents were discovered to have excellent antibacterial activity. The main reason for their clinical development has been the emergence and spread of resistance in gram-positive pathogens. Linezolid (Zyvox) and tedizolid (Sivextro) are the only agents available in this class.

Pharmacokinetics and Pharmacodynamics

Linezolid and tedizolid are well absorbed from the GI tract. Peak levels are achieved within 1 to 2 hours, and levels increase linearly as the dose is increased. The absolute bioavailability of these agents is greater than 90%. The oral formulation may be administered without regard to meals. Oxazolidinones are predominantly eliminated by nonrenal mechanisms, and their metabolism does not involve the CYP enzyme system. Linezolid is removed by hemodialysis and should be dosed following hemodialysis sessions, while tedizolid is not significantly affected. Table 8.16 provides dosing information.

TABLE 8.16 Oxazolidinone Dosages

Drug	Adult Dosages	Pediatric Dosages
linezolid	400–600 mg PO/IV q12h	20 mg/kg/d PO/IV divided q12h OR 30 mg/kg/d PO/IV divided q8h
tedizolid	200 mg PO/IV daily	–

Oxazolidinones are considered bacteriostatic agents. A PAE of 3 to 6 hours has been reported, but this has little clinical significance.

Mechanism of Action and Spectrum of Activity

Oxazolidinones bind to the 50S ribosome at a unique binding site and disrupt bacterial protein synthesis. Antagonism has been described with chloramphenicol and clindamycin.

The principal activity of the oxazolidinones is against gram-positive aerobic organisms, including staphylococci, streptococci, and enterococci. In particular, activity against resistant pathogens, including MRSA, penicillin-resistant streptococci, and VRE, is excellent.

Clinical Uses

Linezolid has FDA approval for the treatment of community and nosocomial pneumonia, skin and skin structure infections, and vancomycin-resistant *Enterococcus faecium*, while tedizolid is only approved for the treatment of skin and skin structure infections.

Adverse Events

In general, oxazolidinones are well tolerated when used for short-course therapy. The most common adverse events include diarrhea, nausea, taste perversion, and vomiting. As mentioned earlier, this class of agents was initially investigated for its antidepressant activity. Thrombocytopenia has been reported on average in 3% to 4% of patients in studies of linezolid. Additionally, anemia, leukopenia, and pancytopenia have been reported. A complete blood count should be monitored in patients, especially if receiving linezolid for longer than 2 weeks.

Drug Interactions

Linezolid and tedizolid possess weak monoamine oxidase inhibitory activity. There is a potential for drug interactions with sympathomimetic agents, such as pseudoephedrine, SSRI antidepressants like citalopram, some herbal products, and foods rich in tyramine.

Lipopeptides

Daptomycin is an antibacterial agent belonging to the class known as the lipopeptides. This class of agents has been studied for its antibacterial activity for several decades; however, daptomycin is the only agent available. Daptomycin is a natural product developed for the treatment of MDR gram-positive pathogens.

Pharmacokinetics and Pharmacodynamics

Daptomycin pharmacokinetics are nearly linear and time independent at doses up to 6 mg/kg administered once daily for 7 days. Its half-life is approximately 8 hours. The apparent volume of distribution in healthy adults is approximately 0.1 L/kg. Daptomycin reversibly binds human plasma proteins, primarily to serum albumin, with a mean serum protein binding of 90%. Because renal excretion is the primary route of elimination, dosage adjustments are necessary in patients with severe renal insufficiency (creatinine clearance less than 30 mL/min). The dose for patients with normal renal function is 4 to 6 mg/kg IV administered daily. There is very limited information to support the use of daptomycin in pediatric patients. Daptomycin exhibits rapid, concentration-dependent bactericidal activity against gram-positive organisms.

Mechanism of Action and Spectrum of Activity

The mechanism of action of daptomycin is distinct from that of any other antibiotic. It binds to bacterial membranes and causes a rapid depolarization of membrane potential. The loss of membrane potential leads to bacterial cell death.

Daptomycin covers most gram-positive pathogens such as *S. aureus* (including methicillin-resistant strains), streptococcus, and enterococcus. It is active against MRSA and VRE.

Clinical Uses

Daptomycin is indicated for the treatment of complicated skin and skin structure infections and *S. aureus* bloodstream infections (bacteremia), including those with right-sided infective endocarditis, caused by methicillin-susceptible and methicillin-resistant isolates. Daptomycin is a useful alternative to other agents (linezolid, quinupristin/dalfopristin) for treating infections caused by resistant gram-positive pathogens because there are few options at present for treating these infections. For complicated skin and skin structure infections, combination therapy may be clinically indicated if the documented or presumed pathogens include gram-negative or anaerobic organisms. Daptomycin is not indicated for the treatment of pneumonia.

Adverse Events

Daptomycin may cause GI reactions such as constipation, nausea, diarrhea, and vomiting. Injection site reactions and headache may occur. Skeletal muscle toxicity manifested as muscle pain has been reported with daptomycin. This is accompanied by an increase in creatinine phosphokinase (CPK) levels.

Drug Interactions

CPK monitoring should be done at least weekly for patients concomitantly receiving a statin and/or those with renal insufficiency. Otherwise, daptomycin does not have any significant drug–drug interactions.

Streptogramins

The streptogramin antibiotics are naturally occurring products that have been used clinically in Europe for more than 40 years. The semisynthetic derivative, quinupristin/dalfopristin (Synercid), is the only streptogramin antibiotic available in the United States. It is a combination of two antibiotics.

Pharmacokinetics and Pharmacodynamics

Quinupristin/dalfopristin is not absorbed from the GI tract. After IV administration, both quinupristin and dalfopristin have a serum half-life of approximately 1 hour. Each drug is moderately protein bound; the volume of distribution is 0.45 and 0.24 L/kg for quinupristin and dalfopristin, respectively. Metabolism of both agents is through the liver. The drug is primarily excreted in the feces.

Quinupristin/dalfopristin is a bactericidal agent against most organisms, with the noted exception of vancomycin-resistant *E. faecium*. Quinupristin/dalfopristin possesses a PAE ranging from 8 to 18 hours. The dosage for adults and children is 7.5 mg/kg every 8 to 12 hours. It is not significantly removed by hemodialysis or peritoneal dialysis.

Mechanism of Action and Spectrum of Activity

The streptogramins inhibit protein synthesis by binding to the 50S ribosome. The interaction of quinupristin and dalfopristin is synergistic. Either compound alone is bacteriostatic, whereas the combination results in a bactericidal effect.

The principal activity of quinupristin/dalfopristin is against gram-positive aerobic organisms, including staphylococci, streptococci, and enterococci. In particular, its activity against resistant pathogens, including methicillin-resistant staphylococci, penicillin-resistant streptococci, and vancomycin-resistant *E. faecium*, is excellent. Quinupristin/dalfopristin is not active against *Enterococcus faecalis*.

Clinical Uses

Quinupristin/dalfopristin is approved by the FDA for treating skin and skin structure infections and vancomycin-resistant *E. faecium* infections. The use of this agent is limited due to adverse effects and the need for administration through a central venous line. It can be used to treat gram-positive infections caused by methicillin-resistant staphylococci, penicillin-resistant *S. pneumoniae*, and vancomycin-resistant *E. faecium* when alternative agents are contraindicated.

Adverse Events

The most common adverse reactions are infusion related. Infusion site reactions, including pain, inflammation, edema, and thrombophlebitis, have been reported in as many as 75% of patients receiving quinupristin/dalfopristin through a peripheral IV catheter. Arthralgias and myalgias have also been reported. They may be severe and result in discontinuation of therapy. They usually occur after several days of therapy. After discontinuation of therapy, these reactions are uniformly reversible. The most common laboratory abnormality is an increased level of conjugated bilirubin.

Drug Interactions

The CYP3A4 isoenzyme (responsible for the metabolism of many drugs) is significantly inhibited by quinupristin/dalfopristin. Close clinical or serum level monitoring of known substrates of the CYP3A4 enzyme is recommended.

Antianaerobic Agents: Clindamycin

Clindamycin (Cleocin) has been used extensively in treating gram-positive and anaerobic bacterial infections. It was first used orally to treat streptococcal and staphylococcal infections, but it soon became the drug of choice for anaerobic infections. The combination of clindamycin and gentamicin (Garamycin) is still frequently used in treating mixed aerobic and anaerobic infections.

Pharmacokinetics and Pharmacodynamics

Both the hydrochloride and palmitate hydrochloride salts of clindamycin are well absorbed and converted to active forms in the blood. Clindamycin reaches most tissues and bone, but its distribution into CSF is limited. It is 93% bound to proteins. The half-life is approximately 3 hours. Clindamycin is metabolized by the liver, necessitating dosage adjustment in patients with liver impairment (Table 8.17). Hemodialysis and peritoneal dialysis do not remove clindamycin to a significant extent.

TABLE 8.17 Clindamycin Dosages

Drug	Adult Dosages	Pediatric Dosages
clindamycin	150–450 mg PO q6–8h	10–30 mg/kg/d PO divided q6–8h
	600 mg IV q8h	25–40 mg/kg/d IV divided q6–8h

Note: Dosage adjustment recommended for patients with liver dysfunction.

Mechanism of Action and Spectrum of Activity

Clindamycin binds to the 50S subunit of the bacterial ribosome and inhibits protein synthesis. It acts at the same site as chloramphenicol and the macrolides.

Clinical Uses

Clindamycin is typically included in regimens for its anaerobic coverage in mixed infections and may also be used in treating gram-positive infections, toxoplasmosis, and PCP or in combination with other agents to treat PID. In addition, it is frequently used to inhibit toxin production as part of the treatment for staphylococcal or streptococcal toxic shock.

Adverse Events

The major side effect associated with clindamycin is diarrhea and associated *C. difficile* colitis. This adverse event is unrelated to dose and may range from acute, self-limiting symptoms to life-threatening toxic megacolon. Pain at the site of IV administration may occur.

Drug Interactions

In rare cases, clindamycin use in combination with skeletal muscle relaxants has been reported to potentiate neuromuscular blockade.

Antianaerobic Agents: Metronidazole

Metronidazole (Flagyl) was first recognized for its antiprotozoal activity in treating *Trichomonas vaginalis* infections. Subsequently, its utility as an antianaerobic agent was used in treating *B. fragilis* infections. Metronidazole has become a treatment of choice for anaerobic infections, *C. difficile* colitis, and is part of a number of regimens to eradicate *Helicobacter pylori*–associated duodenal ulcers.

Pharmacokinetics and Pharmacodynamics

Metronidazole is completely absorbed from the GI tract after oral administration. It penetrates well into most tissues, with an apparent volume of distribution of 0.3 to 0.9 L/kg. Its binding to plasma protein is minimal. The liver metabolizes metronidazole, and dosage adjustments are necessary in patients with hepatic impairment (Table 8.18). The half-life is approximately 6 to 9 hours. Metronidazole is removed by hemodialysis and peritoneal dialysis.

TABLE 8.18 Metronidazole Dosages

Drug	Adult Dosages	Pediatric Dosages
metronidazole	250–500 mg PO q6–8h 500 mg IV q6–12h	15–35 mg/kg/d PO/ IV divided q6h

Note: Dosage adjustment recommended for patients with severe liver or kidney dysfunction.

Mechanism of Action and Spectrum of Activity

Metronidazole is reduced to a toxic product that interacts with DNA, causing strand breakage and resulting in protein synthesis inhibition. Metronidazole has excellent activity against gram-positive and gram-negative anaerobes, *H. pylori*, and protozoa such as *T. vaginalis*.

Clinical Uses

Metronidazole is typically included in regimens for its anaerobic coverage in mixed infections. In addition, metronidazole is the treatment of choice for bacterial vaginosis, trichomoniasis, and *C. difficile* diarrhea.

Adverse Events

Metronidazole is usually safe and well tolerated. GI side effects such as nausea, vomiting, abdominal pain, and a metallic taste are most common. More serious but rare effects include seizures, peripheral neuropathy, and pancreatitis. Seizures have been associated with high doses, whereas peripheral neuropathy has been documented in patients receiving prolonged courses of metronidazole.

Drug Interactions

Metronidazole enhances the anticoagulant effect of warfarin, resulting in a prolonged half-life of warfarin. A disulfiram-like reaction characterized by flushing, palpitations, nausea, and vomiting may occur when alcohol is consumed during metronidazole therapy. Metronidazole is an inhibitor of the CYP3A4 isoenzyme. It has the potential to interact with multiple medications. Additionally, phenobarbital, phenytoin, and rifampin increase the metabolism of metronidazole, which may result in treatment failure. A careful review of a patient's medication list for drug interactions should be done before initiating metronidazole.

Miscellaneous Antimicrobial Agents: Chloramphenicol

Chloramphenicol has a wide spectrum of activity against gram-positive, gram-negative, and anaerobic organisms. However, its use has been limited by its toxicity profile, which includes “gray baby” syndrome, optic neuritis, and fatal aplastic anemia. Nonetheless, in selected situations, chloramphenicol remains an important agent.

Pharmacokinetics and Pharmacodynamics

Chloramphenicol is available as an IV succinate ester. The dose is based on age and indication (Table 8.19). The ester formulation is hydrolyzed in the body to the active drug. Chloramphenicol penetrates well into most tissues and bodily fluids, including the CSF. Chloramphenicol readily crosses the placenta in pregnant females. It is conjugated in the liver and excreted by the kidney in an inactive, nontoxic form. The serum half-life is 3 to 4 hours. Chloramphenicol is 25% to 50% bound to protein.

TABLE 8.19 Chloramphenicol Dosages

Patient Group	Dosage
Older children and adults	50–100 mg/kg/d IV divided q6h (max 4,000 mg daily)
Older children and adults with meningitis	75–100 mg/kg/d IV divided q6h

Note: Chloramphenicol should be used with caution in patients with renal impairment, and serum concentrations should be monitored to guide dosing and prevent toxicity.

Serum levels are frequently monitored in high-risk patients. The therapeutic range of chloramphenicol is 5 to 20 mg/dL. Dose-related myelosuppression typically occurs at serum levels exceeding 25 mg/dL.

Mechanism of Action and Spectrum of Activity

Chloramphenicol reversibly binds to the larger 50S subunit of the ribosome, thereby inhibiting bacterial protein synthesis. It is variably bactericidal.

Chloramphenicol is active against gram-positive and gram-negative aerobes and anaerobes as well as atypical organisms, including mycoplasma, chlamydia, and rickettsiae. Its gram-negative activity includes *E. coli*, *Proteus* species, and *Salmonella* species, but not *P. aeruginosa*.

Clinical Uses

Newer agents have reduced the need to use chloramphenicol in treating infection. However, it can be used as an alternative in treating bacterial meningitis when a patient has a life-threatening penicillin allergy. It is also useful in treating rickettsial diseases such as Rocky Mountain spotted fever and typhus fever in patients allergic to tetracyclines or in pregnant women. Chloramphenicol may be used in treating VRE infections as well.

Adverse Events

The major adverse events associated with chloramphenicol are "gray baby" syndrome, blood dyscrasias, and optic neuritis. "Gray baby" syndrome typically occurs in neonates and is manifested by vomiting, lethargy, respiratory collapse, and death. It results from drug accumulation because neonates cannot conjugate chloramphenicol. Two forms of hematologic toxicity may occur with chloramphenicol administration. Dose-related bone marrow suppression has occurred in patients receiving doses exceeding 4 g/d and at serum levels exceeding 25 mg/dL. It may present as a combination of anemia, leukopenia, and thrombocytopenia. Aplastic anemia is an idiosyncratic effect independent of dose and may occur weeks after therapy with chloramphenicol. It is associated with a greater than 50% mortality rate and often necessitates bone marrow transplantation. Optic neuritis is a major neurologic complication and is associated with long courses of chloramphenicol. The toxicity involves red-green color changes and loss of vision. It may be reversible or permanent. GI side effects have been associated with high doses of chloramphenicol.

Drug Interactions

Chloramphenicol is metabolized by the liver and is an inhibitor of the CYP2C19 and CYP3A4 enzymes. It prolongs the half-life of warfarin, phenytoin, and cyclosporine.

Miscellaneous Antimicrobial Agents: Rifampin

Rifampin is a macrocyclic antibiotic used in a variety of settings, and it is a first-line agent in treating tuberculosis. It is typically combined with other antibiotics such as vancomycin in treating MRSA infections.

Pharmacokinetics and Pharmacodynamics

Rifampin is completely absorbed after oral administration. It distributes into most tissues and fluids, including the CSF. The half-life of rifampin is approximately 3 hours. It is metabolized by the liver and is not removed by hemodialysis or peritoneal dialysis. Table 8.20 provides dosing information.

TABLE 8.20 Rifampin Dosages

Drug	Adult Dosages	Pediatric Dosages
rifampin	600 mg PO once daily 10–20 mg/kg IV daily	10–20 mg/kg IV generally once daily

Note: Dosage adjustment recommended for patients with liver dysfunction.

Mechanism of Action and Spectrum of Activity

Rifampin suppresses initiation of chain formation for RNA synthesis in susceptible bacteria by inhibiting DNA-dependent RNA polymerase. The β-subunit of the enzyme appears to be the site of action.

Rifampin is extremely active against gram-positive cocci. It has moderate activity against aerobic gram-negative bacilli. *Neisseria meningitidis*, *Neisseria gonorrhoeae*, and *H. influenzae* are the most sensitive gram-negative organisms. Rifampin maintains activity against *M. tuberculosis*.

Clinical Uses

Rifampin is commonly used in combination with a cell wall–active agent to treat serious, gram-positive infections that fail to respond to other courses of therapy. This combination is used for synergistic activity and prevents rapid resistance development. It is the drug of choice for postexposure meningitis prophylaxis against *N. meningitidis* and *H. influenzae* type B. Rifampin is a first-line agent in the treatment of *M. tuberculosis* infection, and it is used to treat nontuberculous mycobacterial infections as well.

Adverse Events

The most common side effects associated with rifampin are GI distress (nausea, vomiting, and diarrhea), headache, and fever. Rifampin changes bodily fluids such as sweat, saliva, and tears to a red-orange color. Hepatotoxicity is rare, but the risk increases when it is administered in combination with isoniazid. Liver function tests should be monitored while patients receive rifampin. Anemia or thrombocytopenia also has been reported.

Drug Interactions

Rifampin is a potent inducer of hepatic CYP drug metabolism and precipitates many drug interactions. Rifampin increases the clearance of agents such as antiarrhythmics, azole antifungals, clarithromycin, estrogens, most statins, warfarin, and many HIV medications. A careful review of a patient's medication list for drug interactions should be done before initiating rifampin.

Miscellaneous Antimicrobial Agents: Nitrofurantoin

Nitrofurantoin is an antimicrobial agent used only for treating and preventing urinary tract infections. Nitrofurantoin has been used in the United States since 1953 and still remains very effective. It is a synthetic nitrofuran-compound derivative, a class that also includes furazolidone, available in Europe.

Pharmacokinetics and Pharmacodynamics

Following oral administration, nitrofurantoin is rapidly absorbed. The bioavailability of nitrofurantoin is approximately 40% to 50%. Absorption can be enhanced with food. Nitrofurantoin serum concentrations are low, with a serum half-life of less than 30 minutes. For this reason, nitrofurantoin should not be used for complicated urinary tract infections or in patients for which a concern of bacteremia exists. Nitrofurantoin undergoes renal elimination. Inadequate urinary concentrations are achieved in patients with renal insufficiency; thus, the drug is ineffective. It is contraindicated in patients with a creatinine clearance of less than 60 mL/min. Table 8.21 provides dosing information.

TABLE 8.21 Nitrofurantoin Dosages

Drug	Adult Dosages	Pediatric Dosages
nitrofurantoin	50 mg PO q6h (macrocrystal) 100 mg PO q12h (macrocrystal/monohydrate)	5–7 mg/kg/d PO divided q6h

Note: Nitrofurantoin is contraindicated in patients with a creatinine clearance of <60 mL/min.

Mechanism of Action and Spectrum of Activity

The exact mechanism of nitrofurantoin is poorly understood. The drug does inhibit several bacterial enzymes, which results in impaired bacterial cell wall synthesis.

Nitrofurantoin has adequate antimicrobial coverage against common organisms that cause urinary tract infections such as *E. coli*, *Citrobacter* species, *Staphylococcus saprophyticus*, *E. faecalis*, and *E. faecium*. Nitrofurantoin frequently covers strains of VRE. Resistance has increased against some types of bacteria such as *Enterobacter* and *Klebsiella* species.

Clinical Uses

Nitrofurantoin is only used for the treatment and prophylaxis of uncomplicated urinary tract infections. As mentioned earlier, it should not be used for complicated urinary tract infections such as pyelonephritis.

Adverse Events

The most common side effects of nitrofurantoin include nausea and vomiting. Allergic reactions are rare. Pulmonary reactions (pulmonary infiltrates, pneumonitis, pulmonary fibrosis) and hepatic effects (hepatitis, hepatic necrosis) have been reported in rare cases, usually associated with long-term use. Additionally, peripheral neuropathy has been associated with long-term use in patients with renal failure.

Drug Interactions

Nitrofurantoin is not associated with significant drug interactions.

Antimicrobial Resistance

There are multiple mechanisms by which bacteria form or acquire antibiotic resistance. Some types of resistance occur naturally, while others are acquired from another strain of bacteria. Additionally, resistance can sometimes be induced during antibiotic treatment. Table 8.22 summarizes the most common resistance mechanisms:

TABLE 8.22 Antimicrobial Resistance

Antibiotic/Antibiotic Class	Bacterial Enzyme Production	Decreased Membrane Permeability	Promotion of Antibiotic Efflux	Altered Target Sites/Protection of Target Site	Altered Target Enzymes	Overproduction of Target
Penicillins	✓	✓	✓		✓	
Cephalosporins	✓	✓	✓		✓	
Monobactams	✓	✓				
Carbapenems	✓	✓	✓			
Fluoroquinolones		✓	✓	✓	✓	
Macrolides	✓		✓	✓		
Aminoglycosides	✓			✓		
Tetracyclines	✓		✓	✓		
Sulfamethoxazole/trimethoprim					✓	✓
Glycopeptides				✓		
Oxazolidinones				✓		
Streptogramins	✓		✓	✓		
Clindamycin	✓			✓		
Metronidazole		✓			✓	
Chloramphenicol	✓	✓				
Rifampin				✓		
Nitrofurantoin					✓	

1. The first and most common type of resistance is bacterial enzyme production. For example, bacteria frequently produce enzymes that disrupt beta-lactam antibiotics, altering the structure so they cannot bind to the PBPs. There are hundreds of different types of these enzymes known as *beta-lactamases*. Some enzymes have activity only against penicillins (penicillinases), whereas others, such as extended-spectrum beta-lactamases, can render almost all beta-lactam antibiotics ineffective. Separate from beta-lactamases, bacteria also produce enzymes that can alter the chemical structure or inactivate the drug. This can occur with aminoglycosides, chloramphenicol, macrolides, streptogramins, and tetracyclines.
2. Resistance can occur as the bacteria alter their own cell membranes, not permitting antibiotics to enter the bacteria. An example of this is loss of porins on the gram-negative bacterial cell outer membrane. Specifically with beta-lactam antibiotics, loss of these porins alters the ability of the antimicrobial agent to enter the cell.
3. A third, common mechanism of resistance is the activation of efflux pumps that expel antibiotics out of the intracellular space back across the cell membrane. This prevents antibiotics from acting at their intracellular target site. This is a common mechanism of resistance with classes such as tetracyclines and macrolides.
4. A fourth type of resistance is alteration of the antibiotic's target site of action. This occurs with macrolides, among other classes, when mutations alter the ribosomal binding site. The antibiotic does not bind at all or as well to the ribosome anymore. Similarly, VRE is a result of altered cell well precursors. Plasmid-mediated resistance results in a modified peptidoglycan precursor that binds vancomycin, preventing it from binding to its intended target site.
5. A fifth type of resistance is alteration of target enzymes. For example, the FQs work by inhibiting the enzymes DNA gyrase and topoisomerase IV. Mutations to a variety of different chromosomes on these enzymes can reduce the efficacy of the FQs.
6. Last, overproduction of target enzymes can result in resistance. The best example of

this is with sulfonamides and TMP. SMX/TMP works by inhibiting folic acid synthesis by inhibiting the dihydropteroate synthetase and dihydrofolate reductase enzymes, respectively. These enzymes are required for bacterial folic acid synthesis. Excess production of these two enzymes in some strains of bacteria can render the antibiotic ineffective.

A specific area of interest in antimicrobial development is targeting the prevention or overcoming drug resistance.

Antimicrobial Stewardship

Overuse of antibiotics is well documented and has led to increased resistance to various strains of bacteria worldwide. Some examples of drug-resistant bacteria include extended-spectrum beta-lactamases against *E. coli* and *Klebsiella*, carbapenem-resistant *Klebsiella*, FQ-resistant gonococcus, MRSA, and vancomycin-intermediate *S. aureus*. Given the slow development of new antibiotics for the treatment of resistant pathogens, appropriate antibiotic use is crucial. The Infectious Diseases Society of America has developed antibiotic stewardship guidelines. These guidelines recommend a multidisciplinary approach to improving antibiotic use, particularly in the hospital setting. A few ways to improve antibiotic use include formulary restrictions, evidence-based prescribing, dose optimization, antibiotic streamlining, and de-escalation. To minimize resistance, all prescribers must make an effort to ensure appropriate antibiotic use.

Case Study*

M.T., a 62-year-old woman, is started on linezolid for MRSA vertebral osteomyelitis. Her medications include warfarin, atorvastatin, and citalopram.

1. Which of the following is true for linezolid?
   a. It is effective against MRSA but not VRE.
   b. It works by disrupting bacterial cell wall synthesis.
   c. She can be converted to oral treatment as soon as her white blood cells return to normal.
   d. Thrombocytopenia occurs in a small percentage of patients.

2. A few days later, M.T. exhibits signs of confusion, high blood pressure, and tremor. Which of the following is a probable reason for these signs/symptoms?
   a. Linezolid is known for increasing blood pressure in elderly patients.
   b. Linezolid is a mild monoamine oxidase inhibitor and is creating increased interacting with citalopram to created increase levels of serotonin.
   c. M.T.'s infection is getting worse and the linezolid needs to be changed to a more wide-spectrum antibiotic.
   d. Atorvastatin is interacting with the linezolid creating a rhabdomyolysis-like syndrome.

After several weeks, M.T.'s infection improves.

* Answers can be found online.

9 Complementary and Alternative Medicine

Virginia P. Arcangelo

There has been a tremendous growth in the use of complementary and alternative medicine (CAM) in the United States in recent years. *Complementary medicine* is defined as that used together with conventional medicine. *Alternative medicine* is that used in place of conventional medicine. In 1995, the National Institute of Health's Office of Alternative Medicine defined CAM as the "broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self-defined by their users as preventing or treating illness or promoting health and well-being." There has also been an increase in the use of integrative medicine by practitioners. *Integrative medicine* is the combination of mainstream medicine and CAM.

In 2012, 33.2% of adults and 11.6% of children in the Unites States used complementary approaches to health care. The most frequent users of CAM are between 45 and 64 years of age with a higher education and income level. Women use CAM more frequently than men (Clarke et al., 2015).

People use CAM because they want more control over their medical care, they feel an affinity for a holistic or "natural" approach, they are dissatisfied with the attitudes of their health care providers, they are discouraged with the increased cost of traditional medical care, or conventional medicine fails to meet their needs (Box 9.1). Most patients do not communicate the use of CAM with their providers unless specifically questioned about this.

BOX 9.1 Reasons to Use CAM

- Advertising
- Affinity to the natural approach
- Deterioration of patient–provider relationship
- Desire to have control over treatment
- Ineffective treatment of chronic disease
- Dissatisfaction with prescription drugs
- High cost of traditional medical care, use of technology, and drugs
- Perceived effectiveness

- Perceived safety
- Rejection of established medical practices

Domains of CAM

There are five domains of CAM (Box 9.2): alternative medicine system, mind/body interventions, biologically based therapy, manipulation and body-based methods, and energy therapies. Alternative medicine systems are based on complete systems of theory and practice. Mind/body interventions incorporate a variety of techniques to enhance the mind's capacity to affect bodily function; a common practice is biofeedback. Biologically based therapy is treatment with substances found in nature. Manipulation and body-based methods are based on manipulation or movement of body parts; an example is chiropractic manipulation. Energy therapies involve the use of energy fields such as magnets.

BOX 9.2 Domains of Complementary and Alternative Medicine

Alternative Medicine Systems—These are built upon complete systems of theory and practice and have often evolved apart from and earlier than the conventional medical approach popular in the United States. Examples are homeopathic and naturopathic medicine and traditional Chinese medicine.

Mind/Body Interventions—This incorporates a variety of techniques designed to enhance the mind's capacity to affect bodily function and symptoms. This includes biofeedback, meditation, dance therapy, and art therapy.

Biologically Based Therapy—This is treatment with substances found in nature, including dietary supplements, herbal supplements, and "natural" but scientifically unproved treatment.

Manipulation and Body-Based Methods—These are based on manipulation or movement of body parts. Examples include chiropractic manipulation and massage therapy.

Energy Therapies—This is the use of energy fields. Biofield therapy affects the energy fields that purportedly surround and penetrate the human body and includes Reiki and Therapeutic Touch. Bioelectromagnetic therapy is based on treatment involving the unconventional use of electromagnetic fields. An example is magnet therapy.

National Center for Complementary and Integrative Health

Today, the National Center for Complementary and Integrative Health (NCCIH) is the federal government's agency responsible for scientific research on health interventions, practices, products, and disciplines that are not within the realm of mainstream medicine. It is the successor of the National Center for Complementary and Alternative Medicine (NCCAM), the predecessor to NCCIH, that was established in 1998 by congressional mandate. The stated mission of NCCAM was to define, through rigorous scientific investigation, the usefulness and safety of complementary and integrative health interventions and their roles in improving health and health care. It was dedicated to explore complementary and alternative healing practices in the context of rigorous science and to serve as an information clearinghouse and facilitate research and training programs, funded by the federal government. The mission of the NCCIH is to define, through rigorous scientific investigation, the usefulness and safety of complementary and integrative health interventions and their roles in improving health and health care (https://nccih.nih.gov/about/ataglance).

NCCIH identifies CAM practitioners. It also publishes alerts and advisories for specific products and practices, lists clinical trials of CAM, and provides treatment information.

Regulation

Dietary supplements, which are defined as products taken orally that contain a "dietary product" intended to supplement the diet, are estimated to be used by one half to two thirds of the U.S. population (Bailey et al., 2011). These may include vitamins, minerals, herbs, amino acids, other botanicals, or substances such as enzymes, organ tissues, and metabolites. The products may be in the form of powder, capsules, tablets, gelcaps, or liquids. The increasing use of dietary supplements reflects the increased interest in "natural" medicine, fitness, health, and disease prevention. Also, consumers want to avoid the high cost of traditional drugs and the side effects of these drugs.

Manufacturers of dietary supplements are not required to perform clinical tests on new ingredients. The FDA can only stop a company from making a product when that product poses a significant risk to health. On the other hand, prescription drugs are put through rigorous clinical testing to determine there is no harm to the patient before they can be put on the market. The patient usually does not report bad side effects experienced, so adverse reactions are more slowly determined. More than 500 herbs are marketed in the United States; indeed, about 25% of the current pharmacopoeia is derived from botanicals. The cardiac glycoside digoxin comes from the foxglove plant. Aspirin comes from willow bark, oral contraceptives from Mexican yam, warfarin from sweet clover, and capsaicin from the red pepper plant.

In March 2003, the U.S. Food and Drug Administration (FDA) published new guidelines for dietary supplements that would prevent contamination with other herbs, pesticides, heavy metals, or prescription drugs. Manufacturers do not have to prove the supplement's quality but must meet certain FDA standards. The FDA can take action only if it finds that a product is unsafe once it is on the market. Each product must have a label accurately listing the product's ingredients. Box 9.3 lists label requirements for herbal preparations.

BOX 9.3 Label Requirements for Herbal Preparations

- Name
- Quantity of contents
- Ingredients and amounts
- Disclaimer: "This statement has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent disease."
- Supplemental facts panel:
    - ™Serving size
    - ™Amount

    - ™Active ingredients
- Other ingredients such as herbs for which no daily values exist
- Name and address of manufacturer, packer, or distributor

Products also have a "Supplemental Facts" panel that lists the appropriate serving size. Natural remedies cannot be patented, so the manufacturer does not need to take the time and money to conduct necessary tests.

Nutrition Labeling and Education Act

The Nutrition Labeling and Education Act (NLEA) was enacted by Congress in 1990 to provide a clear relationship of nutrition to disease. The purpose of the act was to educate consumers. Information required on the label includes nutritional information, in an easy-to-read format, with the amount of ingredient per serving, the percentage of daily values of the ingredients, and the standard serving size. The act also established that disease-related health claims could be used on labeling of nutritional products, provided there is agreement among qualified scientists that the claim is valid.

Dietary Supplement Health and Education Act

The Dietary Supplement Health and Education Act (DSHEA), passed in 1994, restricted the FDA's control over dietary supplements. It defined herbal products as dietary supplements, which are considered foods. Before this, products had to be proven safe by the FDA; those introduced after the act's passage had to be proven safe by the manufacturer. The manufacturer of a herbal preparation is responsible for the truthfulness of the claims made on a label and must have evidence supporting the claims; however, there is no standard for this evidence or does the manufacturer need to submit it to the FDA. The manufacturer may claim that the product affects the structure or function of the body as long as there is no claim of effectiveness in the prevention or treatment of a specific disease. A disclaimer must be provided stating that the FDA has not evaluated the product. Since health claims are not preapproved, the statement "This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure or prevent any disease" must be on the label. Information regarding therapeutic claims for herbal products can be disseminated as long as the information is not misleading or product specific, is physically separated from the product, and has no product stickers affixed to it.

In 2000, the FDA allowed "structure and function" statements to be made. For example, cranberry products could say that the product supports urinary health but not that it treats urinary tract infections. It allowed for claims that do not relate to disease but are health maintenance claims ("maintains a healthy circulatory system"), nondisease claims ("helps you relax"), and claims for minor symptoms associated with life stages ("for common symptoms of premenstrual syndrome"). Anything that uses words such as "prevents," "treats," "cures," "mitigates," or "diagnoses disease" is subject to drug requirements. This act led to enormous growth in the dietary supplement industry, which today grosses over $18 billion annually.

Risks

Many herbs and alternative medicines have not been studied adequately and may in fact be toxic. The fact that plants are "natural" does not make the use of agents from that plant free of risks! Adverse reactions can result from direct exposure to the component of the plant or from poor manufacturing process. The law does not require that adverse events resulting from the use of dietary supplements be reported to the FDA. Research studies of safety in people are not required because, as noted above, these agents are considered dietary supplements, not drugs. There is inappropriate dissemination of information and weak regulation in the industry. Box 9.4 lists the dangers of herbal preparations.

BOX 9.4 Dangers of Herbal Products

- Many herbs and alternative medicines have not been studied adequately and may be toxic.
- Research studies of safety in people are not required.
- Natural remedies cannot be patented, so the manufacturer does not take the time and money to conduct necessary tests.
- There may be unlisted ingredients in the product.
- There is inappropriate dissemination of information and weak regulation in the industry.
- Dosages can vary by manufacturer.
- Herbal supplements can be bought by anyone.
- There can be herb–drug interactions.

One example of an adverse reaction that has brought about governmental action is ephedra. Ephedra, a common ingredient in weight-loss products, can cause an increase in blood pressure, tremors, arrhythmia, seizures, strokes, myocardial infarction, and death. In April 2004, the FDA banned its sale.

There is no check on the ingredients in preparation. Analyses of herbal supplements have found differences between what is on the label and what is actually in the bottle. There may be less or more of the supplement than the label indicates. When tested, some supplements have been shown to contain an ingredient that is not on the label or even to contain contaminants. Some have been shown not to contain any of the herb listed on the label. Some may even contain prescription medications.

Herbal medicines can be purchased and consumed by anyone. They are less expensive than prescription drugs but can still be costly.

Herb–Drug Interactions

Interactions between dietary supplements and drugs can be pharmacokinetic or pharmacodynamic. Pharmacokinetic interactions can be a change in the amount of active compounds available and are the consequence of alteration in absorption, distribution, metabolism, or excretion. For example, senna, a common ingredient in weight-loss products, has a laxative effect that can affect drug transit time and reduce absorption. Zinc lozenges, often used to relieve cold symptoms, may chelate fluoroquinolones and tetracyclines, decreasing serum levels of these antibiotics.

Pharmacodynamic interactions occur at the site of action and may be additive or antagonistic to prescribed drugs or other herbal preparations. Vitamin E doses of greater than 1,000 units per day can increase the anticoagulant effect of warfarin. Ephedra has additive effects with caffeine and at high doses can cause death.

There can be an effect on drug metabolism. Herbal products can affect cytochrome P450 (CYP) isoenzymes. For example, St. John's wort is a potent herbal inducer of CYP3A4.

Patient Education

The practitioner must question each patient about the use of CAM since most don't report usage. Patients must be aware that herbal preparations have pharmacologic properties. There are interactions with many prescription and over-the-counter (OTC) medications. All products should be purchased from a reliable source. The more ambitious the claim, the more suspicious the consumer should be of the product. The consumer can request professional health information from the company such as the nature of the company, testing procedures, quality control standards, and so forth.

Consumers should avoid excessive dosing. Taking higher than the recommended dosage can increase the possibility of adverse effects. All supplements should be discontinued during pregnancy and lactation and avoided in children under age 12.

Dietary supplements should not be used for serious health conditions without the advice and supervision of a qualified health professional. Most dietary supplements are meant to treat mild, short-term disorders.

Combination products should be avoided. Combining more than two or three ingredients in one product is not good because it is impossible to tell which ingredient is causing side effects if they develop. Multivitamins are the exception.

All side effects should be reported to a health professional. The side effects may be due to the dietary supplement or from interaction with a prescribed drug.

Consumers can obtain information about CAM from many Web sites (Box 9.5).

www.drugfacts.com—a free database to check interactions.
www.cfsan.fda.gov (1-888-723-3366)—provides information on safety of supplements. Adverse effects from a supplement can be reported at www.fda.gov/medwatch (1-800-FDA-1088).
www.naturalstandard.com/NaturalMedicines—the authority on integrative medicine and on dietary supplements, *natural medicines*, and *complementary alternative* and integrative therapies. The best and most authoritative Web site available on herbal *medicines*.

Commonly Used Herbs

The following section reviews some commonly used dietary supplements (herbs). Table 9.1 lists them by use for various organ systems. People use CAM for an array of diseases and conditions. American adults are most likely to use CAM for musculoskeletal problems such as back, neck, or joint pain. The supplements most commonly used are fish oil/omega-3s, glucosamine, echinacea, probiotics, and flaxseed oil.

TABLE 9.1 Common Herbal Preparations

Suggested System	Name/Dosage	Use	Selected Adverse Events	Contraindications/Interactions	Special Considerations
Gastrointestinal (GI)	Acidophilus 10 colony-forming organisms per day	Restore normal oral, GI, and vaginal flora altered by antibiotics or *Candida* and bacterial infections	Flatulence	Warfarin—may decrease efficacy	
Health promotion	Black cohosh 40–200 PO mg/d Flaxseed Seed 1 tablespoon bid to tid Oil 15–30 mL daily	Relief of menstrual and menopausal symptoms Protection against prostate, colon, and breast cancers Lowers triglycerides	Increased perspiration, dizziness, nausea/vomiting, visual disturbances, reduced pulse Flatulence, stomach Pain, constipation, potential lowering of blood sugar	Anesthetics, antihypertensives, sedatives—may increase hypotensive effect Not for use in patients with estrogen-dependent tumors May increase hypoglycemic effect of diabetic meds May increase clotting time with anticoagulants	
Respiratory disorders	Echinacea 50–1,000 mg/d	Shorten duration of symptoms of URI, wound healing	Nausea, rash	Those who are immunocompromised (may suppress T cells) Human immunodeficiency virus Tuberculosis Multiple sclerosis	May increase effects of estrogen supplements
Cardiovascular disorders	Garlic 600–800 mg/d, 1 clove of garlic daily	Lower cholesterol, prevent clot formation	Dizziness, irritation of mouth and esophagus, nausea, flatulence, malodorous breath and body, sweating	Warfarin (increased risk of bleeding)	Only taken for 8 wk
Neurologic/psychological	Ginkgo biloba 40–80 mg/d in 2 or 3 divided doses	Peripheral vascular insufficiency, memory loss	Headache, dizziness, heart palpitations	Aspirin (increased risk of bleeding) Nifedipine (elevated nifedipine levels) Trazodone (increased sedation) Warfarin (increased risk of bleeding) Hypoglycemic agents (facilitates clearance to elevate blood sugar) Thiazide diuretics (increases blood pressure when combined)	The preparation must contain allicin, the active ingredient in garlic
Musculoskeletal	Glucosamine 500 mg PO tid	Antiarthritic	Potential to alter blood glucose levels, heartburn, diarrhea, nausea, abdominal pain	Sulfa allergy	
Neurologic/psychological	Kava 100 mg three times per day	Depression	Headaches, disturbance in visual accommodation	Alcohol (increases activity) Alprazolam (may induce coma) Central nervous system (CNS) depressants (additive sedative effects) Levodopa (increases parkinsonian symptoms)	

Suggested System	Name/Dosage	Use	Selected Adverse Events	Contraindications/Interactions	Special Considerations
Neurologic/ psychological	Melatonin 5 mg PO hs Jet lag: 5 mg/d for 3 d before departure and ending 3 d after departure	Insomnia Jet lag	Headache, depression, drowsiness, confusion, hypothermia	Nifedipine (interferes with antihypertensive effect) Increased anxiolytic action with benzodiazepines	
Neurologic/ psychological	St. John's wort 320 mg PO daily	Depression, anxiety, neuralgic pain	Dizziness, restlessness, sleep disturbances, dry mouth, constipation, GI distress, photosensitivity	Oral contraceptives (decreased efficacy) Cyclosporine (decreased levels) Digoxin (decreased levels) Nifedipine (decreased levels) Tricyclic antidepressants (decreased levels) Selective serotonin reuptake inhibitors (increased sedative effects and serotonin syndrome) Simvastatin (decreased cholesterol-lowering effect) Theophylline (decreased levels) Warfarin (decreased anticoagulant effect) Alcohol Monoamine oxide (MAO) inhibitors	Drowsiness may occur within 30 min, so avoid operating machinery
Neurologic/ psychological	Valerian 200–500 mg PO HS for insomnia 200–300 mg PO bid for anxiety	Sleep disorders, anxiety	Excitability Blurred vision, nausea	Additive effects with alcohol and CNS depressants	Considered an MAO inhibitor
Respiratory	Zinc	Cold symptoms, wound healing	Nausea, bad taste, diarrhea, vomiting, mouth irritation		
Genitourinary disorders	Saw palmetto 320 mg/d PO	Benign prostatic hyperplasia	GI side effects, decreased libido, headache, back pain	Warfarin (increased risk of bleeding)	
Cardiovascular disease	Omega-3s 1–6 g/d	Decrease triglyceride levels, slow growth of atherosclerotic patches	GI upset	Blood thinners, antihypertensives	

Black Cohosh

Action and Proof of Efficacy

Black cohosh has vascular and estrogenic activity. Some studies have shown that black cohosh binds to estrogen receptors.

Uses and Dosage

The action of estrogen-receptor binding is thought to mimic natural estrogen activity. Therefore, black cohosh is used for dysmenorrhea and vasomotor menopausal symptoms. The recommended dosage is 20 to 160 mg daily.

Adverse Reactions and Drug Interactions

Black cohosh can cause nausea, dizziness, increased perspiration, and bradycardia. It interacts with several classes of drugs, such as anesthetics and sedatives. It may increase the hypotensive effect of many antihypertensive agents. It also may increase the effects of estrogen supplements. Black cohosh is contraindicated in patients with estrogen-dependent tumors. Black cohosh also has salicylates.

Coenzyme Q10

Action and Proof of Efficacy

CoQ10 has antioxidant properties, is a membrane stabilizer, and is a cofactor in many metabolic pathways. It is produced by the human body and is necessary for the basic functioning of cells. CoQ10 levels are reported to decrease with age and to be low in patients with some chronic diseases such as heart conditions, muscular dystrophies, Parkinson disease, cancer, diabetes, and human immunodeficiency virus/acquired immunodeficiency syndrome. Some prescription drugs may also lower CoQ10 levels.

Uses and Dosage

CoQ10 is used in patients with hypertension, congestive heart failure, and migraines. There are studies being conducted to determine the role of CoQ10 in many other diseases. The recommended dose is 100 to 1,200 mg/d.

Adverse Reactions and Drug Interactions

Reactions may include nausea, vomiting, stomach upset, heartburn, diarrhea, loss of appetite, rash, insomnia, headache, dizziness, itching, irritability, increased light sensitivity of the eyes, fatigue, or flulike symptoms. It may reduce the effectiveness of warfarin or may add to the effects of other blood pressure-lowering drugs. It may affect thyroid hormone levels and alter the effects of thyroid drugs, such as levothyroxine, and may also interact with antiretroviral or antiviral drugs.

Echinacea

Action and Proof of Efficacy

Echinacea stimulates phagocytosis and increases respiratory cellular activity and mobility of leukocytes. A review of 19 German-controlled studies in treatment of the common cold showed that there may be some effect on the immune system, but a recent study showed no effect on children ages 2 to 11 (Karsch-Völk et al., 2014).

Uses and Dosage

Echinacea is used to help heal abscesses, burns, eczema, and skin wounds and to treat the common cold. The recommended dose is 50 to 1,000 mg/d.

Adverse Reactions and Drug Interactions

Echinacea may cause a rash. It should not be taken by immunocompromised patients. Long-term use may suppress T cells. There are no reported drug interactions.

Flaxseed

Action and Proof of Efficacy

Flaxseed is rich in lignans, one of the major classes of phytoestrogens. They are estrogen-like chemical compounds with antioxidant qualities, able to scavenge free radicals in the body. They are also rich in soluble and insoluble fiber. They are also rich ion omega-3 fatty acids.

Uses and Dosages

Consuming flaxseed may help protect against prostate, colon, and breast cancers. Flaxseed is thought to prevent the growth of cancerous cells because its omega-3 fatty acids disrupt malignant cells from clinging onto other body cells. In addition, the lignans in flaxseed have antiangiogenic properties—they stop tumors from forming new blood vessels. It helps with constipation. It also has the potential for lowering cholesterol, preventing hot flashes, and improving blood sugar.

The dosage for seed is 1 tablespoon two to three times a day and oil is 15 to 30 mL daily.

Adverse Reactions and Drug Interactions

Flaxseed can cause flatulence, stomach pains, nausea, constipation, diarrhea, and bloating.

Pregnant women should avoid consuming flaxseed because of its estrogen-like properties, which affect pregnancy outcome. People with a bowel obstruction should avoid flaxseed because of its high fiber content.

Since flaxseed may lower blood sugar, diabetics must monitor blood sugar closely. It may slow blood clotting so patients taking any medication that effects blood clotting should use it with caution, since it may increase the chance of bleeding.

Garlic

Action and Proof of Efficacy

Garlic has lipid-lowering and antithrombotic properties. Results from clinical studies are varied. Cholesterol-lowering effects, if any, have been shown to be small.

Uses and Dosage

Garlic is used to treat hyperlipidemia and to prevent clot formation. The product must contain allicin, the active ingredient in garlic. Fresh garlic is the most effective (one clove a day). The recommended dose is 600 to 800 mg/d.

Adverse Reactions and Drug Interactions

Garlic can cause dizziness, irritation of the mouth and esophagus, nausea, flatulence, malodorous breath and body odor, and sweating. Garlic increases the risk of bleeding when taking with anticoagulants. Garlic oil can reduce CYP2E1 activity by almost 40%, causing elevated serum levels of drugs whose major metabolic pathway includes CYP2E1, such as alcohol.

Ginkgo Biloba

Action and Proof of Efficacy

Ginkgo biloba promotes arterial and venous vascular changes that increase tissue perfusion and cerebral blood flow. It is also considered an antioxidant. Results from clinical trials are varied. Cholesterol-lowering effects, if any, have been shown to be small.

Uses and Dosage

Ginkgo biloba is used to treat peripheral vascular insufficiency and dementia. The recommended dose is 40 to 80 mg/d.

Adverse Reactions and Drug Interactions

Ginkgo biloba can cause headache, diarrhea, flatulence, nausea, and dermatitis. It interacts with anticoagulants and antiplatelets by affecting platelet activity. When taken with insulin and oral hypoglycemic agents, it causes increased clearance of insulin and oral hypoglycemic agents, resulting in elevated blood glucose levels. When taken with thiazide diuretics, it increases blood pressure.

Glucosamine

Action and Proof of Efficacy

Glucosamine stimulates the production of cartilage components and allow rebuilding of damaged cartilage. Studies have proven its safety and effectiveness in the treatment of osteoarthritis.

Uses and Dosage

Glucosamine is used for osteoarthritis and other joint diseases. The recommended dosage is 1,500 mg/d. It may take 2 weeks to realize the positive effect.

Adverse Reactions and Drug Interactions

Glucosamine can cause drowsiness, headache, abdominal pain, constipation, diarrhea, epigastric discomfort, and nausea. There are no known drug interactions. Glucosamine contains sodium, so care needs to be used in a patient with sodium restrictions.

Kava

Action and Proof of Efficacy

Kava inhibits the limbic system, suppressing emotional excitability and mood enhancement. Randomized, controlled clinical trials of kava use with anxiety provide some reasonable support for its use, but there are no clinical comparison trials with existing anxiolytics.

Uses and Dosage

Kava has been used to treat anxiety disorders. The recommended dosage is 100 mg three times per day.

Adverse Reactions and Drug Interactions

Kava can cause headaches, dizziness, and disturbances in visual accommodation. Alcohol can increase kava's activity. Central nervous system (CNS) depressants can cause an additive sedative effect. Taken together, levodopa and kava can cause an increase in parkinsonian symptoms. Absorption of kava is increased if it is taken with food. Kava increases the effects of alcohol.

Melatonin

Action and Proof of Efficacy

Melatonin release corresponds to periods of sleep. Studies have proven melatonin to be safe and effective for the short-term prevention of jet lag.

Uses and Dosage

Melatonin is used to prevent and treat jet lag and sleeping disturbances. The recommended dosage for sleeping disturbances is 5 mg at bedtime. The recommended dosage for jet lag is 5 mg/d for 3 days before departure and ending 3 days after departure.

Adverse Reactions and Interactions

Melatonin can cause altered sleep patterns, confusion, headache, hypothermia, sedation, tachycardia, hypertension, hyperglycemia, and pruritus. Interactions include increased anxiolytic action when taken with benzodiazepines.

Omega-3s/Fish Oil

Action and Proof of Efficacy

Omega-3s promote the relaxation and contraction of muscles, blood clotting, digestion, cell division, and the growth and movement of calcium and other substances in and out of cells. It also decreases inflammation and platelet aggregation.

Uses and Dosages

Omega-3s are primarily used to decrease triglyceride levels and slow the growth of atherosclerotic plaques. There is research being done to look at the effect of omega-3s on diabetes mellitus, rheumatoid arthritis, systemic lupus erythematosus, and osteoporosis. The recommended dosage is 1 to 6 g/d.

Adverse Reactions and Interactions

Omega-3s can cause gastrointestinal (GI) upset, including diarrhea, heartburn, and abdominal bloating. In high doses, they can interfere with blood thinners and antihypertensives.

Probiotics

Action and Proof of Efficacy

Probiotics are nonpathologic bacteria that reside in the GI tract. They help maintain a healthy balance of organisms in the intestines, promote binding of enterocytes within the GI tract, and prevent harmful bacteria from attaching to these cells.

Uses and Dosage

Probiotics are commonly used to restore normal oral, GI, and vaginal flora. They treat diarrhea, urinary tract infections, vaginitis, and irritable bowel syndrome. They may be used to manage atopic dermatitis in children. They are potentially useful in patients taking antibiotics because the normal flora may be disturbed by the bactericidal or bacteriostatic activity of the drug. Further, patients with *Candida* and bacterial infections may have an imbalance of normal flora. The recommended dosage is 1 capsule of 10 colony-forming units per day.

Adverse Reactions

Adverse reactions are GI related, primarily flatulence. Warfarin's efficacy may be reduced because acidophilus may enhance the intestinal absorption of vitamin K.

Saw Palmetto

Action and Proof of Efficacy

Saw palmetto inhibits the production of enzymes responsible for converting testosterone to more reactive dihydrotestosterone (DHT). Saw palmetto blocks the binding of DHT to prostate cells, inhibiting enlargement. Studies have shown a decrease in symptoms in patients with noncancerous enlargement of the prostate. Saw palmetto also increases urine flow and improves emptying of the bladder.

Uses and Dosage

Saw palmetto is used to treat benign prostatic hyperplasia (BPH). (See Chapter 33 for more information on BPH.) The recommended dosage is 320 mg daily.

Adverse Reactions and Drug Interactions

Adverse reactions include headache, hypertension, constipation, diarrhea, decreased libido, and back pain. There are no known drug interactions.

St. John's Wort

Actions and Proof of Efficacy

St. John's wort is a monoamine oxidase (MAO) inhibitor. It inhibits reuptake of serotonin, noradrenaline, adrenaline, and dopamine. Numerous studies of St. John's wort in patients with depressive disorders have shown that it is more effective than placebo and as effective as antidepressants; however, these studies had many flaws, and more studies need to be done.

Uses and Dosage

St. John's wort is used to treat depression, anxiety, and neuralgic pain. The recommended dosage is 100 to 500 mg daily.

Adverse Reactions and Drug Interactions

St. John's wort can cause dizziness, restlessness, sleep disturbances, dry mouth, constipation, GI distress, and photosensitivity. Drug interactions include an increase in MAO inhibition activity when taken with alcohol, MAO inhibitors, narcotics, and OTC cold and flu medicines. There is a decrease in levels of digoxin and cyclosporine. Serotonin syndrome may develop when used concurrently with amphetamines, selective serotonin reuptake inhibitors, trazodone, and tricyclic antidepressants.

Valerian

Actions and Proof of Efficacy

Valerian binds to gamma-aminobutyric acid alpha-receptor sites in the brain and CNS. It acts in a competitive action with any benzodiazepine. In nine randomized, placebo-controlled, double-blind studies in which valerian was used as a treatment for sleep disorders, some studies showed effectiveness but others showed none (Hadley & Petry, 2003).

Uses and Dosage

Valerian is used for insomnia, anxiety, and stress. The recommended dosages are 200 to 500 mg at bedtime for insomnia and 200 to 300 mg two times per day for anxiety.

Adverse Reactions and Drug Interactions

Valerian can cause excitability, blurred vision, and nausea. There are additive effects with alcohol and CNS depressants.

Recommending Dietary Supplements

When recommending dietary supplements, the practitioner must be aware of several key points. The patient must be educated on the use of alternative therapies. Discussions and recommendations must be documented. The provider and patient must be aware of potential interactions.

Increasing Awareness

Since the use of CAM is increasing, health care providers must be aware of the different modalities. At each visit, the patient should be asked about the use of OTC medications, vitamins, and supplements. The health care provider should check whether there are any interactions between medications and supplements.

Patients who choose to use CAM can be directed to reliable providers and reliable dietary supplements. NCCAM is an excellent source of information for both the patient and provider and can be accessed on the Internet (www.nccam.nih.gov) or by phone (1-888-644-6226).

Case Study*

L.L. is a 67-year-old male who has been diagnosed with BPH. He is having difficulty with urination. He is currently on Cozaar 100 mg for HTN and his BP is well controlled. He is taking no other medications. The doctor has recommended medication for his BPH, but he would like to try a herbal supplement before taking a prescription medication.

1. What herbal supplement would he take?
2. What is the recommended dosage?
3. What are possible side effects of the herbal supplement?
4. What warnings should you give L.L. before he starts the herbal supplement.

* Answers can be found online.

10 Pharmacogenomics

Isabelle Mercier ■ Andrew M. Peterson ■ Amalia M. Issa

Pharmacogenomics and Personalized Medicine

Interpatient variability in drug therapy response is a well-known pharmacotherapeutic concept. Indeed, as far back as 1892, William Osler is reputed to have said "if it were not for the great variability among individuals, medicine might be a science and not an art" (Golden, 2004). In addition to factors such as age, sex, drug–drug interactions, and comorbidities, genetics also is known to play a role in interpatient variability of drug response.

The ability of genetic variability (inherited differences) to influence therapeutic drug response is the basis of pharmacogenetics and pharmacogenomics. Generally, pharmacogenetics refers to single or a few gene variations (called polymorphisms), whereas pharmacogenomics refers more broadly to the genome-wide (or an individual's entire DNA sequence) effects on drug therapy. Personalized medicine is a more recently coined term that includes pharmacogenetics/pharmacogenomics and refers to "an emerging practice of medicine that uses an individual's genetic profile to guide decisions made in regard to the prevention, diagnosis, and treatment of disease" (National Human Genome Research Institute, 2015) according to the National Institutes of Health (NIH). This term is now evolving to be "precision medicine."

We can think of pharmacogenomics as the basic science of personalized medicine, and indeed, much of the progress that has been made in the field of personalized medicine to date has been largely focused on pharmacogenomics.

This chapter is geared toward future clinicians, particularly nurse practitioners and physician assistants, to provide them with an overview of pharmacogenomics, the current state of the science, including some pertinent examples, some relevant applications, and promises, pitfalls, and policy implications.

Basic Concepts

Because pharmacogenomics is rooted in genetics, it is helpful to review some basic genetic concepts. Several of the definitions of key terms that are associated with genetics and pharmacogenomics can be found in Box 10.1.

BOX 10.1 Definitions

Adenine (A)—One of the four nucleotide bases. Pairs with thymine

Alleles—Multiple versions of a gene. Each person typically inherits two alleles of each gene, one from the mother and one from the father.

Biomarkers—Molecules that indicate the status of a biological process

Chromosome—The organized structure of DNA and proteins, the "double helix." It contains genes and nucleotide sequences.

Cytosine (C)—One of the four nucleotide bases. Pairs with guanine

DNA (deoxyribonucleic acid)—A nucleic acid that contains genetic information and/or instructions used in the function of living organisms

Exon is the portion of a gene that codes for amino acids

Gene—A sequence of DNA that codes for a type of protein or RNA, serving a particular function in a cell

Genome—All of the genetic material in chromosomes of an organism

Guanine (G)—One of the four nucleotide bases. Pairs with cytosine

Haplotype—A combination of alleles. A haplotype may be a single locus of alleles, multiple loci, or even an entire chromosome.

Nucleotide—Molecules that make up the structural units of DNA and RNA. The four DNA nucleotides are adenine, cytosine, guanine, and thymine. For RNA, uracil is substituted for thymine.

Personalized medicine—A more recently coined term that includes pharmacogenetics/pharmacogenomics and refers to "an emerging practice of medicine that uses an individual's genetic profile to guide decisions made in regard to the prevention, diagnosis, and treatment of disease" (National Human Genome Research Institute, 2015).

Pharmacogenetics refers to the study of inherited differences in single gene variations (called polymorphisms) or a few genes, in drug metabolism and response.

Pharmacogenomics refers to the effects of genome-wide (or an individual's entire DNA sequence) effects on drug therapy.

Polymorphism—DNA sequence variation

RNA (ribonucleic acid)—A nucleic acid that carries genetic information and produces proteins used in the function of living organisms

SNPs (single nucleotide polymorphism)—A DNA sequence variation occurring when

a single nucleotide differs between members of a species
Thymine (T)—One of the four nucleotide bases. Pairs with adenine
Wild type—The normal, as opposed to the mutant, gene, or allele

The human genome is the underpinning to every human's individuality. With the exception of identical twins, the genome is different for every individual, though in the grand scheme of things there are only small differences among people's DNA that make us unique. The human genome consists of approximately 3 billion base pairs, 99.9% of which are the same among all humans with only 0.1% variation among individuals. The variations that occur with DNA (polymorphisms), along with environmental and dietary factors, create a patient's individuality, susceptibility to disease, and response to treatments. Included in this individuality is a person's ability to absorb, distribute, metabolize, and excrete drugs. Understanding the genetic components affecting these pharmacokinetic processes can help the clinician tailor treatment for a patient.

Each human has 23 pairs of chromosomes—22 are autosomal and look the same in males and females, and 1 pair is the sex chromosome, in which females have two X chromosomes and males have an X and a Y chromosome (Figure 10.1). These chromosomes reside in the nucleus of a cell (Figure 10.2). Each chromosome is composed of DNA, which carries the genetic information for the individual. Each chromosome can have hundreds or thousands of genes; it is estimated that there are more than 25,000 genes on the human genome. However, genes only make up about 1% of the total DNA found in humans.

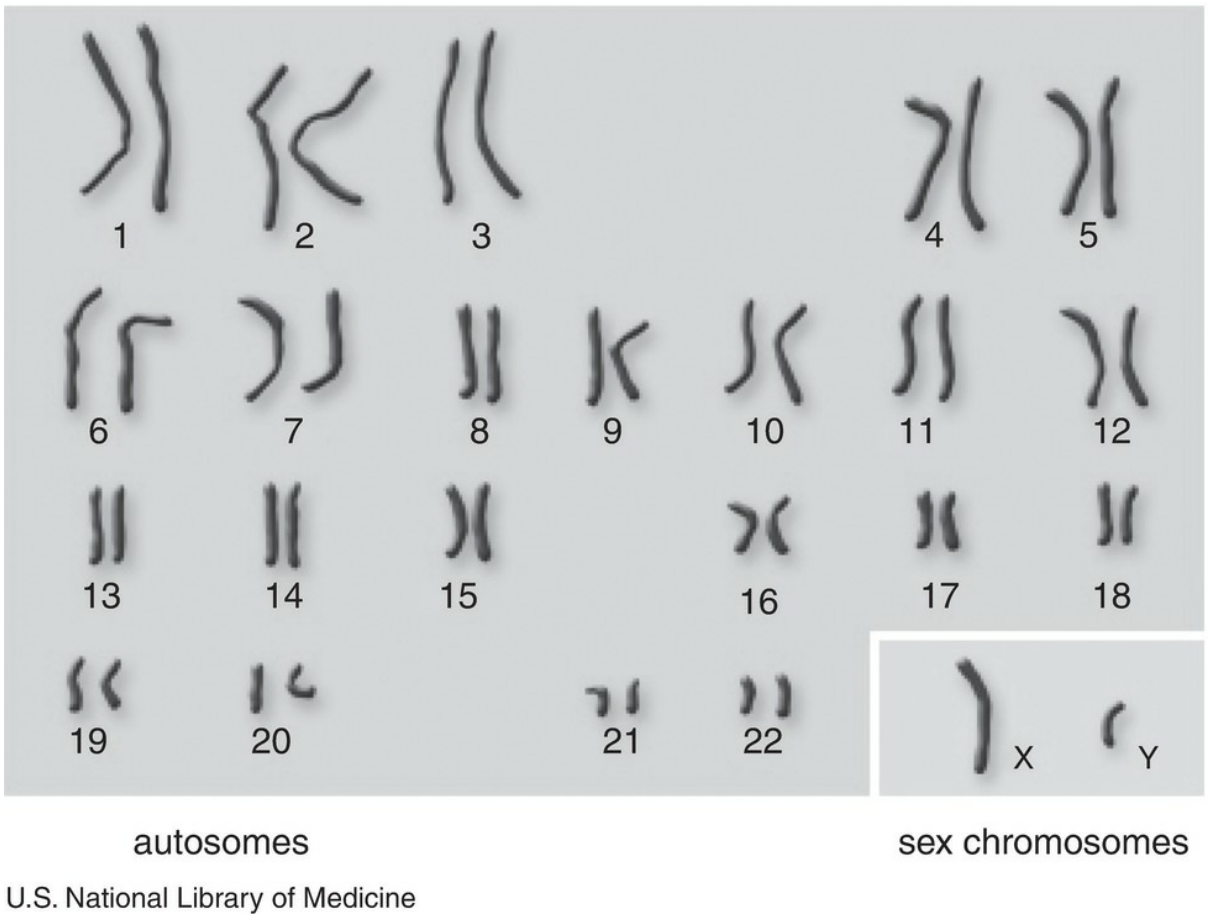

FIGURE 10.1 Human chromosomes. (Source: Genetics Home Reference [Internet] National Library of Medicine 2010. Retrieved from http://ghr.nlm.nih.gov/handbook/basics/howmanychromosomes. Cited December 30, 2010.)

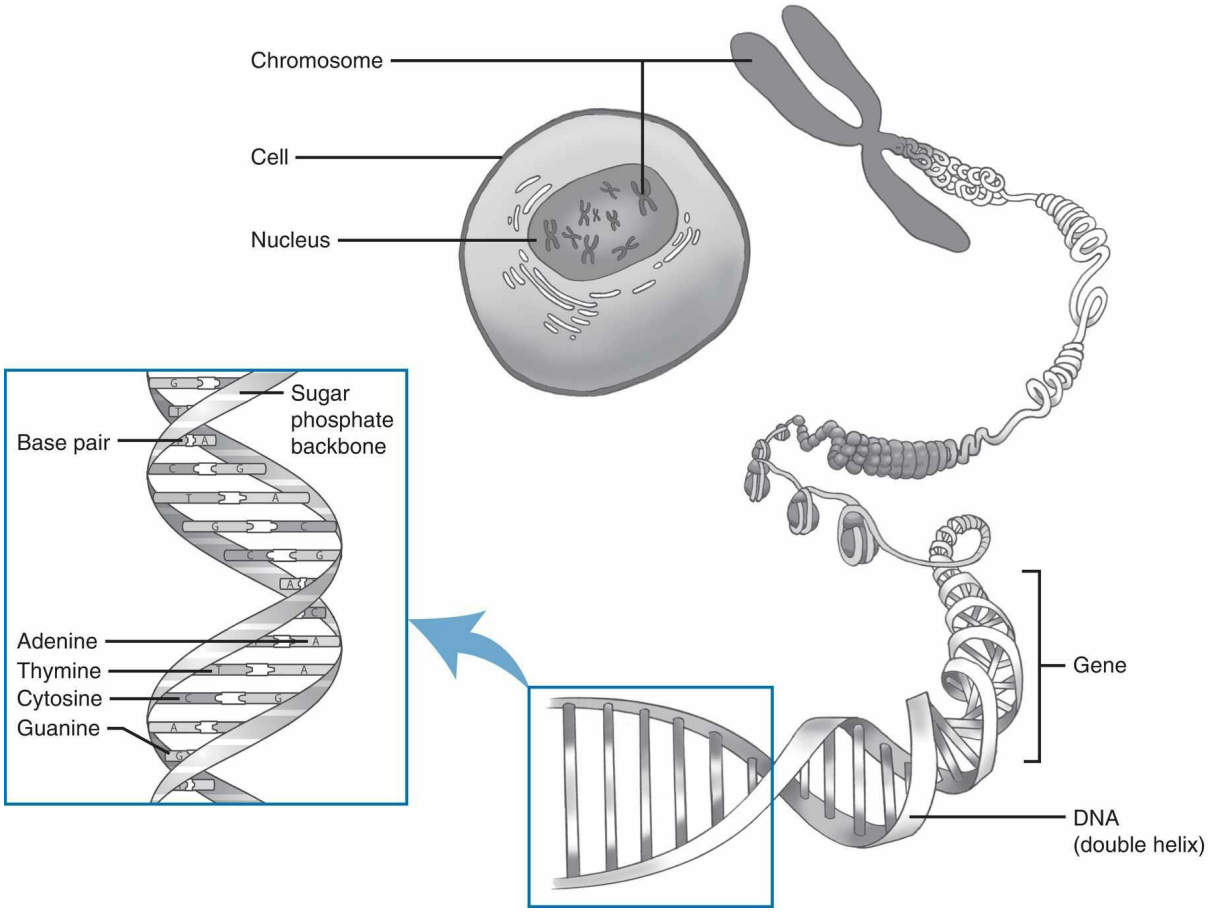

FIGURE 10.2 Relationship among human cell, chromosome, genes, and DNA.

Genes function to produce proteins involved in the millions of biological processes that support the function of the body every day. Genes that mutate or malfunction can have profound effects on the body. In the case in which a single gene mutates or malfunctions, the result is a monogenic disease, such as sickle cell anemia or cystic fibrosis. In most cases, however, there are multiple genes involved in the disease process. These are referred to as polygenic disorders.

Polygenic disorders may appear as a single clinical disorder but at the molecular level have multiple biomarkers. Biomarkers are molecules that indicate the status of a biological process. Examples of biomarkers include prostate-specific antigen (PSA) for prostate cancer or blood glucose level for diabetes. Genetic biomarkers, specific DNA sequences, are also being discovered.

The building blocks of DNA are the four nucleotide bases, including the two purines —adenine (A) and guanine (G)—and the two pyrimidines—thymine (T) and cytosine (C). DNA strands are linked through base pairing of the pyrimidines with the purines (A with T, G with C), conceptually forming the well-known double helix (see Figure 10.2). The arrangement of these base pairs along each chromosome is called the *DNA sequence*. Variations in the base pairings range from single nucleotide polymorphisms, insertions or

deletions of a nucleotide base, to changes in the number of copies of genes. These variations can alter the production or function of proteins, thus creating the variation in the expression of a disease or the response to drug therapy.

Single Nucleotide Polymorphisms

An SNP is a variation in the DNA sequence that differs between members of a species or paired chromosomes in an individual. For example, the following are two sequenced DNA fragments from different individuals: AAGCTA and AAGTTA. Note the only difference between these sequences is the substitution of thymidine (T) for cytosine (C). In this case, there are two versions (or alleles) of this gene. Each person typically inherits two alleles of each gene: one from the mother and one from the father. There can be up to 10 million SNPs in humans, but only those SNPs on coding regions of the gene or the area of the DNA responsible for turning genes on or off have an effect on humans. This concept of SNPs and differing alleles is important in the study of pharmacogenomics, as many of the genes responsible for drug activity and metabolism (e.g., cytochrome P-450 [CYP]) have different alleles on the same gene, producing different metabolic effects.

Clinical Applications of Pharmacogenomics

A major current issue in medical care is that many therapies given to patients to treat their diseases (e.g., cardiovascular, cancer, diabetes) are misaligned with the patient's genetic makeup. There are two main consequences that directly result from this lack of molecular knowledge at the time of drug treatment: (1) patients can be given a therapy that inefficiently treats the underlying cause of the disease (lack of therapeutic effect) and (2) patients can be given a medication that can lead to adverse drug reactions (ADRs) that can be harmful or even fatal due to a difference in their genetic makeup. Clinicians and health care professionals must understand and acknowledge that some patients could be genetically predisposed to respond differently to a given drug. This genetic information should then be utilized to assure tailored therapy and safety.

The main organ involved in detoxification/metabolism of drugs is the liver. The cytochrome P-450 (CYP) superfamilies of liver enzymes are key players in drug metabolism as they are directly involved in the modification and processing of approximately 75% of all medications taken (Di, 2014; Guengerich, 2004). The impact of genetic modifications in these CYP enzymes has therefore an important impact on patient treatment. The following examples are focused on genetic alterations in these CYP enzymes and their clinical implications.

Clopidogrel Metabolism and Polymorphism

The P-450 2C19 (CYP2C19) liver enzyme is one of the best characterized P-450 isoenzyme with clinical implications linked to this genetic polymorphism. The *CYP2C19* gene has nine exons and is situated on chromosome 10. To date, more than 30 different SNPs have been identified for this gene. Interestingly, several years ago, reports emerged that not all patients metabolized clopidrogel in a similar manner, regardless of their age or weight.

Clopidogrel is a very common medication that is prescribed to patients undergoing acute coronary syndrome (ACS). When patients arrive at the hospital with a partial coronary obstruction, antiplatelet agents are the gold standard in preventing irreversible cardiac ischemia. Clopidogrel is given as an inactive prodrug that is rapidly converted to its active metabolite via hepatic bioactivation through CYP2C19 enzymes (see Chapters 2 and 3 for a review of prodrugs and biotransformation). Clopidogrel inhibits ADP-mediated platelet activation and aggregation by irreversibly binding to the platelet purinergic receptor P2RY12. About 15% of clopidogrel is modified into an active compound and 85% is hydrolyzed to inactive forms to be excreted.

Due to its potent nature, a timely intervention with these pharmacological agents is essential in preventing further blockage and death making dosage key in attaining efficacious and safe treatment. The metabolism of clopidogrel to its active metabolite is critical to successful treatment, and thus, inherited genetic polymorphisms associated with *CYP2C19* have a high impact on the physiological responses to clopidogrel in patients. Genetic variants of the *CYP2C19* gene result in normal, reduced, or absent enzyme activity or can directly lead to an overactive enzyme. As summarized in Figure 10.3, different mutations are responsible for these levels of enzymatic activity. While CYP2C19*1 is the wild-type allele resulting in normal enzyme activity, the most common loss-of-function variant is referred to as CYP2C19*2 (681G>A) (Shuldiner et al., 2009). The CYP2C19*2 allele is inherited as an autosomal codominant trait that cosegregates mostly to Asian population and is less common in Caucasian and Africans (Scott et al., 2011). A much less common variant associated with a reduced or absent function of this enzyme is referred to as CYP2C19*3 (636G>A), which is only detected in less than 10% of the Asian population. The distribution of these mutations in patients dictates how patients metabolize clopidogrel. Around 2% to 15% of patients carry loss-of-function mutations (*2/*2,*2/*3,*3/*3) on both alleles resulting in significantly reduced or lack of CYP2C19 activity, and these patients are referred to as poor metabolizers (PM). Other individuals carry a gain-of-function mutation, which makes CYP2C19 more active (*1/*17,*17/*17); these patients are referred to as ultrarapid metabolizers (URM) and consist of about 5% to 30% of patient populations. Most patients, however, have either a normal *CYP2C19* gene

(*1/*1) without any mutations called extensive metabolizers (EM) or those with only one loss-of-function allele (*1/*2,*1/*3) are referred to as intermediate metabolizers (IM). Both EMs and IMs consist of 35% to 50% and 18% to 45% of a given population, respectively.

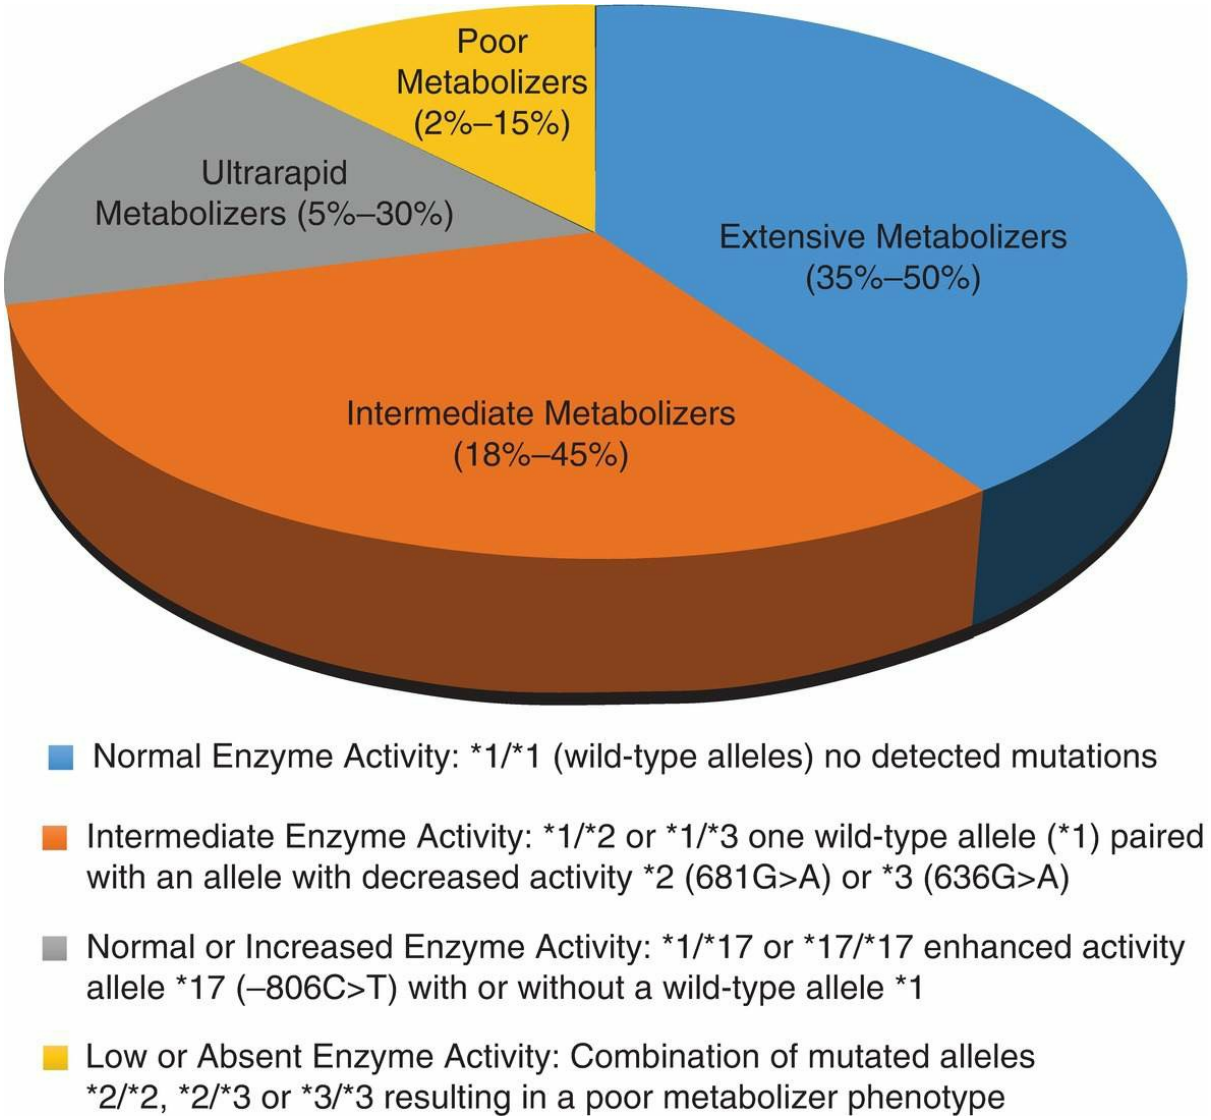

FIGURE 10.3 Clopidogrel therapy and CYP2C19.

Warfarin Metabolism and Polymorphism

Warfarin is a commonly prescribed blood thinner used to prevent atrial fibrillation–induced strokes, as well as permanent damage following the onset of venous thromboembolism or pulmonary embolism. Warfarin exists as a racemic mixture of R-warfarin and S-warfarin (Qayyum et al., 2015). S-warfarin possesses the most anticoagulant properties through its action as a vitamin K antagonist. Vitamin K plays a crucial role in the coagulation cascade as its reduced form acts as a cofactor of γ-glutamyl carboxylase, an important enzyme that renders the coagulation factors II, VII, IX, and X functional through postribosomal synthesis (Figure 10.4). Importantly, in order for the coagulation cascade to be fully active, vitamin K needs to be in its reduced form. This is accomplished by an upstream enzyme called vitamin K epoxide reductase complex, subunit 1 (VKORC1). VKORC1 is the therapeutic target of warfarin and its inhibition results in decreased amounts of reduced vitamin K preventing coagulation factors from being activated (Figure 10.4) (Pan et al., 2015). Once its therapeutic window is achieved, S-warfarin is rapidly metabolized through the P-450 liver enzyme CYP2C9 to its inactive oxidized form (7-hydroxy warfarin). The rate at which S-warfarin is metabolized is highly dependent on the enzymatic activity of CYP2C9. As one might expect, a less efficient metabolism and clearance of warfarin could lead to accumulation of its active form systemically leading to sustained anticoagulation effects. Indeed, several incidents have been reported where accidental deaths have occurred due to excessive bleeding following warfarin treatment. It was later discovered that some patients do not have a fully functional CYP2C9 enzyme due to alleles containing mutations, preventing the proper inactivation of the potent S-warfarin. There are two main CYP2C9 SNPs found in patients, *2 (R144C) and *3 (I359L), and *1 is referred to as the wild-type allele without mutations. The CYP2C9*1 individuals possess normal enzyme activity while CYP2C9*2 carriers exhibit a 30% decrease in activity and CYP2C9*3 patients have as much as 90% decrease in their enzymatic activity. Patients can carry two normal copies *1/*1, a normal copy and a polymorphic *1/*2, or could have both copies with polymorphism *2/*3. Clinical implication will be discussed below. The target enzyme VKORC1 has also shown the presence of inactivating mutation, the most common being -1639G>A.

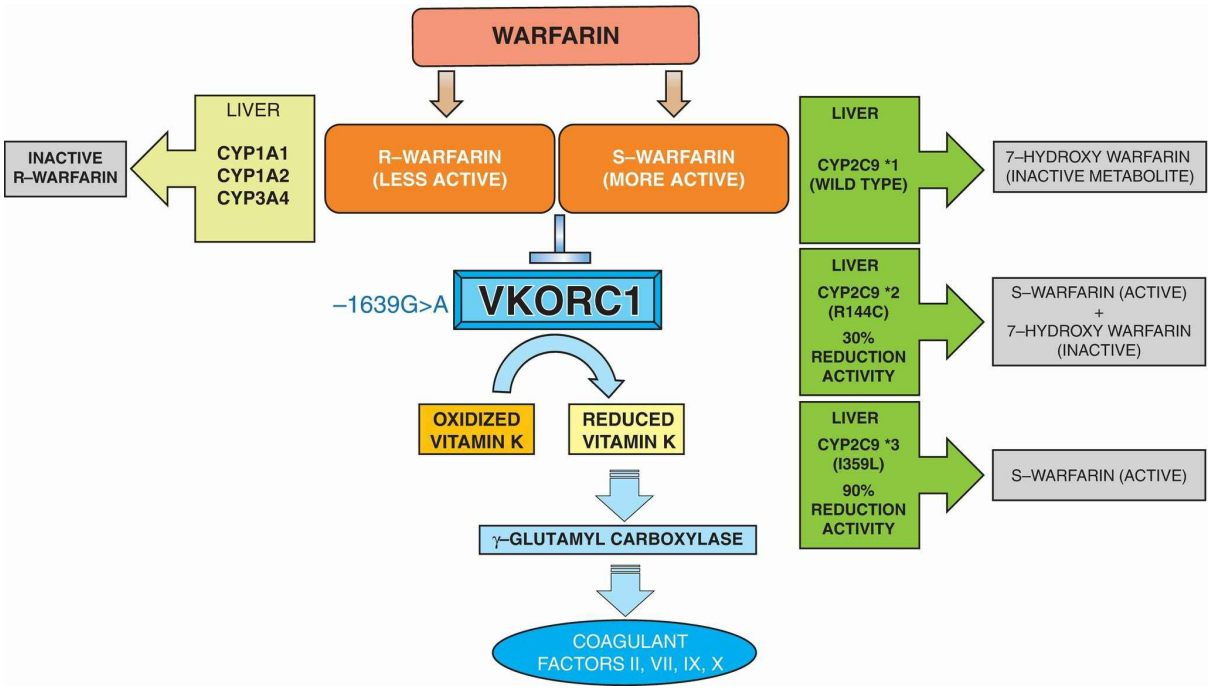

FIGURE 10.4 Warfarin therapy and VKORC1/CYP2C9 polymorphism.

Genetic Testing

The active metabolite of clopidogrel dictates its therapeutic efficacy. Therefore, the extent to which patients are capable of effectively producing these active metabolites through their liver CYP2C19 enzymes is directly linked to their treatment success and recovery from an ACS. In the case of clopidogrel, the PM are those who could benefit the most from genetic testing prior to therapy, as stated on package inserts and as suggested by the U.S. Food and Drug Administration (FDA). These PM are incapable of producing the active metabolite of clopidogrel and would suffer from an unsuccessful treatment of their coronary blockage. The Clinical Pharmacogenetics Implementation Consortium (CPIC) also recommends special attention be given to URM and that alternative therapies be used in PM to treat their coronary obstruction (Scott et al., 2011). In addition, IM are also challenging to treat with clopidogrel as these patients have a higher number of residual platelets, which could lead to adverse cardiovascular outcomes (Shirasaka et al., 2015) and might also benefit from other forms of therapy.

For patients receiving warfarin treatment, genetic testing is recommended in order to predict which patients are carrying these mutations who would be at higher risk of bleeding (Maluso, 2015). For example, those that carry the VKORC1 mutation 1639 G>A produce less VKORC1 (referred to as A haplotype) than those with the regular G allele (G haplotype). Consequently, the A haplotype individual would require less warfarin to inhibit VKORC1 to produce similar anticoagulant effects. The same is true for patients that carry CYP2C9 *2 and *3 where the active form of warfarin does not go through clearance normally leading to immediate excessive bleeding. As a consequence, the therapeutic index of this blood thinner is extremely narrow and needs to be carefully assessed. Genetic testing is thus highly suggested to assess those patients that are genetically predisposed to metabolize clopidogrel and warfarin differently. Genetic testing offers a knowledge of this genetic information ahead of time to predict the efficacy of these lifesaving drugs and guide the therapeutic window toward more successful therapy.

Promises, Pitfalls, and Policy Implications

In addition to pharmacogenomics, progress is being made with newer technologies such as next-generation sequencing (NGS) including whole genome sequencing (WGS), exome sequencing, and targeted RNA sequencing. Collectively, the rapid scientific developments are leading to a number of implications for policy, including both opportunities and challenges (Issa, 2015).

Pharmacogenomics and personalized medicine provide both economic opportunities and challenges. The cost of different pharmacogenomic tests continues to decline and there is increasing evidence for cost-effectiveness of pharmacogenomics, particularly its potential to reduce ADRs. It is also important to consider how pharmacogenomics might increase costs, including the storage of genetic samples, resources for computational analysis, and interpretation of the findings. While electronic health records (EHRs) and clinical decision support (CDS) systems are getting better and more user-friendly, they are generally not yet well equipped for the large amount of data that are being generated by the increasing amount of genomic information, particularly from WGS. In order for EHRs and CDS systems to become more useful for the greater implementation of pharmacogenomics and personalized medicine, a substantive investment in computational and clinical laboratory infrastructure has to be made at a national level.

Biobanks and handling of DNA samples present both scientific opportunities and policy challenges for regulatory agencies worldwide. Efforts to establish best practices and address regulation of processing, storage, and uses of samples are being undertaken by a number of national and international regulatory agencies including the FDA, the European Medicines Agency (EMA), Japan's Pharmaceuticals and Medical Devices Agency (PMDA), and Health Canada. One promising opportunity is that these agencies are working toward global harmonization of standards for the use of pharmacogenomic tests and targeted therapeutics.

Another area that is broadly presenting policy challenges involves ethical, legal, and social issues (ELSI) such as patient privacy and protection of data and genetic samples, return of results obtained within the context of research studies to patients, and decisions related to the use of genomic information and insurance coverage. Aimed at protecting Americans from future genetic discrimination, the *Genetic Information Nondiscrimination Act* (GINA) was passed in 2008 (GINA, 2008). However, a number of ELSI issues related to privacy and protection of genetic data remain to be addressed by legislators and policymakers. Issues surrounding education of health care providers and other stakeholders are also increasingly presenting barriers and challenges to the full implementation of pharmacogenomics. A number of studies have concluded that there remains a serious lack of knowledge of genetics and genomics on the part of clinicians. Steps are increasingly being taken to address the educational needs of current and future health care providers. Pharmacogenomics is being incorporated in the curricula of medical and pharmacy schools.

Guidelines for clinical competencies in genetics and genomics have been proposed for physician assistants (Rackover et al., 2007) and PA students and others would benefit from reviewing the guidelines.

Keeping up with Clinical Pharmacogenomic Science

The above discussion on the educational needs for future clinicians, including nurse practitioners and physician assistants, brings us to discuss how nurse practitioner or PA students can keep up with the state of science and clinical practice in pharmacogenomics. Although this is a rapidly evolving and fast-moving field, there are some resources that students and clinicians should be aware of and consult on a regular basis. Currently, there are over 150 U.S. FDA–approved drugs that incorporate pharmacogenomic information in the label (http://www.fda.gov/drugs/scienceresearch/researchareas/pharmacogenetics/ucm083378.htn In addition to the FDA Web site and the FDA's "Table of Pharmacogenomic Biomarkers in Drug Labeling," there are other useful Web sites. For example, the DailyMed project (http://dailymed.nlm.nih.gov/dailymed/index.cfm), administered by the National Library of Medicine of the National Institutes of Health (NIH), provides detailed information about "package inserts" of many prescription drugs, including pharmacogenomic information. The DailyMed Web site is user-friendly and has a powerful search engine, making it easy to navigate (National Library of Medicine, Daily Med Project).

The NIH also maintains the clinicaltrials.gov (National Library of Medicine, 2000) Web site, which is a mandatory listing of all clinical trials being conducted and this Web site includes information on the purpose of the clinical trial, the study's eligibility requirements, sites where the clinical study is being conducted, the status of patient recruitment and enrollment, and contact information for the investigators. Although clinicaltrials.gov is not restricted to pharmacogenomics and includes all ongoing trials, it is possible to search for pharmacogenomic studies, thereby allowing clinicians opportunities to learn more about the latest in clinical pharmacogenomic research, and possibly provide their patients with opportunities to enroll in specific trials.

Conclusion

In summary, among the most promising applications of pharmacogenomics is the potential to minimize or prevent ADRs. Progress has been made in the clinical implementation of pharmacogenomics, with several molecular companion diagnostics paired with targeted therapeutics. Many other biomarkers are currently being tested to predict response to therapies. However, to date, the implementation of pharmacogenomics into clinical practice has presented with various ELSI and policy challenges.

Case Study*

J.T. suffers from an irregular heart beat called atrial fibrillation. On a Sunday afternoon, his wife noticed as J.T. was watching the football game on television that his face started to droop and his speech seemed abnormal. She asked him to smile and his smile was all of sudden very uneven. After he arrives at the hospital, it is determined he is having a stroke as a consequence of his atrial fibrillation.

1. The therapy of choice for J.T. in this particular case is warfarin. However, following a few hours of warfarin therapy, J.T.' wife noticed several bruises appearing under his skin that seemed to be coming out of nowhere. From a genetic standpoint, what could be happening to J.T.?
   a. He could have a mutation in his liver CYP2C19 enzyme causing a 90% decrease in warfarin clearance leaving more S-warfarin in his blood causing excessive bleeding.
   b. He could have a mutation in his liver CYP2C9 enzyme causing a 90% decrease in warfarin clearance leaving more S-warfarin in his blood causing excessive bleeding.
   c. He could have a mutation in his liver CYP2C9 enzyme causing a 90% decrease in warfarin clearance leaving more R-warfarin in his blood causing excessive bleeding.
   d. He could have a mutation in his liver CYP1A1 enzyme causing a 90% decrease in warfarin clearance leaving more S-warfarin in his blood causing excessive bleeding.

2. Following genetic testing, it was discovered that J.T. can metabolize warfarin perfectly through his liver as all his CYP enzymes came back normal (no mutations). Which of the following options could thus explain his excessive bleeding?
   a. J.T. is A haplotype for VKORC1.
   b. J.T. is G haplotype for VKORC1.
   c. J.T. is T haplotype for VKORC1.

d. J.T. is C haplotype for VKORC1.

3. Knowing J.T. genetic testing results, what should be done concerning the dose of warfarin?
   a. A lower dose should be given.
   b. A higher dose should be given.
   c. No change in the dosage is necessary.
   d. No warfarin should be given to J.T. in the first place.

UNIT 2
Pharmacotherapy for Skin Disorders

11 Contact Dermatitis

Virginia P. Arcangelo

Dermatitis is an alteration in skin reactivity caused by exposure to an external agent. It is a combination of genetic and environmental factors. It can occur after a single exposure or multiple exposures to an agent or in response to an allergen. The resulting dermatitis usually appears as an inflammatory process. According to the American Academy of Dermatology, contact dermatitis is a common problem and results in approximately 5.7 million visits to health care providers each year. Almost any substance can be a potential irritant. Diaper dermatitis (sometimes called *diaper rash*) is the most common form of irritant contact dermatitis (ICD) in childhood.

Causes

Two types of contact dermatitis are irritant and allergic dermatitis. ICD results from exposure to any agent that has a toxic effect on the skin. *Allergic* contact dermatitis (ACD) results from exposure to an antigen that causes an immunologic response. Atopic dermatitis (eczema), a form of allergic dermatitis characterized as a pruritic, chronic inflammatory condition, affects between 5% and 10% of the population in the United States (Goodheart, 2008). It most often begins in childhood.

Pathophysiology

ICD is not an allergic response. It is a result of damage to the water–protein–lipid matrix of the outer layer of skin. It appears as an erythematous, scaly eruption resulting from friction, exposure to a chemical, or a thermal injury. The severity of the reaction depends on the condition of the skin, the concentration and the toxicity of the irritant, and the length of exposure. The reaction appears only in the area exposed to the irritant.

ACD (e.g., poison ivy) is an immunologically mediated response to an allergen (antigen). During the initial sensitization phase, the host is immunized to the allergen. After reexposure, a more rapid and potent secondary immune response occurs. The second phase manifests in ACD, and T cells are key mediators of the reaction. On activation, T cells release cytokines, chemokines, and cytotoxins, causing stimulation of local blood vessels; recruitment of immune cells, such as macrophages and eosinophils; and subsequent amplification of the sensitization response. Within 5 to 7 days after sensitization, there is visual evidence of the response. On subsequent exposures, however, dermatitis may develop within 6 to 18 hours. Hypersensitivity can occur after one exposure or after years of repeated exposures. Contact dermatitis may spread extensively beyond the area of contact.

In atopic dermatitis, there are high concentrations of serum immunoglobulin (Ig) E, decreased numbers of immunoregulatory T cells, defective antibody-dependent cellular cytotoxicity, and decreased cell-mediated immunity. The pathogenesis of atopic dermatitis involves genetic factors, skin barrier defects, and immune dysregulation. The genetics of atopic dermatitis is an area of intense research and plays a significant role in IgE production and allergic sensitization. More recently, the association of atopic dermatitis with filaggrin (FLG) gene mutations suggests the role of skin barrier defects in the pathogenesis of atopic dermatitis. FLG is a protein essential to the normal barrier function of the skin. Deficiency in FLG may contribute to the physical barrier defects in atopic dermatitis and predispose patients to increased transepidermal water loss, infection, and inflammation associated with the exposure of cutaneous immune cells to allergens.

Pharmacogenomics

A genetic basis for atopic dermatitis has long been recognized with a family history of disease as a risk factor. Before characterization of the human genome, heritability studies combined with family-based linkage studies supported the definition of atopic dermatitis as a complex trait in which interactions between genes and environmental factors and the interplay between multiple genes contribute to disease manifestation. The gene encoding FLG has been most consistently replicated as associated with atopic dermatitis. Most gene studies to date have focused on adaptive and innate immune response genes, but there is increasing interest in skin barrier dysfunction genes (Barnes, 2010).

Diagnostic Criteria

ICD and ACD appear as linear streaks of papules, vesicles, and blisters that are very pruritic. In ICD, the lesions are found only in the area of exposure to the irritant. In ACD, the lesions are usually more diffuse, and they may present over an underlying area of edema.

Lesions in atopic dermatitis include papules, erythema, excoriations, and lichenification. In infants, the face, chest, legs, and arms are the most commonly involved areas; lesions are scaly and red and may be crusted patches and plaques. In children, the most common sites are the antecubital and popliteal fossae, the neck, wrists, ankles, eyelids, scalp, and behind the ears. Lesions are usually lichenified because of constant scratching. In adults, the neck, antecubital and popliteal fossae, face, wrist, and forearms are the most commonly involved areas. Lesions may appear as poorly defined, pruritic, erythematous papules and plaques. This may present specific therapeutic opportunities; however, at this time, maintaining a normal epidermal barrier is key.

Initiating Drug Therapy

The most effective form of treatment for contact dermatitis is prevention. The patient must become aware of the causes or triggers and plan ways to avoid them. Before initiating therapy, the practitioner first needs to determine the severity of the problem. If the symptoms are mild, cool compresses may offer relief, and baths with colloidal oatmeal may offer relief from pruritus. Compresses of Burow solution are effective for drying the vesicles and bullae that may be associated with contact dermatitis. If these treatments fail or if the dermatitis is more extensive, drug therapy is initiated.

Before initiating drug therapy, delivery of the drug to the skin, protection/barrier function, and cosmetic acceptability must be considered. Ointment and gels offer the best delivery and protection barrier. Creams are less greasy but less effective. Lotions are dilute creams. Solutions are alcohol-based liquids and are useful for treating the scalp because they do not coat the hair.

Moisturizers used generously and frequently increase skin hydration, and their lipid component improves the damaged skin barrier. Lipid-rich moisturizers both prevent and treat ICD.

Barrier creams containing dimethicone or perfluoropolyethers, cotton liners, and softened fabrics help to prevent ICD.

Goals of Drug Therapy

The goals of drug therapy for dermatitis are as follows:

- Restoration of a normal epidermal barrier
- Treatment of inflammation of skin
- Control of itching

The mainstays of therapy for contact dermatitis are topical corticosteroids. There are also topical immunosuppressives available. Systemic corticosteroids are recommended for widespread symptoms, and antihistamines are used for relieving intense pruritus.

For mild or moderate localized dermatitis, topical corticosteroids applied twice daily are usually effective within a few days and should be continued for 2 weeks. Lower-potency agents should be applied to the face and intertriginous areas, and higher-potency steroids should be reserved for the extremities and torso. Topical calcineurin inhibitors (e.g., tacrolimus or pimecrolimus) may be used as an alternative to low-potency topical corticosteroids in chronic ICD.

Emollients or occlusive dressings may improve barrier repair in dry, lichenified skin. Traditional petrolatum-based emollients are accessible and inexpensive, and they have been shown to be as effective as an emollient containing skin-related lipids. To relieve pruritus, a lotion of camphor, menthol, and hydrocortisone (Sarnol-HC) is soothing, drying, and antipruritic. Pramoxine, a topical anesthetic in a lotion base (Prax), can also relieve pruritus.

Topical Corticosteroids

Topical steroidal therapy is safer than systemic steroidal therapy. Steroidal agents are effective for smaller outbreaks. Because of their anti-inflammatory and antimitotic actions, they reduce inflammation and the buildup of scale.

Topical corticosteroids are classified according to potency (Table 11.1), with the fluorinated agents being more potent. Ideally, the least potent topical corticosteroid should be used for the shortest possible time in treating dermatitis. Topical corticosteroids should be avoided if there are additional bacterial, viral, or fungal skin infections, and they are not recommended for prophylaxis.

TABLE 11.1 Classification of Topical Corticosteroids by Potency

Low Potency	Intermediate Potency	High Potency	Very High Potency
alclometasone dipropionate 0.05% (Aclovate—c, o)	betamethasone valerate 0.12% (Luxiq foam)	amcinonide 0.1% (Cyclocort—c, l, o)	betamethasone dipropionate augmented 0.05% (Diprolene—o, g)
fluocinolone acetonide 0.01% (Synalar—s)	desonide 0.05% (DesOwen—c, l, o, Tridesilon—c, o)	betamethasone dipropionate augmented 0.05% (Diprolene AF—emollient cream, Diprolene—lotion)	clobetasol propionate 0.05% (Temovate—c, g, o, scalp preparation, Temovate-E—emollient cream, Clobex, Cormax, Olux)
hydrocortisone base or acetate 0.5% (Cortisporin—c, Mantadil—c)	desoximetasone 0.05% (Topicort LP—emollient cream)	desoximetasone 0.05% (Topicort—g)	diflorasone diacetate 0.05% (Psorcon—o)
hydrocortisone base or acetate 1% (Cortisporin—o, Hytone [1% or 2.5%]—c, l, o, Proctocort—c, Vytone—c)	fluocinolone acetonide 0.025% (Synalar—c, o)	desoximetasone 0.25% (Topicort—emollient cream, o)	fluocinonide 0.1% (Vanos—c)
triamcinolone acetonide 0.025% (Aristocort—c, Aristocort A—c, Kenalog—c, l, o)	flurandrenolide 0.025% or 0.05% (Cordran SP—c, Cordran—o)	diflorasone diacetate 0.05% (Florone—o, Psorcon—c)	flurandrenolide 4 mcg/sq c (Cordran tape)
	fluticasone propionate 0.005% or 0.05% (Cutivate—o 0.005%, c 0.05%)	fluocinonide 0.05% (Lidex—c, g, o, s, Lidex-E—emollient cream)	halobetasol propionate 0.05% (Ultravate—c, o)
	hydrocortisone butyrate 0.1% (Pandel—c)	halcinonide 0.1% (Halog—c, o, s, Halog-E—emollient cream)	
	hydrocortisone butyrate 0.1% (Locoid—c, o, s)	triamcinolone acetonide 0.5% (Aristocort—c, o, Aristocort A—c, Kenalog—c)	
	hydrocortisone valerate 0.2% (Westcort—c, o)		
	mometasone furoate 0.1% (Elocon—c, o, l)		
	prednicarbate 0.1% (Dermatop—emollient cream)		
	triamcinolone acetonide 0.1% (Aristocort—c, o, Aristocort A—c, o, Kenalog—c, o)		
	triamcinolone acetonide 0.2% (Kenalog—aerosol)		

c, cream; l, lotion; o, ointment; g, gel; s, solution.

Dosage

Treatment may be initiated with an intermediate- or high-potency topical corticosteroid. A lower-potency corticosteroid may be used after the symptoms subside. As a rule, short-term therapy with more potent topical corticosteroids is preferred to longer-term therapy with less potent corticosteroids. Low-potency corticosteroids should be used in the facial and intertriginous regions because fluorinated and high-potency corticosteroids applied to the face may cause atrophy of the tissue or trigger steroidal rosacea. If it is necessary to use

either type of agent, use should be limited to a very brief time. The maximum recommended length of treatment with topical corticosteroids is 2 weeks for adults and 1 week for children.

Preparations

Topical corticosteroids are available in creams, ointments, lotions, gels, solutions, or sprays. Creams are the most desirable because they are not as obvious when applied. They are, however, water based, which causes more skin drying. Ointments and gels are the most potent and the most lubricating, and they have occlusive properties. In areas with large amounts of hair or widespread dermatitis, lotions, gels, spray products, and solutions are easiest to apply. Occlusion by a dressing of an area of a topical corticosteroid application increases hydration and hence penetration, thereby enhancing efficacy.

Correct Usage

Tolerance to a topical corticosteroid is common. To prevent this, chronic use is not recommended. Using the topical corticosteroid preparation only in the case of recurrence of contact dermatitis, and not prophylactically, or prescribing intermittent dosing (e.g., every 4 days) may be effective methods of controlling tolerance.

Application

Penetration of a topical corticosteroid is enhanced when the skin is hydrated. This can be accomplished by moistening the skin before application or by using an occlusive dressing constructed from a material such as a plastic shower cap (for the scalp), gloves (for hands), or plastic wrap or a sock (on other extremities).

Adverse Events

Although topical corticosteroids are relatively safe to use, some adverse events may occur (Table 11.2). The prolonged use of fluorinated corticosteroids on the face can cause atrophy and acne-like eruptions. This usually is seen after therapy stops and may last for several months. With prolonged use, ecchymoses may develop on the arms in elderly patients. Moreover, epidermal atrophy, manifested by striae; shiny, thin skin; or telangiectases, can occur with prolonged use, or a hypersensitivity reaction may occur, usually in response to the vehicle in which the medication is delivered. Frequent and prolonged use of topical corticosteroids in fold areas can cause atrophy, telangiectasia, or striae, and their use on the face can also cause steroid rosacea. Topical corticosteroids can potentiate or cause cataract formation or glaucoma when used around the eyes for prolonged periods.

TABLE 11.2 Topical Corticosteroids Used for Contact Dermatitis: Selected Adverse Events and Special Considerations

	Selected Adverse Events	Special Considerations
See Table 11.1 for listing of topical corticosteroids by potency.	Skin irritation Acneiform lesions Striae Skin atrophy Burning Irritation Pruritus Erythema Folliculitis	Applying to moist skin and covering with occlusive dressing increase efficacy except with very high–potency topical corticosteroids Can cause or intensify cataracts or glaucoma if used near eyes Use lowest potency on thin/atrophic skin and children. Pregnancy category C
Topical Immunosuppressants		
pimecrolimus (Elidel) 1% tacrolimus (Protopic) 0.03%, 0.1% Apply a light layer BID For use in children age 2 years and older	Skin burning Pruritus Flu-like symptoms Erythema	Do not use with occlusive dressing. Apply for 1 week after clearing. Pregnancy category C Not recommended for children under age 2

Systemic Corticosteroids

If the dermatitis is widespread or resistant to treatment with topical steroidal preparations, oral corticosteroids may be used. Systemic corticosteroids inhibit cytokine and mediator release, attenuate mucus secretion, upregulate beta-adrenergic receptors, inhibit IgE synthesis, decrease microvascular permeability, and suppress the influx of inflammatory cells and the inflammatory process.

Systemic corticosteroids are prescribed in a tapering dose schedule. The starting dose of 1 mg/kg is decreased by 5 mg every 2 days for 2 to 3 weeks. The entire dose of steroids can be taken at the same time in the morning. This will minimize sleep disturbances. Taking the corticosteroids for less than 2 weeks may cause rebound dermatitis, especially with poison ivy. If dermatitis flares up during the tapering, the dosage can be increased and tapered again.

Although these medications are readily absorbed when taken orally, peak plasma concentrations are not achieved for 1 to 2 hours. For more information about systemic corticosteroids, refer to Chapter 25.

Contraindications

Because they suppress the immune response, systemic corticosteroids are contraindicated in patients with systemic mycoses and in patients receiving a vaccination. These drugs also should be used cautiously in people with tuberculosis, hypothyroidism, cirrhosis, renal insufficiency, hypertension, osteoporosis, and diabetes mellitus.

Adverse Events

Systemic corticosteroids mask infection. In short-term use, they may cause gastrointestinal upset. Mood changes (hyperactivity, anxiety, depression) may be evident and sleep disturbances may occur, especially if medication is taken late in the day. The effects of systemic corticosteroids may be decreased if they are administered with barbiturates, hydantoins, or rifampin.

Topical Immunosuppressives

Topical immunosuppressives act on T cells by suppressing cytokine transcription. These agents are used in patients with moderate to severe atopic dermatitis who cannot tolerate topical steroids or are not responsive to other treatments or where there is a concern for topical steroid–induced atrophy. Because they do not cause skin atrophy, these medications are especially useful for the treatment of atopic dermatitis involving the face, including the periocular and perioral areas.

Tacrolimus and pimecrolimus are the preparations currently available. They are applied twice a day until the lesions clear and then for an additional 7 days. The skin is dried before application.

Contraindications

Care should be used when administering these drugs with drugs in the CYP3A family. The drugs should not be used under occlusive dressings.

Adverse Effects

There can be transient burning and pruritus, which disappear with continued use. The concomitant ingestion of alcohol can cause redness and flushing. Sun protection is recommended.

Antihistamines

Antihistamines are used to relieve pruritus associated with contact dermatitis. The best time to use them is before bed to promote sleep because the main side effect is drowsiness. Antihistamines are discussed in Chapter 47.

Selecting the Most Appropriate Agent

In contact and atopic dermatitis, topical corticosteroids are the first line of therapy (see Table 11.1). These agents are for short-term use. The recommended treatment order is listed in Table 11.3.

TABLE 11.3 Recommended Order of Treatment for Contact Dermatitis

Order	Agent	Comments
First line	Apply low-potency topical corticosteroid two times a day. Take oral antihistamine for relief of symptoms.	Occlusive dressing is helpful. Apply to moist skin surface. Use only for 14 d in adult and 7 d in child.
Second line	Increase potency of topical corticosteroid.	Avoid using moderate- or high-potency topical corticosteroid on face or intertriginous areas.
Third line	Prescribe oral corticosteroid on tapered-dosage regimen.	Common dosage: 1 mg/kg decreased by 5 mg every 2 d Continue therapy for at least 2 wk. Consider increasing dose if dermatitis flares up; then, taper as above.

First-Line Therapy

A topical corticosteroid preparation with low to intermediate potency applied twice a day is the appropriate first-line therapy. If improvement does not occur, a higher-potency topical corticosteroid may be tried rather than increasing the time of administration of the lower-potency agent. Occlusive dressings and application to moist skin may be efficacious in treating the acute phase. Low-potency topical corticosteroids are used on the face and intertriginous areas. Oral antihistamines are used to relieve pruritus and reduce the response to the cause.

Second-Line Therapy

Second-line therapy calls for a more potent topical corticosteroid. Topical immunosuppressants are another consideration for second-line therapy.

Third-Line Therapy

Systemic corticosteroids are useful for treating widespread dermatitis. They are given on a tapered-dose schedule. The recommended dose is 1 mg/kg, with the dose decreased every 2 days for at least 2 weeks and up to 3 weeks. If a flare-up occurs during the tapering, the dosage can be increased again. When treating severe poison ivy, for example, oral corticosteroids are continued for 2 to 3 weeks to prevent rebound dermatitis, which may occur if therapy is discontinued before that time.

Figure 11.1 provides an algorithm of contact dermatitis treatment.

FIGURE 11.1 Treatment algorithm for contact dermatitis.

Special Populations

Pediatric

Topical corticosteroids should be used for only 7 days in children younger than age 6 and at the lowest potency. Topical corticosteroids can cause atrophy of the skin. Topical immunosuppressants are considered only for patients age 2 and older. Topical immunosuppressants will not cause atrophy of the skin.

Geriatric

The most common causes of contact dermatitis in elderly patients are topical medications (e.g., neomycin [Myciguent]) and the bases of other topical medications. The adhesives on adhesive patches may also cause contact dermatitis. The rash of contact dermatitis does not present in a classic pattern in the elderly. Instead of vesicles or inflammation, the area exposed to the irritant may simply become scaly. Topical corticosteroids can cause atrophy of the skin in elderly people, which is a problem because their skin is already friable.

Monitoring Patient Response

The response to therapy is monitored by visual examination of the affected parts of the anatomy and the reported resolution of symptoms. The patient should return for follow-up evaluation within 2 or 3 days of initiation of therapy. If a bacterial infection recurs secondary to contact dermatitis, it may be treated as discussed in Chapter 14.

Patient Education

Drug Information

Education includes teaching patients to avoid the causative substance. Using mild soaps without perfume is an important preventive measure. As appropriate, the practitioner can demonstrate how to apply topical preparations to moist skin and apply an occlusive dressing to increase the efficacy of topical corticosteroids. Penetration of topical steroids is enhanced 10- to 100-fold by hydrating (moistening) the area before applying the medication. An easy-to-make occlusive dressing consists of plastic wrap applied over the medicated area and held in place by a sock or tape. On the hands, a glove can act as an occlusive dressing. On the head area, a shower cap can be used.

Occlusive dressings should not be used with topical immunosuppressants. The patient should avoid alcohol and should use sunscreen.

Most patients with atopic dermatitis require hydration through the liberal use of bland emollients, which serve to hydrate the stratum corneum and maintain the lipid barrier. Sufficient emollients applied liberally several times a day may be enough to significantly reduce the disease activity of atopic dermatitis. Parents of infants and toddlers should apply a bland emollient to the entire body with each diaper change. Older children should apply bland emollients in the morning, after school, and at bedtime. Bathing should be limited to brief, cool showers once daily. Soap, which dries and irritates the skin, should be avoided, but gentle lipid-free cleansers are beneficial.

Skin hydration is best accomplished through daily soaking baths for 10 to 20 minutes. It is important to remind patients and caregivers to apply a topical medication or moisturizer immediately after bathing. This is to seal in the water that has been absorbed into the skin and to prevent evaporation that can lead to further drying of the skin.

Complementary and Alternative Medicine

Some supplements are thought to be helpful in atopic dermatitis. Ginkgo biloba antagonizes platelet-aggregating factors, a key chemical mediator in atopic dermatitis. Zinc can be used at a dosage of 50 mg/day until the condition clears. Use of fish oil supplements incorporates omega-3 fatty acids into the membrane phospholipid pools.

Recommendations for supplements are as follows:

- Vitamin A 50,000 international units daily
- Vitamin E 400 international units daily
- Zinc 50 mg daily, to be decreased as the condition clears
- EPA 540 mg and DHA 360 mg daily or flaxseed oil 10 g daily
- Evening primrose oil 3,000 mg daily

Case Study*

J. F., a 15-year-old boy who weighs 110 pounds, is seeking treatment for a very itchy rash consisting of linear streaks of papules, vesicles, and blisters on his arms, legs, and face. He tells you he was hiking in the woods 2 days ago along trails lined with patches of shiny weeds with three leaves. He tried using calamine lotion and over-the-counter hydrocortisone cream but has had no relief from the itching.

Diagnosis: Contact Dermatitis (Poison Ivy)

1. List specific goals of treatment for J. F.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and alternative medications would be appropriate for J. F.?
8. What lifestyle changes would you recommend to J. F.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

12 Fungal Infections of the Skin

Virginia P. Arcangelo

Fungi live in the dead, horny outer layer of the skin. The organisms penetrate only the stratum corneum—the surface layer of the skin—and infect the skin, hair, and nails. They cause tinea, tinea versicolor, and candidiasis.

Tinea

Dermatophytes are a group of fungi that infect nonviable keratinized cutaneous tissues. Dermatophytosis, more commonly called *tinea*, is a condition caused by dermatophytes. Tinea is further classified by the location of the infection (Box 12.1).

BOX 12.1 Varieties of Tinea Infections

Tinea infections are identified by their location on the body as follows:

- Head: tinea capitis
- Body: tinea corporis
- Hand: tinea manus
- Foot: tinea pedis
- Groin: tinea cruris
- Nails: tinea unguium (onychomycosis)

Tinea capitis primarily affects children ages 3 to 9. This age group may also be infected with tinea corporis. *Tinea pedis* most commonly affects the adolescent population and young adults. Immunocompromised patients have an increased incidence and more intractable dermatophytosis. *Tinea unguium*, infection of the nails, is also called *onychomycosis*. It is caused by various yeast, fungi, and molds.

Causes

General factors that predispose to fungal infections include warm, moist, occluded environments, family history, and a compromised immune system. Infection is spread from person to person by animals, especially cats and dogs, and by inanimate objects.

Pathophysiology

Dermatophytes grow only on or within keratinized structures. Most infections result from five specific species of fungus: *Trichophyton rubrum*, *Trichophyton tonsurans*, *Trichophyton mentagrophytes*, *Microsporum canis*, and *Epidermophyton floccosum*. These can be found on humans, on animals, and in the soil. They produce enzymes (keratinases) that allow them to digest keratin, causing epidermal scale; thickened, crumbly nails; or hair loss.

Diagnostic Criteria

General symptoms of fungal infections in hair and skin include pruritus, burning, and stinging of the scalp or skin. An inflammatory dermal reaction may cause erythema and vesicles. Diagnosis is confirmed by several mechanisms. One mechanism is microscopic evaluation of the stratum corneum with 10% potassium hydroxide (KOH) preparation. At the margin of the lesion, scale is scraped with a No. 15 knife blade and placed on a slide. KOH is then added and the slide inspected under the microscope. Fungi appear as rod-shaped filaments with branching.

Another mechanism for diagnosis is the fungal culture. A specimen of infected tissue is applied to a dermatophyte test medium on an agar plate. If the infecting organism is a fungus, the plate will change color—from yellow to pink or red—in approximately 2 weeks.

A third diagnostic method involves using a Wood lamp, which produces a bright green fluorescence in the presence of a tinea infection caused by *Microsporum* species. A major disadvantage of this test is that other fungal infections may be undiagnosed because the Wood lamp test identifies only *Microsporum*.

Tinea Capitis

Presentation of tinea capitis varies widely. There may be generalized, diffuse seborrheic dermatitis-like scalp scaling, although more common signs and symptoms include impetigo-like lesions with crusting and redness, areas of hair loss with broken hairs, and possibly inflammatory nodules. Although often impressive, cervical lymphadenitis does not correlate with the extent of scalp inflammation. Finally, approximately 15% of patients have a cross-infection with tinea corporis. Most cases of tinea capitis are found in prepubertal children, with a disproportionate amount in African Americans. It is very contagious.

Most cases (90%) are caused by *T. tonsurans*. *Microsporum audouinii*, spread from human to human, and *M. canis*, spread from animals, are other organisms.

Tinea capitis presents in several ways:

- Inflamed, scaly, alopecic patches, especially in infants
- Diffuse scaling with multiple round areas with alopecia secondary to broken hair shafts, leaving residual black stumps
- "Gray patch" type with round, scaly plaques of alopecia in which the hair shaft is broken off close to the surface
- Tender, pustular nodules

Tinea Corporis

Tinea corporis is called "ringworm" when it affects the face, limbs, or trunk, but not the groin, hands, or feet. The typical presentation of tinea corporis is a ring-shaped lesion with well-demarcated margins, central clearing, and a scaly, erythematous border. It is caused by contact with infected animals, by human-to-human transmission, and from infected mats in wrestling. The organisms responsible are *M. canis*, *T. rubrum*, and *T. mentagrophytes*.

Tinea Cruris

Tinea cruris is often referred to as *jock itch*. A fungal infection of the groin and inguinal folds, tinea cruris spares the scrotum. The most common causes are *T. rubrum* or *E. floccosum*. Typically, the lesion borders are well demarcated and peripherally spreading. The lesions are large, erythematous, and macular, with a central clearing. A hallmark of tinea cruris is pruritus or a burning sensation. There is often an accompanying fungal infection of the feet.

Tinea Pedis

Interdigital tinea pedis, commonly called *athlete's foot*, is characterized by scaling and itching in the web spaces between the toes and sometimes denudation and sodden maceration of the skin. Another variation is inflammatory tinea pedis, which presents with vesicles involving the toes or instep. A third variety is the moccasin style, which presents with itching, chronic noninflammatory scaling, and thickness and cracking of the epidermis on the sole, heel, and often up the side of the foot. This is a common problem in young men.

Most cases are caused by *T. rubrum*, which evokes a minimal inflammatory response. The *T. mentagrophytes* organism produces vesicles and bullae.

There are three types of tinea pedis:

- Interdigital, which presents as scaling, maceration, and fissures between the toes
- Plantar, which presents as diffuse scaling of the soles, usually on the entire plantar surface
- Acute vesicular, which presents as vesicles and bullae on the sole of the foot, the great toe, and the instep

Tinea Manus

Tinea manus is a dermatophyte infection of the hand. This is always associated with tinea pedis and is usually unilateral. The lesions are marked by mild, diffuse scaling of the palmar skin, and vesicles may be grouped on the palms or fingernails involved.

Tinea Unguium

Tinea unguium (onychomycosis) is a fungal infection of the nail. Typically affected are the toenails, which become thick and scaly with subungual debris. Onycholysis, a separation of the nail from the nail bed, may be seen. The infection usually begins distally at the tip of the toe and moves proximally and through the nail plate, producing a yellowish discoloration and striations in the actual nail. Under the nail, a hyperkeratotic substance accumulates that lifts the nail up. If untreated, the nail thickens and turns yellowish brown. Onychomycosis is usually asymptomatic but can act as a portal of entry for a more serious bacterial infection.

Organisms causing onychomycosis include dermatophytes, *E. floccosum*, *T. rubrum*, *T. mentagrophytes*, *Candida albicans*, *Aspergillus*, *Fusarium*, and *Scopulariopsis*.

Some health insurance plans refuse to reimburse for drug therapy without confirmation of the diagnosis. Tests that verify the diagnosis include the KOH test and culture.

Initiating Drug Therapy

Fungal infections can be prevented by applying powder containing miconazole (Monistat) or tolnaftate (Tinactin) to areas prone to fungal infections after bathing. The areas can be dried completely with a hair dryer on low heat.

Goals of Drug Therapy

Pharmacologic therapy is directed against the offending fungus and the site of infection. Therapy is topical or systemic, depending on the location of the lesion. Topical therapy is used for most skin infections. The exceptions are tinea capitis and tinea unguium (onychomycosis).

Topical Azole Antifungals

Topical azoles (Table 12.1) impair the synthesis of ergosterol, the main sterol of fungal cell membranes. This allows for increased permeability and leakage of cellular components and results in cell death. Topical azoles are fungicides that are effective against tinea corporis, tinea cruris, and tinea pedis as well as cutaneous candidiasis. They should be applied once or twice a day for 2 to 4 weeks. Therapy should continue for 1 week after the lesions clear. However, therapy is not recommended during pregnancy or lactation and is administered cautiously in hepatocellular failure. Ketoconazole (Nizoral), in particular, should be avoided in patients with sulfite sensitivity. Adverse effects include pruritus, irritation, and stinging.

TABLE 12.1 Overview of Antifungal Medications

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Topical Agents			
clotrimazole ointment (Lotrimin), powder (Desenex). Gently massage ointment into affected and surrounding skin areas bid × 4 wk; powder as needed.	Erythema, irritation, stinging, pruritus	Pregnancy or lactation Use cautiously in patients with hepatocellular failure	May be purchased OTC
miconazole (Micatin, Monistat Derm). Cover affected areas with cream lotion or powder bid for 2–4 wk.	Irritation, maceration	Pregnancy or lactation	Avoid applying near eyes.
ketoconazole (Nizoral). Apply to affected and surrounding areas once daily for 2–4 wk.	Irritation, stinging, pruritus	Asthma Not administered to people who are sensitive to sulfites Pregnancy or lactation	Not recommended in children
oxiconazole (Oxistat). Apply to affected and surrounding areas one to two times daily for 2–4 wk.	Pruritus, burning	Pregnancy or lactation	Avoid applying near eyes or mucous membranes.
sulconazole (Exelderm). Apply to affected and surrounding areas bid × 4 wk.	Pruritus, burning sensation, erythema	Pregnancy or lactation	Not recommended in children Avoid contact with eyes.
ciclopirox (Loprox). Apply to affected area bid × 4 wk.	Pruritus, burning sensation		Not recommended in children younger than age 10 Lotion formulation good for nails Avoid occlusive dressing.
naftifine (Naftin). Apply to affected area once daily × 4 wk	Burning, stinging, dryness, erythema, itching		Not recommended in children Avoid occlusive dressings. Avoid contact with mucous membranes.
terbinafine (Lamisil). Apply to affected area bid × 4 wk.	Burning, irritation, skin exfoliation, dryness		Not recommended in children Avoid occlusive dressings. Avoid contact with mucous membranes.
tolnaftate (Tinactin). Apply small amount bid × 4 wk.	Stinging, burning, irritation		Not recommended in children younger than age 2
selenium sulfide (Selsun) 1% (OTC), 2.5%. Massage into affected area, rest 15 min, and rinse thoroughly	Irritation, hair loss		
nystatin (Mycostatin) 100,000 units/mL. Infants: 1 mL each side of mouth Adults: 2–3 mL each side of mouth	GI upset, oral irritation		Continue use for at least 48 h after clinical cure. Keep in mouth as long as possible before swallowing.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Oral Agents			
griseofulvin (Grifulvin V) Microsize: Adult 500–1,000 mg Child 10–15 mg/kg/d Ultramicrosize: Adult: 330–660 mg Child: 10 g/kg/d	Headaches, nausea, vomiting, diarrhea, photosensitivity	Pregnancy Patients with porphyria or hepatic failure	Ultramicrosize particle increases absorption. Prescribe with caution to patients who are sensitive to penicillin. Drug is most effective when taken with a high-fat meal. Drug is well tolerated in young children. Monitor complete blood count and LFT with long-term use. Drug use may aggravate lupus erythematosus. Use with alcohol produces antabuse-like effects. Drug interactions: antagonizes oral contraceptives and warfarin and is antagonized by barbiturates
ketoconazole (Nizoral) 200 mg/d	Nausea, vomiting, abdominal pain, urticaria, pruritus	Do not use with other drugs metabolized by CYP3A.	Not recommended in children
itraconazole (Sporanox) 200 mg/d	GI upset, rash, fatigue, headache, dizziness, edema	Do not use with other drugs metabolized by CYP3A	Not recommended in children May use pulse dosing Remains in nails for 4–5 mo Ingestion of food increases absorption.
terbinafine (Lamisil) 62.5–250 mg/d	GI disturbance, LFT abnormalities, urticaria, pruritus	Liver or renal disease	Not recommended in children
fluconazole (Diflucan) Adults: 100–200 mg/d Children: 3–6 mg/kg/d	GI disturbance, headache, rash, hepatotoxicity		Decrease dose if creatinine clearance <50 mL/min. Drug interactions: potentiates warfarin, theophylline, oral hypoglycemics. May increase serum levels of phenytoin, cyclosporine. Thiazides increase fluconazole levels. May decrease effect of oral contraceptives

CYP3A, cytochrome P-450 enzyme 3A; GI, gastrointestinal; LFT, liver function tests; OTC, over the counter.

Topical Allylamine Antifungals

These agents are effective against dermatophyte infections but have limited effectiveness against yeast. Patients treated with these agents may undergo a shorter treatment period with less likelihood of relapse. Topical allylamines are applied twice daily. Potential side effects include burning and irritation.

Griseofulvin

Mechanism of Action

Griseofulvin is a fungistatic that deposits in keratin precursor cells, increasing new keratin resistance to fungal invasion.

Adverse Events

Adverse effects include nausea, vomiting, diarrhea, headache, or photosensitivity. Evaluation of renal, hepatic, and hematopoietic systems is recommended before initiating therapy, particularly because this drug may aggravate lupus erythematosus.

Interactions

Griseofulvin increases levels of warfarin (Coumadin) and decreases levels of barbiturates and cyclosporine (Sandimmune). It may decrease the efficacy of oral contraceptives and may cause a serious and unpleasant reaction with alcohol. Patients should be advised not to drink beverages or any other preparation containing alcohol while taking the drug.

Systemic Allylamine Antifungals

Terbinafine (Lamisil) is a synthetic allylamine derivative that inhibits squalene epoxidase, a key enzyme in fungal biosynthesis. This causes a deficiency of ergosterol causing fungal cell death. It is used in the treatment of onychomycosis.

Dosage

For fingernail onychomycosis, the dose is 250 mg/d for 6 weeks; toenail onychomycosis requires 250 mg/d for 12 weeks.

Adverse Events

Adverse events include diarrhea, dyspepsia, rash, increase in liver enzymes, and headache. Evaluation of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels is recommended before starting therapy and at 6 to 8 weeks into therapy if it is long-term because it can cause liver failure, although this is rare.

Interactions

Terbinafine is potentiated by cimetidine (Tagamet) and antagonized by rifampin (Rifadin). Cyclosporine levels should be monitored when the patient is taking both cyclosporine and terbinafine.

Systemic Azole Antifungals

Systemic azoles inhibit cytochrome P-450 (CYP) enzymes and fungal 14-α-demethylase, inhibiting synthesis of ergosterol. Systemic therapy is required for tinea capitis and tinea unguium. Itraconazole (Sporanox), a systemic azole, has a high affinity for keratin and is lipophilic, which causes high levels to accumulate in the hair and nail. It has a long half-life, so pulse dosing, in which periods of drug therapy are alternated with periods without therapy, is feasible.

Dosage

The dosage of itraconazole is 200 mg once daily for 12 weeks for toenail infection. For fingernail infection, the dose is 200 mg twice daily for 1 week, then 3 weeks off, and repeat dosing with 200 mg twice daily for 1 week. The drug is not recommended for children, and ingestion of food increases absorption.

The dosage of fluconazole is usually 200 mg on the first day and then 100 mg each day for at least 2 weeks. For children, it is 6 mg/kg/d on day 1 and then 3 mg/kg/d.

Contraindications

A systemic azole should not be given with drugs metabolized by the CYP3A enzyme, including β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors such as quinidine (Quinidex) or others. The azole antifungals should not be used in pregnancy.

Adverse Events

Adverse effects associated with systemic azole therapy include gastrointestinal upset, rash, fatigue, hepatic dysfunction, edema, and hypokalemia.

Interactions

Severe hypoglycemia may occur with hypoglycemic drugs. In addition, systemic azole therapy may potentiate triazolam (Halcion), midazolam (Versed), and warfarin. Fluconazole (Diflucan) levels are increased with use of hydrochlorothiazide (HydroDIURIL). Anticholinergics, histamine-2 blockers, and antacids should be avoided within 2 hours of taking an oral azole so that absorption is not compromised.

Selecting the Most Appropriate Agent

Topical agents work well for most tineas but not for tinea capitis and tinea unguium. If tinea capitis is especially severe and painful in a child, prednisone (Deltasone) 1 mg/kg/d can be given for 3 to 4 days as adjunct therapy. To be effective, all therapy must be adequate in dose and duration. If a pet carries the fungus, the pet must be treated. For more information, see Figure 12.1.

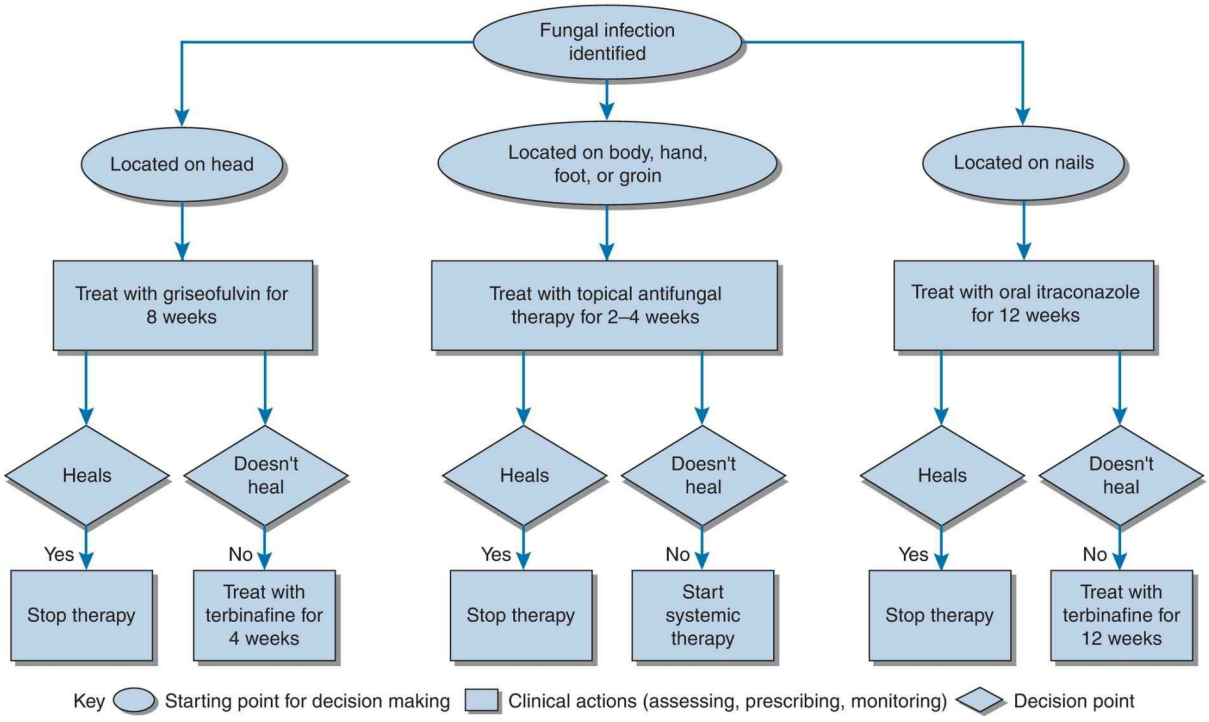

FIGURE 12.1 Treatment options for fungal skin infections.

When selecting an oral agent to treat onychomycosis, consideration must be given to cost of the agent, patient motivation and compliance, the age and health of the patient, and drug interactions and side effects of the medications.

First-Line Therapy

Topical therapy is recommended for cases of tinea corporis, pedis, cruris, or manus when the infection affects a limited area. The topical antifungal is applied 3 cm beyond the margin of the lesion. Therapy should continue for at least 2 weeks and for 1 week after the lesion clears (Table 12.2).

TABLE 12.2 Recommended Order of Treatment for Tinea Capitis

Order	Agent	Comments
First line	griseofulvin (Grifulvin V)	Treatment lasts a minimum of 8 wk. Take medication with a high-fat meal.
Second line	terbinafine (Lamisil) or itraconazole (Sporanox)	Treatment lasts 4 wk.

First-line therapy for tinea capitis is microsize griseofulvin (Table 12.3) administered with milk or food to promote absorption. Treatment is for 8 weeks. The adult dose is 500 mg daily, and the pediatric dose ranges between 10 and 20 mg/kg/d. Children may attend school during therapy.

TABLE 12.3 Recommended Order of Treatment for Tinea Corporis, Tinea Cruris, and Tinea Pedis

Order	Agent	Comments
First line	Topical azole antifungals for 2–4 wk (1 wk past clinical cure)	Use medications for 2 wk even after the rash is gone.
Second line	Systemic therapy: terbinafine (Lamisil) or fluconazole (Diflucan)	

First-line therapy for tinea unguium (onychomycosis) consists of systemic agents. Topical preparations are not effective because they penetrate the nails poorly. Itraconazole is given by pulse dosing, 200 mg twice daily with a full meal for 7 days of each month. Treatment for fingernails lasts 3 months and for toenails, 4 months. Also effective for toenails is 200 mg itraconazole per day for 12 weeks (Table 12.4). Pulse dosing has less impact on the liver and is more popular than continuous dosing. Fluconazole can be given at a dose of 150 to 400 mg/d for 1 to 4 weeks or 150 mg once a week for 9 to 10 months. Treatment for onychomycosis is only 40% to 50% effective.

TABLE 12.4 Recommended Order of Treatment for Onychomycosis

Order	Agent	Comments
First line	itraconazole (Sporanox) or terbinafine (Lamisil)	Take with food. Treatment lasts 12 wk. Not recommended for children

Second-Line Therapy

Second-line therapy for tinea corporis, pedis, cruris, or manus is needed if the infection fails to respond to topical therapy, if there are multiple lesions, or if treatment areas are repeatedly shaved. Second-line therapy consists of terbinafine 250 mg/d for 2 to 6 weeks or fluconazole 150 mg/wk for 2 to 4 weeks.

Second-line therapy for tinea capitis involves using itraconazole, terbinafine, or fluconazole if treatment failure occurs with griseofulvin despite adequate dosage and time.

Monitoring Patient Response

When patients use terbinafine or itraconazole, the AST/ALT levels and white blood cell counts need to be monitored at 6 to 8 weeks. Follow-up evaluations need to monitor both the effectiveness of the therapy and results of liver, kidney, and hematopoietic diagnostic studies. If tests disclose elevated liver function or if creatinine clearance exceeds 40 mL/min, drug therapy should be discontinued.

Patient Education

An important role of the practitioner is to teach the patient about hygiene and ways to avoid transferring fungal infection to others. Patients should be instructed to complete the full course of treatment and not to stop treatment when symptoms subside. Parents and other caregivers also need to know that children can attend school while being treated.

Patients may dry areas susceptible to fungus with a hair dryer after bathing to ensure full drying. The hair dryer should be set to cool or low to avoid burns.

Vinegar soaks and Vicks VapoRub may be used for onychomycosis. Vinegar is mixed with one part vinegar to two parts warm water. Feet are soaked for 15 to 20 minutes daily. It should not be used long term. Vicks VapoRub can be applied to the toenails and socks put over the feet. Neither of these remedies has been thoroughly researched. Areas with fungal infections should be carefully dried. Antifungal powders and sprays can be used for prophylaxis.

Tinea Versicolor

Tinea versicolor, also called pityriasis versicolor, is an opportunistic superficial yeast infection. It is a chronic, asymptomatic infection characterized by well-demarcated, scaling patches of varied coloration, from whitish to pink, tan, or brown.

Causes

An overgrowth of the hyphal form of *Pityrosporum ovale* causes tinea versicolor, which is most common in young adults (older than age 15). The fungal infection occurs mostly in subtropical and tropical areas. In temperate zones, it is more common in the summer months but is seen in physically active people year-round. Moist skin surfaces predispose to tinea versicolor. The infection rarely causes symptoms other than discoloration, and patients usually seek treatment for cosmetic purposes.

Pathophysiology

Pityrosporum ovale has an enzyme that oxidizes fatty acids in the skin surface lipids, forming dicarboxylic acids, which inhibit tyrosinase in epidermal melanocytes and cause hypomelanosis (loss of pigmentation).

Diagnostic Criteria

Skin lesions of tinea versicolor are well-defined, round or oval macules with an overlay of scales that may coalesce to form larger patches. They most often form on the trunk, upper arms, and neck. There may be mild itching. The diagnosis is confirmed by positive KOH test findings, which reveal budding yeast and hyphae.

Initiating Drug Therapy

Topical agents for treating tinea versicolor include selenium sulfide lotion or shampoo and azole creams. The treatment may be repeated in 3 to 4 weeks and before the next warm season or travel to a tropical area. For widespread or stubborn disease, systemic itraconazole or fluconazole may be prescribed for 7 to 10 days.

Goals of Therapy

The goal of therapy for tinea versicolor is resolution of lesions. Therapy lasts for 3 to 4 weeks. Because the lesions may recur in warm weather, prophylaxis consists of applying selenium sulfide lotion or shampoo twice a month.

Selenium Sulfide

Selenium sulfide, the drug of choice for tinea versicolor, has antifungal properties (Table 12.5). It is applied once a day to the affected skin for 15 minutes and then rinsed off. Contraindicated during pregnancy and lactation, it can be used with caution in instances of acute inflammation or exudation. Skin folds and genitalia are carefully rinsed. Selenium sulfide must be kept away from eyes. Potential adverse effects include irritation and increased hair loss.

TABLE 12.5 Recommended Order of Treatment for Tinea Versicolor

Order	Agent	Comments
First line	selenium sulfide solution 1% or 2.5% topical azole cream or spray	Topical therapy is used for localized lesions. Use if lesions are resistant or widespread.
Second line	itraconazole (Sporanox)	

Selecting the Most Appropriate Agent

Lesions may reappear because the infection is a result of microorganisms that normally inhabit the skin, so twice-monthly application of selenium sulfide is suggested as prophylaxis.

First-Line Therapy

Selenium sulfide solution (2.5%) as a lotion or shampoo (Selsun) is applied once a day. Pyrithione zinc (Head and Shoulders shampoo) can also be used. An antifungal topical agent is used. Choices include terbinafine cream or spray, ketoconazole, or sulconazole nitrate (Exelderm) for 3 to 4 weeks. The treatment can be repeated before the next warm season.

Second-Line Therapy

For resistant or widespread tinea versicolor, systemic therapy with itraconazole (200 mg for 5 days) may be prescribed.

Patient Education

It may take several months for the discoloration to disappear. Prophylactic application of ketoconazole cream or shampoo one to two times a week can prevent recurrence. The treatment can be repeated before the next exposure to warm weather.

Candidiasis

Cutaneous candidiasis is a superficial fungal infection of the skin and mucous membranes. It is commonly found in the diaper area, oral cavity, intertriginous areas, nails, vagina, and male genitalia. It can occur at any age and in both sexes. It is classified by its location on the body (Box 12.2).

BOX 12.2 Varieties of Candidiasis

Candidal infections are identified by their location on the body as follows:

- Axillae, under pendulous breasts, groin, intergluteal folds: intertrigo
- Glans penis: balanitis
- Follicular pustules: candidal folliculitis
- Nail folds: candidal paronychia
- Mouth and tongue: oral candidiasis (thrush)
- Area included under diaper: diaper dermatitis

Causes

Cutaneous candidiasis, which is caused by *C. albicans*, a yeastlike fungus, occurs on moist cutaneous sites. Predisposing factors include infection, diabetes, use of systemic and topical corticosteroids, and immunosuppression. It is commonly found in people who immerse their hands in water. It thrives in occluded sites.

Pathophysiology

Normally found on the skin and mucous membranes, *C. albicans* invades the epidermis when warm, moist conditions prevail or when there is a break in the skin that allows overgrowth.

Diagnostic Criteria

Candidiasis has several classifications. Intertrigo presents as red, moist papules or pustules. It is found in the axillae, inframammary areas, groin, and between fingers and toes.

Diaper dermatitis presents as erythema and edema with papular and pustular lesions, erosion, and oozing. Scaling may be evident at the margin of the lesions.

Interdigital candidiasis is an erythematous eroded area with surrounding maceration between the fingers and toes, whereas balanitis presents as multiple discrete pustules on the glans penis and preputial sac. Balanitis that involves the scrotum can be painful. It is most common in uncircumcised men.

Paronychia and onychia present as redness and swelling of the nail folds. Swelling lifts the wall from the nail plate, causing purulent infection.

Follicular candidiasis appears as small, discrete pustules in the ostia of hair follicles, and oral candidiasis (thrush) presents as white plaques on an erythematous base. It is found mostly in infants and immunocompromised patients. The tongue is usually involved.

Initiating Drug Therapy

Candidiasis can be prevented by keeping intertriginous areas dry when possible. Also, washing with benzoyl peroxide and applying powder containing miconazole may be beneficial.

Goals of Therapy

The goal of therapy is restoration of the mucous membranes to normal.

Nystatin

Nystatin (Mycostatin) is a fungicide that binds to sterols in the cell membrane of the fungus, causing a change in the membrane's permeability. This allows intracellular components to leak, thereby causing cell death.

Used to treat thrush in infants and adults, nystatin is placed in each side of the mouth three times daily (see Table 12.1). The solution is kept in the mouth as long as possible and then swallowed. Therapy continues for 10 to 14 days and at least 48 hours after clinical clearing. Adverse effects include GI upset and oral irritation.

Selecting the Most Appropriate Agent

First-Line Therapy

For cutaneous candidiasis, cool wet soaks with Burow solution can be applied two to three times daily in macerated areas. Intertriginous areas are kept dry by powdering (e.g., with Zeasorb AF Powder), by exposing them to air, or by drying with a hair dryer after bathing. Antifungal creams (clotrimazole [Lotrimin], ketoconazole) can be applied once or twice a day for 10 days (Table 12.6).

TABLE 12.6 Recommended Order of Treatment for Candidiasis

Order	Cutaneous Agent	Oral Agent	Comments
First line	Cool soaks with Burow solution Topical azole	Oral nystatin (Mycostatin)	Burow solution is used in macerated areas. Topical azole is used for 10 d. Systemic therapy is used if no response to topical therapy.
Second line	itraconazole (Sporanox) or fluconazole (Diflucan)	itraconazole or fluconazole	NA

For oral candidiasis, oral nystatin is used for 10 to 14 days, or one clotrimazole troche is given orally five times a day for 2 weeks.

Second-Line Therapy

For failure to respond to treatment, patients have the option of second-line therapy. Systemic itraconazole may be prescribed to adults only for cutaneous or oral candidiasis.

For children and adults, oral fluconazole may be prescribed.

Monitoring Patient Response

Response to therapy should be evaluated in 2 weeks. Follow-up for patients receiving long-term systemic therapy (2 weeks; not necessary for pulse therapy) is recommended every month to monitor liver function. Patients undergoing pulse therapy do not need monitoring as regularly. Human immunodeficiency virus infection and diabetes mellitus should be ruled out in patients who have recurring problems with candidiasis.

Complementary and Alternative Medicine

There are several over-the-counter remedies that may be helpful in treating fungal infections. One is apple cider vinegar taken orally. This has antimicrobial properties and helps kill the fungus. It can also promote a faster recovery. Two tablespoons of apple cider vinegar are mixed in one cup of warm water and drunk two times a day. It can also be applied externally when mixed with equal parts vinegar and water.

The application of plain yogurt is another remedy. The probiotics present in plain yogurt can keep the growth of fungi in check by producing lactic acid.

Tea tree oil has natural antifungal compounds that help kill the fungi that cause fungal infections. Plus, its antiseptic qualities inhibit the spread of the infection to other body parts.

Tea is another remedy for fungal infections. The tannins in tea can help kill the fungi responsible for fungal infections. Plus, tea has antibiotic and astringent properties that help get rid of the symptoms of a fungal infection like the burning sensation, swelling, and skin irritation. Tea bags are steeped and then cooled and applied to the affected area.

Case Study*

M.B. is a 42-year-old diabetic woman who presents with thickened, yellow toenails that are painful when she wears dress shoes. Her blood sugar level is well controlled. She is taking the following medications: metformin 500 mg tid, cimetidine 300 mg qid, and Accupril 10 mg daily. A toenail culture comes back positive for fungus.

1. List specific goals of treatment for M.B.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for M.B.?
8. What lifestyle changes would you recommend to M.B.?

9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

13 Viral Infections of the Skin

Virginia P. Arcangelo

Viruses producing skin lesions may be categorized into three groups: herpes viruses, papillomaviruses, and pox viruses. Herpes and papillomaviruses each affect approximately 20% of the adult population in the United States, with an even distribution between the sexes.

Viruses are further classified by family—either the ribonucleic acid family or the deoxyribonucleic acid (DNA) family. Herpes viruses, papillomaviruses, and pox viruses are members of the DNA family.

Viruses are obligate intracellular parasites that consist of a nucleic acid core surrounded by one or more proteins. A host cell is required for viral replication. Several mechanisms exist for viral replication, and different DNA viruses replicate by their own specific mechanism. Pox viruses replicate entirely in the cytoplasm. Herpes viruses replicate their own polymerase, along with several of their own enzymes. Papillomavirus proteins contribute to the initiation of DNA replication.

Herpes Virus Infections

Causes

Seven types of herpes viruses are associated with human illness: herpes simplex virus type 1 (HSV-1), herpes simplex virus type 2 (HSV-2), varicella-zoster virus (VZV), Epstein-Barr virus, cytomegalovirus, human herpes virus type 6 (HHV-6), and human herpes virus type 8 (HHV-8).

HSV-1 infection usually involves the face and skin above the waist. HSV-2 is most commonly associated with the genitalia and the skin below the waist. A life-threatening neonatal infection is associated with HSV-2 in a baby whose mother is infected with the virus; the infection is transmitted during vaginal birth. Herpes zoster (shingles) and varicella (chickenpox) are the result of VZV infection. The overall incidence of herpes zoster is 3.2 per 1,000 (Htwe et al., 2007). Risk factors include aging, female gender, recent transplant, human immunodeficiency virus (HIV) infection, and cancer. Infectious mononucleosis is a result of Epstein-Barr virus infection. HHV-6 is associated with a mild childhood illness called roseola. HHV-8 is associated with Kaposi sarcoma, especially in patients with HIV infection. HSV-1 and VZV are discussed in this chapter; HSV-2 is discussed in Chapter 35.

Pathophysiology

Herpes viruses replicate their own polymerase along with several of their own enzymes. HSV is highly contagious. It is spread by direct contact with skin or mucous membrane. After the primary infection, the virus retreats to the dorsal root ganglion, where it remains latent until it is reactivated by triggers such as stress, viral infections, or sunlight.

Those who have had varicella virus infection are most prone to herpes zoster. After the primary infection resolves, the virus retreats to the dorsal root ganglion, where it remains dormant. Herpes zoster is caused by reactivation of the virus, most often with no apparent cause. There is a migration of virions through the axon to the skin of one or several adjacent axons. In immunocompetent patients, recurrent episodes are uncommon.

Diagnostic Criteria

Infection with HSV-1 and HSV-2 causes vesicular eruptions that are painful and often recurrent. The common incubation period of 4 to 10 days is followed by the eruption of clustered vesicles on an erythematous base. Distribution of the virus into autonomic and sensory nerve endings allows the virus to remain latent.

Typically, HSV-1 causes oral or facial infections, with the most common sites being the mouth, pharynx, lips, or face. Primary occurrences usually have intense symptoms. Prodromal symptoms include burning, tingling, or itching; these symptoms may accompany recurrent infection as well. Recurrence of the infection is thought to be precipitated by fatigue, stress, trauma, fever, or ultraviolet radiation. The lesion presents as a single vesicle or group of vesicles that overlie an erythematous base. They become pustules and become crusted or erode. Lesions recur at the site innervated by the dorsal root ganglion inhabited by the virus.

The two different diseases caused by VZV (chickenpox and shingles) have similar symptoms. After an incubation period of 10 to 20 days, chickenpox (primary varicella) manifests with fever and malaise followed by the outbreak of itchy, vesicular lesions on an erythematous base. The outbreak usually begins on the trunk and progresses to the extremities and face. Primary varicella occurs most often in children. Adults infected with primary varicella tend to have more systemic effects, especially if they have preexisting medical conditions.

A reactivation of VZV in the nerve root ganglion is referred to as herpes zoster, or shingles. The infection characteristically begins with neuralgia in the affected dermatome, followed by an outbreak of grouped vesicles on an erythematous base, clustered in a unilateral pattern of the dermatome. In two thirds of infections, the lesions are on the trunk. Additional symptoms include fever, myalgia, and increasing localized pain. The most common presentation of herpes virus infection in the elderly is VZV in the form of herpes zoster. Three fourths of all cases of shingles occur in patients older than age 50. A significant complication of herpes zoster is postherpetic neuralgia, pain in the dermatome site that lasts longer than 6 weeks after resolution of the infection.

Initiating Drug Therapy

Although nonpharmacologic interventions, such as soaks with Burow's solution, help to relieve symptoms, HSV-1 infection is treated primarily with other topical agents. In the case of severe infection in an immunocompromised patient, treatment may be with systemic drug therapy, which shortens the duration of symptoms; however, there is no treatment to prevent recurrence.

For oral HSV-1 infections (oral herpes), symptoms may or may not respond to viscous lidocaine (Xylocaine) 2% applied to the lesion. A solution of diphenhydramine (Benadryl) elixir and aluminum hydroxide/magnesium hydroxide (Maalox) mixed in a 1:1 proportion can be used as an oral rinse four times a day. Sucking on popsicles also can provide temporary relief.

For primary VZV infections that manifest as chickenpox, systemic therapy is used only in special cases and is not recommended for uncomplicated disease. For VZV infections that manifest as herpes zoster, antiviral agents may help relieve symptoms. Patients should be treated if the rash has been present for fewer than 72 hours or if new lesions are still developing. If therapy starts within 72 hours of the appearance of the lesion, systemic therapy decreases the duration of the rash and the acute pain associated with herpes zoster. In addition, any patient older than age 50 who is immunocompromised should be treated with antiviral agents. The use of antiviral therapy in herpes zoster decreases the symptoms of postherpetic neuralgia from 62 days with placebo to 20 days with acyclovir. Antiviral agents used are acyclovir, famciclovir, and valacyclovir. All antiviral agents have shown to shorten the duration of postherpetic neuralgia, but none prevent it.

Goals of Drug Therapy

In herpes virus infections, the goal of therapy is to reduce the duration of symptoms and suppress pain. The treatment aim is to stop reproduction of the virus.

Topical Antiviral Agents

Two topical agents—acyclovir 5% and penciclovir (Denavir)—are available to treat herpes infections. These agents work by inhibiting viral DNA synthesis (Table 13.1). They may decrease healing time.

TABLE 13.1 Overview of Antiviral Agents for Herpes Virus Infections

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Topical Therapy			
acyclovir 5% (Zovirax) Apply every 3 h, six times per day for 7 d	Pruritus, pain on application	Do not use on mucous membranes or near eyes.	Must use glove or finger cot for application
penciclovir 1% (Denavir) Apply every 2 h for 4 d while awake	Headache, mild skin irritation	Renal impairment	Begin using drug at earliest sign or symptom.
Systemic Therapy			
acyclovir (Zovirax) *For HSV-1* 200 mg five times per day for 10 d for initial outbreak; 200 mg five times a day for 5 d for recurrence *For VZV infection* Children: 20 mg/kg qid for 5 d Adults: 800 mg five times a day for 7 d	Nausea, vomiting, headache, CNS disturbance, rash, malaise	Renal impairment	Do not exceed maximum dose. Least effective antiviral Reserved for use in children
famciclovir (Famvir) *For HSV-1* 250 mg tid for 10 d for initial outbreak; 125 mg tid for recurrence or 1,000 mg bid for 1 day *For VZV infection* 500 mg tid for 7 d	Headache, GI disturbance, paresthesias	Renal dysfunction	May be affected by drugs metabolized by aldehyde oxidase
valacyclovir (Valtrex) *For HSV-1* 1 g bid for 10 d *For VZV infection* 1 g tid for 7 d *For recurrent HSV* 2,000 mg bid for 1 d	GI upset, headache, dizziness, abdominal pain	Renal impairment HIV	Be alert for renal or CNS toxicity with nephrotoxic drugs.

HSV, herpes simplex virus; VZV, varicella-zoster virus.

Patients usually apply topical acyclovir every 3 hours, six times per day, for 7 days. Penciclovir is applied every 2 hours, during waking hours, for 4 days. Adverse effects include mild skin irritation and pruritus.

Systemic Antiviral Agents

The three first-line systemic agents are acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex), although famciclovir and valacyclovir are more bioavailable than acyclovir. Systemic antivirals are highly effective against herpes virus. In general, antiviral therapy is recommended for adolescents, adults, and high-risk patients, but not usually for healthy children younger than age 12 (see Table 13.1).

Contraindications

Caution should be used in patients with renal disease because antivirals are excreted by the renal system. They are also contraindicated in patients with congestive heart failure and in lactation. Dosage adjustments are made for patients with a creatinine clearance rate less than 25 mL/min.

Adverse Events

Adverse effects include headaches, vertigo, depression, and tremors. Patients may also experience gastrointestinal symptoms and rashes.

Interactions

The effect of antiviral agents is increased in patients taking probenecid, and patients taking zidovudine (Retrovir) may experience drowsiness.

Acyclovir

The prototypical antiviral agent acyclovir acts by inhibiting viral DNA replication. The drug works only in cells infected by HSV. A disadvantage of oral acyclovir is its low bioavailability of 10% to 20%.

The recommended acyclovir dosage for an initial episode of HSV disease in an immunocompetent host is 200 mg orally five times per day for 7 to 10 days (see Table 13.1). The recommended dosage for recurrent episodes is 200 mg five times per day for 5 days. For patients with recurrent infections, treatment prophylaxis is recommended with 400 mg twice daily. For an immunocompromised patient, the recommended treatment is 400 mg five times per day for 7 to 10 days. For suppression therapy, 400 mg twice a day is the dosage. The children's dosage of acyclovir is 5 mg/kg/d in five divided doses for 7 days.

The recommended dosage for treating VZV infections in children is 20 mg/kg four times per day for 5 days. Adult dosing is 800 mg five times per day for 7 to 10 days.

Famciclovir

Famciclovir is the diacetyl ester prodrug of penciclovir. It is an acyclic guanosine analog. After first-pass metabolism, it is well absorbed and converted to penciclovir. The oral

bioavailability of famciclovir ranges from 5% to 75%.

The dosage of famciclovir is 250 mg three times per day for 7 to 10 days for an initial episode of illness; for recurrent episodes, the dose is 1,000 mg twice daily for 1 day and 250 mg twice a day for suppression therapy.

Valacyclovir

Valacyclovir is a prodrug of acyclovir and is converted rapidly. First-pass metabolism converts valacyclovir to acyclovir with 50% bioavailability.

The dosage of valacyclovir is 1,000 mg three times a day for 7 to 10 days for initial infection, 2,000 mg two times a day for 1 day for recurrent infections, and 1,000 mg daily for suppression therapy.

Selecting the Most Appropriate Agent

Of the various antiviral agents available, which is most effective for which disorder? Which agents are used when the first choice fails?

First-Line Therapy: Herpes Simplex Virus Type 1

First-line therapy for HSV-1 is topical acyclovir 5% every 3 hours six times a day for 7 days or penciclovir cream 1% every 2 hours during waking hours for 4 days in immunocompetent patients. Acyclovir is usually the first choice because it is less expensive than valacyclovir or famciclovir. Immunocompromised patients may need oral acyclovir 200 mg five times a day for 7 days, valacyclovir 500 mg twice a day for 5 days, or famciclovir 500 mg twice a day for 7 days (Figure 13.1 and Table 13.2).

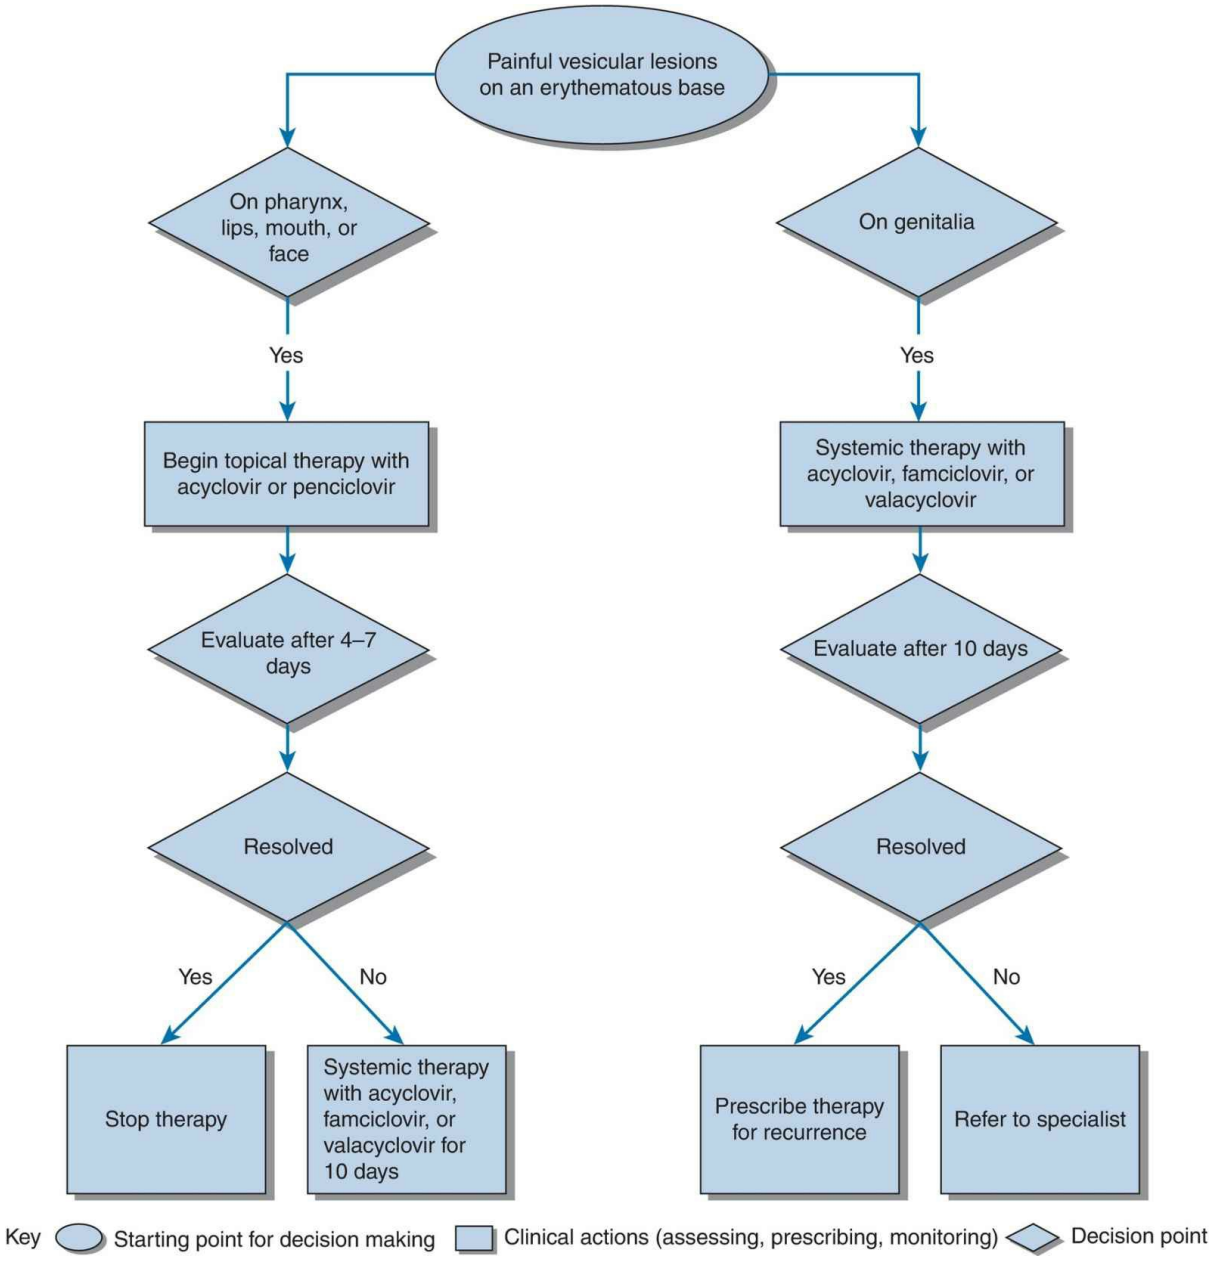

FIGURE 13.1 Treatment recommendations (left) for outbreaks of herpes simplex virus type 1 (HSV-1) and (right) for HSV-2.

TABLE 13.2 Recommended Order of Treatment for HSV-1 Infection

Order	Agent	Comments
First line	Topical therapy with acyclovir 5% (Zovirax) or penciclovir 1% (Denavir)	Begin treatment at earliest sign of outbreak.
Second line	Systemic therapy with acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir (Valtrex)	

First-Line Therapy: Varicella-Zoster Virus

Systemic therapy is used only in patients with complicated disease or in children with pulmonary disease or taking steroids and not for uncomplicated disease. It is prescribed only if the rash has been present for less than 24 hours. Acyclovir is used at a dosage of 20 mg/kg four times a day for 5 days (Figure 13.2 and Table 13.3).

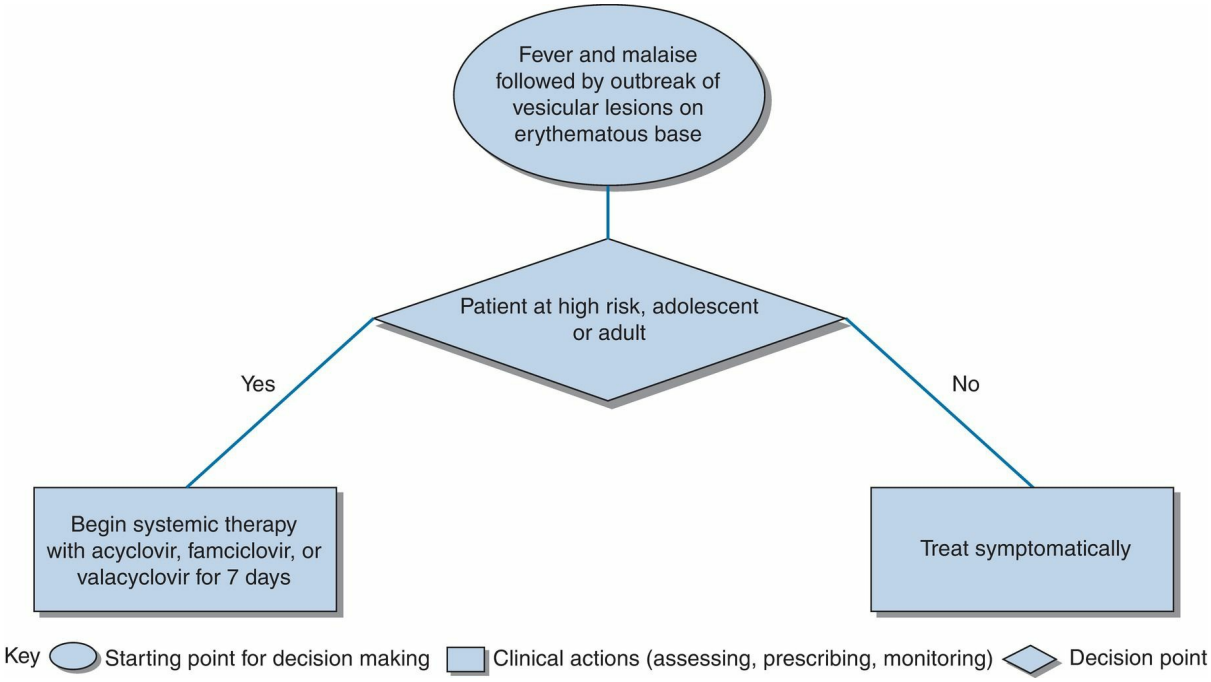

FIGURE 13.2 Treatment algorithm for the varicella-zoster virus infection manifested as chickenpox.

TABLE 13.3 Recommended Order of Treatment for Varicella-Zoster Virus Infection

Order	Agents	Comments
First line	acyclovir (Zovirax), famciclovir (Famvir), valacyclovir (Valtrex)	For children, the maximum dose is 800 mg qid. Acyclovir is the only approved agent for primary varicella. Antiviral therapy for primary varicella is recommended for adolescents, adults, and high-risk patients, but not for healthy children.

First-Line Therapy: Herpes Zoster

Systemic antiviral therapy can be started if the herpes zoster outbreak is less than 72 hours in duration or longer than 72 hours but with new lesions appearing, the patient is older than age 50, or the patient is immunosuppressed. Therapy consists of acyclovir 800 mg five

times a day for 7 to 10 days, valacyclovir 1 g three times a day, or famciclovir 500 mg three times a day for 7 days (Figure 13.3). Cost is a driving force in prescribing acyclovir before valacyclovir and famciclovir because it is less expensive.

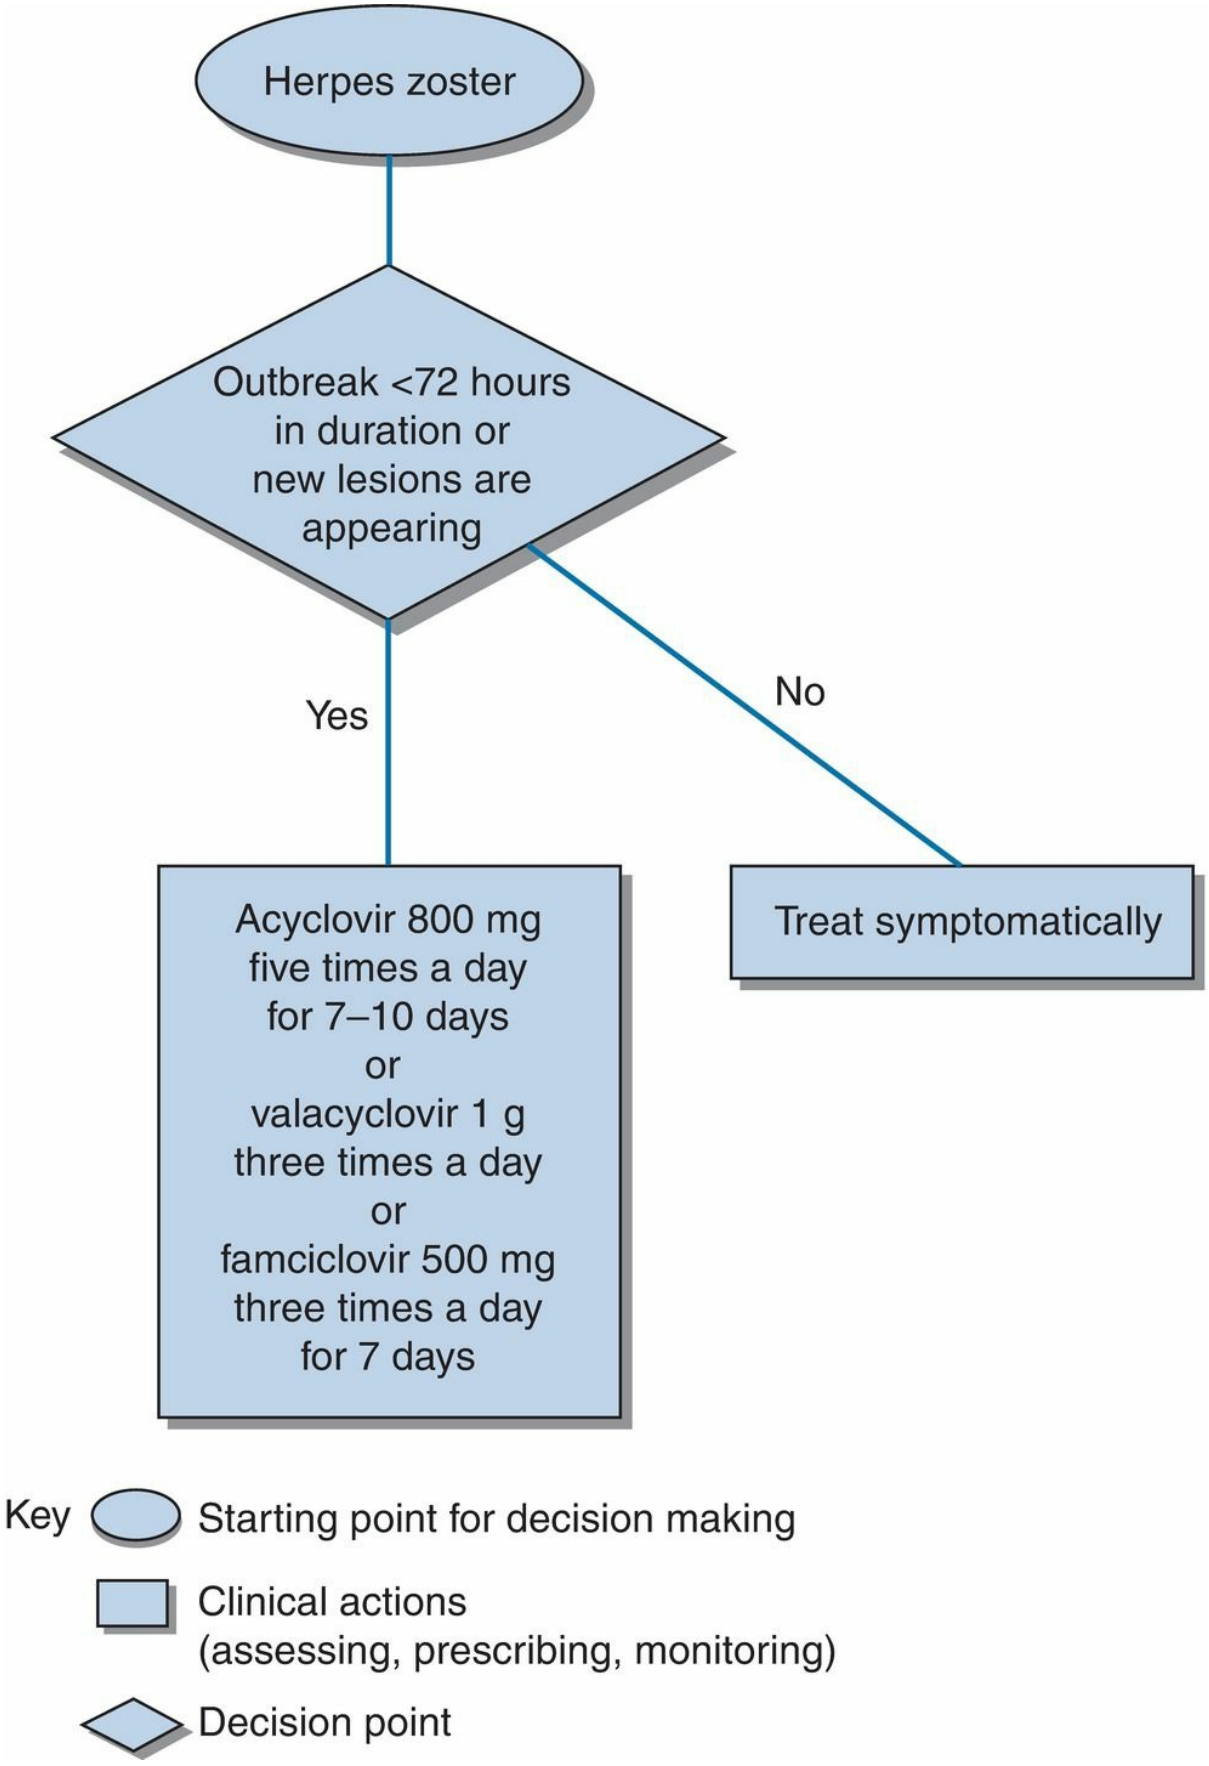

FIGURE 13.3 Treatment algorithm for the varicella-zoster virus infection manifested as

shingles.

Oral analgesics, such as acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs, are helpful in pain control.

Monitoring Patient Response

Follow-up evaluation of HSV infection is not required if the symptoms resolve. For patients with herpes zoster, follow-up is recommended at 3 days after starting therapy and then at 1 week.

Patient Education

Lifestyle Changes

Educating the patient about hygiene, precipitating factors, and prevention is imperative. For patients with the HSV-2 infection manifested as genital herpes, education regarding sexual activity, recurrence, and the unpredictable course of the disease is necessary. Moreover, these patients should be screened for other sexually transmitted diseases. (See Chapter 35 for more information.) In patients with more than five recurrences per year, prophylactic treatment is recommended.

In patients with herpes zoster, follow-up monitoring for postherpetic neuralgia is important. Patients with postherpetic neuralgia should understand that pain management is the goal of therapy.

Because the herpes virus is spread by skin contact, patients need to recognize the importance of wearing gloves when applying medications and of thorough, careful hand washing. Skin-to-skin contact is avoided. Patients with herpes zoster can transmit the virus as chickenpox to anyone who has not been infected with the virus.

Complementary and Alternative Medicine

Capsaicin is used for pain control in herpes zoster. It is most effective when applied three or four times a day. Tea tree oil has reported antiseptic properties and is used in herpes simplex.

Special Populations

VZV infections occur occasionally during pregnancy. A primary VZV infection (varicella) may result in severe fetal abnormalities, but herpes zoster does not appear to harm the fetus.

Prevention

A vaccine, Zostavax, is now available. It is approved for everyone older than age 60 who has had chickenpox. It reduces the risk of developing herpes zoster and results in less frequent, less painful, and shorter courses of postherpetic neuralgia.

Warts (Verrucae)

Warts are caused by the human papillomavirus (HPV). There are more than 80 types of HPV. They are transferred by skin-to-skin contact. The common viruses can be classified as those causing anogenital infections and nonanogenital infections. Anogenital infections are discussed in Chapter 35. The most common nonanogenital infections present as warts. These are very common, especially in children: at some time in their life, approximately 20% of school-age children have one or more warts, which usually regress spontaneously. Categories of warts include plantar, filiform, flat, and common.

Causes

Plantar warts result from HPV-1 and commonly occur on the soles of the feet and the palms of the hands. *Verruca vulgaris*—common warts—is an infection with HPV-2. These present on the fingers or toes or at sites of trauma. They are flesh-colored to brown, hyperkeratotic papules. HPV-3 produces flat warts, which are located on the face, neck, and chest or flexor regions of the forearms and legs.

Factors that predispose to HPV include the following:

- Infection with HIV
- Intake of drugs that decrease cell-mediated immunity (prednisone, cyclosporin)
- Chemotherapeutic agents
- Pregnancy (may cause proliferation)
- Handling raw meat, fish, or other animal matter

Pathophysiology

HPV proteins contribute to the initiation of DNA replication. Plantar warts are most commonly caused by HPV-1, HPV-2, HPV-4, HPV-31, and HPV-32. The virus enters through skin abrasions and infects the cells of the basal layers of the skin. There is no diffusion to the deep tissues. Viral replication is slow and is closely dependent on the differentiation of the host cells. Viral DNA is present in the basal cells, but the viral antigens and the infecting virus are produced only when the cells start to become squamous and keratinized once they reach the surface. The incubation period is usually 4 to 6 months, with transmission by direct contact or by fomite.

Diagnostic Criteria

Warts are papillomatous, corrugated, hyperkeratotic growths found only on the epidermis, especially in areas subjected to repeated trauma. They can be solitary, multiple, or clustered. Warts are named based on their clinical appearance, location, or both.

Filiform warts are found primarily on the face and neck and present as tan, finger-like projections. Plantar warts (verruca plantaris) are found on the metatarsal areas, heels, and toes. Common warts (*V. vulgaris*) occur most often on the hands and fingers, knees, and elbows and have an asymmetric distribution. Flat warts (*Verruca plana*) are found mostly on the forehead, chin, cheeks, arms, and dorsa of the hands. They are flat and well defined and may be flesh colored or darker brown. Flat warts can be spread by shaving and are found in the beard area in men and on the legs in women. These HPV infections are rarely associated with malignancy. Typically, the incubation period is 2 to 6 months.

Initiating Drug Therapy

The natural history of cutaneous HPV infection is spontaneous resolution in months or a few years, so aggressive therapy may not be needed unless the patient reports pain. If treatment is initiated, the choice of medication depends on age of the patient, whether pain is involved, and the location of the wart. Filiform and flat warts are removed by a dermatologist. Topical treatment with salicylic acid (DuoFilm) is usually the starting point for all other warts. It is easier to treat small verrucae rather than waiting until they are large.

Goals of Therapy

The goal of therapy is eradication of the virus and lesion, although there is no way to actually kill HPV.

Salicylic Acid

Salicylic acid is a keratolytic (peeling) agent. It is available in a variety of strengths for specific types or sites of verrucae. It comes in liquid, gel, and patches. Usually, 17% salicylic acid is used to treat small lesions. Mediplast is a patch product that is 40% salicylic acid plaster; it is useful for large lesions and can be cut to fit the wart.

Dosage

The solution is left on overnight. The patch is applied and left on for 5 to 6 days. Treatment continues for up to 12 weeks. The patient is instructed to soak the area in water for 5 minutes and dry the area before applying the topical preparation.

Contraindications

Topical therapy is contraindicated in patients with diabetes mellitus or impaired circulation and on moles, birthmarks, or unusual warts with hair growth. The most common adverse effect is skin irritation.

Selecting the Most Appropriate Agent

Since the immune system seems to play the most important role in HPV, treatment stimulates the immune system to deal more effectively with the virus. Most warts cure themselves over time, especially in the immunocompetent host.

First-Line Therapy

Filiform or flat warts are removed by a dermatologist. For common warts, topical salicylic acid in a 17% concentration is used; it is applied at bedtime for approximately 8 weeks or until the wart is gone. For plantar warts, a 40% salicylic acid preparation is used in plaster or patch form that is cut to the size of the wart and applied at bedtime. The preparation remains in place for 24 to 48 hours. When removed, the area is rubbed with a pumice stone to remove dead white keratin. This is repeated for approximately 8 weeks or until the wart is gone (Figure 13.4 and Table 13.4).

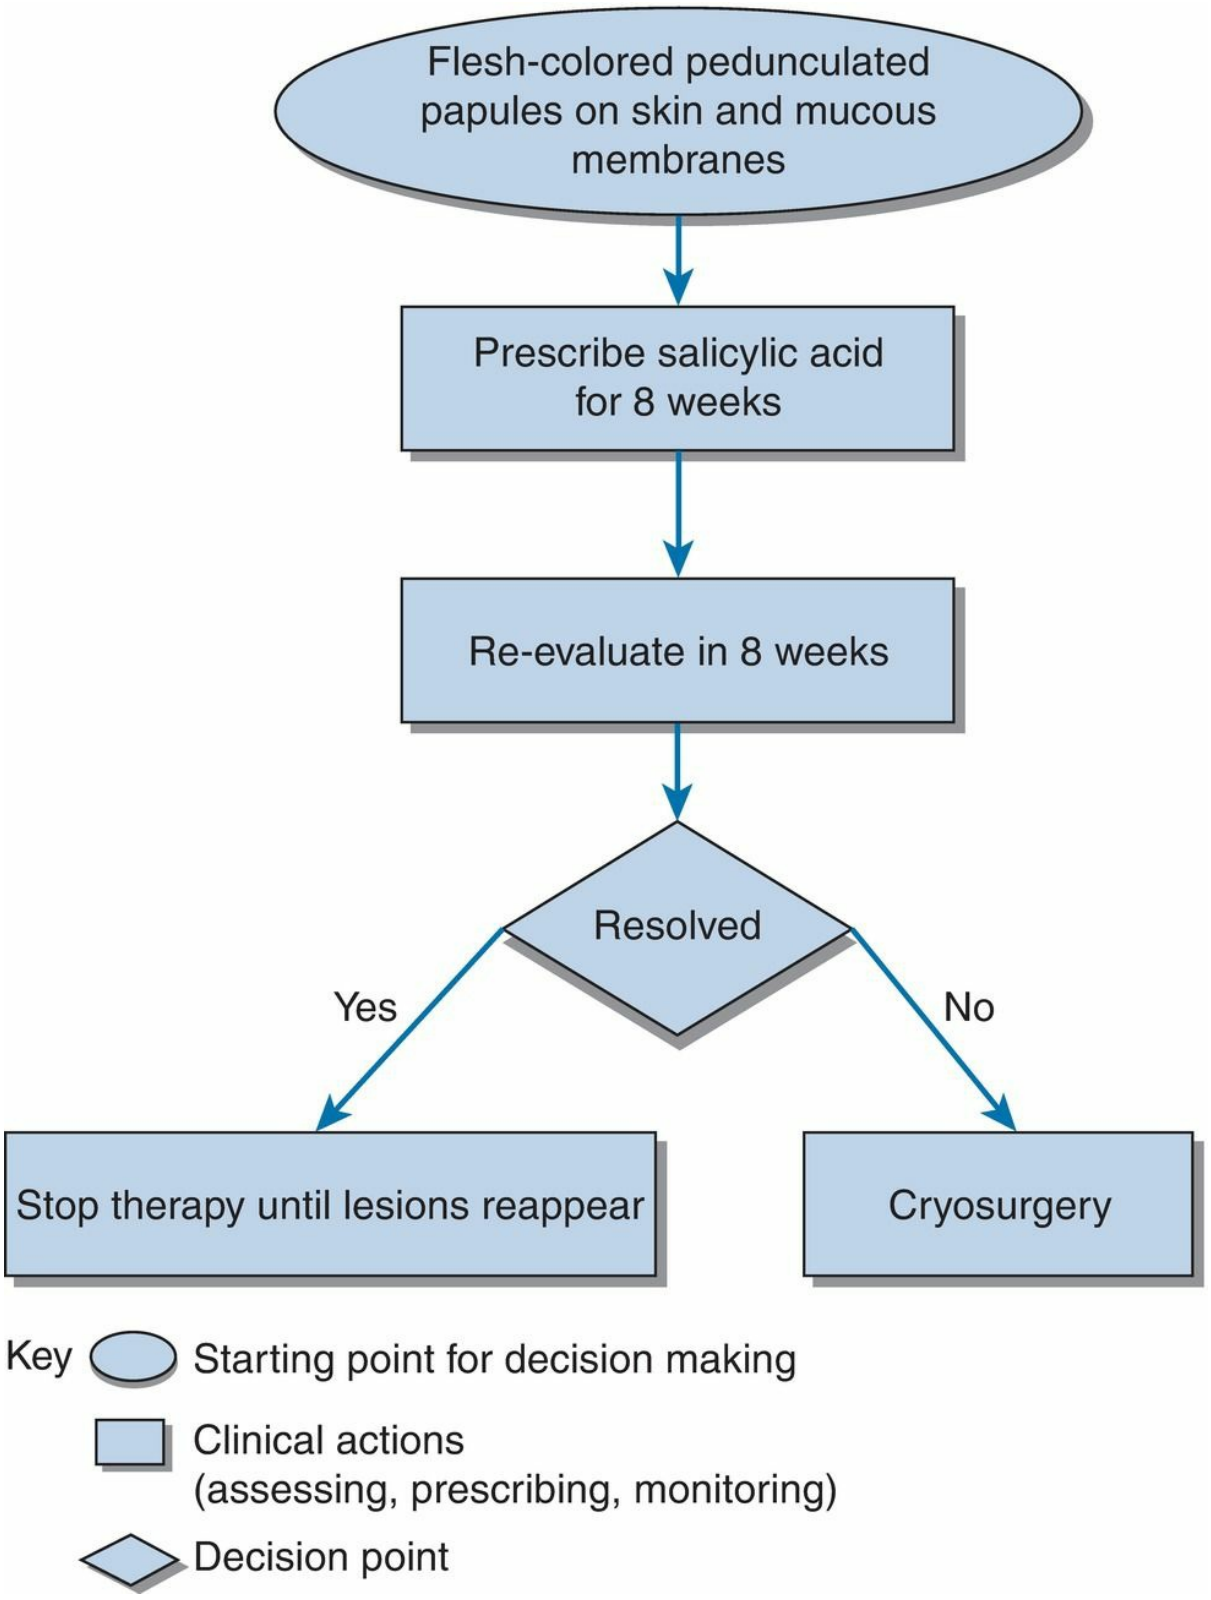

FIGURE 13.4 Treatment algorithm for nonanogenital human papillomavirus infection.

TABLE 13.4 Recommended Order of Treatment for Nonanogenital Infection with Human Papillomavirus

Order	Agent	Comments
First line	Salicylic acid	Used as first-line agent to treat all types of verrucae
Second line	Cryosurgery, electrosurgery, or carbon dioxide laser surgery	Refer patient to specialist.

Second-Line Therapy

If patient-applied therapy fails, cryosurgery, electrotherapy, or carbon dioxide laser surgery can be performed.

Monitoring Patient Response

In nonanogenital HPV infections, multiple treatments may be necessary. Patients should understand the importance of follow-up beyond the initial wart removal, because the virus may remain. Patients may need weekly treatment until the wart is eradicated.

Patient Education

Patients need to be informed that viral warts may recur.

Case Study*

B.H. is a 72-year-old man who presents for evaluation of several painful red bumps on his left side. The pain radiates around to his chest. The rash resembles blisters that are just forming. He noticed them yesterday, and more are forming. His wife is receiving chemotherapy for breast cancer. His laboratory results are all normal, and his creatinine is 1.2.

Diagnosis: Herpes Zoster

1. List specific treatment goals for B.H.
2. What, if any, drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on his history and the therapy.
5. List one or two adverse effects he may get from the prescribed therapy.
6. What over-the-counter medications and/or alternative therapy might you recommend?
7. What lifestyle changes might you recommend for B.H.?
8. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

14 Bacterial Infections of the Skin

Jason J. Schafer ■ Maria C. Foy

Bacterial skin infections range from those that are minor and heal without consequence to those that are more severe and may be disfiguring or even life threatening. Minor infections are quite common and are often self-treated by patients without formal medical care. The majority of wounds seen in health care practice are easily managed with appropriate wound care and antibiotic therapy, if indicated.

Common primary skin infections resulting from bacteria include impetigo, bullous impetigo, folliculitis, felons, paronychias, and cellulitis. (See Box 14.1 for information about associated problems.) These are discussed in this chapter, along with the less common infections erysipelas, ecthyma, furuncles, and carbuncles. This chapter also contains a brief discussion of necrotizing fasciitis, a very serious infection treated in an inpatient setting by specialists. See the accompanying color plates for an illustration of some of these infections.

BOX 14.1 Danger: Bites and Other Puncture Wounds

Human and animal bites and puncture wounds of other sorts are infections waiting to develop. Because these wounds are associated with such a high risk for infection, antibiotic prophylaxis with a broad-spectrum penicillin or quinolone usually begins with the patient's request for health care. Tetanus is also an important consideration in puncture wounds and bites, and patients should be immunized as needed.

If the wound was created by a clean object and is in an area that is well vascularized, treatment, in addition to antibiotics, may consist simply of washing thoroughly; soaking in warm, soapy water several times a day; and observing the site for a few days.

If the wound was made by an object contaminated with fecal material, soil, or other debris, or if the patient is diabetic or has a compromised circulation, broad-spectrum antibiotics are required based on the probable causative organism.

Care for bite wounds depends on several factors, including whether the biter was a human or an animal, the location of the wound, and whether the wound is primarily a puncture or a laceration. All bite wounds should be cleaned thoroughly with soap and water. Puncture bites should be irrigated with normal saline solution. Extensive wounds may require surgical debridement, tendon repair, or suturing. If the bite is located on an

extremity, elevation of the extremity will help prevent swelling.

All human bites that break the skin should be treated with antibiotics. Appropriate choices include amoxicillin– clavulanate or ampicillin–sulbactam for IV treatment. Oral doxycycline can be used for patients who are allergic to penicillin. Treatment should be given for a full 7 to 10 days.

Minor animal bites may not require antibiotic therapy unless the wound is on the hand, foot, or face. However, the infection rate in animal bites can range from 2% to 20%, and it may be prudent to treat the wound with a course of antibiotics. The possibility of rabies must also be addressed. The same agents used for human bites are also appropriate for animal bites.

Although most puncture wounds heal without incident, patients should be instructed to observe for signs of infection, including inflammation, persistent pain, swelling, or purulent drainage. If a puncture wound becomes infected, further systemic antibiotic therapy is required and should be based on Gram stain and culture results. A follow-up visit should be scheduled within days to ensure that the wound is healing without further infection.

Causes

The bacterial organisms most commonly responsible for causing skin infections are *Staphylococcus aureus* and beta-hemolytic forms of streptococci such as *Streptococcus pyogenes* (group A *Streptococcus* or GAS) and *Streptococcus agalactiae* (group B *Streptococcus*) (Tables 14.1 and 14.2).

TABLE 14.1 Selected Organisms That Cause Skin Infections

	Impetigo and Ecthyma	Bullous Impetigo	Erysipelas	Folliculitis, Furuncles, and Carbuncles	Paronychias
Gram-Positive Organisms					
Staphylococcus aureus	X	X	X (very few)	X	X
Group A *Streptococcus*	X		X		X
Group B *Streptococcus*	X (newborn impetigo)		X (newborn)		
Gram-Negative Organisms					
Proteus mirabilis				X (facial) (folliculitis)	
Pseudomonas aeruginosa	X (occasionally ecthyma)			X (hot tub folliculitis)	X
Klebsiella species				X (folliculitis)	
Enterobacter species				X (occasionally folliculitis)	

TABLE 14.2 Organisms That Cause Cellulitis

Organism	Condition
Staphylococcus aureus	Common
Group A *Streptococcus*	Common
Haemophilus influenzae B	Children (periorbital cellulitis*)
Streptococcus pneumoniae	Children
Escherichia coli	Opportunistic in compromised patients
Pseudomonas aeruginosa	Folliculitis from underchlorinated hot tubs
Klebsiella species	Opportunistic in compromised patients
Enterobacter species	Opportunistic in compromised patients
Pasteurella multocida	Animal bites and scratches
Anaerobic organisms	Diabetes, ulcers, trauma, crush wounds
Erysipelothrix rhusiopathiae	Fish handlers, usually on the hand
Aeromonas hydrophila	Freshwater-related injury, immunosuppressed patients
Vibrio species	Seawater-related injuries

*Uncommon now because of the use of HIB vaccine.

Impetigo and Ecthyma

In the past, superficial skin infections, such as impetigo, a common infection characterized by scattered vesicular lesions, were caused by GAS. However, a shift in normal skin flora has occurred in the United States, and now impetigo is due primarily to *S. aureus* alone or less commonly in combination with GAS. Bullous impetigo, a variation of impetigo, is caused primarily by *S. aureus*.

Ecthyma is a chronic form of impetigo that affects deeper layers of the skin. Usually the causes are the same as those of impetigo; however, gram-negative organisms, such as *Pseudomonas aeruginosa*, or fungal organisms may also play a role. This is especially true in diabetic or immunocompromised patients. Ecthyma can develop from minor wounds, scabies, insect bites, or any condition that causes itching, scratching, and excoriation.

Impetigo is more common in children but can also be seen in adults. It is most often diagnosed during hot, humid weather when bacterial colonization of the skin occurs more easily. Both impetigo and ecthyma are communicable and can be transmitted through person-to-person contact, often in schools or day care centers. Poor hygiene and crowded living conditions are other factors that can contribute to the development of these infections (Gorbach, 2004).

Cellulitis and Erysipelas

Cellulitis is an infection involving the skin and subcutaneous layers. It has the potential to spread systemically and cause serious illness. It can develop in any type of wound, ranging from a minor break in the skin to more serious laceration, puncture, or burn. Other common precipitants include stasis dermatitis, stasis ulcers, edema of the lower extremity, venous insufficiency, and obesity (Odell, 2003). In intravenous (IV) drug users, cellulitis typically develops at injection sites. The characteristics of infection depend on many factors, including the type of wound, the organisms involved, and the patient.

Most cases of cellulitis are caused by GAS or *S. aureus.* Patients with certain predisposing factors, however, may be at risk for infections caused by other organisms, including *Escherichia coli, P. aeruginosa*, and *Klebsiella* species (Table 14.2). *Pasteurella multocida* is the primary cause of cellulitis from animal bites and scratches, although *S. aureus* and GAS may also be present. Table 14.2 lists additional causes.

Staphylococcus aureus organisms that are resistant to commonly used antibiotics have recently emerged as a major cause of community-acquired skin infections. These organisms are resistant to all penicillins and cephalosporin agents and are referred to as community-associated methicillin-resistant *S. aureus* (CA-MRSA) (DeLeo et al., 2010). Infections resulting from these organisms can be particularly challenging to manage because of their resistance to commonly used antibiotics. Also, as opposed to other skin infections, CA-MRSA infections may occur in otherwise healthy individuals but are most common among patients with close contact with others colonized or infected with CA-MRSA. Transmission of this pathogen appears to occur most commonly when there are crowded living conditions (e.g., military bases, prisons) or close physical contact between individuals, particularly when injury to the skin is common (e.g., athletes).

Erysipelas, predominantly caused by *S. pyogenes*, is a superficial form of cellulitis and is seen more often in children, especially infants, and the elderly. Also known as *St. Anthony's fire*, it is an acute condition that can spread rapidly through the skin and lymphatics, causing significant mortality (up to 5%) if left untreated.

Pustular Infections

Pustular infections include folliculitis, furunculosis, and carbunculosis. Folliculitis is a superficial infection of the hair follicle commonly caused by *S. aureus*. Patients who have been taking prolonged antibiotic therapy for acne, however, may acquire folliculitis from gram-negative organisms such as *Klebsiella, Enterobacter*, or *Proteus* species. Lesions associated with folliculitis are usually found on the cheek or chin, under the nose, or on the central facial areas (Trent et al., 2001). *Pseudomonas aeruginosa* can also cause folliculitis, particularly in those who frequently use hot tubs, as a result of inadequate chlorination.

Furunculosis (furuncles) and carbunculosis (carbuncles) are also pustular infections usually caused by *S. aureus*. Both conditions involve deeper areas of the skin and can develop from unresolved cases of folliculitis.

Irritation from shaving, plucking, and waxing of hair may contribute to folliculitis. Other predisposing factors include humid conditions, tight clothing, diabetes, occlusion of the hair follicles from cosmetics or sunscreens, poor hygiene, and occupational exposure to heavy grease or solvents.

Other common skin infections, such as paronychia (an infection surrounding a nail bed) and a felon (an infection affecting the tip of a digit), are usually caused by *S. aureus*, *S. pyogenes*, or *Pseudomonas* species and occasionally other gram-negative bacilli.

Necrotizing Fasciitis

Necrotizing fasciitis is an extremely serious infection of the subcutaneous tissues that can be life threatening if not diagnosed early and treated appropriately. Management often requires emergent surgical interventions to remove infected tissue in combination with antibiotic therapy. It is most likely to occur in middle-aged, elderly, or seriously debilitated patients (Sadick, 1997). The mortality rate is typically 20% to 30% but can approach up to 50% in patients with underlying vascular disease. Often, the initial lesion is minor, such as an insect bite or boil; it is rarely associated with Bartholin gland or perianal abscesses (Gorbach, 2004). However, 20% of cases have no visible lesions (Gorbach, 2004). Patients with diabetes and alcoholism may have no evidence of trauma (Odell, 2003).

Necrotizing fasciitis is often a polymicrobial infection caused by combinations of pathogens that include *S. pyogenes*, *S. aureus*, and anaerobic bacteria such as *Bacteroides fragilis* and Peptostreptococci. GAS and *S. aureus* can also cause necrotizing fasciitis alone as a monomicrobial infection. C*lostridium perfringens*, an anaerobic bacterium commonly found in soil, can cause "gas gangrene," a type of necrotizing fasciitis that can occur following deep penetrating trauma injuries (Ustin & Malangoni, 2011). Varicella infection is often considered a risk factor for invasive skin infections, including necrotizing fasciitis (Wilhelm & Edson, 2001).

Patients with necrotizing fasciitis are very ill and require intensive care. Surgical debridement of infected areas and IV antibiotic therapy are also commonly indicated. Patients who are elderly or debilitated or who have predisposing medical conditions, such as diabetes, advanced atherosclerotic disease, and lesions starting in an extremity and progressing into the back, chest wall, or buttock muscles, have a poor prognosis (Gorbach, 2004).

Pathophysiology

The skin is composed of three layers. The outer layer is the epidermis, the first line of defense against infection. Nail tissue is part of the epidermis. Underneath is the dermis, which contains connective tissue, blood vessels, nerves, hair follicles, sweat glands, and sebaceous glands. The innermost layer is composed of subcutaneous tissue. Skin infections may be classified according to the depth of penetration and the layer and skin structure affected.

Under normal circumstances, bacteria present on the skin as normal flora cause no harm. However, a break in the skin can allow these organisms to penetrate and proliferate, resulting in a skin infection. Some people are persistent carriers of *S. aureus* in the nasal, perineal, or axillary areas. These individuals may be more prone to developing skin infections and more likely to experience recurrences.

Patients with predisposing medical conditions (Box 14.2), such as diabetes, immune system disorders, and malnutrition from alcoholism or other causes, are more prone to skin infection because of poor wound healing. Also at a higher risk for skin infection are those with circulatory compromise of the arterial, venous, or lymphatic systems. Wound infections in patients with these conditions have the potential to become more serious and invasive, requiring IV antibiotic therapy, hospitalization, or referral to a specialist. Wound infections can also become more serious when treatment is delayed. The practitioner must be alert for these situations and act promptly.

BOX 14.2 Predisposing Factors in Skin Infections

Chronic carriers of *Staphylococcus aureus*
Diabetes mellitus
Peripheral vascular disease
Venous stasis
Alcoholism (malnutrition)
Immune deficiency
Corticosteroid therapy
Obesity
Trauma or burns
Poor hygiene
Warm, humid conditions
Topical irritants
Tight clothing

In addition, many organisms aside from GAS or *S. aureus* may cause skin infections in

patients with chronic conditions like diabetes. These organisms include *E. coli*, *Klebsiella* species, and *P. aeruginosa*. Infections in these patients are often more difficult to manage clinically and have the tendency to become chronic. Infections that do resolve with appropriate therapy have a high risk of recurrence. A common example of this scenario is a diabetic foot infection.

Diagnostic Criteria

Impetigo and Ecthyma

Impetigo, a highly contagious, common primary skin infection in children, is most frequently found on the face, scalp, or extremities. It begins as scattered, discrete macules that itch and are spread by scratching. These macules then develop into vesicles and pustules on an erythematous base that eventually rupture, oozing a purulent liquid. Once dried, the lesions appear thick, with a characteristic honey-colored crust on the surface. Once healed, scarring is rare. Regional lymphadenopathy may be present, and lesions may itch; however, fever or other systemic complaints are uncommon. The infection is diagnosed clinically by the appearance of hallmark honey-colored crusts. A Gram stain of the vesicular fluid can confirm the diagnosis if there is clinical uncertainty.

Impetigo may also present with bullous lesions and can be referred to as bullous impetigo. Found on the face, scalp, extremities, trunk, and intertriginous areas, it affects primarily newborns and children ages 3 to 5 (Wilhelm & Edson, 2001). Bullous impetigo is characterized by the formation of superficial, flaccid bullae on the skin. The brownish-gray lesions are sometimes crusted or have an erythematous halo. They also appear to be smooth and shiny, as if they were coated with lacquer.

In the most severe form of bullous impetigo, exfoliation of large areas of the skin can occur in what is called “scalded skin” syndrome. This presentation is most common in infants but can also occur in those who are immunosuppressed. It is thought to occur more often in patients who are sensitive to toxins produced by staphylococcal organisms (Barg et al., 1998). Such cases carry a greater risk for more invasive infection because of the loss of large amounts of the skin, the body’s protective barrier.

Ecthyma occurs when a case of impetigo worsens and spreads deeply to the dermis. Much less common than impetigo, ecthyma usually affects debilitated individuals and the elderly (Odell, 2003). Signs of ecthyma are usually found on the lower extremities, beginning with the formation of vesicles that then develop into shallow ulcerations. The ulcerations enlarge over several days and are surrounded by an erythematous halo. Because the infection affects the deeper layers of the skin, scarring is often seen after ulcerations heal (Wilhelm & Edson, 2001). Lesions are usually painful and may persist for weeks to months.

Cellulitis and Erysipelas

Cellulitis is a potentially serious infection involving the skin and subcutaneous tissue. In adults, it most commonly affects the lower extremities and begins with a skin break resulting from a localized trauma that may not be apparent. In children, cellulitis usually results from an insect bite or wound. The disease can spread through the superficial layers of skin and cause painful erythema, with the affected area warm and tender to the touch. Pitting edema can also be present, and the skin may be shiny and have an "orange peel" appearance. The margins of cellulitis are diffuse, not sharply demarcated, and the affected area is flat and usually edematous. In open wounds, purulent drainage and necrosis may be present. Red streaks may develop proximal to the area of infection, indicating lymphatic spread or lymphangitis. Crepitus may be present, suggesting involvement of anaerobic organisms. Systemic symptoms of fever, chills, and malaise and regional adenitis are also common and can indicate bacteremia. In fact, these symptoms may be present before cellulitis is clearly evident.

Cellulitis due to CA-MRSA may be accompanied by the presence of an abscess or a furuncle that contains a necrotic center (DeLeo et al., 2010). These infections may progress rapidly and cause local tissue destruction, possibly leading to systemic infection. In addition to painful erythema, the abscess present may spontaneously drain but often will require an incision and drainage procedure for proper management.

Erysipelas, a type of cellulitis limited to the superficial layers of the skin, is most common in children, especially infants and the elderly, but it can occur in healthy individuals who have sustained only minor wounds. Other patients who are at risk include those with venous insufficiency or underlying skin ulcers, diabetics, alcoholics, or those with nephritic syndrome. Erysipelas is most commonly found on the lower extremities but can also be present on the face and scalp. Erysipelas begins as an area of sharply demarcated erythema that spreads rapidly over a period of minutes to hours. The affected area is slightly raised, firm, warm, and tender to the touch. Erythema spreads along local lymphatic channels, which gives the skin a typical "orange peel" appearance due to lymphatic obstruction.

Common systemic symptoms include pain, malaise, chills, and fever. In more serious cases, patients may appear seriously ill. Erysipelas occurring on the face often follows a respiratory infection; this presentation can be particularly serious due to the potential occurrence of cavernous sinus thrombosis (Odell, 2003). Erysipelas can recur, usually in the same area as a previous infection, especially in patients with venous insufficiency or lymphedema (Wilhelm & Edson, 2001).

Pustular Infections

Folliculitis is usually superficial and occurs on hairy areas of the skin, especially the bearded parts of the face and the intertriginous areas. Early lesions appear as erythematous papules that turn into small pustules within approximately 48 hours. As a result, it is common to see various lesions at different stages of development. These lesions may itch initially and then rupture and form crusts. Folliculitis is often recurrent and can represent over months or even years.

A furuncle, which develops from folliculitis, is a painful, pus-filled nodule that encircles a hair follicle. The condition is most commonly found in adolescents or in those with predisposing conditions such as diabetes, immunodeficiency, or poor hygiene. A carbuncle is a confluence of several furuncles that form deep within the dermis. They are often found on the upper back or the thick skin at the back of the neck, especially in men over age 40.

Furuncles and carbuncles are found in hairy areas or in areas of friction. Common sites are the neck, face, axillae, forearms, upper back, groin, buttocks, and thighs. A lesion begins with pruritus and tenderness. It becomes fluctuant in several days as the collection of pus enlarges. Ranging in size from 0.5 to 3 cm, it appears as a pointed, yellow lesion on the skin. As the lesion enlarges, tenderness increases and the lesion often ruptures spontaneously. Systemic manifestations are not usually seen with furuncles, but carbuncles are frequently accompanied by systemic signs such as fever, malaise, and headache.

A paronychia is an infection of the tissue surrounding a nail bed. It is associated with nail biting, hangnails, or finger sucking; it may occur in people who have their hands in water frequently. Diabetic patients are also at a higher risk. A paronychia involving the toenail most often results from an ingrown nail. The infected area appears red and swollen and is painful. Pus, which may accumulate, may sometimes be expressed with gentle pressure; this usually relieves the discomfort. Systemic symptoms are uncommon.

A felon, which may follow a fingertip wound, is an infection that involves the pulp space in the tip of a digit. It is potentially more serious than a paronychia because it is confined in a closed space. The affected digit is erythematous, edematous, and exquisitely tender. The edema has the potential to compromise the arterial supply of the digit. If left untreated, abscess and tissue necrosis can occur. An additional danger is the possibility of bony or joint involvement, which can lead to loss of function.

Necrotizing Fasciitis

Patients with necrotizing fasciitis are extremely ill, requiring intensive care and treatment by specialists. The infection may initially appear similar to cellulitis, although severe pain, erythema, and edema are commonly present. Necrotizing fasciitis may be differentiated from cellulitis by its rapid spread, tissue destruction, and lack of response to usual antibiotic therapy. The subcutaneous tissue will have a wooden-hard feel, as compared to cellulitis and erysipelas, where this tissue is usually yielding and can be palpated. Other symptoms that distinguish necrotizing fasciitis from cellulitis are high fever (102°F to 105°F [38.9°C to 40.6°C]), intense pain and tenderness at the site, and swelling of the affected extremity. Drainage is also usually present and is described as "dishwater pus" (Sadick, 1997). As this infection progresses and tissue destruction spreads, pain may be replaced by anesthesia, and patients may show signs of sepsis, including hemodynamic instability and multiorgan dysfunction.

Initiating Drug Therapy

An increasing challenge in treating skin infections is the problem of antibiotic-resistant organisms. Choosing the appropriate agent is not as simple as it once was, and prescribers must be aware of resistance, as well as regional variations in the prevalence and susceptibility of infecting organisms.

Because warm, humid conditions and poor hygiene may play a role in skin infections, especially impetigo, treatment begins with good hygiene (Box 14.3), avoidance of irritants, and meticulous wound care as appropriate. For some very minor infections, these measures along with a topical agent may be sufficient. Adjunctive treatment for most skin infections (e.g., bullous impetigo and erysipelas) includes warm soaks and elevation of the affected area if the infection involves an extremity. However, most bacterial skin infections require treatment with systemic antibiotics.

BOX 14.3 Strategies to Prevent Skin Infections

Wash hands frequently to prevent spread of infecting organisms.
Clean skin twice daily with soap and water or antibacterial soap (e.g., Hibiclens, Lever 2000).
Avoid scratching.
Use warm soaks to promote drainage of pustular matter.
Avoid irritants, including tight clothing, shaving, sunscreens, and occlusive cosmetics and deodorants.

The majority of infections are treated in the outpatient setting with oral antibiotic agents. Patients with more serious infections, however, may require hospitalization and IV medications or referral to a specialist. Treatment decisions are based on the practitioner's knowledge of the patient's predisposing conditions, the patient's present state of health, and the type and stage of the infection.

In many cases, systemic antibiotic therapy (Table 14.3) is prescribed empirically based on knowledge of the organisms commonly responsible for specific skin infections, such as *S. aureus* and GAS. With potentially serious infections such as a felon or cellulitis, a specimen of wound drainage should be obtained for culture and sensitivity testing. Empiric therapy will be initiated pending the results.

TABLE 14.3 Overview of Selected Antibiotics for Skin Infections

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Broad-Spectrum Penicillins			
amoxicillin–clavulanate (Augmentin) Adults: 500–875 mg q12h or 250–500 mg q8h PO Children: 22.5 mg/kg q12h PO or 13.3 mg/kg q8h PO	Nausea, vomiting, diarrhea, rash, allergic reactions, fungal infection **Serious:** pseudomembranous colitis, seizures (high doses)	Allergy to penicillin Use with caution in severe renal disease, less severe allergy to cephalosporins.	Take with or without food. Food may decrease GI symptoms. Interactions: warfarin, oral contraceptives Safe for young children.
dicloxacillin (Dynapen) Adults: 125–250 mg 6h PO Children: 3.125–6.25 mg/kg q6h PO	Same as amoxicillin–clavulanate Drug-induced hepatitis	Penicillin allergy Use with caution in severe renal or hepatic disease, pregnancy, lactation.	Take on empty stomach for best absorption. Interactions: warfarin.
First-Generation Cephalosporins			
cephalexin (Keflex) Adults: 500 mg q12h PO Children: 12.5–25 mg/kg q12h PO	Nausea, vomiting, diarrhea, rash, allergic reactions, fungal infections **Serious:** pseudomembranous colitis, seizures (high doses) Stevens-Johnson syndrome, hemolytic anemia	Serious penicillin allergy, allergy to cephalosporins Use with caution in renal disease, pregnancy, lactation.	Take with or without food. Food may decrease GI symptoms.
cefazolin (Ancef) Adults: 500 mg q12h PO or 1 g q6–8h IV Children: 25–50 mg/kg divided into 3 or 4 equal doses PO	Same as cephalexin	Same as cephalexin.	Same as cephalexin.
Second-Generation Cephalosporins			
cefaclor (Ceclor) Adults: 250–500 mg q8h or 375–500 mg q12h PO (extended release) Children: 6.7–13.3 mg/kg q8h not to exceed 1 g/d	Same as cephalexin	Same as cephalexin.	Same as cephalexin.
cefprozil (Cefzil) Adults: 250–500 mg q12h PO or 500 mg q24h PO Children: 20 mg/kg q24h	Same as cephalexin	Same as cephalexin.	Same as cephalexin.
cefuroxime (Ceftin, Zinacef) Adults: 250–500 mg q12h PO Children: 15 mg/kg q12h PO	Same as cephalexin	Same as cephalexin.	Same as cephalexin; swallow whole because of bitter taste.
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
Third-Generation Cephalosporins			
cefpodoxime (Vantin) Adults: 400 mg q12h PO	Same as cephalexin	Same as cephalexin.	Same as cephalexin.
ceftriaxone (Rocephin) Adults: 0.5–1.0 g q12h IM or IV or 1–2 g q24h IM or IV Children: 50–75 mg/kg q24h IM or IV not to exceed 2 g	Same as cephalexin and also pseudolithiasis	Same as cephalexin.	No known interactions IM: dilute with lidocaine to reduce pain at injection site.
Fluoroquinolones			
ciprofloxacin (Cipro) Adults: 500–750 mg q12h PO Children: not approved	Nausea, diarrhea, altered taste, dizziness, drowsiness, headache, insomnia, agitation, confusion **Serious:** pseudomembranous colitis, Stevens-Johnson syndrome	Allergy to fluoroquinolone. Children younger than age 18, pregnancy. Use with caution in renal disease, central nervous system disease, elderly, lactation (safety not established).	Food slows absorption. Interactions: antacids, zinc, sucralfate, iron, theophylline, warfarin, probenecid, foscarnet, glucocorticoids, didanosine.
levofloxacin (Levaquin) Adults: 500–750 mg qd PO Children: not approved	Same as ciprofloxacin		
moxifloxacin (Avelox) Adults: 400 mg qd PO	Same as ciprofloxacin		
Miscellaneous			
clindamycin (Cleocin) Adults: 150–450 mg q6h PO Children: 2–5 mg/kg q6h PO or 2.7–6.7 mg/kg q8h	Nausea, vomiting, diarrhea, rash, allergic reaction, fungal infections **Serious:** pseudomembranous colitis	Allergy, previous pseudomembranous colitis, severe hepatic disease Use with caution in pregnancy and lactation.	Take with or without food with full glass of water. Interactions include kaolin (decreases absorption).
daptomycin (Cubicin) Adults: 4 mg/kg IV daily Children: not approved	Creatine phosphokinase (CPK) elevation with or without myopathy (reversible)	Allergy to daptomycin, children younger than age 18.	Monitor for CPK elevations, especially in patients receiving HMG-CoA reductase inhibitors.
linezolid (Zyvox) Adults: 600 mg IV or PO q12h Children: 10 mg/kg q8h	Bone marrow suppression, rare optic neuritis, or peripheral neuropathy with long-term use	Allergy, uncontrolled hypertension, and concurrent use of monoamine oxidase (MAO) inhibitors.	Interaction with selective serotonin reuptake inhibitors and MAO inhibitors.
tigecycline (Tygacil) Adults: 100 mg × 1 dose, then 50 mg q12h Children: not approved	Nausea (26%) and vomiting (18%) are common	Allergy to tigecycline; also use caution in patients with allergies to tetracyclines.	Dosage adjustment is necessary for severe hepatic impairment.
trimethoprim/sulfamethoxazole (Bactrim) Adults: 1–2 double-strength tablets q12h Children: 8 mg/kg trimethoprim component/day orally divided q12h	Bone marrow suppression, rash, nausea, and vomiting	Allergy to sulfonamides or trimethoprim, pregnant patients at term, nursing mothers.	Should not be used to treat infections due to group A *Streptococcus*.
vancomycin (Vancocin) Adults: 15 mg/kg IV q12h Children: 10 mg/kg IV q6h	Infusion-related reactions, phlebitis, renal impairment	Allergy to vancomycin.	Monitor serum concentrations.

In the case of puncture or bite wounds that are not initially infected, antibiotics are prescribed as prophylaxis because of the high risk of infection associated with these wounds.

Topical medications, such as mupirocin (Bactroban) ointment, can be occasionally used as primary therapy for minor infections (e.g., impetigo) or alternatively used in combination with systemic agents for more serious infections. In some patients thought to be chronic carriers of *S. aureus*, infections may be recurrent. Topical mupirocin ointment applied to the nares or perineal or axillary areas may be used prophylactically as an attempt to eliminate this chronic carrier state and prevent recurrent infections (Fitzpatrick et al., 1997).

Several other adjunctive measures may also be used in combination with drug therapy. Bedside warm soaks and incision and drainage procedures may help resolve pustular lesions. Sterile saline dressings and cool Burow's compresses may be used to decrease the pain associated with cellulitis (Rose, 2004). Patients with a paronychia may need to have the nail bed decompressed to relieve the pressure, and deeper and more invasive infections almost always require incision and drainage.

Goals of Drug Therapy

The goals in treating bacterial skin infections are to cure the infection, prevent worsening, minimize scarring, and prevent recurrence. Many minor infections resolve within 10 to 14 days. If resolution does not occur, alternative agents may be prescribed. The prescriber must decide when it is appropriate to initiate treatment with an alternative agent or whether a referral to a specialist for more definitive diagnosis and treatment is indicated.

Antibiotics

Several classes of antibiotic agents are useful for treating bacterial skin infections. For information on specific agents, refer to Table 14.3. In certain circumstances, a combination of antibiotics may be necessary to treat an infection because of multiple pathogens (i.e., a polymicrobial infection). Agents may be administered topically, orally, intramuscularly, or intravenously, depending on the specific infection and the condition of the patient.

The most common adverse effects occurring with most antibiotics are nausea, vomiting, diarrhea, rashes, allergic reactions, and urticaria. Also, patients taking antibiotic therapy, especially prolonged therapy, can develop fungal infections such as vaginal candidiasis or thrush.

A less common but potentially life-threatening adverse effect of antibiotic therapy is pseudomembranous colitis. This causes severe diarrhea and is the result of overgrowth of the bacterium *Clostridium difficile*. Anaphylaxis and seizures (especially when high doses of antibiotics are used) may also occur. To minimize the risk of these events, a thorough patient history is essential before prescribing these drugs. There are also many interactions between antibiotics and other medications a patient might be taking. For information on selected drug interactions, see Table 14.3.

Broad-Spectrum Penicillins

Most skin infections are caused by GAS and *S. aureus*. In the past, therapy with penicillin was usually effective in treating these infections. With the growing problem of antibiotic resistance, however, it is now necessary to choose a broad-spectrum agent. For example, many strains of *S. aureus* produce the enzyme penicillinase, which can inactivate penicillin. In this case, the provider should choose an agent that is penicillinase resistant. Useful agents in this class for treating specific skin infections include amoxicillin–clavulanate (Augmentin) or dicloxacillin (Dynapen).

Amoxicillin–clavulanate has bactericidal action against many organisms, including beta-hemolytic streptococci, *S. aureus*, *E. coli*, and *P. mirabilis*. The clavulanate portion of the drug is a beta-lactamase inhibitor which allows amoxicillin to remain active in the presence of certain beta-lactamase enzymes such as the penicillinase produced by *S. aureus*. Amoxicillin–clavulanate is well absorbed orally and is more resistant to acid inactivation than other penicillins.

Common side effects are nausea, vomiting, diarrhea, rash, and urticaria. Patients who are allergic to penicillin should not be given this agent, and it should be used with caution in patients with severe renal impairment.

Dicloxacillin has bactericidal activity against penicillinase-producing strains of *S. aureus*. It is administered orally, and the adverse effect profile is similar to that of

amoxicillin–clavulanate. In addition, dicloxacillin should be used with caution in patients with severe renal and hepatic impairment (see Table 14.3).

First-Generation Cephalosporins

In this class, commonly used drugs for treating skin infections are cephalexin (Keflex) and cefazolin (Ancef). These agents have bactericidal activity against many organisms, including GAS and penicillinase-producing *S. aureus*. They also have limited activity against *Klebsiella pneumoniae*, *P. mirabilis*, and *E. coli*.

Cephalexin is administered orally and has excellent bioavailability, while cefazolin is administered intravenously. Their adverse effect profiles are similar to that of the broad-spectrum penicillins. These drugs should not be used in patients with a severe penicillin allergy, and dosage adjustments are necessary in patients with renal insufficiency (see Table 14.3).

Second-Generation Cephalosporins

Second-generation cephalosporins that are useful for skin infections include cefaclor (Ceclor), cefuroxime (Ceftin, Zinacef), and cefprozil (Cefzil). They are effective against the same organisms as first-generation cephalosporins but have additional activity against certain gram-negative organisms, including *H. influenzae*, *E. coli*, *K. pneumoniae*, and *Proteus* organisms. These agents are all well absorbed orally and their adverse effect profiles are similar to that of the first-generation cephalosporins. They should not be given to patients who have a severe allergy to penicillin or an allergy to other cephalosporins. Dosage adjustments are necessary in patients with renal insufficiency (see Table 14.3).

Third-Generation Cephalosporins

Useful third-generation cephalosporins for treating skin infections include cefpodoxime (Vantin), ceftriaxone (Rocephin), and ceftazidime (Fortaz). These drugs are usually reserved for more serious infections and are not typically chosen as first-line agents. In addition, ceftriaxone and ceftazidime are not available as oral agents. Ceftriaxone is administered either intramuscularly or intravenously, and ceftazidime can only be administered intravenously. Cefpodoxime is available only as an oral agent.

The spectrum of antibacterial activity for these agents is similar to that of the second-generation cephalosporins. However, they are less effective against *S. aureus* and more effective against certain gram-negative organisms, including *Enterobacter, H. influenzae, E. coli, K. pneumoniae*, and *Proteus* species. Ceftazidime is the only agent in this group that can be recommended for infections caused by *P. aeruginosa*. Ceftriaxone is absorbed intramuscularly, but this route of administration may be painful. Cefpodoxime is well absorbed orally.

The adverse effect profile for these agents is similar to that of the other cephalosporins and broad-spectrum penicillins. Care should be taken in prescribing them in the presence

of severe renal or hepatic impairment, and these agents cannot be administered to patients with severe penicillin or cephalosporin allergies. Rarely, ceftriaxone may cause pseudolithiasis (see Table 14.3).

Clindamycin

Clindamycin (Cleocin) is an alternative agent that can be considered for treating bacterial skin infections due to *S. aureus* and GAS when patients are allergic to penicillins and cephalosporins. It also may retain activity against CA-MRSA strains of bacteria, but susceptibility testing should be performed prior to use, especially in geographic regions where activity for CA-MRSA is inconsistent. In addition, clindamycin may be considered when anaerobic bacterial coverage is necessary for polymicrobial infections.

Clindamycin is available for oral or IV administration and is generally well tolerated. Common side effects include diarrhea, nausea, and abdominal pain. Also, this agent has been more commonly associated with *C. difficile*–associated pseudomembranous colitis.

Fluoroquinolones

Levofloxacin (Levaquin), moxifloxacin (Avelox), and ciprofloxacin (Cipro) are the fluoroquinolone antibiotics used in the treatment of skin and skin structure infections. They are useful for serious infections in patients with penicillin allergies that have infections caused by gram-negative organisms. Their spectrum of activity includes many gram-negative bacteria, such as *E. coli*, *Klebsiella,* and *Enterobacter* species. In addition, levofloxacin and ciprofloxacin are often active against *P. aeruginosa*. Each fluoroquinolone agent is available IV and orally and each has excellent bioavailability.

Common adverse effects are diarrhea, nausea, abdominal pain, dizziness, drowsiness, headache, and insomnia. Uncommon but severe events include Stevens-Johnson syndrome, seizures, Achilles tendon rupture, and pseudomembranous colitis. These agents also have several drug interactions (see Table 14.3).

Fluoroquinolone antibiotics are not recommended in children younger than age 18 or during pregnancy and lactation. They are also contraindicated in patients allergic to other fluoroquinolones. These medications should be used cautiously in elderly patients and patients with central nervous system diseases, seizure disorders, or renal impairment.

Vancomycin, Daptomycin, Telavancin, Dalbavancin, Oritavancin, Linezolid, Tedizolid, and Tigecycline

These agents have consistent antibacterial activity against drug-resistant, gram-positive pathogens including MRSA. Vancomycin remains the drug of choice for bacterial skin infections due to MRSA when parenteral therapy is necessary; however, daptomycin, telavancin, dalbavancin, oritavancin, linezolid, tedizolid, and tigecycline are also effective but are more expensive options. Dalbavancin and oritavancin are unique due to their very

long half-lives. As a result, treatment with dalbavancin requires only two doses given one week apart, while oritavancin is indicated to treat bacterial skin infections using only a single IV dose. Linezolid and tedizolid are the only agents in this group that are available orally, which provides an option for clinicians to switch from IV to oral therapy when patients are clinically stable but require additional treatment.

Despite their activity against MRSA, each agent has significant side effects and the potential for drug–drug interactions should be considered prior to initiating therapy.

Trimethoprim/Sulfamethoxazole

Trimethoprim/sulfamethoxazole is another useful agent for the treatment of CA-MRSA infections that can be managed with oral therapy. It is important, however, to remember that this agent does not have reliable activity for infections caused by GAS. Therefore, the diagnosis of CA-MRSA should be certain prior to treatment.

Adverse effects associated with trimethoprim/sulfamethoxazole include GI intolerance, rash, pruritus, and hyperkalemia. In addition, this agent may cause photosensitivity, and patients should be counseled to wear sun protection during therapy.

Topical Agents

Topical agents may be used as first-line treatment or adjunctively in bacterial skin infections. Mupirocin ointment is effective against *S. aureus* and some streptococcal infections. It is also used over the long term to eliminate nasal, axillary, or groin carriage of *S. aureus*, which is thought to contribute to recurrent infections in some patients.

Mupirocin ointment is minimally absorbed systemically. It is metabolized by the skin and usually well tolerated. Adverse effects are few but include headache, cough, rhinitis, pharyngitis, upper respiratory tract congestion, and taste perversion with nasal use. Burning, stinging, rash, erythema, or itching can occur when applied topically. Mupirocin should not be used in patients with an allergy to the drug and should not be used with other nasal products. It should be used with caution in patients with impaired renal function due to possible absorption of polyethylene glycol through an open wound (*Drug Facts and Comparisons*, 2004).

The topical preparation of gentamicin is available in a cream or an ointment. It is a powerful topical agent and is effective against many organisms, including GAS, *S. aureus*, and *Pseudomonas* species. Topical gentamicin can be used for a variety of primary and secondary skin infections. It is safe for children older than age 12 months. It is usually well tolerated, although irritation may occur. Occasionally, fungal infection or overgrowth of nonsusceptible bacteria may occur at the site of use.

Selecting the Most Appropriate Agent

Practice guidelines are available to assist clinicians in the management of skin infections including the selection of appropriate antimicrobial therapy (Stevens et al., 2014). Most bacterial skin conditions are treated empirically based on the prescriber's knowledge of the organisms most likely to cause a particular infection (Table 14.4). When the organism is not known, the potential for serious infection is present, or the patient is already extremely ill, the prescriber needs to confirm the diagnosis and organism either by skin biopsy or wound culture. In such cases, empiric treatment begins with a broad-spectrum agent until organism susceptibility is available and a diagnosis is made.

TABLE 14.4 Recommended Order of Treatment for Bacterial Skin Infections

Infection	First-Line Therapy	Second-Line Therapy	Third-Line Therapy
Impetigo, bullous impetigo, and ecthyma	Oral antibiotic for 7–10 d	Alternate oral antibiotic for 7–10 d or refer	
Cellulitis	Oral antibiotic for 7–10 d	Admit for IV antibiotic treatment or refer	
Erysipelas	Oral antibiotic for 7–10 d	Admit for IV antibiotic treatment or refer	
Furuncles and carbuncles	Oral antibiotic for 7–10 d or refer	Alternate oral antibiotic for 7–10 d or refer	
Paronychias	Tetanus prophylaxis, as appropriate, and oral antibiotic for 7–10 d	Alternate oral antibiotic for 7–10 d or refer	
Felon and puncture wound	Tetanus prophylaxis, as appropriate, and oral antibiotic for 7–10 d	Continue oral antibiotic if infection continues	Alternate oral antibiotic for 7–10 d or refer

Other important factors in choosing an antibiotic agent include patient allergies, pregnancy status, renal and hepatic function, and age. Practical concerns that affect compliance include the taste of the medication (especially in treating children), its adverse effect profile, how frequently it must be taken, and how much it costs. An antibiotic agent may be changed if the condition does not improve or if intolerable effects impede compliance or pose a danger to the patient. Figures 14.1 and 14.2 give an overview of the drug selection process.

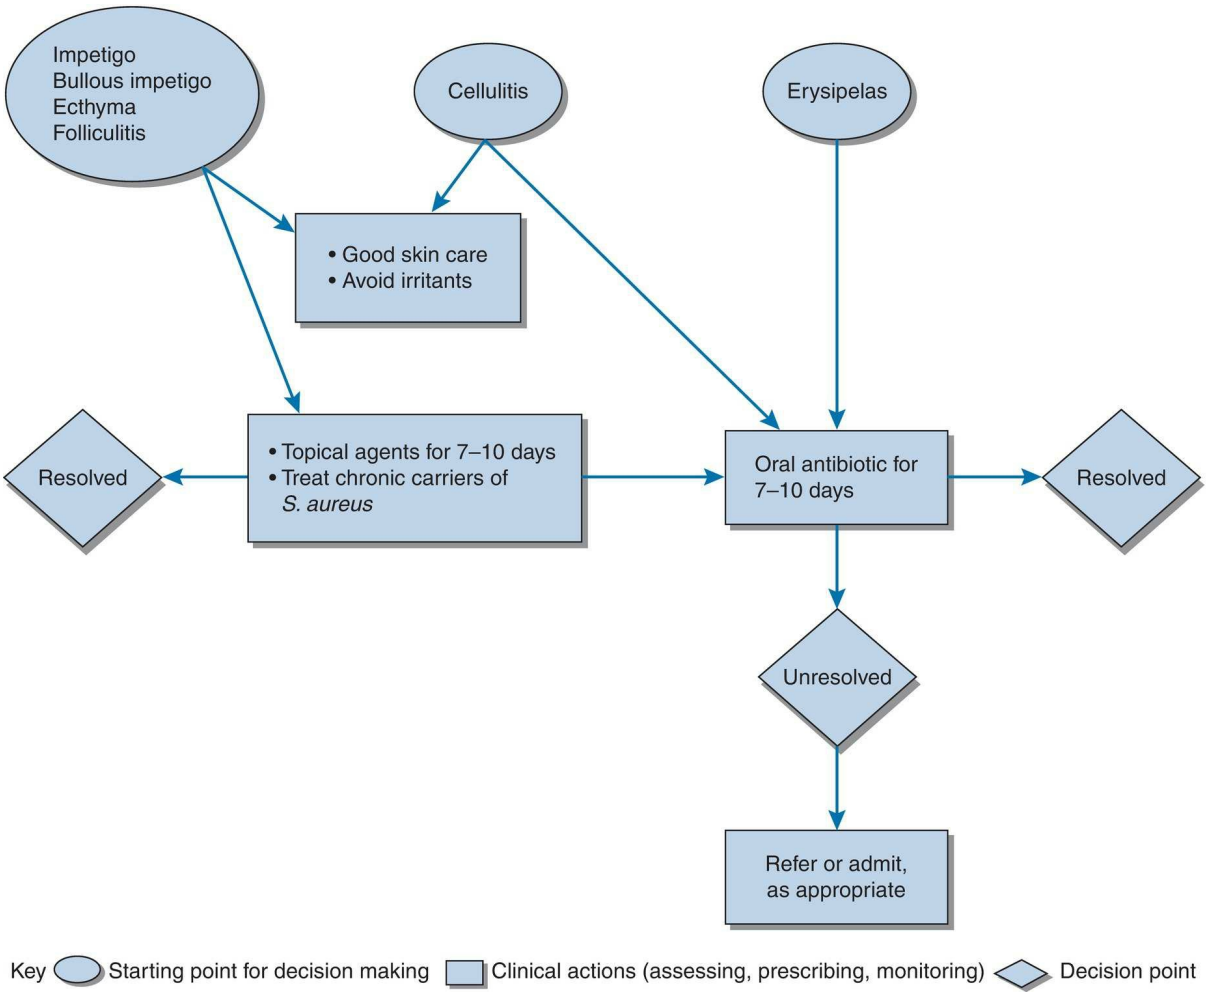

FIGURE 14.1 Treatment algorithm for impetigo, cellulitis, erysipelas, and other bacterial skin infections. *Note:* If the patient has necrotizing fasciitis, admit to hospital and refer to specialist.

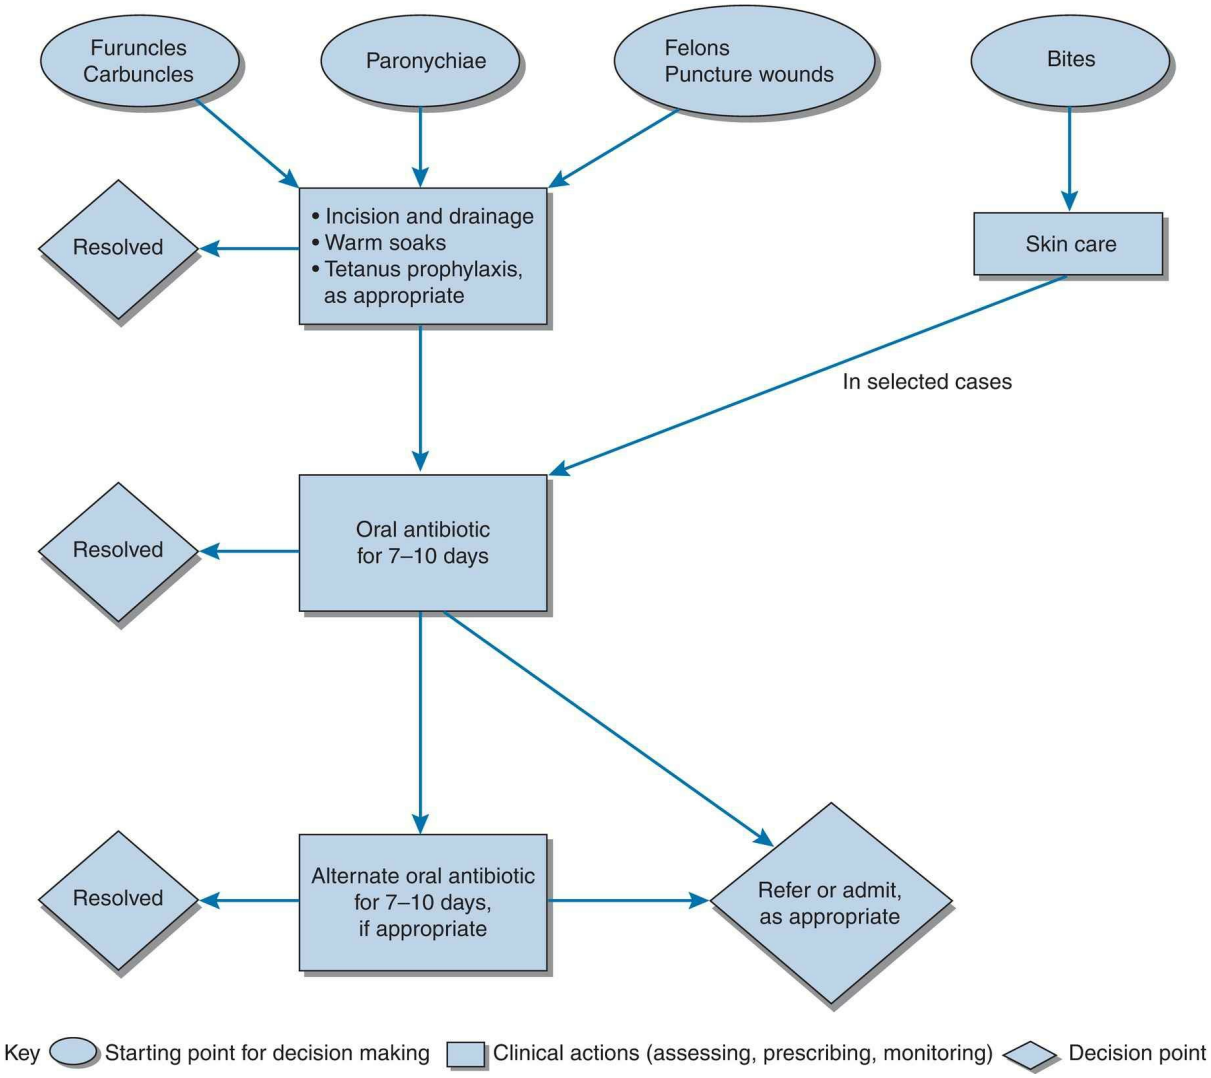

FIGURE 14.2 Treatment algorithm for pustular infections.

First-Line Therapy: Impetigo and Ecthyma

For minor cases of impetigo, topical mupirocin ointment applied three times daily for 7 to 10 days may be sufficient treatment (Fitzpatrick et al., 1997). Some practitioners advocate debriding the crusts to promote topical absorption, but debridement is painful and often unnecessary. Mupirocin is less effective in the bullous form of impetigo (Gorbach, 2004).

In most cases, an oral antibiotic is prescribed for 7 to 10 days. A broad-spectrum penicillin (e.g., amoxicillin–clavulanate or dicloxacillin) or a first-generation cephalosporin (e.g., cephalexin) is a good first choice. In cases of penicillin allergy, clindamycin is a good alternative, but in many communities, *S. aureus* has become resistant to this agent. In patients suspected of being chronic carriers of *S. aureus*, topical mupirocin ointment may be applied to the nares to eradicate the organisms and prevent recurrence (Fitzpatrick et al., 1997).

Oral agents, such as dicloxacillin or cephalexin, are usually required for the treatment

of ecthyma. Because of the chronicity of this condition, antibiotics are often given for a 2- to 3-week period; IV antibiotics may be required (Swartz, 2000). The same agents used to treat impetigo are effective for ecthyma unless the practitioner suspects infection due to *P. aeruginosa*. In these cases, a medication that provides appropriate coverage, such as ciprofloxacin, may be prescribed. Because of the depth of ulceration and chronic nature of ecthyma, healing may take weeks to months, and scarring is probable (Fitzpatrick et al., 1997). Debridement is not recommended due to the increased chance of bacteremia.

Second-Line Therapy: Impetigo and Ecthyma

Although bullous impetigo is treated initially with the same agents used for impetigo (Table 14.4), severe cases, or cases of scalded skin syndrome, may need to be treated intravenously with a drug such as nafcillin (Swartz, 2000).

First-Line Therapy: Cellulitis and Erysipelas

Treatment for mild cellulitis should begin promptly and usually on an outpatient basis with oral antibiotic therapy. Those who are more seriously ill require parenteral therapy and possibly hospitalization. Systemic treatment is always required for cellulitis.

In addition to severity, current guidelines suggest evaluation skin infections for the presence of purulence to assist clinicians in their antibiotic decision making (Stevens et al., 2014). For example, patients with mild-to-moderate cellulitis without systemic signs of infection or the presence of purulence should receive antibiotic therapy directed against GAS. Penicillin VK, amoxicillin/clavulanate, or dicloxacillin would be acceptable options. In contrast, purulent infections (furuncles, carbuncles, and abscesses) should be managed with incision and drainage procedures often in combination with empiric antibiotic therapy directed against *S. aureus* including CA-MRSA. Patients with infection due to CA-MRSA cannot be effectively treated with cephalosporins or penicillins. These patients will require antibiotics with CA-MRSA activity, including trimethoprim-sulfamethoxazole, minocycline, clindamycin, or linezolid. Patients with serious CA-MRSA infections requiring parenteral therapy can be treated with vancomycin, linezolid, or daptomycin (DeLeo et al., 2010).

Erysipelas is treated aggressively because it has the potential to spread so rapidly. A good first choice is an oral agent such as oral penicillin V or amoxicillin–clavulanate or a cephalosporin such as cephalexin. In patients who are seriously ill, hospitalization and IV antibiotic therapy are required. Even in serious cases, improvement usually occurs rapidly within the first 48 hours.

Second-Line Therapy: Cellulitis and Erysipelas

If the infection does not respond to the initial course of treatment, patients should be promptly referred or admitted for IV therapy. Wounds that become secondarily infected may require debridement, with frequent cleansing and dressing changes. Surgical

debridement may be necessary.

First-Line Therapy: Pustular Infections

Systemic therapy may not be needed for folliculitis; warm compresses can be used to facilitate drainage. Topical treatments may be helpful and include mupirocin, gentamicin, or bacitracin. However, if folliculitis is deep, with extensive involvement, systemic therapy may be started empirically with an oral antistaphylococcal agent. *P. aeruginosa* folliculitis may be treated with an antipseudomonal penicillin, a cephalosporin, or a fluoroquinolone if it is persistent or severe (Rose, 2004).

Moist heat applications are usually adequate for the treatment of mild furunculosis. However, if drainage is performed, if the furuncle is located above midface, or if the furuncle is surrounded by an area of cellulitis, oral antistaphylococcal antibiotics (dicloxacillin, cephalexin, or clindamycin) may be indicated. Treatment is continued for up to 2 weeks until the area of acute inflammation has improved. IV antibiotics may be indicated in patients who are systemically ill.

For patients with a paronychia, systemic antibiotics are necessary if the infection does not resolve on its own or after surgical drainage. Topical preparations do not penetrate the nail bed well and generally are not indicated for treatment (Hacker & Roaten, 1999). Effective agents include amoxicillin– clavulanate, cephalexin, dicloxacillin, or erythromycin. This condition is often recurrent.

After surgical drainage, a felon is treated with antibiotic therapy based on culture and Gram stain results. Tetanus prophylaxis is given as needed.

Second-Line Therapy: Pustular Infections

Folliculitis and furuncles may recur in patients who are chronic carriers of *S. aureus.* Topical mupirocin applied to the nostrils, perineum, or axillae may be needed to eradicate the organism and prevent recurrence. Very severe cases of furunculosis or carbunculosis may require parenteral therapy.

First-Line Therapy: Necrotizing Fasciitis

Aggressive surgical intervention is usually needed for the treatment of necrotizing fasciitis. Empiric antibiotic therapy usually includes combination therapy to cover for the variety of pathogens that are possible causes of infection. Examples of antibiotic combinations for necrotizing fasciitis include piperacillin–tazobactam, clindamycin, and vancomycin or linezolid; imipenem–cilastatin and vancomycin or linezolid; ceftazidime, clindamycin, and vancomycin or linezolid. Once culture results are available, antibiotic therapy can be tailored appropriately.

Special Considerations

When choosing topical or systemic therapy in a pregnant patient, a drug in category B should be chosen over a drug in category C whenever possible. Below is a list of commonly used medications for skin and skin structure infections and their associated categories. Of particular note, tigecycline, a derivative of tetracycline, is a category D medication and should be avoided during pregnancy.

Amoxicillin–clavulanate: category B
Cephalexin and other cephalosporins: category B
Clarithromycin: category C
Clindamycin: category B
Daptomycin: category B
Dicloxacillin: category B
Erythromycin and azithromycin: category B
Fluoroquinolones: category C
Gentamicin topical: category C
Linezolid: category C
Mupirocin: category C
Tigecycline: category D
Trimethoprim/sulfamethoxazole: category C
Vancomycin: category C

Monitoring Patient Response

The therapy for bacterial skin conditions is monitored by follow-up visits (see Figures 14.1 and 14.2). Most cases of impetigo heal rapidly without scarring or other adverse effects. These patients may not need to be seen again unless the condition does not resolve. However, untreated lesions may last for weeks and develop into ecthyma, which is the more chronic and severe form of impetigo. These patients should continue to be followed. Folliculitis, although not serious, is often recurrent or chronic. Emphasis should be placed on controlling aggravating factors and promoting good hygiene measures. Follow-up or referral is required if the condition spreads or does not resolve.

Secondary infection such as osteomyelitis or endocarditis is a risk in carbunculosis. For this reason, systemic antibiotics are always given after lesions are drained. These patients also may require parenteral therapy. In recurrent cases of carbunculosis, the patient should be tested for human immunodeficiency virus. Close follow-up is important.

Patients with cellulitis and erysipelas should be followed closely because of the potential for a serious systemic infection. It is sometimes necessary to change antibiotic agents or increase the duration of treatment if the patient fails to improve. Follow-up or referral may be necessary for paronychia, which often recurs.

Patient Education

Drug Information

Patients treated with systemic antibiotic therapy must be taught to take their medication around the clock to sustain the proper blood level. They also must understand the importance of taking the medication for the prescribed length of time and not to discontinue their medication even if they feel their infection is resolved.

There are common side effects with most antibiotics, such as nausea, vomiting, diarrhea, and rash. Some medications must be taken with or without food. These instructions should be emphasized to the patient. Some medications may cause dizziness, drowsiness, or photosensitivity, and patients should be advised accordingly.

Antibiotics can predispose a patient to fungal infections such as vaginal candidiasis or oral thrush. Patients should be told to report these symptoms so that appropriate treatment can be implemented. Some antibiotics may cause a decreased effectiveness of oral contraceptives, so patients should be told to use an alternate form of contraception while on their medication until their next menstrual cycle. They should also be told if their medication is not safe to use during pregnancy or lactation if applicable. Alternate medication should be prescribed in those cases or if there is any uncertainty about their pregnancy status.

Patients should be told to report signs of allergic reaction, fever, or severe diarrhea, especially if it contains blood, mucus, or pus. Unusual bleeding or bruising should also be reported. These adverse effects may be signs of a serious medication reaction.

Most topical medications are relatively well tolerated. However, some are in an alcohol base and are flammable. Patients should avoid smoking while and shortly after applying their medication. Other topical agents, such as clindamycin, may be absorbed systemically even when used in the topical form, putting the patient at risk for adverse effects.

Nutrition/Lifestyle Changes

Patients need to learn proper methods of hygiene (Box 14.3) to prevent the spread of infection, secondary infection, or recurrence. Patients with paronychia must be instructed to keep their hands dry as much as possible. An antifungal cream may be useful when indicated to prevent superinfection.

In cases where there are open wounds, wound care instruction is essential. Some infections, such as impetigo, present a risk to others. Patients with impetigo should avoid contact with infants, small children, the elderly, or those who are debilitated due to the highly contagious nature of the illness.

Although most bacterial skin infections are self-limiting and resolve quickly with treatment, some have the potential to become much more serious. Patients should be taught to report symptoms such as fever, increased erythema or streaking, chills, or malaise that may indicate a worsening of their condition. Also, the chronic nature of some skin infections, such as folliculitis, should be emphasized so that patients understand that treatment may be long term and recurrent.

Complementary and Alternative Medicine

Topical magnesium and iodine topical solutions are likely to be effective for the treatment of skin infections. Magnesium can speed the healing of wounds in patients with skin ulcers, boils, and carbuncles. However, if treatment is prolonged, damage can occur to the skin around the area of treatment (Natural Medicines Comprehensive Database, 2004). Iodine is an effective antiseptic agent; a 2% solution is recommended. Skin irritation, stains, and sensitization have been associated with its use.

Topical trypsin is possibly effective for wound cleansing and wound healing. Trypsin is contained in some U.S. Food and Drug Administration–approved products for wound debridement such as Granulex and Dermuspray (Natural Medicines Comprehensive Database, 2004). Pain and burning may occur with its use.

Other complementary therapies have been tried for wound healing, but most have insufficient data regarding their effectiveness. Some of these therapies include aloe, gotu kola, hyaluronic acid, goldenseal, bee propolis, and cartilage.

Case Study*

M.R. is a 66-year-old woman with diabetes mellitus. She is obese and has difficulty caring for herself. She presents with a nonpurulent erythematous area on her left lower leg that began 2 weeks ago as an insect bite. The area was itchy but not painful. She has had an intermittent, low-grade fever for the past week but otherwise feels well. She states that the redness has gotten worse and there is now mild swelling in her lower leg near the lesion. Her only medication is insulin, and she has no allergies.

Diagnosis: Cellulitis

1. List specific goals of treatment for M.R.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter or alternative medications would be appropriate for M.R.?
8. What lifestyle changes would you recommended for M.R.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

15 Psoriasis

Shelly Schneider

Psoriasis is a debilitating disease characterized by recurrent exacerbations and remissions. It affects between 2% and 3% of the U.S. population, with a higher incidence in whites and an equal distribution between the sexes. Approximately 36% of patients with psoriasis have a positive family history. The cost of outpatient treatment for psoriasis averages $1.6 to $3.2 billion annually.

There appear to be two peak ages of onset: between ages 16 and 22 and between ages 57 and 60. Psoriasis has an element of physical discomfort, with pain, itching, stinging, cracking, and bleeding of the lesions. In approximately 10% of patients with psoriasis, the disease develops into psoriatic arthritis.

Psoriasis affects almost all aspects of life, including sexual relationships and emotional well-being. In addition, patients with psoriasis spend 1 or more hours a day caring for their skin. Of a survey group of patients with psoriasis, up to 25% felt at some point in their life that they would rather be dead than alive with psoriasis.

Psoriasis affects approximately 2.5% of Whites and 1.3% of Blacks in the United States, with approximately 150,000 newly diagnosed cases every year. The incidence of psoriasis is somewhat lower in Asians (0.4%). Generally, it is more common in individuals living at higher latitudes or in colder locales and less common in individuals who have greater sun exposure. There seems to be a genetic factor associated with psoriasis. Based on population studies, the risk of psoriasis in children is estimated to be 41% if both parents are affected, 14% if one parent is affected, and 6% if one sibling is affected, and a family history can be found in 5% to 10% of patients who have psoriasis.

Causes

A definitive cause for psoriasis is unknown, although there are several possible etiologic factors: abnormal epidermal cell cycle, hereditary factors, and trigger factors, including trauma, infection, endocrine imbalance, climate, and emotional stress.

Physical trauma, such as rubbing, scratching, or sunburn, is a major exacerbating factor in psoriasis, and this is referred to as *Koebner phenomenon*. A precipitating event, in some cases of guttate psoriasis, is a streptococcal infection. Stress plays a role in as many as 40% of psoriasis flares in adults and children. Exacerbations of psoriasis may develop from the use of certain drugs (Box 15.1).

BOX 15.1 Drugs Known to Exacerbate Psoriasis

Systemic corticosteroids (when dose is decreased or stopped)
Lithium carbonate
Antimalarials
Beta-blockers
Systemic interferon
Alcohol

Pathophysiology

Psoriasis is an autoimmune-mediated process driven by abnormally activated helper T cells. Activation of these T cells can occur through specific interactions with antigen-presenting cells (APCs) or via nonspecific superantigen interactions (i.e., guttate psoriasis is triggered by streptococcal antigens). APC activation requires costimulatory signals. Once activated, psoriatic T cells produce a type 1 helper T cell–dominant cytokine profile that includes interleukin-2 (IL-2), tumor necrosis factor-alpha (TNF-α), interferon-γ, and IL-8. These cytokines act to attract and activate neutrophils, which are responsible for much of the inflammation seen in psoriasis. Other factors leading to neutrophil recruitment and activation are complement split products and leukotrienes (arachidonic acid metabolites from the 5-lipoxygenase pathway).

Diagnostic Criteria

Psoriasis is diagnosed by observation of characteristic, well-demarcated, erythematous papules or plaques surrounded by silvery or whitish scales. The lesions are symmetric and usually found on the face, extensor joints, anogenital area, palms and soles, intertriginous areas (known as inverse psoriasis), trunk, scalp, ears, and nails.

The varieties of psoriatic disease include plaque, guttate, erythrodermic, and pustular. The plaque type is the most common form. The guttate type is characterized by small, scattered, teardrop-shaped papules and plaques. In many cases, psoriasis begins as the guttate form. The erythrodermic form is characterized by generalized intense erythema and shedding of scales. Finally, the pustular type has three additional forms: generalized, localized, and palmar–plantar. All share a similar characteristic: 2- to 3-mm sterile pustules on specific body regions.

Clinical presentation of the plaque type of psoriasis consists of sharply demarcated, erythematous papules and plaques with marked silvery-white scales. Bleeding may follow removal of the scales (Auspitz sign). The elbows, knees, and scalp are the most common areas for psoriatic plaques. Pitting and discoloration of the nails also characterizes psoriasis. In some cases, the nail may separate from the nail bed—referred to as onycholysis.

Initiating Drug Therapy

Before beginning drug therapy, the patient is usually counseled to avoid precipitating factors. Cigarette smoking is discouraged since this can exacerbate the condition.

There are three treatment modalities available: topical agents, phototherapy, and systemic agents. To select the most appropriate treatment, the prescriber must determine whether the patient has localized or generalized psoriasis. Patients with 10% or less of body involvement can usually be successfully treated in a primary care setting with topical agents, whereas those with greater body surface area (BSA) involvement usually require treatment by a dermatologist with phototherapy or systemic therapy. In estimating BSA involvement, the prescriber keeps in mind that the palm represents 1% BSA; this can be used as a tool to estimate total BSA involvement.

Goals of Drug Therapy

The goals of therapy are to:

- Decrease the size and thickness of the plaques
- Decrease pruritus
- Improve emotional well-being and quality of life
- Put the patient in remission
- Have minimal side effects from treatment

It is imperative to use a management strategy that has the least possible toxicity and that is acceptable to the patient. Sequential therapy is thought to be effective because psoriasis is a chronic disease requiring long-term maintenance therapy and treatment of exacerbations. The three phases of sequential therapy are the clearing, transitional, and maintenance phases. Table 15.1 identifies topical and systemic preparations used in psoriasis treatment.

TABLE 15.1 Overview of Selected Agents for Psoriasis

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Topical Agents			
Emollients (Eucerin, Lubriderm, Moisturel, CeraVe, Cetaphil) Apply to affected skin three or four times daily.	Folliculitis, maceration, miliaria		Avoid applying near eyes.
Tar Preparations			
Coal tar Apply at bedtime and allow to remain on skin. Emulsion: 15–25 mL dissolved in bath water Shampoo	Irritation, photoreactions, unpleasant odor, folliculitis	Open or infected lesions	Preparation may stain skin and clothing. With emulsion, immerse affected area for 10 to 20 min three to seven times a week. Shampoo should be massaged into wet scalp and rinsed, then applied a second time and left on for 5 min.
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
Antipsoriatics			
anthralin (Drithocreme, Micanol) Apply for 30–60 min, and then remove.	Irritation	Renal disease, acute psoriasis	Preparation may stain skin, towels, sinks, and tubs. Avoid applying near eyes and mucous membranes. Irritation can be avoided by applying emollients to unaffected skin.
Vitamin D Analogs			
calcipotriene (Dovonex) Apply bid.	Burning and stinging, skin peeling, rash	Hypercalcemia, vitamin D toxicity	Do not use on face.
Vitamin A Derivatives			
tazarotene (Tazorac) Once a day at bedtime	Pruritus, erythema		Avoid vitamin A.
Topical Corticosteroids			
hydrocortisone (Cortisporin)	Burning, folliculitis, hypothalamic–pituitary–adrenal axis suppression	Primary bacterial infections or fungal infections	Use lowest effective dose. Avoid prolonged use. Use occlusive dressing.
Systemic Agents			
apremilast (Otezla)	GI upset, diarrhea	Known hypersensitivity	Starter kit to minimize side effects.
cyclosporine (Cyclosporine A, Sandimmune) Maximum dose 2–5 mg/kg/d	Tremor, gingival hyperplasia, GI upset, hypertension, renal dysfunction, acne	Pregnancy and lactation; caution in impaired renal and hepatic function	Increased risk of digoxin toxicity. Interacts with lovastatin, diltiazem, ketoconazole. Decreased therapeutic effect with use of hydantoins, rifampin, sulfonamides.
etretinate (Acitretin) 25–50 mg daily	Elevation in lipid levels, abnormal liver function, alopecia, rash, dry skin, pruritus	Alcohol use, pregnancy, and lactation	Perform pretreatment lipid and liver function tests. Advise female patients not to become pregnant while taking this medication. Take with meals.
methotrexate (MTX, Rheumatrex) 12.5–25 mg/kg/wk	Headache, blurred vision, fatigue, malaise, GI distress, gingivitis, hepatotoxicity, chills, bone marrow depression, rash alopecia, fever	Pregnancy and lactation; caution inpatients with renal and hepatic compromise, leukopenia	Drug decreases the level of digoxin. Increased risk of toxicity with salicylates, phenytoin, sulfonamides. Take folic acid 1 mg on nontreatment days.
Biologics			
adalimumab (Humira) 80 mg subcutaneously initially then 40 mg every other week	Headache, nausea, rash, reaction at injection site	Concurrent live vaccine, active infection; caution in pregnancy	Used for psoriatic arthritis.
etanercept (Enbrel) 50 mg twice a week for 3 mo, then 50 mg weekly by subcutaneous injection	Infection, injection site pain, localized erythema, rash, upper respiratory infection, abdominal pain, vomiting	Concurrent live vaccine, active infection; caution in pregnancy, impaired renal function, asthma, blood dyscrasia, central nervous system demyelinating disease, history of recurrent infections	A maximum of 25 mg can be given in each site, requiring two injections. It is given subcutaneously. Not to be given with live vaccines.
infliximab (Remicade) IV 5 mg/kg	GI upset, headache, fatigue, cough, congestive heart failure	Severe congestive heart failure	Not to be given with live vaccines.
Secukinumab (Cosentyx) 150–300 mg	Nasopharyngitis, upper respiratory infection	Infection	
Ustekinumab (Stelara)	Infection	Malignancy, infection	

Emollients

Emollients are useful for all cases of psoriasis as an adjunct therapy. These agents hydrate the stratum corneum, decrease water evaporation, and soften the scales of the plaques. They are available in lotions, creams, and ointments. The thicker the preparation, the more effective it is. Commercially available agents include Eucerin cream/lotion, Lubriderm, and Moisturel. In addition to preserving moisture, emollients have a mild antipruritic effect. Newer products include CeraVe and Cetaphil.

Topical Corticosteroids

The foundation of topical treatment is topical corticosteroids. They play an important role in treating psoriasis by decreasing erythema, pruritus, and scaling. They promote vasoconstriction. They are fast acting but not intended for long-term use. Topical corticosteroids are classified into several categories based on potency and vasoconstrictive properties. Low-potency corticosteroids are safer for long-term use and for use at thin-skinned sites such as the face and groin. The most effective topical treatment is a medium- or high-potent agent used for a limited time, followed by a less potent agent for maintenance. Occlusion of the area where the topical steroid is applied is recommended. Saran wrap can be used, or Cordran tape is also effective. This method increases the absorption (hence the potency) of the topical preparation.

Topical corticosteroids may be used for longer periods on thicker skin because thicker skin does not absorb medication as well as thinner skin. Topical corticosteroids have a rapid onset of action. They decrease erythema, inflammation, and pruritus. For more information on topical corticosteroids, see Chapter 11.

Coal Tars

Coal tar (Cutar) contains polycyclic hydrocarbon compounds formed from bituminous coal. It depresses deoxyribonucleic acid (DNA) synthesis and has anti-inflammatory and antipruritic properties. Several preparations are available, including an ointment, a gel preparation, a bath preparation, and shampoo. Coal tar can be used as an initial therapy, usually with adjunct topical corticosteroids.

Coal tar is applied overnight and at home because of the offensive odor. The emulsion is dissolved in bath water (15 to 25 mL), and the patient immerses the affected area in the water for 10 to 20 minutes. It is used for 30 to 45 days, three to seven times a week. The shampoo preparation is massaged into a wet scalp and rinsed. It is applied a second time and left on the scalp for 5 minutes.

Efficacy of the ointment or gel is based on the amount of time that the medication is on the body. There is a slow response to coal tar therapy, and it is not used for acute exacerbations or on open or infected lesions.

Some disadvantages of coal tar include the unpleasant odor, staining of clothes, skin and fiberglass (even with the clear preparation), and photosensitivity. These disadvantages tend to lead to poor compliance. In addition, folliculitis commonly occurs, especially in areas with dense hair follicles. This requires discontinuing the medication.

Anthralin

Anthralin (Drithocreme, Micanol) is another topical treatment for psoriasis. It is a coal tar derivative.

Mechanism of Action

There are two possible mechanisms of action: inhibition of DNA synthesis and a decrease in epidermal proliferation. Anthralin is a good therapy if the patient has a limited number of lesions, but its use is time consuming.

Dosage

Anthralin is applied for 30 minutes to 1 hour and then removed. It should be applied only to the lesion, not to unaffected skin. Treatment starts with a low strength that is gradually increased. Staining of the psoriasis plaques signifies that treatment is decreasing cellular proliferation. Treatment is time consuming but short term.

Time Frame for Response

There is a slow onset of action, and response is slow as well.

Contraindications

Anthralin therapy is contraindicated in acute psoriasis and inflammation.

Adverse Events

Anthralin therapy may be limited by irritation of the unaffected skin. Irritation can be prevented by applying emollients to the normal skin. The medication stains clothing a brownish-purple and permanently stains towels, tubs, and sinks.

Vitamin D Analogs

Calcipotriene (Dovonex) and Calcipotriol are vitamin D analogs for treating mild to moderate psoriasis. They are supplied in creams, ointments, and topical foam.

Mechanism of Action

Its mechanism of action is a reduction of cell proliferation by binding to receptors in epidermal keratinocytes. The drug is also thought to have an anti-inflammatory effect. It is effective for long-term use and maintenance therapy and is often used as rotational therapy with topical steroids.

Dosage

A thin layer is applied twice a day to affected skin for 6 to 8 weeks. It is also used as rotational therapy or by pulse dosing (off-and-on therapy), in which the patient follows the therapeutic regimen for 2 weeks, followed by 1 week off. Use with a potent topical corticosteroid is most effective. The patient must be cautioned not to use more than 100 g/wk.

Time Frame for Response

Some improvement is usually seen in 2 to 4 weeks, although therapy is recommended for 6 to 8 weeks. An advantage of calcipotriene is its similar efficacy to that of medium- to high-potency topical corticosteroids. Unlike corticosteroids, however, calcipotriene does not cause skin atrophy or hypothalamic–pituitary–adrenal axis suppression. However, it is an irritant and therefore should not be used on the face. It is contraindicated in patients with hypercalcemia and vitamin D toxicity.

Adverse Events

The most common adverse effects of calcipotriene are mild and include dry skin, peeling, and rash. Hypercalcemia may be caused by vitamin D ingestion but is rare if the patient uses less than 100 g of calcipotriene per week.

Retinoid (Vitamin A Derivative)

Tazarotene (Tazorac) is a topical retinoid used for mild to moderate psoriasis.

Mechanism of Action

This drug normalizes epidermal differentiation, decreases hyperproliferation, and diminishes inflammation of the cells in the skin. Use of tazarotene promotes longer remission of psoriasis.

Dosage

It comes in a clear, nonstaining gel and cream (0.05% and 0.1%) and is applied in a thin layer once a day at bedtime. Skin must be air dried and the area left unoccluded. The preparation can be used for the body, scalp, hairline, and face but not on the genitalia or intertriginous areas or around the eyes.

Time Frame for Response

After 1 week of therapy, diminished scaling is noted. Clearing is seen in approximately 8 weeks.

Contraindications

Tazarotene can cause fetal harm, so it is started in menstruating women during menses; these women should ensure that they do not become pregnant during therapy.

Adverse Events

Adverse effects of tazarotene include pruritus, erythema of the skin, and mild to moderate burning. The use of topical corticosteroids counteracts these effects. The patient must be warned that the psoriasis may get worse before it improves.

Interactions

Vitamin A ingestion is to be avoided, and tazarotene is used with caution with other photosensitizers such as tetracyclines and with other topical irritants such as abrasives, depilatories, or permanent wave solutions.

Systemic Retinoids

Acitretin (Soriatane) is a systemic retinoid used for long-term psoriasis therapy.

Mechanism of Action

Acitretin normalizes epidermal differentiation and diminishes hyperproliferation and inflammation of cells in the skin.

Dosage

Initially, acitretin starts at 25 mg a day and then can be increased to a 25- to 50-mg dose given once a day with the main meal until the lesions clear, which occurs gradually.

Contraindications

Acitretin is contraindicated in pregnancy and lactation and with the use of alcohol. It cannot be used in patients with severe renal impairment and increased lipid levels. The patient cannot donate blood for 3 years after therapy. Caution is used if there is a history of depression, obesity, or alcohol abuse.

Adverse Events

Adverse effects include lipid elevations, abnormal liver function, alopecia, skin peeling, pruritus, dry skin, dry mouth, epistaxis, paresthesia, paronychia, and pseudotumor cerebri.

Interactions

Drug interactions occur with methotrexate (MTX, Rheumatrex), alcohol, and progestin-only contraceptives. Women must not ingest alcohol during therapy or for 2 months afterward because alcohol prolongs the teratogenic potential of the drug.

Methotrexate

Methotrexate is used to treat generalized psoriasis.

Mechanism of Action

Methotrexate inhibits folic acid reductase, resulting in the inhibition of cellular replication and selection of the most rapidly dividing cells.

Dosage

The initial dose is 2.5 mg a week administered in three doses over a 24-hour period. It is then titrated to a dose of 12.5 to 25 mg a week. With improvement in the disease, the dose is reduced and other agents are used. Folic acid, 1 mg daily, should be taken on nontreatment days.

Contraindications

Methotrexate is contraindicated in pregnancy and lactation, and the drug is used with caution in patients with renal and hepatic disorders and leukopenia.

Adverse Events

Common adverse effects include headache, blurred vision, fatigue, malaise, gastrointestinal (GI) distress, gingivitis, hepatic toxicity, bone marrow depression, rash, alopecia, and chills and fevers.

Interactions

There is an increased risk of toxicity if the patient is taking other medications, such as salicylates, phenytoin (Dilantin), and sulfonamides. Use of methotrexate also decreases the serum level of digoxin (Lanoxin).

Cyclosporine

Mechanism of Action

Cyclosporine suppresses cell-mediated immune reactions and humoral immunity. It inhibits production of IL-2, which is responsible for producing T-cell proliferation. Cyclosporine promotes rapid remission for severe psoriasis. It is usually used for short-term treatment of severe exacerbations.

Dosage

The maximum dose for use in psoriasis is 2 to 5 mg/kg/d. Maintenance therapy is at lower doses.

Contraindications

Cyclosporine is contraindicated in pregnancy and lactation and must be used cautiously in patients with impaired renal function and malabsorption.

Adverse Events

Adverse effects include tremor, gingival hyperplasia, GI upset, hypertension, nephrotoxicity, hirsutism, and acne. Lesions can recur within days to weeks after treatment, and rebounds with worse symptoms are not uncommon.

Interactions

Cyclosporine use increases the risk for nephrotoxicity if the patient uses other nephrotoxic agents, and it also increases the risk for digoxin toxicity. Cyclosporine interacts with lovastatin (Mevacor), diltiazem (Cardizem), and ketoconazole (Nizoral), and its therapeutic effect is decreased with concomitant hydantoin (Dilantin), rifampin (Rifadin), and sulfonamide use.

Phosphodiesterase 4 Inhibitors

Apremilast (Otezla)

Mechanism of Action

Apremilast is an oral small molecule specific to cyclic adenosine monophosphate (cAMP).

The specific mechanism is not well understood.

Dosage

A starter pack is designed to allow for titration and then progress up to 30 mg twice daily.

Contraindications

Patients with a known hypersensitivity to apremilast or to other ingredients.

Adverse Events

The most common adverse event is GI distress and diarrhea which may be self-limiting.

Interactions

Apremilast exposure is decreased when Otezla is coadministered with strong CYP450 inducers (i.e., rifampin) and may decrease efficacy.

The "Biologics"

The "biologics" interact with specific targets in the T cell–mediated inflammatory process. They have an anti-inflammatory effect through the inhibition of cytokine release, prevention of T-cell activation, depletion of pathologic T cells, and blocking the interactions that lead to T-cell activation or migration into the tissue. They also alter the balance of the T-cell types and inhibit key inflammatory cytokines, such as tumor necrosis factor (TNF).

Etanercept

Etanercept (Enbrel) contains human TNF receptor.

Mechanism of Action

It binds and inhibits TNF, the cytokine that helps regulate the body's immune response to inflammation. It is used in moderate to severe psoriasis.

Dosage

The dose of etanercept in psoriasis is 50 mg subcutaneously twice a week initially for 3 months. Maintenance dose is 50 mg sq weekly, with a maximum of 25 mg given at one site. It requires two injections in separate sites. A purified protein derivative test must be negative before treatment starts.

Contraindications

Contraindications include a concurrent live vaccine and an active infection. Caution is recommended in pregnant patients (although it is a category B drug) and patients with impaired renal function, asthma, a history of blood dyscrasias, central nervous system demyelinating disease, and a history of chronic recurrent infections.

Adverse Events

Adverse events include infection, injection site pain, localized erythema, rash, upper respiratory infections, abdominal pain, and vomiting.

Interactions

There is an increased chance of infection with immunosuppressants. Live vaccines should be given 2 weeks before or 1 month after therapy to ensure adequate immunization.

Infliximab

Mechanism of Action

Infliximab (Remicade) is a monoclonal antibody that targets TNF-α and inhibits its activity.

Dosage

Infliximab is given by intravenous infusion over at least 2 hours. The dose is 5 mg/kg at week 0, week 2, and week 6 and then once every 8 weeks. Patients must be tested for tuberculosis (TB) before administration.

Contraindications

It is contraindicated in moderate to severe congestive heart failure. It should not be given in conjunction with live vaccines.

Adverse Events

Adverse events include infection, headache, GI upset, fatigue, cough, pruritus, and congestive heart failure.

Interactions

Immunosuppressants increase the risk of infection.

Adalimumab

Mechanism of Action

Adalimumab (Humira) is a recombinant humanized immunoglobulin G1 monoclonal antibody that binds to TNF-α. It reduces signs and symptoms of active arthritis and psoriatic arthritis.

Dosage

Adalimumab is given subcutaneously into the thigh or abdomen. The dose is initially 80 mg followed by 40 mg every other week starting the week after the initial dose and is rapid acting. Patients must be tested for TB before administration.

Contraindications

It should not be given in conjunction with live vaccines.

Adverse Events

Adverse events include headache, injection site reactions, nausea, and rash.

Interactions

Immunosuppressants increase the risk of infection.

Ustekinumab

Mechanism of Action

Ustekinumab (Stelara) is a human interleukin-12 and interleukin-23 antagonist.

Dosage

Administered subcutaneously, two weight-based doses are available, 45 mg for patients weighing less than 100 kg (220 lb) and 90 mg for patients weighing greater than 100 kg (220 lb) four times a year.

Contraindications

Ustekinumab is not recommended for patients with a sensitivity to any of the excipients.

Adverse events

May include nasopharyngitis and upper respiratory tract infections. Serious infections and malignancies may occur.

Interactions

Live vaccines should not be given to patients taking ustekinumab.

Secukinumab

Mechanism of Action

Secukinumab (Cosentyx) is a monoclonal antibody that binds to interleukin-17 blocking the cytokine interaction with its receptor.

Dosing

Three hundred milligrams administered subcutaneously (in divided doses of 150 each) every week for 5 weeks and then once every month.

Contraindications

Similar to all other biologic agents.

Adverse Events

Similar to all other biologic agents.

Interactions

No live vaccines.

Selecting the Most Appropriate Agent

Selection of therapy depends on the patient's age, type of lesion, site and involvement, and previous treatments. Mild to relatively moderate psoriasis (less than 10% BSA) can be treated by a primary care provider. Topical treatment of psoriasis is the first step and is usually effective for mild disease. Patients with more generalized disease are referred to a dermatologist for treatment and phototherapy, and systemic agents are used (Table 15.2 and Figure 15.1).

TABLE 15.2 Recommended Order of Treatment for Psoriasis

Order	Therapy	Comments
First line	High-potency topical corticosteroids applied to moist skin and use of occlusive dressing twice a day for 2 wk. Use emollients as adjunct therapy.	Use when <10% of body surface area is affected.
Second line	If the patient responded well to first-line therapy, provide a 1-wk rest from the topical corticosteroids and initiate another 2 wk of therapy with the same agent for two more times. OR Taper the high-potency topical corticosteroid to once or twice a week and add a vitamin D analog twice a day.	If there is remission, applying the topical steroids once or twice a week may maintain remission.
Third line	Refer to dermatologist for systemic therapy.	For use with >20% body surface area, PUVA is used with coal tar or anthralin; PUVB is used with psoralens.

PUVA (B), psoralens with ultraviolet A (B).

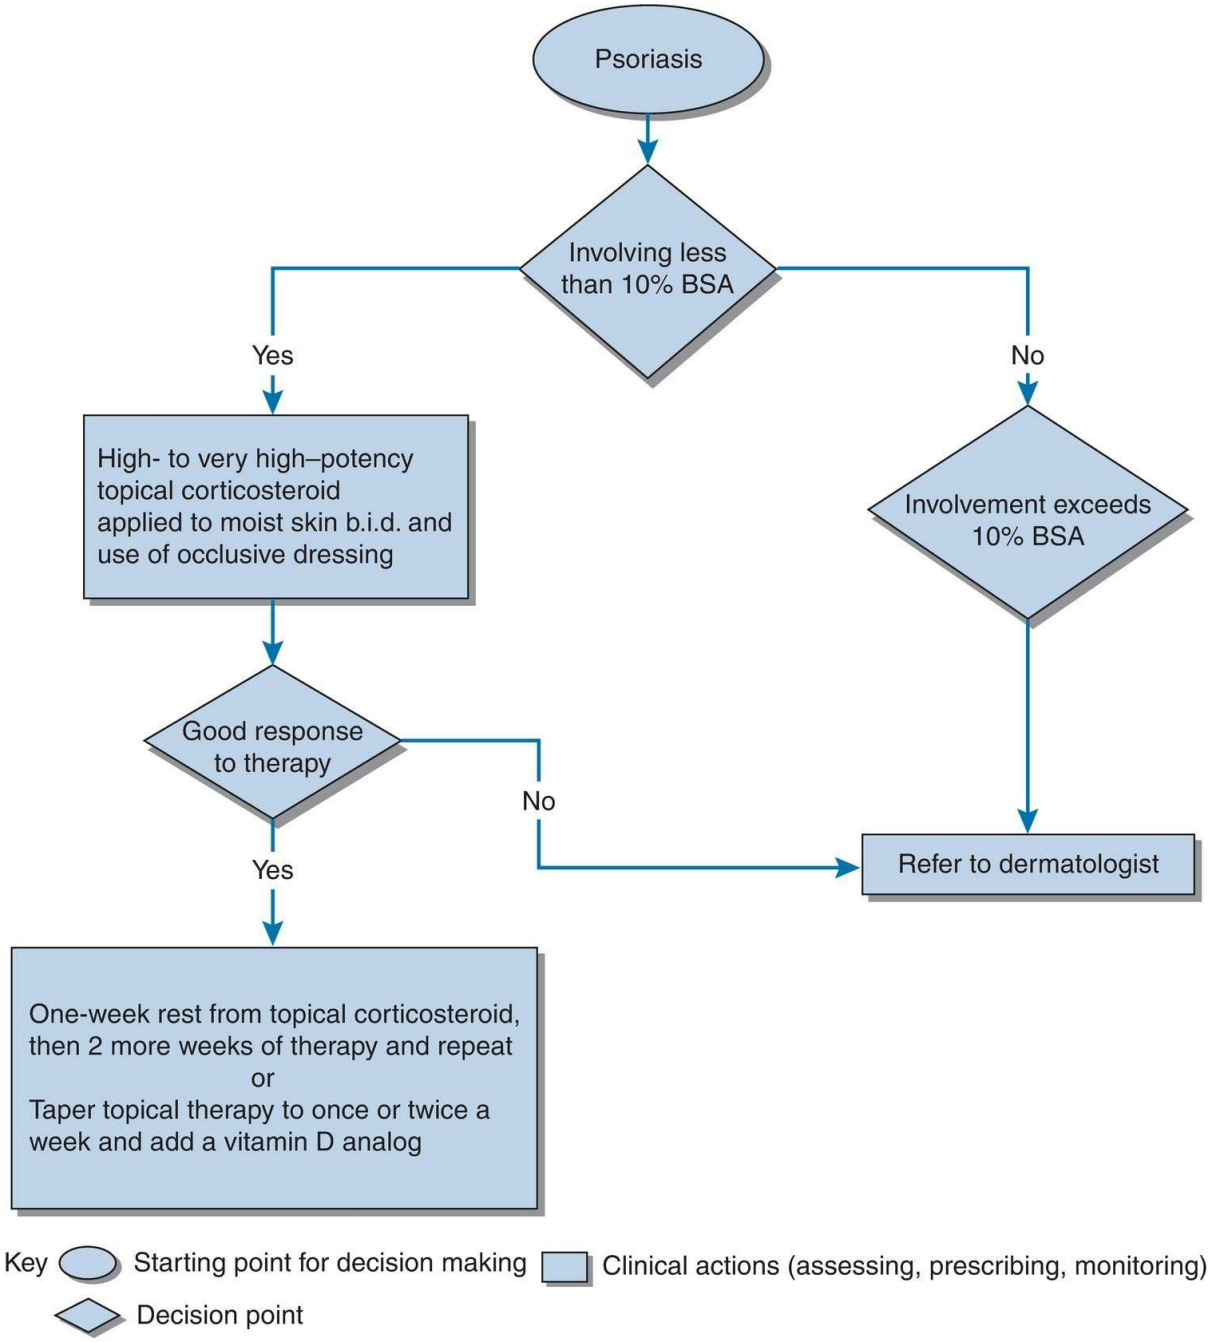

FIGURE 15.1 Treatment algorithm for psoriasis.

It appears that combination therapy with systemic agents and other modalities has synergistic value. In combination therapy, the dose can often be reduced, causing less toxicity from the drugs. Systemic therapy with phototherapy is also effective.

First-Line Therapy

First-line therapy includes moisturizers and topical steroids. For 2 weeks, a high-potency or very high–potency topical steroid is applied twice a day and covered by an occlusive dressing of plastic wrap. A low-potency preparation is used on the face and intertriginous

areas. An ointment is recommended because it provides the most moisture. An emollient also is used to keep the area moist.

Second-Line Therapy

If the patient's response to first-line therapy is not optimal, several second-line choices are available. If the patient had a good response to first-line therapy, therapy may consist of a 1-week rest from the topical corticosteroids and then another 2 weeks of therapy with the same agent for two more times. If the psoriasis goes into remission, applying the topical steroids once or twice a week may maintain the remission.

Another option is to taper the high-potency topical corticosteroid use to once or twice a week and add a vitamin D analog twice a day to the regimen. This produces a better result than either drug used alone. The topical corticosteroid helps clear the plaques and reduces irritation from the vitamin D preparation.

Third-Line Therapy

If first- and second-line treatments fail, a patient is referred to a dermatologist, who may use ultraviolet B light treatments, antimetabolites, etanercept, or psoralens plus ultraviolet A light therapy.

Monitoring Patient Response

The goal of chronic topical corticosteroid therapy is to use the lowest effective potency to control symptoms. Follow-up initially may need to be monthly and then may progress to every 2 to 3 months. In addition, referral for counseling, if desired, may help address related emotional issues.

Patient Education

Drug Information

In patients with psoriasis, education regarding stress monitoring and control is important, as is education regarding the disease process and treatment goals. The patient should understand that psoriasis is not contagious.

Patients may also benefit from information and support from groups such as the National Psoriasis Foundation (1-800-723-9166, www.psoriasis.org).

Showing the patient how to apply topical steroids is an important aspect of care, particularly if the medications are to be used only twice a day and applied lightly on moist skin.

Lifestyle Changes

Symptom control, rather than cure, is the goal of therapy. Patients may help control symptoms by exposing their skin to the sun. This should be accomplished by gradually increasing the length of exposure. Emphasis should be placed on the importance of using sunscreen and avoiding sunburn. To prevent infection, patients must take care not to cut the lesions when shaving (if there are lesions in the area).

Psoriasis can be triggered by infections, stress, and changes in climate that can dry skin. These should be avoided when possible.

Complementary and Alternative Medicine

Fish oil is thought to alter the immune response and in small quantities can relieve itching and scaling. It has an effect on chronic plaque psoriasis in doses of 6 to 15 g daily. An alternative is to eat fish three times a week. Aloe vera was shown to be effective in treatment of psoriasis. In a 16-week study, there was 82.8% clearing of psoriatic plaque using 0.5% hydrophilic aloe vera cream three times a day. Glucosamine has been shown to relieve some of the pain of arthritis from psoriasis.

Case Study*

P.B. is a 58-year-old woman with a history of hypertension. She seeks treatment for scattered plaques with a silvery-white scale on her elbows, forearms, and knees. The BSA affected is approximately 8%. She is very self-conscious about the lesions: "I just want them to go away." Her medications include propranolol 40 mg tid and furosemide 40 mg daily. She has a positive family history of psoriasis and reports high levels of stress in her job and life. She smokes a pack of cigarettes per day.

Diagnosis: Psoriasis

1. List specific goals for treatment for P.B.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What OTC or alternative medications would be appropriate for P.B.?
8. What lifestyle changes would you recommend to P.B.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

16 Acne Vulgaris and Rosacea

Virginia P. Arcangelo

Acne Vulgaris

Acne vulgaris is viewed by many as a rite of passage during the adolescent years. Up to 90% of all teenagers report having some form of acne. Adults suffer from the effects of acne as well: between 30% and 50% of adult women report experiencing acne. Consumers spend millions of dollars annually on prescription and over-the-counter (OTC) acne preparations.

The psychosocial costs of acne are great. Adolescents are particularly affected by physical defects, no matter how minor they appear to others. The health care practitioner must be particularly sensitive to the perceived seriousness of the acne in addition to the clinical picture. What may seem inconsequential to the practitioner may be devastating to the patient. No matter how minor the acne may appear to the provider, it is important to ask patients if they are concerned about their acne and whether they would like treatment.

Causes

Historically, numerous theories of the cause of acne vulgaris have been proposed, yet the exact cause remains unknown. Foods, stress, and dirt, although not causative, may exacerbate existing acne, which is why it is important to obtain a complete health history to ascertain precipitating factors. For example, a variety of drugs, physical occlusants, and conditions may exacerbate acne. Certain drugs used to treat tuberculosis, seizure disorders, or steroid-dependent chronic illness or depression may cause a drug-induced acneiform rash (Table 16.1). Drug-induced acne should be suspected when all lesions are in the same stage (e.g., the lesions are uniformly all pustules or all open comedones), covering the face, chest, trunk, arms, and legs.

TABLE 16.1 Medications That Cause Acneiform Rash

Medication	Underlying Condition
Corticosteroids	Chronic inflammatory conditions
Isoniazid	Tuberculosis
Lithium	Depression
Phenytoin	Seizure disorder
Trimethadione	Seizure disorder

Acne may be exacerbated in teenagers and adults whose skin is exposed to oily agents, such as makeup, oil-based sunscreen, and oil-based hair products that come in contact with the forehead and temporal regions of the face (referred to as *pomade acne*). Friction acne from tight-fitting clothes, such as football helmets and hatbands, is found over the skin rubbed by the clothes. Exposure to animal-, vegetable-, and petroleum-based oils used in workplaces such as fast food restaurants and automotive garages may also exacerbate acne. Thus, although eating French fries may not cause acne, cooking them may make the acne worse. Emotional stress may contribute to acne exacerbations in persons prone to breakouts, but studies have not consistently proven the correlation.

Women with a history of menstrual irregularities, hirsutism, and treatment-resistant acne should be evaluated for androgen excess associated with polycystic ovarian disease.

Pathophysiology

Acne usually begins 1 to 2 years before the onset of puberty, when androgen production increases. Excess androgen causes increased sebum production. For unknown reasons, abnormal keratinization causes retention of sebum in the pilosebaceous follicle. This produces open comedones (blackheads) and closed comedones (whiteheads).

When closed comedones continue to produce keratin and sebum, the pilosebaceous follicle ruptures and inflames the surrounding tissue. If the inflammation is close to the surface, a papule forms. If it is deeper in the dermis, a larger papule or nodule forms. These deeper, nodular acne cysts cause permanent scars.

Although *Propionibacterium acnes*, an anaerobic gram-positive bacterium, is present as normal flora in the pilosebaceous follicle, acne vulgaris is not an infectious entity. Rather, it is believed that *P. acnes* produces lipolytic enzymes that in turn produce biologically active extracellular products. These in turn attract polymorphonuclear leukocytes and monocytes, which increase inflammation.

Diagnostic Criteria

Acne vulgaris is diagnosed from the clinical presentation of the patient's skin. It is classified and subsequently treated depending on its severity.

The mildest form of acne is comedonal. Both open and closed comedones may be present. Mild inflammatory acne is manifested by papules. Moderate inflammatory acne consists of pustules and some cysts. Severe cystic acne consists of cysts, nodules, and scarring (Table 16.2).

TABLE 16.2 Classification of Acne Vulgaris

Classification	Physical Findings
Comedonal acne	Open comedones (blackheads), closed comedones (whiteheads)
Mild inflammatory acne	Papules
Moderate inflammatory acne	Pustules, cysts
Severe cystic acne	Cysts, nodules, "ice-pick" scarring

Initiating Drug Therapy

Skin care is the most important nonpharmacologic tool in the management of acne vulgaris. The patient should be instructed to wash the face gently two or three times a day with a mild soap such as Basis, Cetaphil, Neutrogena, or Purpose. Care should be taken to avoid harsh, drying cleansers. Washing should be gentle because scrubbing the skin may exacerbate the acne. Comedo removal, although therapeutic, should be undertaken only by someone skilled in the proper technique. Picking or popping pimples may increase tissue damage and infection. The health care provider should advise the patient to avoid manipulating the acne with the fingers.

In general, use of personal care products should be minimized. Moisturizers and cosmetics should be water based, noncomedogenic, and fragrance free. If hair preparations are used, they should also be water based. The patient should be instructed to apply hair products so that they do not come in contact with facial skin.

The practitioner also needs to stress that ingestion of specific foods, such as chocolate, greasy foods, colas, and iodide-containing foods, does not cause acne. Elimination diets are not considered therapeutic unless the patient reports an exacerbation associated with a certain food. In that case, the food must be avoided for 4 to 6 weeks and then gradually reintroduced to see what effect that food has on the acne.

Goals of Drug Therapy

The goal of pharmacotherapy is to minimize the number and severity of new lesions, prevent scarring, and improve the patient's appearance. The patient must be counseled that improvement of acne vulgaris takes time—usually 4 to 6 weeks. Some form of therapy will probably need to be continued throughout adolescence and even into young adulthood.

Pharmacotherapy choices are based on the severity of the acne. Currently, successful therapy usually relies on a combination of medications. The synergistic effect of two or more drugs from different classes produces the best results. See Table 16.3 for a summary of acne medications.

TABLE 16.3 Overview of Topical and Oral Acne Preparations

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Topical Medications			
tretinoin (Retin-A, Avita) 0.025%, 0.05% cream, gel 0.04%, 0.1% microspheres Apply once daily; increase strength as tolerated.	Erythema, local skin irritation, photosensitivity	Eczema, sunburn	Apply to dry skin for short periods or on alternate nights until better tolerated. Avoid products with high concentrations of alcohol, astringents, spices, lime. Pregnancy category C
benzoyl peroxide (many) 2.5%–5.0% once a day; increase to two or three times daily.	Irritation	Sunscreens containing para-aminobenzoic acid (PABA) may cause transient skin discoloration.	Product may bleach fabrics. Apply at different time from other topical medications.
azelaic acid (Azelex) 20% cream Apply twice a day.	Pruritus, irritation		Darker-pigmented people may have hypopigmentation. Exacerbation of asthma.
clindamycin (Cleocin T) Apply to skin twice a day.	Burning; stinging of eyes; possibly pseudomembranous colitis		Discontinue use if diarrhea develops. Pseudomembranous colitis may develop. Drug may potentiate neuromuscular blocking agents.
erythromycin (many) 2%–3% topical Apply twice daily.	Irritation	Allergy to erythromycin	None
tazarotene (Tazorac) 0.05%, 0.1% gel, cream Apply once daily.	Irritation, photosensitivity	Pregnancy category X	Obtain negative pregnancy test and use reliable contraception during medication use.
Oral Medications			
tetracycline (many) 500–1,000 mg daily divided bid/qid Taper to 250 mg/d after improvement; attempt to discontinue after 4–6 mo of therapy.	Photosensitivity, gastric irritation, decreased effectiveness of oral contraceptives	Age younger than 12 y Pregnancy category D	Drug may increase serum digoxin levels. Drug absorption is reduced if taken with antacids, iron, zinc, dairy products. Drug use may increase blood urea nitrogen values if renal system is impaired.
erythromycin (many) 500–1,000 mg/d divided bid/qid	Nausea, vomiting, diarrhea, rash, allergic reactions, fungal infection, hepatitis, ototoxicity	Allergy to erythromycin or macrolide Not recommended for children younger than age 2 mo	Take on an empty stomach for better absorption 1 h before or 2 h after a meal. Enteric-coated form can be taken with or without food. Interactions: warfarin, theophylline, cisapride, digoxin, and others
isotretinoin (Accutane, generic) 0.5–1.0 mg/kg bid	Increased cholesterol and triglyceride levels; dry skin and mucous membranes; depression; aggressive, violent behaviors; back pain; arthralgias in pediatric patients	Adolescents before cessation of growth Pregnancy category X	Prescriber must be registered in SMART program. Female patients of childbearing age must have two negative pregnancy tests prior to therapy initiation and monthly negative pregnancy test while on therapy. Monitor cholesterol and triglyceride levels, complete blood count, liver function tests before therapy, at 4 wk, and as indicated
ethinyl estradiol with norgestimate (Ortho Tri-Cyclen, Tri-Sprintec) 1 tablet daily		Premenarchal girls, male patients	Women who smoke should avoid use of oral contraceptives.

Comedolytics

Retinoic Acid (Tretinoin)

Marketed under the trade names Retin-A and Avita, retinoic acid is the acid form of vitamin A. When applied topically, retinoic acid acts on the epidermis with little systemic absorption to decrease cohesion between epidermal cells and increase epidermal cell turnover. The result is expulsion of open comedones and the conversion of closed comedones to open ones.

When used properly, retinoic acid causes mild erythema and peeling of the skin. Some patients cannot tolerate daily use or prolonged contact at the initiation of therapy. For example, fair-skinned patients should be advised to start out using the product every other day. Alternatively, the patient may be instructed to apply retinoic acid to the face for 15 to 30 minutes each night and then wash off the medication. Gradually, the length of time the medication remains on the face is increased until it can be tolerated overnight. It is best to apply the medication on clean, thoroughly dry skin to avoid excessive irritation. Side effects of retinoic acid include erythema, local skin irritation, and photosensitivity. Patients should be advised to avoid prolonged exposure to the sun or to wear a noncomedogenic sunscreen formulated specifically for use on the face.

Retinoic acid is available in cream (0.025%, 0.05%, and 0.1%), gel (0.01% and 0.025%), liquid (0.05%), and microsphere (0.04% and 0.1%) formulations. The microsphere formulation encapsulates the active ingredient in microspheres, which act as a reservoir that slowly releases the retinoic acid. Although the microsphere product contains a higher percentage of medication, the slow-release formulation produces less irritation, making it one of the mildest dosage forms.

Adapalene Gel

Adapalene (Differin), a topical medication for treating noninflammatory acne, is a derivative of naphthoic acid, which binds to retinoid receptors. It is considered less irritating than retinoic acid. Up to 40% of patients report irritation, but it subsides during the first month of treatment. Adapalene is applied in the same way as retinoic acid. A small amount is applied either every other day or for short periods in the evening until the drug can be tolerated overnight. Side effects of adapalene include hyperpigmentation and photosensitivity.

Tazarotene Gel

A retinoid prodrug, tazarotene gel (Tazorac) is effective against both comedonal and inflammatory acne as well as psoriasis. Despite being a topical drug, tazarotene is considered teratogenic (pregnancy category X) and should be used only by women who take systemic contraceptives and who have a negative pregnancy test.

Care should be taken when using the medication with tetracycline because it potentiates the photosensitivity reaction. Other side effects include dry skin, erythema, and pruritus.

Comedolytic Bactericidals

Benzoyl Peroxide

Benzoyl peroxide is both a comedolytic and bactericidal agent specific to *P. acnes*. It has a role in inflammatory acne because of its antibacterial qualities. By decreasing *P. acnes* levels, it decreases the inflammation caused by leukocytic and monocytic attraction to the pilosebaceous follicle.

The major side effect of benzoyl peroxide is irritation. Like all comedolytics, benzoyl peroxide is applied initially in a low-percentage formulation in a nonirritating base. The patient increases the dosage strength and frequency. Because benzoyl peroxide may bleach colored items, the patient should be instructed not to let the product come in contact with brightly colored towels, pillowcases, or clothing. If used with retinoic acid, benzoyl peroxide should be applied in the morning and retinoic acid before bedtime.

Benzoyl peroxide is available in various strengths and bases, both OTC and by prescription. Gel formulations, which are considered more effective, are available in 2.5%, 4%, 5%, 10%, and 20% strengths. Lotions (5%, 10%, and 20%) and creams (5% and 10%) are also available.

Before using prescription-strength benzoyl peroxide, the patient should be instructed to discontinue any washes or lotions containing benzoyl peroxide that he or she may already be using. Inadvertent use of the two products may increase irritation.

Azelaic Acid

Azelaic acid (Azelex) is believed to interfere with the deoxyribonucleic acid synthesis of acne-causing bacteria. The drug is considered as effective as topical macrolide antibiotics in treating papulopustular acne. Azelaic acid is supplied as a 20% cream and is applied topically twice a day. In dark-pigmented people, hypopigmentation may develop from use.

Topical Antibiotics

Topical antibiotics may be prescribed when comedolytic antibacterials are either not effective or not tolerated and systemic antibiotics are not desired. Topical antibiotics inhibit the growth of *P. acnes* and decrease the number of comedones, papules, and pustules. Clindamycin 2% (Cleocin T) or erythromycin 2% or 3% (many brands) is supplied in solutions, saturated pads, lotions, and gels. Rarely, topical clindamycin has been implicated in pseudomembranous colitis and regional enteritis. The practitioner should advise patients to discontinue therapy if diarrhea develops.

Oral Antibiotics

When improvement cannot be achieved with topical therapy, oral antibiotics may be considered. Oral antibiotics are indicated for inflammatory acne because they suppress *P. acnes* as well as inhibit bacterial lipases, neutrophil chemotaxis, and follicular inflammation. There is no indication for their use in noninflammatory acne.

Tetracycline

Tetracycline is the most commonly used oral antibiotic for treating inflammatory acne. Doses begin at 500 to 1,000 mg/d and are tapered to 250 mg/d after improvement occurs. Clinical improvement takes at least 3 to 4 weeks.

Tetracycline permanently stains the teeth in children, so it should not be prescribed for patients younger than 12 years of age. Moreover, the drug is a teratogen. It may also decrease the effectiveness of oral contraceptives. Therefore, caution should be used when prescribing it for sexually active female patients. Patient education should include directions to avoid concurrent ingestion of milk products, iron preparations, and antacids, which decrease absorption. Ideally, the medication should be taken on an empty stomach.

Side effects of tetracycline include photosensitivity, gastric irritation, blood dyscrasias, and pseudotumor cerebri (benign intracranial hypertension). Caution should be used in treating patients who have renal failure or who are concurrently taking digoxin because tetracycline may increase serum digoxin levels.

Erythromycin

Erythromycin and its derivatives are good alternatives when tetracycline fails or is not tolerated. They can also be used when the patient is younger than age 10 or pregnant. A common side effect is gastrointestinal upset. There are drug interactions with digoxin, theophylline, and cyclosporine.

Other Systemic Drugs

Given in doses between 500 and 1,000 mg/d, erythromycin is as effective as tetracycline. It is helpful in treating people with tetracycline allergy. Minocycline and doxycycline have also been used, but there is no advantage over tetracycline or erythromycin. Minocycline is considerably more expensive.

Retinoic Acid Derivatives: Isotretinoin

Isotretinoin (Accutane) has changed the management of acne therapy. It is reserved for patients with severe nodulocystic acne when other treatments fail. Isotretinoin is a retinoic acid derivative. Although the exact mechanism is unknown, it decreases sebum production, follicular obstruction, and the number of skin bacteria. It also has an anti-inflammatory action.

Dosage

Isotretinoin is given at a dose of 0.5 to 1 mg/kg/d. Therapy continues for 15 to 20 weeks unless significant improvement occurs sooner. If therapy needs to be repeated, 2 months should elapse before restarting the drug.

Contraindications

Because isotretinoin, a teratogen, is associated with serious birth defects, only prescribers registered in the SMART (System to Manage Accutane-Related Teratogenicity) program (Roche Laboratory) may prescribe Accutane. Similar programs are in place for generic isotretinoin. The SMART program requires prescribers to study Roche's Guide to Best Practices and sign and return a letter of understanding that details the risks of pregnancy while on Accutane. The letter of understanding is an agreement to follow the recommendations of the SMART program, which includes obtaining two negative pregnancy tests prior to initiation of the drug and obtaining monthly pregnancy tests during therapy for all female patients. A yellow self-adhesive Accutane qualification sticker is to be placed on every prescription written, regardless of the gender of the patient. Only 30 days of drug can be prescribed at one time. Female patients able to bear children should be counseled to use two forms of contraception (Roche Laboratories, 2002). It is recommended that this drug be prescribed by a dermatologist.

Before initiating therapy, a baseline complete blood count and chemistry profile and fasting triglyceride and cholesterol levels should be obtained. A complete blood count and a chemistry profile should then be obtained 1 month after the start of therapy. Pregnancy should be avoided for 1 month after therapy is discontinued.

Adverse Events

The most significant adverse effect of isotretinoin is teratogenicity. A 25-fold increase in fetal abnormalities has been documented. Even without external abnormalities, approximately 50% of children exposed to isotretinoin in utero have subnormal intelligence.

Approximately 25% of patients experience cholesterol and triglyceride elevations. Pseudomotor cerebri has been reported when isotretinoin therapy is combined with tetracycline. Almost all patients report dry skin and mucous membranes, including cheilitis, severe dry skin, and difficulty wearing contact lenses. Other side effects include musculoskeletal aches and corneal opacities. Therapy should not be initiated in adolescents who have not finished growing because the drug may cause premature closure of the epiphyses.

A "black box" warning was added in 2002, warning of an increase in aggressive or violent behaviors in patients as well as back pain in children: 29% of children developed back pain and 22% experienced arthralgias (FDA MedWatch, 2002).

Other Medications

Topical Antibiotic–Benzoyl Peroxide Combinations

Marketed as Benzamycin, the combination of erythromycin 3% and benzoyl peroxide 5% in a gel base may increase compliance when a topical antibiotic is needed in addition to one or more other topical medications. The gel is applied once or twice a day. Although the product requires refrigeration, small quantities may be transferred to another container for up to 10 days, which tends to promote therapeutic adherence. Benzamycin is also marketed in pouches (Benzamycin Pak) that are mixed by the patient and therefore do not require refrigeration. The pack holds the two active ingredients in separate chambers, and they can be mixed as needed.

Similarly, a combination of clindamycin 1% and benzoyl peroxide 5% gel (BenzaClin Gel, Duac Gel) is available. Unlike Benzamycin, these products have a shelf life of 3 months at room temperature and do not require refrigeration.

Hormonal Therapy

Oral contraceptives can be used in women when conventional topical and systemic therapies have failed. Oral contraceptives will be discussed in Chapter 55. Oral contraceptives that contain ethinyl estradiol, levonorgestrel, and norgestimate or drospirenone are effective in the treatment of acne. Some other oral contraceptives may exacerbate acne. Relative to other therapies, oral contraceptives are inexpensive. They reduce both comedonal and inflammatory acnes and are worth considering for women who are already taking or considering taking systemic contraceptives.

Selecting the Most Appropriate Agent

The most important consideration in selecting a therapeutic regimen is matching the severity of the acne to the appropriate pharmacologic agent (Figure 16.1 and Table 16.4).

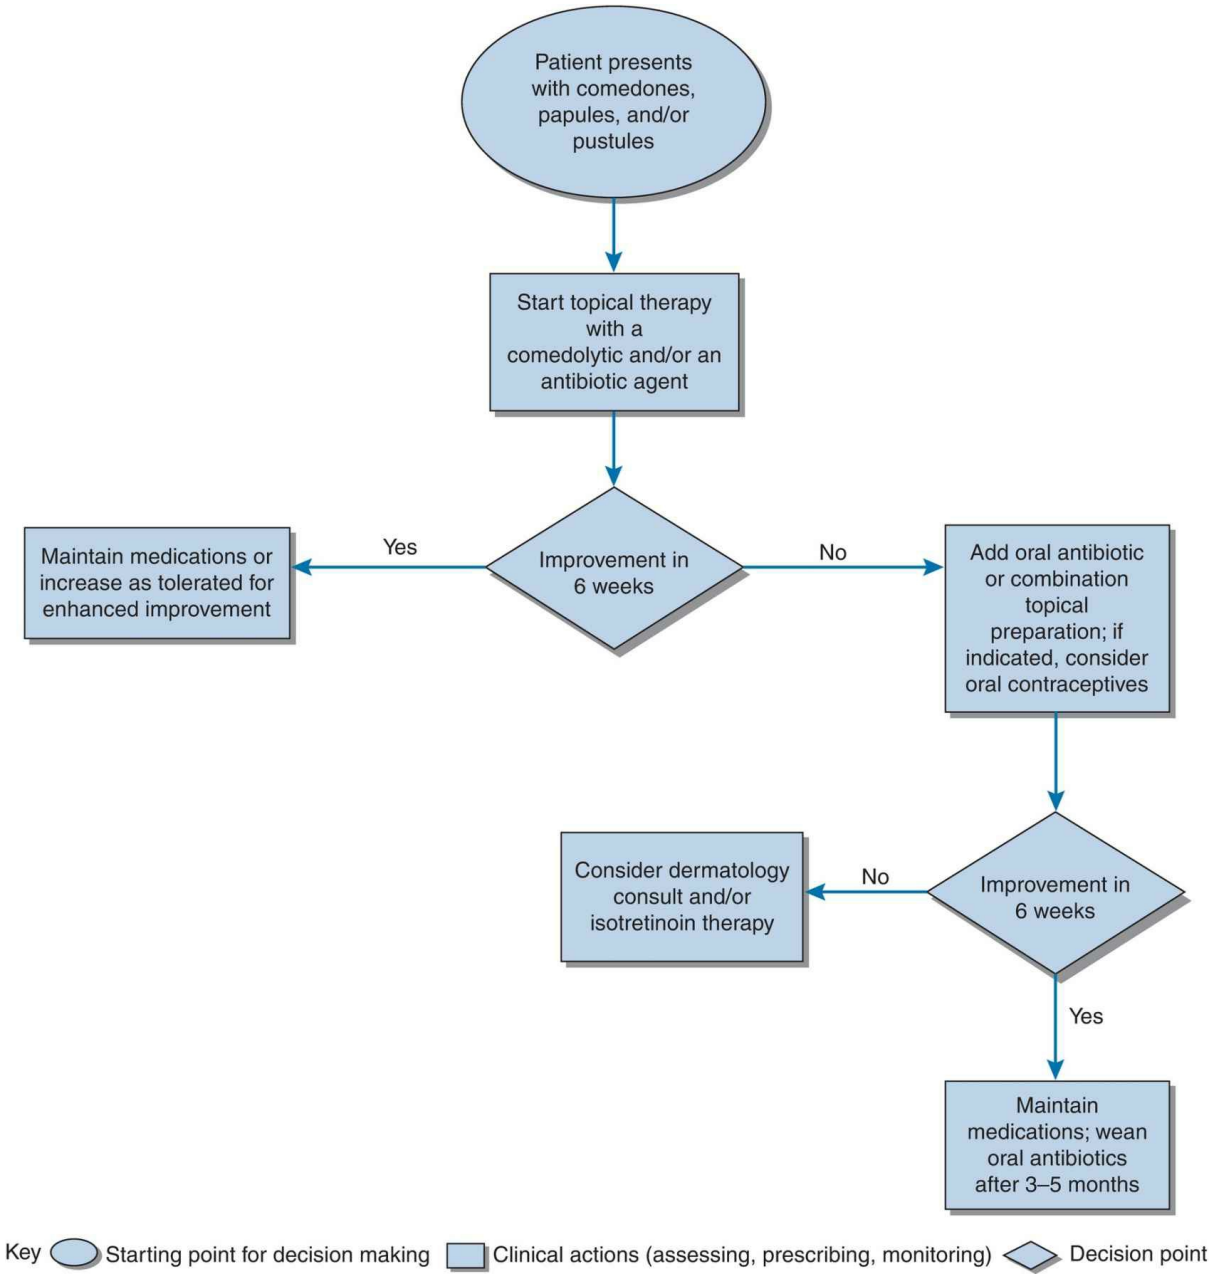

FIGURE 16.1 Treatment algorithm for acne.

TABLE 16.4 Recommended Order of Treatment for Acne

Order	Agent	Comments
First line	Topical therapy	Improvement takes ~6 wk.
Second line	Oral medications	Monitor in 6 wk.
Third line	Isotretinoin or refer to dermatologist	Prescribe with caution to women of childbearing age. Pregnancy category X

First-Line Therapy

The first line of therapy for comedonal acne is topical medication. Topical comedolytics encourage faster turnover of the surface skin. The addition of bactericidals or topical antibiotics enhances results for patients with closed comedones and pustules.

Second-Line Therapy

Patients whose acne does not respond to topical therapy may need oral medications. The practitioner may initiate treatment with oral antibiotics in addition to topical medications for more severe papulocystic acne. Oral contraceptives are a useful and cost-effective alternative for sexually active women.

Third-Line Therapy

Isotretinoin is reserved for the most severe forms of nodulocystic acne. Special care must be taken when prescribing this agent for women who can become pregnant. Practitioners who are not registered with the SMART program or who cannot comply with the necessary monitoring and follow-up may feel more comfortable referring the patient to a dermatologist for evaluation and treatment.

Special Population Considerations

Pediatric

Because of the risk of dental enamel defects and bone growth retardation, the use of tetracycline is contraindicated in children younger than age 12. Growth retardation in children who have not reached adult height is associated with isotretinoin use. Children may also experience increased arthralgias and back pain with the use of isotretinoin.

Women of Childbearing Age

Women of childbearing age who are using isotretinoin or tazarotene gel must not become pregnant because of the teratogenicity of the products. Practitioners may suggest that a long-acting contraceptive, such as Depo-Provera, be used. If pregnancy occurs, the patient must be counseled accordingly. Tetracycline, also considered teratogenic, may decrease the effectiveness of oral contraceptives. Women taking this antibiotic should rely on a long-acting contraceptive or a barrier method to prevent pregnancy. Retinoic acid is labeled pregnancy category C and is not recommended for use in pregnant women or nursing mothers.

Ethnic

Azelaic acid may cause hypopigmentation in patients with dark skin.

Monitoring Patient Response

Follow-up should be scheduled monthly to monitor the patient's response to therapy, provide reassurance, and encourage adherence to therapy. Monthly visits provide the opportunity to adjust medications and dosages as the patient's acne responds to treatment. The ideal management is long-term topical therapy. If isotretinoin is prescribed, laboratory tests should be obtained before therapy and 1 month into therapy, as described previously.

Patient Education

Drug Information

The practitioner may show the patient how to apply topical preparations correctly to prevent excessive irritation (Box 16.1). An important consideration in prescribing topical therapy is that many gels and solutions contain significant amounts of alcohol. If a patient is sensitive to alcohol-based preparations or is experiencing significant dryness despite low concentrations of active ingredients, the practitioner may consider switching to a preparation that does not contain alcohol, such as a cream or aqueous gel.

BOX 16.1 General Principles for Applying Topical Acne Preparations

- Initiate therapy with a lower concentration of active ingredient and then work up to a higher concentration as tolerated.
- Choose a product with a lower percentage of alcohol for people with sensitive skin.
- Apply the product to clean, dry skin. Allow at least 20 minutes to elapse between washing the face and applying the medication.
- Use the smallest amount of medication necessary for coverage.
- Apply in "dots" over the desired area and then rub into skin.
- Apply one drying agent in the morning and another in the evening to avoid excessive irritation.

Nutritional factors play an important role in the pathogenesis of acne. A diet with a low glycemic load, higher in protein than carbohydrates and fats, can decrease lesion counts in acne vulgaris. A low glycemic–load diet has also been associated with a reduction in calorie intake, body mass index, and insulin resistance. Improved insulin sensitivity leads to a decrease in androgen production and a concordant improvement in the symptoms of acne vulgaris.

Patients should be cautioned to avoid using excessive amounts of topical medications in the hope that it will speed improvement. Instead, irritation will most likely be the result, and that may discourage continuation of therapy.

Patience is the key to resolution of acne. Adolescents looking for a quick cure may be disappointed. All forms of acne therapy require a minimum of 4 to 6 weeks before results are seen. It is important to provide appropriate follow-up and encouragement and to have the patient return for evaluation and refinement of the treatment program.

Patient-Oriented Information Sources

The Web sites www.acne.org and www.nih.gov/medlineplus/acne.html (a site from the National Institutes of Health) provide information about acne and treatment.

Complimentary and Alternative Medicine

Brewer's yeast has been use in Western Europe as a treatment for acne. It contains chromium which decreases insulin resistance. In one study of 139 subjects with acne, over 80% showed significant improvement in symptoms (Weber et al., 1989). The recommended dose is 2 g three times a day.

Zinc is involved in the maintenance of skin health and immune function, local hormone activation, and production of retinol-binding protein. It has shown some bacteriostatic action against *P. acnes* and inhibitory action on the production of retinol-binding protein.

Another product that has shown to improve acne severity is tea tree oil. It has less skin irritation that benzoyl peroxide. A solution of 5% to 15% is applied once a day.

Rosacea

Occasionally mistaken for acne vulgaris, rosacea is an acneiform disorder that begins in midlife (ages 30 to 50). It is estimated that rosacea affects over 16 million people by the National Rosacea Society. The rash is symmetric and limited to the central part of the face. Fair-skinned people with a tendency to blush are more often affected. Although rosacea is more likely to develop in women, men who are affected may have a more severe form of the disorder. Rosacea is not frequently seen in skin of color.

Causes

Rosacea does not have a clear cause. Various theories suggest bacterial infection, fungal infection, hair follicle mite (*Demodex folliculorum*) infestation, menopausal changes, and, more recently, *Helicobacter pylori* infection. Sun exposure, excessive face washing, and irritating cosmetics may exacerbate rosacea.

Pathophysiology

Early vascular rosacea consists of simple erythema in response to cold exposure. Extravascular fluid accumulates. As a result, blood flow to the superficial dermis increases. Persistent telangiectasia occurs late in the vascular stage of the disorder. During this period, ocular involvement may develop, consisting of mild conjunctivitis, dry eyes, burning, blepharitis, and occasionally keratitis and corneal ulceration.

The second stage of rosacea represents lymphatic failure. It results in epidermal epithelial hyperplasia and pilosebaceous gland hyperplasia with fibrosis, inflammation, and telangiectasia. Clinical changes include persistent erythema, telangiectases, papules, and pustules. Rhinophyma, the characteristic deep inflammation and connective tissue hypertrophy of the nose, may begin to develop during this stage. Rhinophyma is almost exclusively seen in men older than age 40 and is treatable only by surgery.

Late-stage rosacea is recognized by persistent deep erythema, dense telangiectases, papules, pustules, nodules, and persistent edema of the central part of the face.

Diagnostic Criteria

The diagnosis of rosacea is based on the history and clinical presentation. Fixed telangiectasia is the hallmark of this disorder. In patients younger than age 30, acne should be ruled out. In patients with systemic symptoms, systemic lupus erythematosus should be ruled out. Bacterial cultures should be performed to rule out *Staphylococcus aureus* folliculitis and gram-negative folliculitis. Patients who do not respond to systemic antibiotics should be evaluated for *D. folliculorum* infestation.

Approximately 50% of patients report ocular involvement, so any ocular symptoms should be investigated. Referral to an ophthalmologist should be considered if the practitioner suspects corneal ulceration or keratitis.

Initiating Drug Therapy

The goal of therapy is to minimize the disfiguring effects of rosacea and prevent further tissue damage. As with acne, the patient's concerns with regard to appearance must be considered. Patients with rosacea may feel stigmatized. Treatment during the early phase (vasodilation) is difficult. Patients may not respond to treatment until the condition progresses to the inflammatory stage.

Topical Antibacterials

Metronidazole

Topical metronidazole (MetroGel, Noritate) has anti-inflammatory properties (Table 16.5). It is available in 0.75% and 1% strengths and is applied twice a day in a thin layer on the face, avoiding the eyes. Adverse events include burning, skin irritation, transient erythema, mild dryness, and pruritus. Metronidazole is available in cream, gel, and lotion. Initial results should be seen in approximately 3 weeks and the full effect in approximately 9 weeks. Patients are then maintained on the agent indefinitely. Patients who receive concurrent anticoagulant therapy should be monitored closely for an enhanced anticoagulation effect.

TABLE 16.5 Overview of Topical Agents for Rosacea

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
metronidazole 0.75% gel, cream, lotion (MetroGel, etc.) 1.0% cream (Noritate)	Burning sensation, irritation, erythema (transient), mild dryness, pruritus	Children Breast-feeding mothers	Avoid eyes. With anticoagulant therapy, monitor closely for enhanced anticoagulation.
sodium sulfacetamide 10% with sulfa 5% (Sulfacet-R, Novacet)	Local irritation, allergic dermatitis	Kidney disease Breast-feeding mothers Sulfa allergy	Avoid eyes and denuded skin. Pregnancy category C
sodium sulfacetamide 10% with sulfa 5% and urea 10% (Rosula) One to three times a day in thin layer			
azelaic acid 15% (Finacea) Apply thin film two times daily.	Burning, stinging, pruritus	Children	Hypopigmentation in patients with dark complexions

Combination Medications

Sodium sulfacetamide 10% with sulfur 5% (Sulfacet-R, Novacet, Clenia) also has anti-inflammatory properties when used to treat rosacea. It is applied one to three times a day. It is contraindicated in patients with kidney disease and in those sensitive to sulfa drugs. Application to eyes and areas of denuded skin is to be avoided. Adverse events include local irritation and allergic dermatitis.

Rosula is a combination of sulfacetamide 10%, sulfur 5%, and urea 10%. The addition of urea helps to soothe and relieve redness and inflammation.

Azelaic Acid

Azelaic acid (Finacea), also indicated for acne, has been shown to be effective in treating papules and pustules associated with rosacea. Supplied as a 15% gel, it is indicated for the topical treatment of inflammatory papules and pustules of mild to moderate rosacea. Patients with dark complexions may experience hypopigmentation.

Oral Antibiotics

When topical agents have not improved the patient's condition, oral antibiotic agents may be considered. Antibiotics are used for their anti-inflammatory effect rather than their antibiotic properties. Oral antibiotics are indicated for patients with ocular symptoms.

Tetracycline

Tetracycline is the antibiotic of choice for treating rosacea. Tetracycline is prescribed in doses of 500 mg twice a day to initiate remission. After 2 weeks, the dose can be lowered to 250 mg twice a day for an additional 4 weeks. If no inflammatory lesions are present at 6 weeks, the dose may be lowered to 250 mg once a day. After 3 to 5 months, the practitioner may consider discontinuing the oral antibacterial while continuing topical metronidazole therapy.

Doxycycline

Doxycycline (Vibramycin, Monodox, Doryx), a tetracycline derivative, is sometimes more effective than tetracycline. It is given in doses of 100 mg twice daily and then tapered after 2 weeks to 50 mg twice daily. After improvement occurs, the dose may be lowered to 50 mg/d and then stopped after 3 to 5 months while maintaining metronidazole cream. Patients should be cautioned to avoid sun exposure while taking doxycycline.

Erythromycin

Erythromycin (E-mycin, Ery-Tab) is a useful agent when tetracycline is contraindicated. Dosages and tapering regimens are identical to those used for tetracycline.

Trimethoprim/Sulfamethoxazole

Trimethoprim/sulfamethoxazole has been used successfully in patients with acne refractory to other antibiotics and in gram-negative acne.

Isotretinoin

Isotretinoin (Accutane) may be prescribed for patients who do not respond to oral and topical antibiotics. It is given in doses of 0.5 to 1.0 mg/kg/d for up to 8 months. Precautions and laboratory follow-up as described in the section on acne should be maintained.

Selecting the Most Appropriate Agent

Initial drug therapy choices should include a topical agent. Cases that involve ocular symptoms should be treated with oral antibiotics.

First-Line Therapy

The first-line treatment of rosacea consists of topical therapy. If no improvement is seen after 6 weeks, second-line therapy begins.

Second-Line Therapy

Second-line treatment consists of adding an oral antibiotic. After 2 weeks, the dose is reduced by 50%, and then, after 6 weeks, the oral antibiotic is discontinued altogether and the topical treatment continues indefinitely.

Third-Line Therapy

Third-line treatment consists of oral isotretinoin or referral to a dermatologist. Table 16.6 lists the lines of therapy for rosacea, and Figure 16.2 outlines rosacea treatment.

TABLE 16.6 Recommended Order of Treatment for Rosacea

Order	Agent	Comments
First line	Topical medication	Improvement takes 6 wk.
Second line	Oral antibiotics	Improvement takes 6 wk.
Third line	Oral isotretinoin; consider referral to dermatologist.	Pregnancy category X

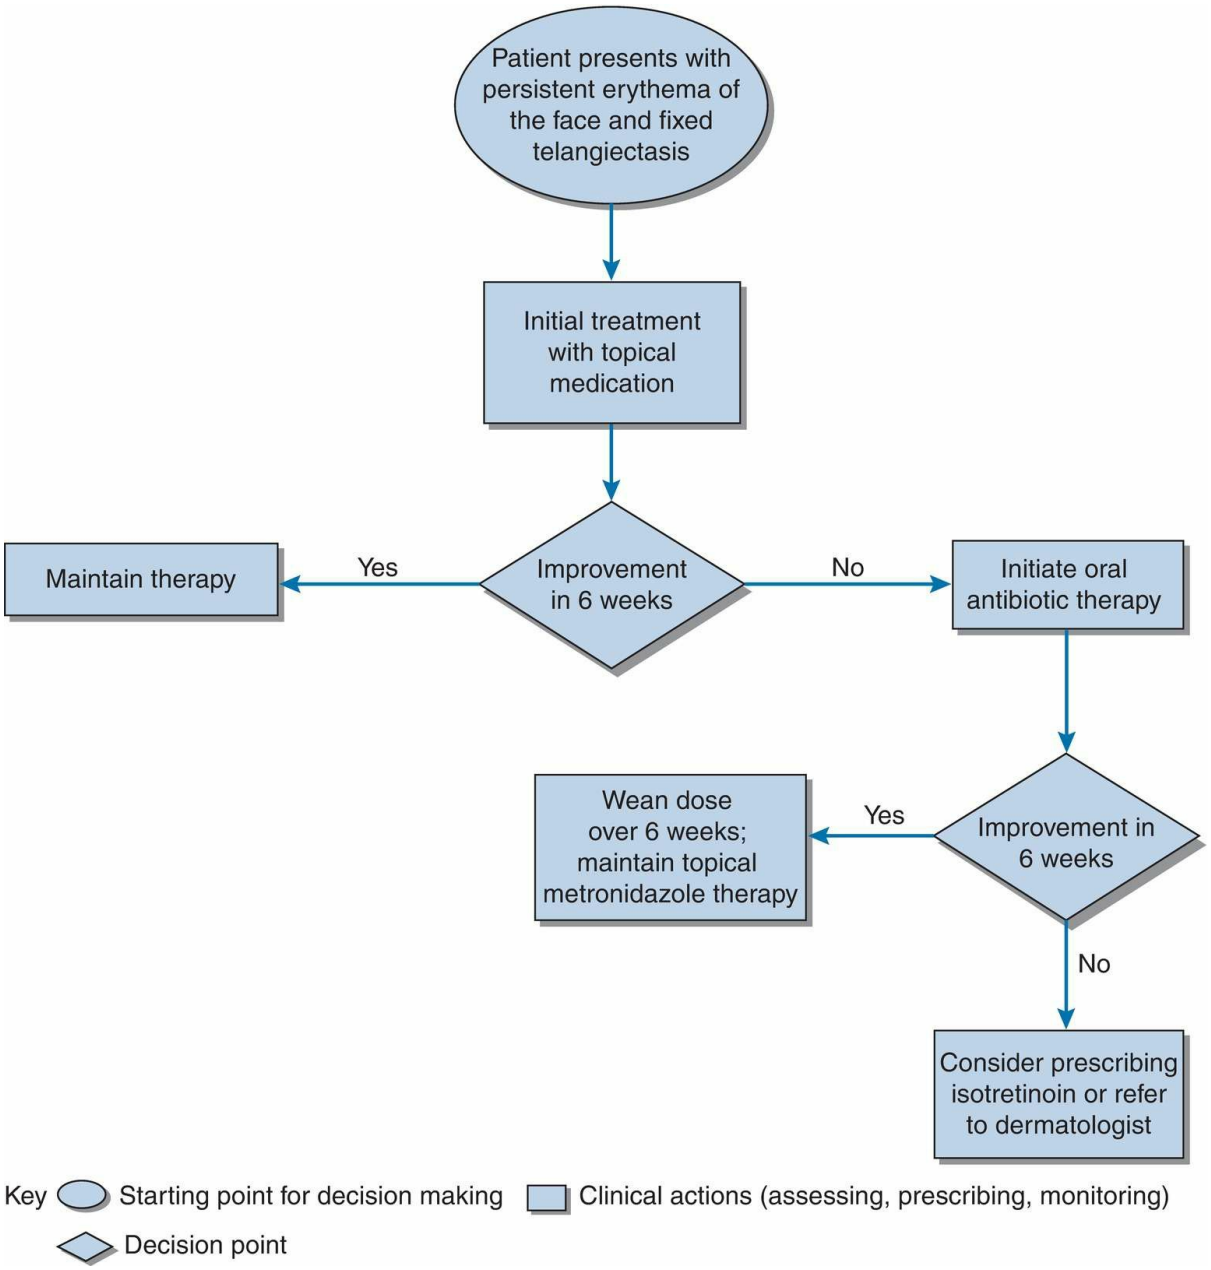

FIGURE 16.2 Treatment algorithm for rosacea.

Monitoring Patient Response

As discussed throughout this chapter, the patient's response is monitored regularly by observation and follow-up visits to adjust medications and provide support and encouragement during therapy.

Patient Education

Patients with rosacea need to recognize what triggers the condition. The goal of management is to avoid flare-ups. Although each patient responds differently to triggers, common triggers are sun exposure, strong winds, cold weather, warm environment, strenuous exercise, alcoholic beverages, spicy foods, hot foods and beverages, and stress.

It is important that a broad-spectrum UVA/UVB sunscreen be used and applied frequently.

Patients may be advised to avoid harsh cleansers, rough washcloths, and pulling or tugging at the skin. Cosmetic foundations with a green tint may camouflage redness. Additional information and consumer education may be obtained through the National Rosacea Society (1-888-NO BLUSH, http://www.rosacea.org).

Case Study*

J.S., age 16, comes to your office for a routine physical examination. You notice that she has facial acne that she is hiding with heavy makeup. She has tried Clearasil inconsistently without relief. She works at a fast food restaurant as a cook after school and on the weekends. Her mother has made her stop eating chocolates and greasy foods, but that has not seemed to help her. She is concerned because her prom is in 6 weeks and she wants her face clear. On physical examination, there are open and closed comedones as well as papules on her face and back. No scarring is evident. J.S. confides that she has recently become sexually active.

Diagnosis: Acne Vulgaris

1. List specific treatment goals for J.S.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Describe specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter or dietary supplement would you recommend to J.S.?
8. What dietary and lifestyle changes should be recommended for J.S.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

* Answers can be found online.

UNIT 3
Pharmacotherapy for Eye and Ear Disorders

17 Ophthalmic Disorders

Joshua J. Spooner

There are many conditions and disorders of the eye, but only a few, such as blepharitis and conjunctivitis, should be diagnosed and treated by a primary care provider. The remaining ocular conditions are usually treated by eye care specialists. Nonetheless, prescribers should be familiar with drug therapy for the more common ophthalmic conditions (glaucoma, keratoconjunctivitis sicca), as they are likely to encounter patients being treated for these disorders.

Eyelid Margin Infections: Blepharitis

The eye is well protected externally by the eyebrow, eyelashes, and eyelids. If these protective mechanisms are compromised, the eye becomes predisposed to disease. Externally, the eyelid structures are composed of skin with a high degree of elasticity, muscles that elevate the upper eyelid and close the eyelids, and the tarsal plate, which contains the meibomian glands. Through frequent blinking, the eyelids maintain an even flow of tears over the cornea. Internally, the eyelid structure is lined by the palpebral conjunctiva, which folds upon itself and then covers the sclera of the eyeball up to the corneoscleral junction. Located at the lid margins are the openings to the long sebaceous meibomian glands; these glands secrete the oily film that prevents tears from evaporating. At the base of the eyelash, hair follicles are the superficial modified sebaceous glands of Zeis and the sweat glands of Moll. Any of these glands may become functionally disrupted.

Blepharitis is an inflammation of the eyelid margin. Although it is a common eye disorder in the United States, epidemiologic information on its incidence or prevalence is not robust.

Causes

Blepharitis can be caused by a bacterial infection (staphylococcal blepharitis), inflammation or hypersecretion of the sebaceous glands (seborrheic blepharitis), meibomian gland dysfunction (MGD blepharitis), or a combination of these (American Academy of Ophthalmology [AAO], 2013a). Staphylococcal and seborrheic blepharitis primarily involve the anterior eyelid; both have also been referred to as anterior blepharitis.

Pathophysiology

Although the gram-positive organisms *Staphylococcus epidermidis* and *Staphylococcus aureus* are found on the eyelids of a high proportion of healthy subjects, *S. aureus* is observed more frequently among patients with staphylococcal blepharitis. While *S. epidermidis* and *S. aureus* are thought to play a role in the development of staphylococcal blepharitis, their role in disease production remains unclear. Toxin production, immunologic mechanisms, *Demodex folliculorum* mite infestation, and antigen-induced inflammatory reactions have all been reported with blepharitis (AAO, 2013a; Zhao et al., 2012).

Seborrheic blepharitis typically occurs as part of the more comprehensive condition of seborrheic dermatitis, with dandruff of the scalp, eyebrows, eyelashes, nasolabial folds, and external ears. Seborrheic blepharitis is more commonly found in the geriatric population because of its association with rosacea.

Manifestations of MGD blepharitis include thickening of the eyelid margin, plugging of the meibomian orifices, prominent blood vessels crossing the mucocutaneous junction, and formation of chalazia (painless firm lumps on the eyelid). These changes may lead to atrophy of the meibomian glands (AAO, 2013a). Compared to healthy patients, meibomian gland secretions are more turbid among patients with MGD blepharitis. These secretions block the gland orifices and become a growth medium for bacteria. Patients with MGD blepharitis frequently have coexisting rosacea or seborrheic dermatitis.

Diagnostic Criteria

There are no specific diagnostic tests for blepharitis; the diagnosis is often based upon patient history and characteristic symptoms. Patients with blepharitis frequently present with irritated red eyes and report a burning sensation. Increases in tearing, blinking, and photophobia are frequently reported, as is eyelid sticking and contact lens intolerance. Upon close inspection, the eyelid margins appear red, greasy, and crusted, with eyelid deposits that cling to the eyelashes. The eyelid margins may be ulcerated and thickened, and eyelashes may be missing.

Although the clinical features of staphylococcal, seborrheic, and MGD blepharitis are similar, there are differences that can aid in the differential diagnosis of these conditions. Eyelash loss and eyelash misdirection frequently occur in staphylococcal blepharitis but are rare in seborrheic blepharitis. The eyelid deposits are matted and scaly in staphylococcal blepharitis, oily or greasy in seborrheic blepharitis, and fatty and possibly foamy in MGD blepharitis. Chalazia are most likely to occur in MGD blepharitis.

Initiating Drug Therapy

The underlying cause of the blepharitis must be treated, particularly if it is due to seborrheic dermatitis or rosacea. Treatment for all types of blepharitis includes strict eyelid hygiene and warm compresses. The use of warm compresses with a clean washcloth can soften adherent encrustations; once-daily use of compresses is generally sufficient (AAO, 2013a). Patients with MGD blepharitis often benefit from eyelid massage following warm compress use to remove excess oil. Following warm compress use, eyelid cleaning is performed by having the patient rub the base of the eyelashes with a commercially available eyelid cleaner (EyeScrub, OCuSOFT) or a diluted mixture of baby shampoo (e.g., Johnson & Johnson) and water on a cotton swab, cotton ball, or gauze pad. Performing eyelid hygiene daily or several times a week often blunts the symptoms of chronic blepharitis (Guillon et al., 2012). Patients should be advised that eyelid hygiene may be required for life because symptoms frequently recur if eyelid hygiene is discontinued.

Patients suspected of having a new case of seborrheic or MGD blepharitis should be referred to an eye care specialist for a workup. Patients with staphylococcal blepharitis need a topical antibiotic.

Goals of Drug Therapy

The goals of drug therapy are to eradicate the pathogens causing the blepharitis and to reduce the signs and symptoms of blepharitis.

Topical Ophthalmic Antimicrobials

Topical ophthalmic antimicrobials are used for the treatment of and prophylaxis against external bacterial infections (Table 17.1). They kill the offending pathogen and other susceptible organisms.

TABLE 17.1 Overview of Antimicrobial Ophthalmic Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Single-Agent Products			
sulfacetamide sodium 10% solution (Bleph-10) Dosing Solution: 1–2 drops every 2–3 h initially according to the severity of infection Dosing may be tapered as the condition responds. Usual duration of therapy is 7–10 d.	Local irritation, itching, stinging, burning, periorbital edema	Allergy to sulfa drugs Do not use in infants less than age 2 mo.	A significant percentage of *Staphylococcus* species are resistant to sulfa drugs. Do not use in patients with purulent exudates.
bacitracin 500 units/g ointment Dosing: apply one to three times a day	Blurred vision, redness, burning, eyelid edema		Ointments may blur vision and retard corneal wound healing.
erythromycin 0.5% ointment Dosing: apply up to 1 cm to the affected eye(s) up to six times a day	Redness, ocular irritation		Ointments may blur vision and retard corneal wound healing.
gentamicin 0.3% solution or ointment (Gentak) Dosing Solution: 1–2 drops in the affected eye(s) every 4 h Ointment: ½ inch to the affected eye two or three times a day	Ocular burning and irritation, nonspecific conjunctivitis, conjunctival epithelial defects, conjunctival hyperemia, bacterial and fungal corneal ulcers		In severe infections, dosage of the solution may be increased to as much as 2 drops every hour. Ointments may blur vision and retard corneal wound healing.
Generic (Trade) Name and Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
tobramycin 0.3% solution or ointment (Tobrex) Dosing Solution: 1–2 drops into the infected eye every 4 h Ointment: ½ inch every 8–12 h	Lid itching, lid swelling, conjunctival hyperemia, nonspecific conjunctivitis, bacterial and fungal corneal ulcers		Ointments may blur vision and retard corneal wound healing. For more severe infections, the initial dose may be increased to 2 drops every 60 min (solution) or 1 inch every 3–4 h (ointment).
besifloxacin 0.6% suspension (Besivance) Dosing: 1 drop in the affected eye(s) three times a day for 7 d	Conjunctival redness, blurred vision, eye irritation, eye pain, pruritus		
ciprofloxacin 0.3% solution or ointment (Ciloxan) Dosing Solution: 1–2 drops every 2 h while awake for 2 d and then 1–2 drops every 4 h while awake for 5 d Ointment: ½ inch three times a day for 2 d and then ½ inch twice a day for 5 d	Local burning and discomfort, white crystalline precipitate formation, conjunctival hyperemia, altered taste		Ointments may blur vision and retard corneal wound healing. This is the only ophthalmic fluoroquinolone available as an ointment.
gatifloxacin 0.3% solution (Zymaxid) Dosing: 1 drop in the affected eye every 2 h while awake for 1 d and then 1 drop in the affected eye up to four times daily while awake for 6 d	Conjunctival irritation, tearing, papillary conjunctivitis, eyelid edema, ocular itching, dry eye		
levofloxacin 0.5% solution (Quixin) Dosing: 1 drop in the affected eye every 2 h while awake for 2 d and then 1 drop in the affected eye up to four times daily while awake for 5 d	Temporarily decreased or blurred vision, eye irritation, itching, dry eye		
moxifloxacin 0.5% solution (Moxeza, Vigamox) Dosing: Moxeza: 1 drop in the affected eye two times a day for 7 d Vigamox: 1 drop in the affected eye three times a day for 7 d	Decreased visual acuity, dry eye, ocular itching and discomfort, ocular hyperemia		
ofloxacin 0.3% solution (Ocuflox) Dosing: 1–2 drops in the affected eye every 2–4 h for 2 d and then 1–2 drops four times a day	Ocular burning and stinging, itching, redness, edema, blurred vision, photophobia		Rare reports of dizziness and nausea with use
azithromycin 1% solution (AzaSite) Dosing: 1 drop in affected eye(s) twice daily for 2 d and then 1 drop once daily for 5 d	Eye irritation, dry eye, ocular discharge		Refrigerate bottle; once opened, discard after 14 d.
Combination Products			
polymyxin B sulfate, bacitracin ointment Dosing: apply every 3–4 h for 7–10 d, depending upon the severity of infection.	Local irritation (burning, stinging, itching, redness), lid edema, tearing, rash		Ointments may blur vision and retard corneal wound healing.
polymyxin B sulfate, trimethoprim sulfate solution (Polytrim) Dosing: 1 drop in the affected eye(s) every 3 h (maximum six doses a day) for 7–10 d	Local irritation (burning, stinging, itching, redness), lid edema, tearing, rash		
polymyxin B sulfate, gramicidin, neomycin solution (Neosporin) Dosing: 1–2 drops into the affected eye(s) every 4 h for 7–10 d	Itching, swelling, conjunctival erythema, local irritation		Dosage of the solution may be increased to as much as 2 drops every hour for severe infections.
polymyxin B sulfate, bacitracin zinc, and neomycin ointment Dosage: apply every 3–4 h for 7–10 d, depending upon the severity of infection.	Itching, swelling, conjunctival erythema, local irritation		Acute infections may require dosing every 30 min. Ointments may blur vision and retard corneal wound healing.

Selecting the Most Appropriate Agent

Topical antimicrobials that are effective against staphylococci are listed in Table 17.2.

TABLE 17.2 Recommended Order of Treatment for Blepharitis

Order	Agent	Comments
First line	Erythromycin 0.5% ophthalmic ointment	Ointments tend to cause a greater degree of blurry vision than solutions.
	or	
	Bacitracin 500 units/g ointment	Erythromycin and bacitracin are available as inexpensive generic products.
	or	
	An ophthalmic fluoroquinolone solution (besifloxacin, gatifloxacin, levofloxacin, or moxifloxacin)	The remaining ophthalmic fluoroquinolones do not provide good staphylococcal coverage.
Second line	Referral to an ophthalmologist	

First-Line Therapy

Topical antibiotics such as bacitracin ointment or erythromycin 0.5% ophthalmic ointment are used first line for staphylococcal blepharitis and should be applied to the eyelid margins one or more times daily or at bedtime for a few weeks. Therapy selection is based on allergies and patient preference for ointment or solution (drops). Ointments tend to cause a greater degree of blurry vision than the solutions; if a patient prefers a solution, a fluoroquinolone (besifloxacin, gatifloxacin, levofloxacin, or moxifloxacin) would be suitable. The AAO (2013a) recommends that the frequency and duration of treatment should be guided by the severity of the condition and the response to treatment.

Second-Line Therapy

If the blepharitis fails to respond to the first-line therapy after several weeks or the condition appears to worsen at any time (including any vision loss or corneal involvement), the patient should be referred to an ophthalmologist for a complete evaluation.

Patient Education

Patients should be educated about the chronic nature of blepharitis. While chronic blepharitis is rarely cured, improved eyelid hygiene, warm massages, and occasional antibiotic use (for staphylococcal blepharitis) can improve symptoms. Counsel contact lens wearers to refrain from wearing contact lenses during an acute case of blepharitis, especially if antibiotic therapy has been initiated. Contact lens wearers with chronic blepharitis should consult with their eye care professional to determine whether contact lens use is safe.

External Surface Ocular Infections: Conjunctivitis

Conjunctivitis is the most common cause of a red, painful eye in the United States (Horton, 2015). Conjunctivitis is an inflammation of the bulbar conjunctiva (the clear membrane that covers the white part of the eye) or the palpebral conjunctiva (the lining of the inner surfaces of the eyelids). Conjunctivitis is commonly referred to as *pink eye*.

Causes

The most common organisms seen in acute bacterial conjunctivitis are the gram-positive *Staphylococcus* and *Streptococcus* species and the gram-negative *Moraxella* and *Haemophilus* species; less common organisms include *Neisseria gonorrhoeae* and *Chlamydia trachomatis* (CDC, 2014). In children, up to 50% of conjunctivitis cases are of bacterial origin. The most common pathogens in neonates are *N. gonorrhoeae* and *C. trachomatis*, while *S. aureus, Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa* are the most commonly isolated organisms in children with bacterial conjunctivitis (Sethuraman & Kamat, 2009).

Viruses account for the majority of conjunctivitis cases in adults. The most common viral etiology is adenovirus infection (Horton, 2015); conjunctivitis due to an adenovirus is highly contagious. Other viruses associated with conjunctivitis include the herpes simplex virus, the varicella-zoster virus, and molluscum contagiosum (AAO, 2013b).

Allergic conjunctivitis is fairly common and is frequently mistaken for bacterial conjunctivitis. There are three common types of allergic conjunctivitis: seasonal (hay fever) conjunctivitis, due to seasonal release of plant allergens; vernal conjunctivitis, which is of unknown origin but is thought to be due to seasonal airborne antigens; and atopic conjunctivitis, which occurs in people with atopic dermatitis or asthma.

Conjunctivitis can also be caused by mechanical or chemical irritants. A foreign body on the eye (typically a contact lens) can lead to giant papillary conjunctivitis.

Pathophysiology

General mechanisms of infection are at work in bacterial and viral conjunctivitis. In bacterial conjunctivitis, the infecting organism is obtained via contact with an infected individual and transmitted to the eye by fingertips. Neonates with conjunctivitis may have become inoculated during childbirth by their infected mother. Transmission of viral conjunctivitis is usually through direct contact with infected persons, contact with contaminated surfaces, or contaminated swimming pool water (Cronau et al., 2010; Wong & Anninger, 2014). In both bacterial and viral conjunctivitis, the infectious agent causes the inflammation of the conjunctiva. Mechanical and chemical irritants that cause conjunctivitis operate in the same manner.

In allergic conjunctivitis, symptoms are caused by the immunoglobulin (Ig)E-mediated release of mast cells in the conjunctiva (Kari & Saari, 2012).

Diagnostic Criteria

In addition to the hallmark red or pink eye, classic patient complaints that occur in conjunctivitis include itching or burning sensations of the eyes, ocular discharge ("leaky eye"), eyelids that are stuck together in the morning, and a sensation that a foreign body is lodged in the eye. Patients may also report a feeling of fullness around the eye. Moderate to severe pain and light sensitivity are not typical features of a primary conjunctival inflammatory process (Azari & Barney, 2013). If these symptoms are present, or if the patient reports blurred vision that does not improve with blinking, the patient should be referred to an eye care professional, as a more serious ocular disease process (such as a corneal abrasion or keratoconjunctivitis) may be occurring. Neonates with signs of conjunctivitis should be referred to an eye care professional for immediate examination, as bacterial conjunctivitis due to *C. trachomatis* or *N. gonorrhoeae* can lead to serious eye damage.

Although many symptoms of conjunctivitis are nonspecific (tearing, irritation, stinging, burning, and conjunctival swelling), inspection and patient history can help determine the cause of illness. Patients who report that their eyelids were stuck together upon awakening most likely have bacterial conjunctivitis (Deibel et al., 2013); this sticking is caused by a purulent ocular discharge. Because gonococcal conjunctivitis produces a copiously purulent discharge, the cause of any copiously purulent conjunctivitis should be suspected as *N. gonorrhoeae* until Gram-stain testing proves otherwise. Bacterial conjunctivitis usually starts in one eye and can become bilateral a few days later.

Viral conjunctivitis produces a profuse watery discharge. Similar to bacterial conjunctivitis, viral conjunctivitis usually starts in one eye and can become bilateral within a few days. While unlikely, photophobia and a foreign body sensation may be reported. Examination may reveal a tender preauricular node. A rapid, in-office immunodiagnostic test with high sensitivity and specificity for adenovirus is available (Sambursky et al., 2013).

In allergic conjunctivitis, itching is the hallmark symptom; it can be mild to severe and may manifest as excessive blinking. A history of recurrent itching or a personal or family history of hay fever, asthma, atopic dermatitis, or allergic rhinitis is suggestive of allergic conjunctivitis. In general, a patient with conjunctivitis who does not report an itchy eye does not have allergic conjunctivitis. Unlike bacterial or viral conjunctivitis, allergic conjunctivitis usually presents with bilateral symptoms. An ocular discharge may or may not be present; if present, it may be watery or mucoid. Aggressive forms of allergic conjunctivitis are vernal conjunctivitis in children and atopic conjunctivitis in adults. Atopic and vernal conjunctivitis are associated with shield corneal ulcers and perilimbal accumulation of eosinophils (Horner-Trantas dots) (Nijm et al., 2011). Atopic conjunctivitis is associated with eyelid thickening, conjunctival scarring, blepharitis, and corneal scarring (AAO, 2013b).

Giant papillary conjunctivitis occurs mainly in contact lens wearers. These patients report excessive itching, mucus production and discharge, and increasing intolerance to contact lens use. Upon examination, the upper tarsal conjunctiva may show inflammation and papillae greater than 0.3 mm (Donshik et al., 2008). Ptosis may occur in severe cases (AAO, 2013b).

Initiating Drug Therapy

Before drug therapy is prescribed, both the patient and the practitioner should be aware that bacterial and viral conjunctivitis are highly contagious and are spread by contact. Therefore, good hand-washing and instrument-cleansing techniques are imperative. The etiology of illness should be determined, as treatment is different for bacterial, viral, and allergic conjunctivitis.

Goals of Drug Therapy

The goals of drug therapy are to eradicate the offending organism (for bacterial conjunctivitis), to relieve symptoms and to quicken the resolution of the disease. A patient with bacterial conjunctivitis should experience improvement in symptoms a few days after the start of antibiotic therapy; the organisms remain active (and contagious) for 24 to 48 hours after therapy begins. With viral conjunctivitis, the disease is contagious for at least 7 days after symptoms appear; it may be contagious for up to 14 days.

Antibiotics

Although bacterial conjunctivitis caused by typical pathogens (*Staphylococcus*, *Streptococcus*, *Pneumococcus*, *Moraxella*, and *Haemophilus* species) is usually self-limiting, antibiotic therapy is justified because it can shorten the course of the disease, which reduces person-to-person spread, and lowers the risk of sight-threatening complications. The choice of antibiotic is usually empirical. Five to seven days of therapy with agents such as erythromycin ointment or bacitracin–polymyxin B ointment or solution is usually effective. While well tolerated, sulfacetamide has weak to moderate activity against many organisms. The aminoglycosides have good gram-negative coverage but incomplete coverage of *Streptococcus* and *Staphylococcus* species and a relatively high incidence of corneal toxicity. The fluoroquinolones also have good gram-negative coverage; the older fluoroquinolones (ciprofloxacin, norfloxacin, and ofloxacin) have poor coverage of *Streptococcus* species, while the newer fluoroquinolones (besifloxacin, gatifloxacin, levofloxacin, and moxifloxacin) offer improved gram-positive coverage.

Because gonococcal infection is serious, immediate treatment of conjunctivitis due to *N. gonorrhoeae* with a 250-mg intramuscular (IM) injection of ceftriaxone (Rocephin) plus a single 1-g dose of oral azithromycin is recommended for adults and children who weigh at least 45 kg. Children who weigh less than 45 kg should receive a single 125-mg IM injection of ceftriaxone, while 25 to 50 mg/kg of ceftriaxone intravenous or IM (not to exceed 125 mg) is the appropriate dose for neonates. Cephalosporin-allergic patients should be referred to an infectious disease specialist. Topical antibiotic therapy is not necessary but is often initiated to prevent secondary infection (AAO, 2013b).

As *C. trachomatis* is now the most common cause of conjunctivitis in neonates in the United States, the long-time standard prophylactic agent for neonates, topical 1% silver nitrate solution, is no longer recommended or commercially available in the United States. Topical treatment of neonatal chlamydial conjunctivitis is ineffective and unnecessary (American Academy of Pediatrics, 2012). In adults and children at least 8 years old, *C. trachomatis* infection is treated with a single 1-g dose of azithromycin or 7 days of therapy with doxycycline 100 mg twice daily. Children who weigh at least 45 kg but are less than 8 years old should receive the single dose of azithromycin 1 g. Neonates and children who weigh less than 45 kg should receive 50 mg/kg/d of erythromycin base or erythromycin ethylsuccinate, divided into four doses a day for 14 days (AAO, 2013b). Identification of either *Chlamydia* or *N. gonorrhoeae* conjunctivitis requires that the patient's sexual partner also be treated.

Antihistamines

The ophthalmic antihistamines alcaftadine and emedastine prevent the histamine response in blood vessels by preventing histamine from binding with its receptor site and are useful in reducing the symptoms of allergic conjunctivitis. Ocular adverse events with these agents include transient stinging or burning upon instillation, dry eyes, red eyes, and blurred vision. Oral antihistamines can also help to relieve symptoms in many patients (see Table 17.3).

TABLE 17.3 Overview of Antiallergy Ophthalmic Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antihistamines			
alcaftadine 0.25% solution (Lastacaft) Dosing: 1 drop in the affected eye once daily	Eye irritation, burning and stinging, itching		Labeling: wait 10 min following administration before inserting contact lenses.
emedastine 0.05% solution (Emadine) Dosing: 1 drop in the affected eye up to four times a day	Blurred vision, burning and stinging, dry eyes, foreign body sensation, hyperemia, itching		Labeling: wait 10 min following administration before inserting contact lenses.
Mast Cell Stabilizers			
bepotastine 1.5% solution (Bepreve) Dosing: 1 drop into the affected eye(s) twice daily	Mild taste following instillation, eye irritation		Labeling: refrain from contact lens use while exhibiting signs and symptoms of allergic conjunctivitis. Labeling: wait 10 min following administration before inserting contact lenses.
cromolyn 4% solution (Crolom) Dosing: 1–2 drops in each eye four to six times a day at regular intervals	Burning and stinging, conjunctival injection, watery eyes, itching, dry eye, styes		Labeling: refrain from contact lens use while under treatment.
lodoxamide 0.1% solution (Alomide) Dosing: 1–2 drops in each eye four times a day	Burning and stinging, ocular itching, blurred vision, dry eye, tearing, hyperemia, foreign body sensation		Labeling: refrain from contact lens use while under treatment.
nedocromil 2% solution (Alocril) Dosing: 1–2 drops in each eye twice a day	Ocular burning and stinging, unpleasant taste, redness, photophobia		Labeling: refrain from contact lens use while exhibiting the signs and symptoms of allergic conjunctivitis.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antihistamine/Mast Cell Stabilizer			
azelastine 0.05% solution (Optivar) Dosing: 1 drop into each affected eye twice daily	Ocular burning and stinging, headache, bitter taste, eye pain, blurred vision		Labeling: wait 10 min following administration before inserting contact lenses.
epinastine 0.05% solution (Elestat) Dosing: 1 drop in each eye twice a day	Burning sensation, folliculosis (hair follicle inflammation), hyperemia, itching		Labeling: wait 10 min following administration before inserting contact lenses.
ketotifen 0.025% solution (Alaway, Zaditor, Thera Tears Allergy) Dosing: 1 drop in the affected eye(s) every 8–12 h, no more than twice daily	Conjunctival injection, burning and stinging, conjunctivitis, dry eye, itching, photophobia		Labeling: wait 10 min following administration before inserting contact lenses.
olopatadine 0.1% (Patanol), 0.2% (Pataday), or 0.7% (Pazeo) solution Dosing 0.1%: 1–2 drops in each affected eye twice daily 0.2%, 0.7%: 1 drop in the affected eye(s) once daily	Ocular burning and stinging, dry eye, headache, foreign body sensation, hyperemia, lid edema, itching		Labeling: wait 10 min following administration before inserting contact lenses.
Nonsteroidal Anti-inflammatory Drugs			
ketorolac 0.5% solution (Acular) Dosing: 1 drop four times a day	Stinging and burning, corneal edema, iritis, ocular irritation or inflammation		Use with caution in patients with aspirin sensitivities and patients with bleeding disorders or those receiving anticoagulant therapy. Labeling: do not administer while wearing contact lenses.
Vasoconstrictors (Decongestants)			
naphazoline 0.012% or 0.03% solutions (Clear Eyes), 0.02% solution (VasoClear), and 0.1% solution (AK-Con) Dosing: 1–2 drops in the affected eye(s) every 3–4 h, up to four times a day	Stinging, blurred vision, mydriasis, redness, punctate keratitis, increased IOP	Narrow-angle glaucoma Narrow-angle without glaucoma	Use should be limited to 72 h. Contains benzalkonium chloride; use with contact lenses not addressed in labeling
oxymetazoline 0.025% solution (Visine L.R.) Dosing: 1–2 drops in the affected eye(s) every 6 h	Stinging, blurred vision, mydriasis, redness, punctate keratitis, increased IOP	Narrow-angle glaucoma Narrow-angle without glaucoma	Use should be limited to 72 h. Contains benzalkonium chloride; use with contact lenses not addressed in labeling
tetrahydrozoline 0.05% solution (Visine, Murine for Red Eyes, Clear Eyes Triple Action) Dosing: 1–2 drops up to four times a day	Stinging, blurred vision, mydriasis, redness, punctate keratitis, increased IOP	Narrow-angle glaucoma Narrow-angle without glaucoma	Use should be limited to 72 h. Contains benzalkonium chloride; use with contact lenses not addressed in labeling
Topical Corticosteroids			
dexamethasone 0.1% solution (AK-Dex, Decadron) or 0.1% suspension (Maxidex) Dosing Solution: 1–2 drops every hour during the day and every 2 h at night initially, reduced to 1 drop every 4 h with favorable response Suspension: 1–2 drops less than four to six times a day in mild disease; hourly in severe disease	IOP elevation, loss of visual acuity, cataract formation, secondary ocular infection, globe perforation, stinging and burning	Dendritic keratitis Fungal disease Viral disease of the cornea and conjunctiva Mycobacterial eye infection	Labeling: wait 15 min following administration before inserting contact lenses.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
fluorometholone 0.1% ointment or suspension (FML, Flarex) or 0.25% suspension (FML Forte) Dosing Ointment: ½ inch ribbon one to three times daily; during initial 24–48 h, dosing may be increased to every 4 h. Suspension: 1 drop two to four times daily; during initial 24–48 h, dosing may be increased to every 4 h.	IOP elevation, glaucoma, posterior subcapsular cataract formation, delayed wound healing	Dendritic keratitis Vaccinia and varicella Fungal disease Viral disease of the cornea and conjunctiva Mycobacterial eye infection	
loteprednol 0.2% or 0.5% suspension (Alrex, Lotemax) Dosing 0.2% solution: 1 drop in the affected eye(s) four times a day 0.5% solution: 1–2 drops in the affected eye(s) four times a day	IOP elevation, loss of visual acuity, cataract formation, secondary ocular infection, globe perforation, stinging and burning, dry eye, itching, photophobia	Dendritic keratitis Fungal disease Viral disease of the cornea and conjunctiva Mycobacterial eye infection	If needed, dosing of the 0.5% solution can be increased to 1 drop every hour during the first week of therapy. Labeling: wait 10 min following administration before inserting contact lenses.
prednisolone 0.12% or 1% suspension (Pred Mild, Omnipred, Pred Forte) or 1% solution Dosing Solution: 2 drops four times a day Suspension: 1–2 drops two to four times a day; dose may be increased during the initial 24–48 h	IOP elevation, cataract formation, delayed wound healing, secondary ocular infection, acute uveitis, globe perforation, stinging and burning, conjunctivitis	Dendritic keratitis Fungal disease Viral disease of the cornea and conjunctiva Mycobacterial eye infection Acute, purulent, untreated eye infections	Labeling: wait 15 min following administration before inserting contact lenses.

Mast Cell Stabilizers

The mast cell stabilizers (bepotastine, cromolyn, lodoxamide, and nedocromil) inhibit hypersensitivity reactions and prevent the increase in cutaneous vascular permeability that accompanies allergic reactions. These agents may be helpful for patients with allergic conjunctivitis. Ocular adverse events include transient burning, stinging or discomfort, pruritus, blurred vision, dry eyes, taste alteration, and foreign body sensation (see Table 17.3).

Antihistamine/Mast Cell Stabilizer

Several products (azelastine, epinastine, ketotifen, and olopatadine) have the combined properties of an antihistamine and a mast cell stabilizer, providing immediate relief of itching and long-term suppression of histamine release. Ketotifen is available without a prescription. These agents are given one or three times a day and have a side effect profile similar to the antihistamines and mast cell stabilizers (see Table 17.3).

Nonsteroidal Anti-Inflammatory Ophthalmic Drugs

The ophthalmic nonsteroidal anti-inflammatory (NSAID) ketorolac may be useful for treating the itch associated with allergic conjunctivitis. The NSAIDs inhibit the biosynthesis of prostaglandin by decreasing the activity of the enzyme cyclooxygenase. Ketorolac is administered 1 drop four times a day into the affected eye. It should be used with caution in patients with aspirin sensitivities and patients who have bleeding disorders or are receiving anticoagulant therapy because ophthalmic NSAIDs are absorbed systemically. Adverse events include transient stinging and burning, irritation and inflammation, corneal edema, and iritis (see Table 17.3).

Vasoconstrictors (Decongestants)

Vasoconstrictor eye drops (naphazoline, oxymetazoline, and tetrahydrozoline) may offer relief to patients with allergic conjunctivitis. With the exception of the higher-strength (0.1%) naphazoline solution, these agents are available without a prescription. Side effects include stinging, blurred vision, mydriasis, and increased redness; punctate keratitis and increased intraocular pressure (IOP) may also occur. These agents are contraindicated in patients with narrow-angle glaucoma or a narrow angle without glaucoma. Rebound congestion may occur with frequent or extended use of these agents; use should be limited to a maximum of 72 hours (see Table 17.3).

Topical Corticosteroids

Topical corticosteroids have been shown to reduce inflammation in allergic conjunctivitis. Low-dose corticosteroid therapy can be used at infrequent intervals for short-term periods (1 to 2 weeks) (AAO, 2013b). Long-term use of topical corticosteroids is associated with severe side effects, including ocular infection, cataract formation, and glaucoma (Bowling & Russell, 2011) (see Table 17.3).

Selecting the Most Appropriate Agent

Treatment of bacterial conjunctivitis is aimed at eradicating the offending organism. Cultures are not indicated unless the infection does not resolve with first-line therapy (Table 17.4 and Fig. 17.1).

TABLE 17.4 Recommended Order of Treatment for Conjunctivitis

Order	Agent	Comments
Bacterial Conjunctivitis (nongonococcal, nonchlamydial)		
First line	Erythromycin ointment *or* Bacitracin–polymyxin B ointment or solution	Ointments tend to cause a greater degree of blurry vision than solutions.
Second line	Ophthalmic fluoroquinolones (besifloxacin, gatifloxacin, levofloxacin, or moxifloxacin)	The remaining ophthalmic fluoroquinolones do not provide good staphylococcal coverage.
Seasonal (Hay Fever) Conjunctivitis		
First line	Topical antihistamine (alcaftadine or emedastine)	Minimization of exposure to the offending allergen, cool compresses, and artificial tears may also be helpful.
Second line	Addition of a brief course of low-potency topical corticosteroid to the first-line agent *or* For recurrent or persistent disease: a product with antihistamine/mast cell stabilizer properties	Use of the topical corticosteroids should not exceed 2 wk.
Third line	Ophthalmic ketorolac	
Vernal/Atopic Conjunctivitis		
First line	Topical antihistamine or oral antihistamine or mast cell stabilizer	Minimization of exposure to the offending allergen, cool compresses, and artificial tears may also be helpful.
Second line	For acute exacerbations: addition of a brief course of low-potency topical corticosteroid to the first-line agent	
Viral Conjunctivitis		
First line	Topical antihistamines *or* Artificial tears *or* Cold compresses	There is no effective treatment for viral conjunctivitis; treatment is for symptom mitigation.
Second line	In severe cases: a low-potency topical corticosteroid	Use of the topical corticosteroids should not exceed 2 wk.
Giant Papillary Conjunctivitis		
Mild disease	One or more of the following: replace contact lenses more frequently, decrease contact lens wearing time, increase the frequency of enzyme treatment, use preservative-free lens care systems, switch to disposable lenses, administer mast cell stabilizer, change the contact lens polymer	
Moderate or severe disease	Same as mild disease *and* Discontinuation of contact lens wear for several weeks or a brief course of topical corticosteroid treatment	

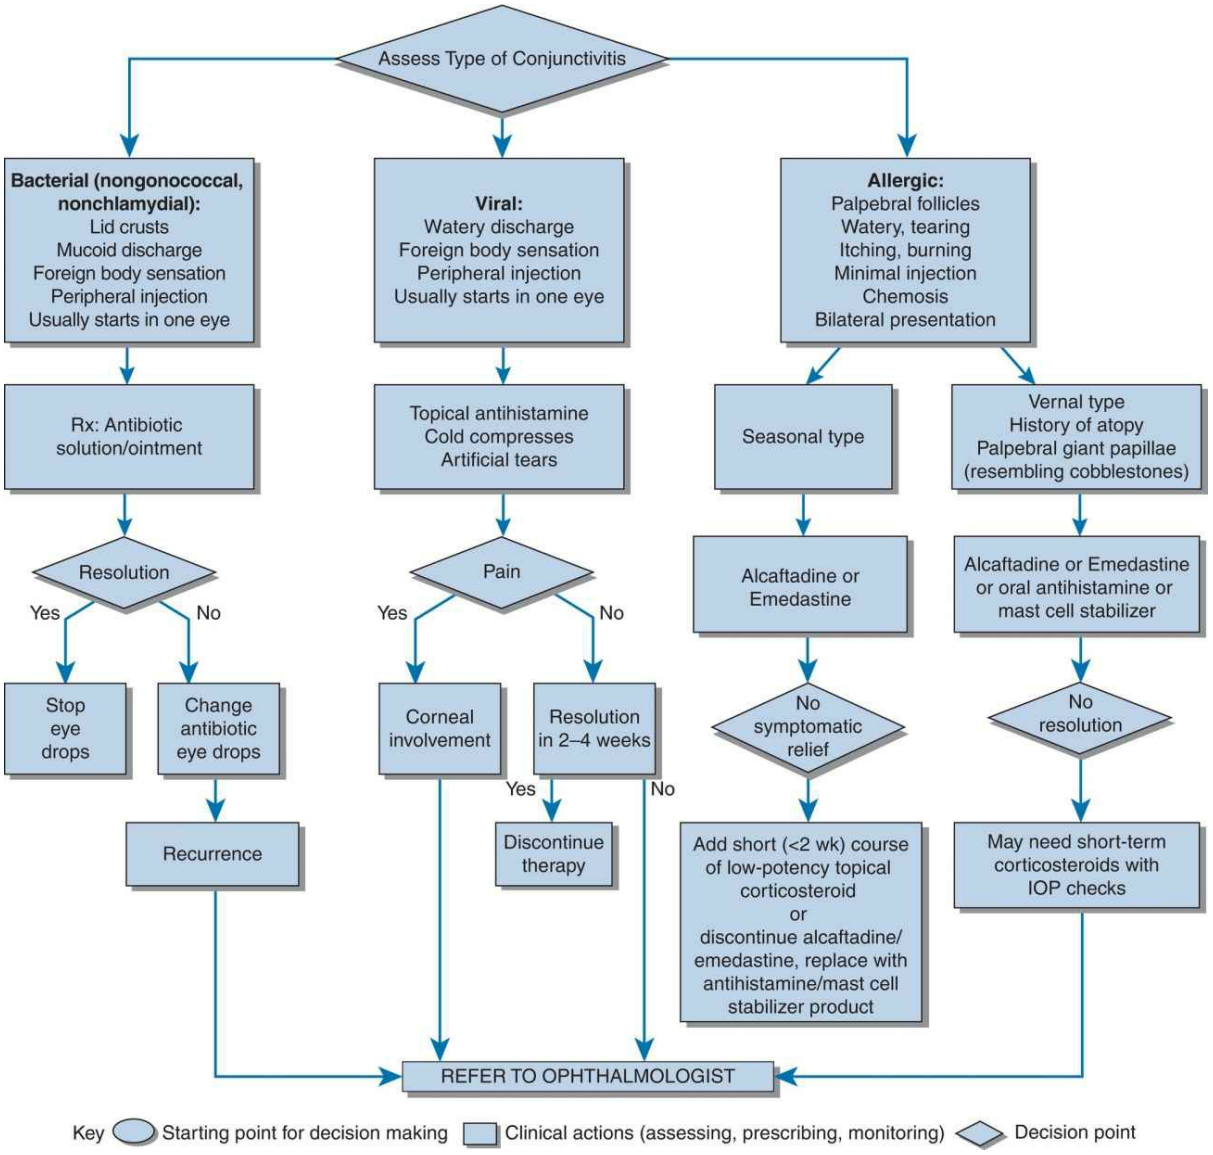

FIGURE 17.1 Treatment algorithm for conjunctivitis.

There is conflicting information about the use of soft contact lenses while taking ophthalmic medications that contain the preservative benzalkonium chloride. This preservative, which is in many of the ophthalmic antihistamines, mast cell stabilizers, NSAIDs, vasoconstrictors, and topical steroids reviewed in this section, may be absorbed by contact lenses. While no products identify contact lens use as an absolute contraindication to therapy, some (e.g., cromolyn, lodoxamide, and nedocromil) have warnings advising against the use of contact lenses during therapy; others advise patients to wait 10 to 15 minutes after administering the medication before reinserting contact lenses (see Table 17.3). Regardless of the etiology, contact lens wearers should refrain from wearing contact lenses during an acute case of conjunctivitis.

Bacterial Conjunctivitis

The treatment of bacterial conjunctivitis is aimed at the organisms *S. aureus*, *S. pneumoniae*, and *H. influenzae*. First-line treatments include 7 to 10 days of therapy with erythromycin ointment (two or three times a day) or polymyxin B–trimethoprim solution (1 drop every 3 to 4 hours). Therapy selection can be based on patient preference for ointment or solution. If bacterial conjunctivitis does not resolve with first-line therapy, the patient should be referred to an eye care professional so that cultures may be taken to rule out *C. trachomatis.* The ophthalmic fluoroquinolones with improved gram-positive organism coverage (besifloxacin, gatifloxacin, levofloxacin, or moxifloxacin) can be used as second-line therapy.

Gonococcal infection requires immediate treatment. Ceftriaxone plus azithromycin is recommended for adults and children who weigh at least 45 kg; children who weigh less than 45 kg and neonates should receive a reduced dose of ceftriaxone. In adults and children at least 8 years old, *C. trachomatis* infection is treated with azithromycin or doxycycline. Azithromycin should be used in children who weigh at least 45 kg but are less than 8 years old, while neonates and children who weigh less than 45 kg should receive erythromycin base or erythromycin ethylsuccinate.

Seasonal (Hay Fever) Conjunctivitis

Steps should be taken to minimize exposure to the offending allergen. The ophthalmic antihistamines alcaftadine or emedastine can be used as first-line therapy for mild seasonal conjunctivitis. If symptom control is inadequate, a brief course (1 to 2 weeks) of a low-potency topical corticosteroid can be added to the regimen. If the condition is persistent, a mast cell stabilizer or, preferably, an agent with antihistamine and mast cell stabilizer properties (azelastine, epinastine, ketotifen, or olopatadine) can be used. The ophthalmic NSAID ketorolac should be reserved for third-line therapy. Patients may also benefit from the use of cool compresses and artificial tears (which dilute allergens and help manage coexisting tear deficiency).

Vernal/Atopic Conjunctivitis

Similar to seasonal conjunctivitis, general treatment measures for vernal/atopic conjunctivitis include minimizing exposure to the offending allergen and use of cool compresses and artificial tears. The topical antihistamines (alcaftadine or emedastine), oral antihistamines, or mast cell stabilizers (bepotastine, cromolyn, lodoxamide, or nedocromil) can be used as first-line agents for the treatment of vernal or atopic conjunctivitis. For patients with acute exacerbations, a topical corticosteroid can be added to the first-line agent for control of severe symptoms.

Viral Conjunctivitis

There is no effective treatment for viral conjunctivitis; patients should be informed of the risk of spreading the infection to the other eye (in unilateral infection) or to other people.

Topical antihistamines, artificial tears, or cool compresses can be used to relieve symptoms. In severe cases of adenoviral keratoconjunctivitis with marked chemosis or lid swelling, epithelial sloughing, or membranous conjunctivitis, topical corticosteroids can be helpful in reducing symptoms and preventing scarring.

Giant Papillary Conjunctivitis

Management of giant papillary conjunctivitis centers around identifying and modifying the causative entity. Treatment of mild giant papillary conjunctivitis due to contact lens use can consist of one or more of the following: more frequent replacement of contact lenses, reduction in contact lens wearing time, increase in the frequency of enzyme treatment, use of preservative-free lens care systems, switching to disposable lenses, administration of a mast cell stabilizer, and change of the contact lens polymer (AAO, 2013b). In moderate or severe giant papillary conjunctivitis due to contact lens use, discontinuation of contact lens use for several weeks or a brief course of topical corticosteroid therapy may be necessary.

Monitoring Patient Response

If symptoms begin to improve within 48 hours, no follow-up is needed. If there is no improvement, the patient should be referred to an eye care professional for evaluation.

Patient Education

It is important to instruct patients with bacterial or viral conjunctivitis to wash their hands carefully to prevent spreading infection. Organisms in bacterial conjunctivitis remain active (and contagious) for 24 to 48 hours after therapy begins, while patients with viral conjunctivitis can remain contagious for up to 14 days. Patients should be taught how to apply the medication in the inner aspect of the lower eyelid. The tip of the container should not touch the eyelashes, as it may contaminate the medication and result in therapy failure or reinfection. Patients should not share eye medications because this can spread the infection. To improve the effectiveness of an ophthalmic antibiotic, crusted eyelids should be gently cleansed before instilling medication. Regardless of the etiology, contact lens wearers should refrain from wearing contact lenses during an acute case of conjunctivitis.

Dry Eye Syndrome: Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca, commonly referred to as dry eye syndrome (DES), is a common ophthalmologic abnormality involving bilateral disruption of tear film on the ocular surface. Estimates of the prevalence of dry eye in the United States range from 10% to 20%, with the prevalence markedly higher for individuals over the age of 80 years compared to those younger than 60 years of age (19.0% vs. 8.4%) (Moss et al., 2000). DES can occur intermittently or as a chronic condition that becomes a self-perpetuating syndrome. While the majority of patients with DES experience non–sight-threatening ocular irritation and intermittently blurred vision, patients with severe DES are at risk for severe vision loss due to ocular surface keratinization, corneal scarring, and corneal ulceration (AAO, 2013c).

Causes

DES is a multifactorial disease. It can be the result of decreased tear production, increased tear evaporation, or a combination of these factors (Akpek & Smith, 2013). In addition, decreased tear secretion and clearance initiate an inflammatory response on the ocular surface, and research suggests that this inflammation plays a role in the pathogenesis of DES (Schaumberg et al., 2011).

Risk factors for DES include advanced age, female gender, and a history of LASIK surgery. Individuals with concomitant inflammatory conditions (allergies, asthma, or rheumatoid arthritis), infectious diseases (hepatitis C, human immunodeficiency virus/acquired immunodeficiency syndrome, or Epstein-Barr virus), or conditions such as Sjögren syndrome, Parkinson disease, or Bell palsy are also at increased risk for DES. Symptoms caused by dry eye may be exacerbated by environmental factors such as wind, reduced humidity, cigarette smoke, and heating and air conditioning. Systemic medications such as antihistamines, diuretics, anticholinergics, antidepressants, beta-blockers, antipsychotics, postmenopausal estrogens, and isotretinoin can also exacerbate dry eye symptoms (AAO, 2013c).

Pathophysiology

Tears are composed of three layers: a mucus layer that coats the cornea, allowing the tear to adhere to the eye; a middle aqueous layer, which provides moisture and supplies oxygen and nutrients to the cornea; and an outer lipid film layer that seals the tear film on the eye and prevents evaporation. The outer lipid film layer is replenished by eyelid blinking, which relubricates and redistributes the lipid layer across the ocular surface. The ocular surface and tear-secreting glands function as an integrated unit to maintain the tear supply and to clear used tears. Aging, ocular surface diseases (such as herpes simplex virus keratitis), or surgeries that disrupt the trigeminal afferent sensory nerves, systemic inflammatory diseases, and systemic diseases and medications that disrupt the efferent cholinergic nerves that stimulate tear secretion can disrupt this functional unit and result in an unstable and poorly maintained tear film (Rocha et al., 2008; AAO, 2013c). Decreased tear secretion and clearance leads to an inflammatory response on the ocular surface, which is also believed to play a role in DES.

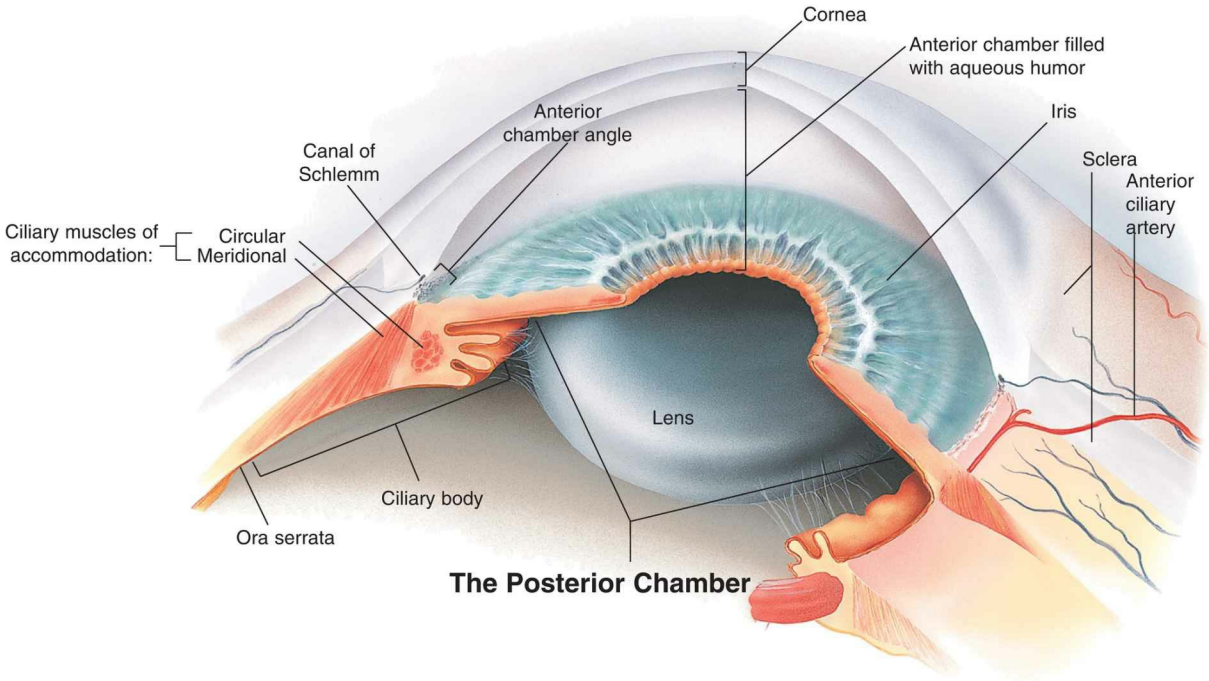

FIGURE 17.2 Anatomy of the eye.

Diagnostic Criteria

Family practitioners should always refer patients reporting dry eye to an ophthalmologist if there is moderate to severe pain, vision loss, corneal infiltration or ulceration, or no response to therapy (AAO, 2013c). Making the diagnosis of DES, particularly the mild form, can be difficult because of the unpredictable correlation between reported symptoms and clinical signs and the relatively poor sensitivity/specificity of existing diagnostic tests (AAO, 2013c). Because most dry eye conditions are chronic, repeat observation will allow a more accurate clinical diagnosis of DES.

Signs and symptoms of DES include a dry eye sensation, ocular irritation, redness, burning, and stinging, a foreign body or gritty sensation, blurred vision, contact lens intolerance, an increased frequency of blinking, and, paradoxically, increased tearing (AAO, 2013c; National Eye Institute [NEI], 2010). The inability to cry under emotional distress has also been reported among DES patients (NEI, 2010). DES symptoms tend to worsen in dry climates, in the wind, during air travel, with prolonged visual efforts, and toward the end of the day (AAO, 2013c).

A physical examination (including a test of visual acuity, an external examination, and slit-lamp biomicroscopy) should be performed to document the signs of DES; to assess the quality, quantity, and stability of the tear film; and to rule out other causes of ocular irritation (AAO, 2013c). Additional tests can be used to lend some objectivity to the diagnosis. Tear breakup time testing can be useful for patients with mild symptoms. For patients with moderate to severe aqueous tear deficiency, the diagnosis can be made with one or more of the following tests (performed in this sequence): tear breakup time, ocular surface dye staining (rose bengal, fluorescein, or lissamine green), or the Schirmer wetting test (AAO, 2013c). Individuals with moderate to severe dry eye who have a family history of autoimmune disorders and/or signs and symptoms of an autoimmune disorder should be evaluated for an underlying autoimmune disorder.

Initiating Drug Therapy

Before starting drug therapy, the patient should try nonpharmacologic interventions such as environmental control (increasing air humidity, avoiding drafts and cigarette smoke) and scheduling regular breaks during computer use and reading. Unfortunately, these interventions result in limited effectiveness and produce few lasting improvements in DES symptoms. Exogenous medical factors that can cause DES (i.e., blepharitis, meibomianitis) should be addressed, and prescription medications that can exacerbate DES symptoms should be discontinued when possible.

If the nonpharmacologic interventions fail to eliminate DES symptoms, drug therapy is appropriate. Table 17.5 gives information about the drugs used to treat DES.

TABLE 17.5 Overview of Dry Eye Syndrome Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Artificial Tear Substitutes			
Solutions containing preservatives: 20/20, Blink Tears, Clear Eyes, Comfort Tears, Fresh Kote, HypoTears, Isopto Tears, Murine, Natural Balance Nu-Tears, OptiZen, Puralube Tears, Refresh Liquigel, Refresh Tears, Soothe Hydration, Soothe XP, Systane, Tearisol, Tears Again, Tears Plus, Tears Naturale, Visine Tears	Stinging, blurred vision		Should not be used more than four to six times per day (except for in severe disease); if use in excess of four times a day is necessary, use a preservative-free preparation.
Preservative-free solutions: Bion Tears, Blink Tears PF, Moisture Eyes PF, Refresh Classic, Refresh Celluvisc, Refresh Optive, Refresh Plus, Soothe PF, Tears Naturale Free, Visine Tears PF, Viva-Drops	Stinging, blurred vision		
Ocular Lubricants			
Ointments containing preservatives: GenTeal PM, Puralube, Refresh Lacri-Lube, Stye, Tears Again, Lacri-Lube S.O.P.	Blurred vision		
Gels containing preservatives: Blink Gel Tears, Tears Again Night & Day	Blurred vision		
Preservative-free ointments: Dry Eyes, Duratears Naturale, HypoTears, Lacri-Lube NP, LubriFresh PM, Refresh PM, Soothe Night Time, Systane Nighttime, Tears Naturale PM	Blurred vision		
Preservative-free gels: GenTeal Severe Eye Relief	Blurred vision		
Cholinergic			
cevimeline 30-mg tablets (Evoxac) Dosing: 1 tablet three times a day	Excessive sweating, nausea, rhinitis, excessive salivation, asthenia	Uncontrolled asthma Acute iritis Narrow-angle glaucoma	Dehydration may develop from excessive sweating. Visual disturbances may impair the ability to drive, especially at night.
pilocarpine 5-mg tablets (Salagen) Dosing: 1 tablet four times a day	Excessive sweating, headache, urinary frequency, nausea, flushing, dyspepsia	Uncontrolled asthma Acute iritis Narrow-angle glaucoma	Dehydration may develop from excessive sweating. Visual disturbances may impair the ability to drive, especially at night.
Anti-inflammatory			
cyclosporine 0.05% emulsion (Restasis) Dosing: 1 drop in each eye twice a day, approximately 12 h apart	Ocular burning, blurred vision, conjunctival hyperemia, discharge, eye pain, foreign body sensation, pruritus, stinging		Use the emulsion from a single-use vial immediately after opening; discard the remaining contents.

Goals of Drug Therapy

The goals of therapy in DES are to relieve discomfort, maintain and improve visual function, and reduce or prevent structural damage (AAO, 2013c). Therapy should attempt to normalize tear volume and composition so that the eye tissues are properly lubricated, nourished, and protected, resulting in improved patient satisfaction and clinical outcomes.

Artificial Tears and Lubricants

Artificial tears and lubricants can be used as palliative therapies to relieve DES symptoms. Designed to mimic the composition of natural tears, artificial tears contain lipids, water with dissolved salts and proteins, and mucin. Artificial tears and lubricants are over-the-counter products, available in a variety of formulations (solutions, gels, ointments). Ointments and gels may make the eyelids sticky and blur vision, and are often used only at bedtime.

For patients with mild DES, use of artificial tears four times daily plus a lubricating ointment at bedtime may be useful. As the severity of dry eye increases, administration of artificial tears can increase to hourly. Preservative-free preparations should be used if the patient applies tears more than four times a day (AAO, 2013c).

Cholinergic Agonists

The cholinergic agonists pilocarpine and cevimeline are indicated for the treatment of dry mouth in patients with Sjögren syndrome. These agents bind to muscarinic receptors, stimulating secretion of the salivary and sweat glands and improving tear function. However, these agents are more effective for treating dry mouth compared to dry eye. The main adverse event with these agents is excessive sweating, reported in 18% to 40% of patients. The use of these agents is contraindicated in patients with uncontrolled asthma and when miosis is undesirable (acute iritis, narrow-angle glaucoma).

Topical Cyclosporine

Cyclosporine ophthalmic emulsion has been reported to increase aqueous tear production and decrease ocular irritation symptoms in patients with DES. It prevents T cells from activating and releasing cytokines that incite the inflammatory component of dry eye. Side effects include ocular burning, conjunctival hyperemia, discharge, itching, and blurred vision.

Topical Corticosteroids

Topical corticosteroids have been shown to reduce inflammation in DES by reducing cytokine levels in the conjunctival epithelium. Low-dose corticosteroid therapy can be used at infrequent intervals for short-term (2 weeks) suppression of irritation secondary to

inflammation (AAO, 2013c). Long-term use of topical corticosteroids is associated with severe side effects, including ocular infection, cataract formation, and glaucoma (Bowling & Russell, 2011).

Selecting the Most Appropriate Agent

Agent selection is determined by the severity of DES and the underlying pathophysiology (Table 17.6).

TABLE 17.6 Recommended Order of Treatment for Dry Eye

Order	Agent	Comments
First line	Mild DES: artificial tear substitute four times a day *or* Moderate to severe DES: preservative-free artificial tear substitute, administered up to hourly	If the patient has underlying Sjögren syndrome, administer pilocarpine tablets 5 mg four times a day or cevimeline tablets 30 mg three times a day.
Second line	Cyclosporine 0.05% ophthalmic emulsion twice a day	Ophthalmic corticosteroid therapy may be useful for the short-term (2-wk) suppression of irritation secondary to inflammation.

First-Line Therapy

For patients with mild DES, the use of a tear substitute four times a day is appropriate. For moderate or severe DES, artificial tears can be used as often as hourly, although administration that frequently may be cumbersome. Preservative-free preparations should be used if the patient uses tears more than four times a day. A lubricating ointment applied at bedtime may also be useful.

A patient with DES and underlying Sjögren syndrome may benefit from therapy with oral pilocarpine 5 mg four times daily or oral cevimeline 30 mg three times daily.

Second-Line Therapy

Patients with moderate to severe DES who fail to experience any improvement in symptoms with artificial tears may benefit from therapy with 0.05% cyclosporine ophthalmic emulsion 1 drop in each eye twice a day. Due to the side effect profile, corticosteroid therapy is limited to second-line therapy for short-term (2 weeks) suppression of irritation secondary to inflammation.

Third-Line Therapy

Patients with severe DES that fails to respond to drug therapy are candidates for permanent punctal occlusion or tarsorrhaphy.

Monitoring Patient Response

The frequency and extent of follow-up will depend upon the severity of DES and the therapeutic approach selected. Patients with mild DES can be seen once or twice per year for follow-up if symptoms are controlled by therapy. Patients with sterile corneal ulceration associated with DES require careful, sometimes daily, monitoring (AAO, 2013c).

Patient Education

Patients with DES should be educated about the chronic nature of the disease and given specific instructions about their therapeutic regimens. Patients with moderate to severe DES are at an elevated risk for contact lens intolerance.

Glaucoma (Primary Open-Angle Glaucoma)

Glaucoma is a group of eye diseases involving optic neuropathy characterized by irreversible damage to the optic nerve and retinal ganglion cells (Fig. 17.2). Over time, this deterioration results in the loss of visual sensitivity and field, which frequently goes unnoticed until a significant amount of damage has occurred. Glaucoma is the leading cause of irreversible blindness in the world (Pascolini & Mariotti, 2012). There are numerous types of glaucoma, including primary open-angle glaucoma (POAG), acute closed-angle glaucoma, normal-tension glaucoma, and narrow-angle glaucoma. POAG accounts for up to 70% of glaucoma cases in the United States and afflicts 2.2 million Americans (AAO, 2015; King et al., 2013); as such, this section will specifically review POAG.

Causes

Several studies have shown that the prevalence of POAG increases with increasing IOP (Gordon et al., 2002; Leske et al., 2003). The median IOP in large populations is 15.5 ± 2.5 mm Hg. Previously, it was thought that increased IOP was the sole cause of POAG, but it is now recognized that IOP is one of several factors associated with the development of POAG, and an increased IOP is not required for the diagnosis of POAG.

Additional risk factors for the development of POAG include increasing age, black race (three times greater than whites), a family history of glaucoma, a thin central cornea, and type 2 diabetes mellitus (AAO, 2015).

Pathophysiology

The pathophysiology of glaucoma-induced vision loss is not well understood. Aqueous humor is produced by the ciliary body and secreted into the posterior chamber of the eye. A pressure gradient in the posterior chamber forces the aqueous humor between the iris and lens and through the pupil into the anterior chamber. Aqueous humor in the anterior chamber leaves the eye through two methods: filtration through the trabecular meshwork to Schlemm canal (80% to 85%) or traversal of the anterior face of the iris and absorption into iris blood vessels (uveoscleral outflow). In POAG, the increase in IOP is a result of degenerative changes in the trabecular meshwork and Schlemm canal that result in a decrease in the outflow of the aqueous humor (Abel & Sorensen, 2013).

Diagnostic Criteria

Symptoms of POAG do not manifest until substantial damage has already occurred. The diagnosis of any glaucoma should be made by an eye care professional. Any patients reporting visual field loss should be referred to an eye care professional for prompt evaluation.

During the physical examination, IOP is measured in each eye, preferably with a Goldmann-type applanation tonometer, before gonioscopy or dilation of the pupil (AAO, 2015). Unfortunately, the measurement of IOP is not an effective method for screening populations for glaucoma. At an IOP cutoff of 21 mmHg, the sensitivity for the diagnosis of POAG by tonometry was 47.1% (Tielsch et al., 1991), and half of all individuals with POAG are measured with an IOP of less than 22 mm Hg at a single screening (Leske et al., 2003). As such, the AAO recommends, in addition to the measurement of IOP, that a physical examination include the following elements: patient history, test of pupil reactivity, slit-lamp biomicroscopy of the anterior segment, determination of central corneal thickness, gonioscopy, evaluation of the optic nerve head and retinal nerve fiber layer, documentation of the optic nerve head appearance, evaluation of the fundus, and evaluation of the visual field (AAO, 2015).

Initiating Drug Therapy

The goals of therapy for POAG are to control IOP, to stabilize the status of the optic nerve and retinal fiber layer, and to stabilize the visual field (AAO, 2015). Most cases of glaucoma can be controlled and vision loss prevented with early detection and treatment. Treatment of POAG entails decreasing aqueous humor production, increasing aqueous outflow, or a combination of both.

Over the past 20 years, glaucoma management has changed significantly, primarily due to the introduction of pharmaceutical agents that have shown clinical effectiveness (Table 17.7). These agents have been associated with a significant reduction in surgery rates among glaucoma patients (Fraser & Wormald, 2006).

TABLE 17.7 Overview of Glaucoma Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Beta-blockers			
betaxolol 0.25% suspension or 0.5% solution (Betoptic S) Dosing: 1–2 drops in the affected eye(s) twice daily	Discomfort on instillation, tearing, allergic reactions, decreased corneal sensitivity, edema, bradycardia, hypotension, dizziness	Cardiogenic shock Second- or third-degree AV block Sinus bradycardia Overt cardiac failure	A cardioselective (beta-1) blocker; it has fewer effects on pulmonary and cardiovascular parameters.
carteolol 1% solution Dosing: 1 drop in the affected eye(s) twice daily	Transient eye irritation, burning, tearing, conjunctival hyperemia, edema, bradycardia, hypotension, arrhythmia, palpitations	Bronchial asthma or severe COPD Sinus bradycardia Second- or third-degree AV block Overt cardiac failure Cardiogenic shock	May be absorbed systemically; the same adverse reactions seen with oral beta-blockers may occur. May mask the symptoms of acute hypoglycemia or hyperthyroidism
levobunolol 0.25% or 0.5% solution (Betagan) Dosing: 1–2 drops in the affected eye(s) once daily (0.5%) or twice daily (0.25%)	Burning and stinging, blepharoconjunctivitis, urticaria, ataxia, bradycardia, arrhythmia, hypotension, syncope, heart block	Bronchial asthma or severe COPD Sinus bradycardia Second- or third-degree AV block Overt cardiac failure Cardiogenic shock	May be absorbed systemically; the same adverse reactions seen with oral beta-blockers may occur. May mask the symptoms of acute hypoglycemia or hyperthyroidism
metipranolol 0.3% solution (OptiPranolol) Dosing: 1 drop in the affected eye(s) twice a day	Transient local discomfort, conjunctivitis, eyelid dermatitis, blepharitis, blurred vision, headache, asthenia, angina, palpitation, bradycardia	Bronchial asthma or severe COPD Symptomatic sinus bradycardia Second- or third-degree AV block Overt cardiac failure Cardiogenic shock	May be absorbed systemically; the same adverse reactions seen with oral beta-blockers may occur. May mask the symptoms of acute hypoglycemia or hyperthyroidism
timolol 0.25% or 0.5% solution (Timoptic, Betimol, Istalol) or gel-forming solution (Timoptic-XE) Dosing: Solution: 1 drop in the affected eye(s) twice daily Gel-forming solution: 1 drop in the affected eye(s) once daily	Ocular irritation, decreased corneal sensitivity, visual disturbances, conjunctivitis, tearing, headache, dizziness, bradycardia, arrhythmia	Bronchial asthma or severe COPD Sinus bradycardia Second- or third-degree AV block Overt cardiac failure Cardiogenic shock	May be absorbed systemically; the same adverse reactions seen with oral beta-blockers may occur May mask the symptoms of acute hypoglycemia or hyperthyroidism. Other ophthalmic medications should be administered 10 min before the gel-forming solution.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Carbonic Anhydrase Inhibitors			
brinzolamide 1% suspension (Azopt) Dosing: 1 drop in the affected eye(s) three times a day	Blurred vision, bitter taste, blepharitis, dermatitis, dry eye, headache, hyperemia ocular pain, pruritus	Sulfa allergy	
dorzolamide 1% solution (Trusopt) Dosing: 1 drop in the affected eye(s) three times a day	Ocular burning and stinging, bitter taste, keratitis, ocular allergy, blurred vision, tearing, photophobia	Sulfa allergy	
Prostaglandins			
bimatoprost 0.03% solution (Lumigan) Dosing: 1 drop in the affected eye(s) once daily in the evening	Conjunctival hyperemia, growth of eyelashes, ocular pruritus, dry eye, iris discoloration, visual disturbance, eye pain, pigmentation of the periocular skin, foreign body sensation		Iris discoloration is irreversible; incidence less than with latanoprost.
latanoprost 0.005% solution (Xalatan) Dosing: 1 drop in the affected eye(s) once daily in the evening	Iris discoloration, blurred vision, burning and stinging, conjunctival hyperemia, itching, eyelash changes, eyelid skin darkening		Iris discoloration is irreversible. Requires refrigeration until dispensed.
tafluprost 0.0015% solution (Zioptan) Dosing: 1 drop in the affected eye(s) once daily in the evening	Conjunctival hyperemia, ocular stinging, headache, ocular pruritus, dry eye, growth of eyelashes, iris discoloration, pigmentation of the periocular skin		Iris discoloration is irreversible.
travoprost 0.004% solution (Travatan Z) Dosing: 1 drop in the affected eye(s) once daily in the evening	Ocular hyperemia, decreased visual acuity, eye discomfort, foreign body sensation, eye pain, pruritus		Iris discoloration is irreversible. May interfere in pregnancy; should not be used during pregnancy or by those attempting to become pregnant
Adrenergic Agonists			
apraclonidine 0.5% solution (Iopidine) Dosing: 1–2 drops in the affected eye(s) three times a day	Hyperemia, tearing, pruritus, lid edema, dry mouth, foreign body sensation, eyelid retraction	Hypersensitivity to clonidine Patients receiving MAO inhibitors	For short-term use only A 1% solution is available for prevention of postsurgical elevations in IOP.
brimonidine 0.1%, 0.15%, or 0.2% solution (Alphagan P) Dosing: 1 drop in the affected eye(s) three times a day, approximately 8 h apart	Ocular hyperemia, ocular pruritus, visual disturbance, somnolence, headache, fatigue, drowsiness, dry mouth	Patients receiving MAO inhibitors	Not recommended in children less than age 2.
Cholinergic Agonists			
pilocarpine 1%, 2%, or 4% solution (Isopto Carpine) Dosing: 1–2 drops three or four times a day	Stinging and burning, tearing, ciliary spasm, blurred vision, brow ache, hypertension, tachycardia, bronchospasm, salivation	Acute iritis or other conditions where papillary constriction is undesirable	
Combination Products			
brimonidine and timolol 0.2%–0.5% solution (Combigan) Dosing: 1 drop in the affected eye(s) every 12 h	See individual components.	See individual components.	Combined effect results in greater IOP lowering than either agent alone, but not as great as brimonidine three times a day and timolol two times a day administered concomitantly.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
dorzolamide and timolol 2%–0.5% solution (Cosopt) Dosing: 1 drop into the affected eye(s) two times a day	See individual components.	See individual components.	Combined effect results in greater IOP lowering than either agent alone, but not as great as dorzolamide three times a day and timolol two times a day administered concomitantly.
brinzolamide and brimonidine 1%–0.2% solution (Simbrinza) Dosing: 1 drop into the affected eye(s) three times a day	See individual components.	See individual components.	

AV, atrioventricular mode; COPD, chronic obstructive pulmonary disease; MAO, monoamine oxidase.

Once a target IOP has been determined, treatment may include drug therapy, laser therapy, or surgery. Topical medication is, in most cases, indicated as first-line therapy. Several trials have clearly shown that reducing IOP by treatment with ocular hypotensive medication can prevent or reduce the risk of progression of glaucoma. Further, the more IOP is reduced, the risk of glaucomatous eye damage decreases.

Goals of Drug Therapy

The goals of drug therapy for POAG are to reduce IOP to a target level and to prevent or slow the progression of vision loss. In patients with POAG, the initial IOP target should be 20% to 30% lower than baseline. Additional IOP lowering may be justified, based upon the severity of the existing optic nerve damage, the speed at which the damage occurred, and the presence of other risk factors such as family history and age (AAO, 2015). Visual fields and optic nerve status should be monitored for signs of change; if progression is detected, the IOP target should be lowered.

Beta-Blockers

Beta-blockers are the benchmark against which other IOP-lowering medications are measured. Beta-blockers reduce adenylyl cyclase activity, which in turn reduces the production of aqueous humor in the ciliary body. Beta-blockers lower IOP an average of 20% to 25%. There are five ophthalmic beta-blockers available in the United States: timolol, levobunolol, carteolol, and metipranolol are nonselective beta-blockers, while betaxolol is a $beta_1$-selective agent. Although nonselective beta-blockers may be more efficacious in lowering IOP, selective beta-blockers appear to be better tolerated systemically, particularly in patients with chronic obstructive pulmonary disease.

The ophthalmic beta-blockers are typically applied twice daily. Timolol is available in a solution that forms a gel upon application, allowing once-daily dosing. Side effects include stinging, burning, dry eye, and blurred vision. Topical beta-blockers can be absorbed systemically and may cause bradycardia, reduced blood pressure, aggravation of congestive heart failure, heart block, bronchospasm in asthma patients, and central nervous system (CNS) side effects such as hallucinations and depression. Betaxolol is less likely to cause these systemic side effects, but a risk still exists. All of the ophthalmic beta-blockers are contraindicated in patients with sinus bradycardia, second- or third-degree atrioventricular node block, overt cardiac failure, and cardiogenic shock, and all except betaxolol are contraindicated in patients with bronchial asthma or severe chronic obstructive pulmonary disease.

Prostaglandins

The prostaglandin $F_{2\alpha}$ analogs bimatoprost, latanoprost, tafluprost, and travoprost reduce IOP by improving the uveoscleral outflow of aqueous humor. Given once a day, the prostaglandin $F_{2\alpha}$ analogs reduce IOP by 25% to 33%. Studies of bimatoprost, latanoprost, and travoprost found no statistical difference in IOP lowering between agents (Li et al., 2006).

These agents are more effective when given at bedtime rather than in the morning. Latanoprost requires refrigeration until dispensed; latanoprost and travoprost should be discarded within 6 weeks of the time the package is opened. Tafluprost is supplied in single-use containers packaged within a foil pouch; unused single-use containers should be discarded 28 days after opening the pouch. Side effects of the prostaglandins include ocular hyperemia, blurred vision, pruritus, dry eye, lengthening and thickening of the eyelashes, and conjunctival hyperemia. These agents are also associated with irreversible iris discoloration, most often affecting patients with mixed-color irises. Iris discoloration is reported by 7% to 12% of latanoprost users, with discoloration starting between 18 and 26 weeks after commencement of therapy. Compared to latanoprost, the incidence of iris discoloration is lower for bimatoprost and travoprost. In addition, darkening of the eyelid skin (periocular hyperpigmentation) can occur with these agents; therapy discontinuation often results in reversal of periocular hyperpigmentation 3 to 6 months after therapy discontinuation.

Carbonic Anhydrase Inhibitors

The topical carbonic anhydrase inhibitors (CAIs) brinzolamide and dorzolamide work through the reversible and competitive binding of carbonic anhydrase. Carbonic anhydrase acts as a catalyst for the reversible hydration of carbonic acid, which plays a role in fluid transport in various cell systems. By decreasing bicarbonate formation, the movement of bicarbonate, sodium, and fluid into the posterior chamber of the eye declines, and less aqueous fluid is generated, reducing IOP (Abel & Sorensen, 2013). While the topical CAIs reduce IOP to a lesser extent (15% to 26%) than beta-blockers, prostaglandins, or systemic CAIs, they are rarely associated with systemic side effects.

The topical CAIs are given three times a day. Side effects include ocular burning and stinging, bitter taste, blurred vision, itching, tearing, and keratitis. The topical CAIs are contraindicated in patients with hypersensitivity to sulfonamides and are not recommended for use in patients with severe renal impairment, respiratory acidosis, and electrolyte disorders.

The systemic CAIs (acetazolamide, methazolamide, and dichlorphenamide) are the most potent agents for reducing IOP, producing a 25% to 40% decrease in IOP. However, these agents produce severe side effects such as paresthesias, gastrointestinal disturbances (anorexia, nausea, and weight loss), metallic taste, CNS effects (lethargy, malaise, and depression), electrolyte disturbances, and renal calculi, which limit their use in the elderly population (Swenson, 2014).

Adrenergic Agonists

The adrenergic agonists apraclonidine and brimonidine activate the presynaptic alpha-2 receptors, inhibiting the release of norepinephrine. As less norepinephrine is available for activation of postsynaptic beta receptors on the ciliary epithelium, the formation of aqueous humor is reduced.

Apraclonidine and brimonidine reduce IOP by 18% to 27%. Brimonidine is a highly selective alpha-2 agonist, causing little or no alpha-1 activity. In addition to decreasing aqueous humor, it increases uveoscleral outflow. Side effects include dry mouth, fatigue, ocular hyperemia, somnolence, and headache. Apraclonidine is a relatively selective alpha-2 agonist; it is associated with some alpha-1 activity, which can lead to mydriasis, conjunctival bleeding, and eyelid retraction. Apraclonidine is primarily indicated for short-term adjunctive therapy, as the efficacy of apraclonidine diminishes over time; the benefit for most patients lasts less than 1 to 2 months. Both agents are contraindicated in patients taking monoamine oxidase inhibitors. In addition, brimonidine has been associated with respiratory and cardiac depression in infants and should be used with caution in children under age 2.

The nonselective ophthalmic adrenergic agonists epinephrine and dipivefrin (epinephrine prodrug) are no longer available in the United States. These agents provided lackluster IOP control and were associated with adverse reactions such as stinging and tearing, brow ache, and the formation of black conjunctival spots and conjunctival deposits.

Cholinergic Agonists

Pilocarpine is a direct-acting cholinergic agonist. Pilocarpine stimulates the parasympathetic muscarinic receptor site to increase aqueous outflow through the trabecular meshwork. While effective in lowering IOP by 20% to 30%, pilocarpine usually needs to be given four times a day. Side effects include eye pain, brow ache, blurred vision, and accommodative spasms. It can also provoke miotic responses such as papillary constriction, which can decrease night vision. The intense dosing regimen and the side effect profile make adherence difficult.

Combination Products

Combination products simplify administration and can promote adherence to therapy. Solutions of timolol 0.5% in combination with dorzolamide 2% or brimonidine 0.2% are available, as is a combination of brimonidine 0.2% and brinzolamide 1%. The combined effect results in additional IOP reduction compared to either agent alone, but the result is often less than each agent administered separately.

Selecting the Most Appropriate Agent

The AAO does not recommend a specific agent as first-line therapy. When the first-line agent drug fails to reduce IOP, the AAO recommends that it be discontinued in favor of another therapy before the original agent is supplanted by other medications. If a first-line agent lowers IOP but fails to lower IOP to the target level, combination therapy and discontinuation of therapy in favor of another agent are appropriate options. When selecting the first-line therapy for glaucoma, factors such as efficacy, side effects, cost, and dosing frequency should all be considered. Table 17.8 lists the recommended order of treatment for these agents.

TABLE 17.8 Recommended Order of Treatment for Glaucoma

Order	Agent	Comments
First line	Prostaglandin ophthalmic solution (bimatoprost, latanoprost, tafluprost, or travoprost)	An ophthalmic beta-blocker may be substituted if the patient cannot afford the prostaglandins.
Second line	Substitution of an ophthalmic beta-blocker (if failure to decrease IOP to a significant extent) *or* Addition of an ophthalmic beta-blocker (if IOP is significantly decreased but not to goal)	
Third line	Addition of an ophthalmic carbonic anhydrase inhibitor *or* addition of brimonidine	Dorzolamide is available in a combination product with timolol.

First-Line Therapy

The prostaglandins are often utilized as first-line therapy for POAG because they possess the best balance between efficacy, safety, and ease of dosing regimen.

Second-Line Therapy

If the prostaglandin fails to decrease IOP to a significant extent, the patient should be switched to a different class of medicine. Beta-blockers are recommended because of their efficacy, tolerability, and ease of dosing. If the IOP decreases with a prostaglandin but fails to reach the target IOP, an additional medication from a different class (such as a beta-blocker) should be added.

Third-Line Therapy

If a patient fails to reach the target IOP with the first-line and second-line therapies, a

topical CAI (usually the fixed combination of timolol and dorzolamide to keep the dosing regimen simple) can be added. If this fails, dorzolamide should be discontinued in favor of brimonidine.

Monitoring Patient Response

Patients with POAG should receive follow-up evaluations and care from their eye care professional to determine the effectiveness of therapy. In addition to a recent history, a physical examination including a slit-lamp biomicroscopy and tests of visual acuity and IOP in each eye should be performed (AAO, 2015). The practitioner must distinguish between the impact of a prescribed agent on IOP and ordinary background fluctuations of IOP.

Patient Education

Patients should wash their hands before administering glaucoma medications. Patients should be taught how to apply the medication in the inner aspect of the lower eyelid. The tip of the container should not touch the eyelashes or any part of the eye because this may contaminate the medication. Contact lenses should be removed prior to administration, and patients should separate administration of different glaucoma medications by at least 10 minutes.

Case Study*

V.S., age 12, presents with a feeling that there is sand in his eye. He had a cold a week ago and woke up this morning with his left eye crusted with yellowish drainage. On physical examination, he has injected conjunctiva on the left side, no adenopathy, and no vision changes. His vision is 20/20. Fluorescein staining reveals no abrasion. He is allergic to sulfa.

Diagnosis: Conjunctivitis

1. List specific goals of treatment for V.S.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring the success of the therapy?
4. Discuss the education you would give to the parents regarding drug therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter or alternative medications would be appropriate for V.S.?
8. What dietary and lifestyle changes should be recommended for V.S.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

18 Otitis Media and Otitis Externa

Laura L. Bio

Infections of the ear are a common problem in children due to anatomical predisposition, but they can also affect adults. Acute otitis media (AOM), otitis media with effusion (OME), and otitis externa (OE; also known as *swimmer's ear*) are the most common infection or inflammatory conditions of the ear. Although antibiotics and vaccination programs have decreased the frequency of infections, identification, diagnosis, and management of these infections are essential to prevent permanent hearing loss, chronic or recurrent ear infections, mastoiditis, meningitis, and speech or language delay.

Otitis Media and Otitis Externa

Otitis media (OM) may manifest as AOM or chronic OME (Lieberthal et al., 2013). OM has historically posed a major social and economic burden, occurring at an alarming rate of 19 million cases per year. It continues to impact antibiotic expenditures because it is the most common infection for which antibiotics are prescribed for children. In spite of the strict 2004 American Academy of Pediatrics (AAP) AOM guideline, the rate of antibiotic prescribing for OM has remained constant. The recent 2013 AAP AOM guideline and clinical reports emphasize the need for judicious antibiotic prescribing for upper respiratory infections (URIs) to reduce the risk of antibiotic resistance and adverse effects (Hersh et al., 2013).

AOM is defined as an acute onset of signs and symptoms of a middle ear infection and inflammation, such as middle ear effusion and erythema, respectively (Table 18.1). AOM is the most common bacterial respiratory tract infection in children and predominantly effects infants and children age 6 months to 2 years. During the year 2006, 11.8% of all children under age 18 years were diagnosed with OM (8.8 million cases) (Soni, 2006). Meanwhile, OME is inflammation of the middle ear with fluid collection behind the TM, but signs and symptoms of an acute infection are absent (Pelton, 2012). OME typically precedes or follows AOM (Pichichero, 2013).

TABLE 18.1 Comparing Types of Otitis

Type of Otitis	Etiology	Symptoms	Clinical Findings
Acute otitis media	*Streptococcus pneumoniae* *Haemophilus influenzae* nontypable *Moraxella catarrhalis*	Otalgia Ear pulling Upper respiratory infection symptoms	Diffuse erythema and bulging of the TM Decreased mobility of the TM
Otitis media with effusion	Eustachian tube obstruction causing sterile effusion in the middle ear	Hearing loss that may be manifested by delayed language development in young children or decreased school performance in older children Feeling of ear fullness Popping sensation with swallowing, yawning, or blowing the nose	Clear, yellowish, or bluish-gray fluid behind the TM, with or without air bubbles TM may be retracted with decreased movement
Otitis externa	Infectious: *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Streptococcus* species Necrotizing (malignant): *P. aeruginosa*	Infectious: erythema and swelling of the external canal with otalgia and itching, muffled hearing, watery or thick discharge from the ear Necrotizing: persistent foul-smelling discharge, deep ear pain	Infectious: pain with movement of tragus, raised area of induration on the tragus, swollen external auditory canal, red pustular lesions Necrotizing: progressive cranial nerve palsies, granulations in the external ear canal

TM, tympanic membrane.

Otitis externa (OE) may present in acute and chronic forms. OE is defined as an inflammation of the outer ear and ear canal. Acute OE roughly affects 1 in 123 persons in the United States based on the 2.4 million visits to ambulatory care centers and emergency departments in 2007 (CDC, 2011). Children 5 to 14 years of age account for approximately half of all visits. OE is most often associated with swimming, local trauma,

use of hearing aids, and high, humid temperatures (Table 18.1). Unlike AOM, in which the mainstay of treatment is systemic antibiotics, topical antibiotic therapy is usually adequate for the treatment of OE. Oral antibiotics may be recommended for patients with acute OE infections extending outside the ear canal or certain host factors such as diabetes, immune deficiency, or inability to effectively deliver topic therapy. Systemic antibiotics should also be considered for patients with recurrent episodes of OE or clinical signs of necrotizing (i.e., malignant) OE, which is a serious and potentially life-threatening complication of the infection extending to the mastoid or temporal bone. Immunocompromised patients, including the elderly with diabetes and human immunodeficiency virus, are at the highest risk of necrotizing OE. Chronic OE is a single episode lasting longer than 3 months or four or more episodes in 1 year and often the result of allergies, chronic dermatologic conditions, or inadequately treated acute OE (Rosenfeld et al., 2004; Schaefer & Baugh, 2012).

Causes

Acute Otitis Media and Otitis Media with Effusion

The most frequently isolated bacteria from middle ear fluid are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, and *Moraxella catarrhalis*, followed by the less common group A *Streptococcus* and *Staphylococcus aureus*. The precise frequency for each AOM pathogen has changed over time due to changes in vaccination coverage. Historically, *S. pneumoniae* dominated AOM etiology, but after implementation of the 13-serotype conjugate vaccine, beta-lactamase producing *H. influenzae* and *M. catarrhalis* has emerged as more common (Pichichero, 2013).

Although many cases are caused by bacterial pathogens, viruses play a significant role in the pathogenesis and course of treatment. Viral pathogens, such as respiratory syncytial virus, influenza A and B, parainfluenza, enterovirus, and rhinovirus, have all been isolated in nasopharyngeal secretion of children with URI (Pichichero, 2013). Most cases of AOM follow viral URI since it facilitates bacterial AOM by enhancing the bacteria's ability to ascend the nasopharynx and infect the middle ear (Pelton, 2012). Single virus isolates are recovered from 2% to 20% of AOM tympanocenteses.

Otitis Externa

Ninety-eight percent of OE cases in the United States are caused by bacteria, most commonly *Pseudomonas aeruginosa* and *S. aureus* (Schaefer & Baugh, 2012). The etiology of OE is different than that of OM because the flora of the external auditory canal is similar to that of the skin including *Staphylococcus epidermidis*, *S. aureus*, *Corynebacteria* species, and *Propionibacterium acnes*. Fungi, predominantly *Aspergillus* and *Candida* species, cause less than 5% of OE in the United States but may be more common in subtropical or tropical climates (Boyce, 2012). Fungal OE, otomycosis, may also occur in cases in which prolonged antibiotic courses are given for bacterial OE, causing an alteration in ear canal skin flora. Chronic OE may be noninfectious but caused by inflammatory skin disorders and allergic reactions (Schaefer & Baugh, 2012). Necrotizing (malignant) OE is caused by *P. aeruginosa*.

Pathophysiology

Otitis Media

AOM frequently follows a URI (usually of viral etiology) in which the eustachian tube closes secondary to inflamed mucous membranes (Lieberthal et al., 2013). The pathophysiology of AOM is multifactorial but is mainly the result of eustachian tube dysfunction. The eustachian tube protects the middle ear from nasopharyngeal secretions, provides drainage of secretions produced in the middle ear into the nasopharynx, and permits equilibration of air pressure to atmospheric pressure in the middle ear. The structure of a child's eustachian tube differs from that of an adult's. The adult eustachian tube lies at 45 degrees to the horizontal plane and allows for secretions to drain from the middle ear to the nasopharynx. The child's eustachian tube, however, is short and horizontal. When a child develops mild inflammation or edema of the eustachian tube, the ear has difficulty clearing secretions due to the almost horizontal placement of the eustachian tube. Persistent secretions, incomplete drainage, and the absence of aeration breed an environment for bacterial growth within the middle ear, resulting in AOM (Pelton, 2012). The incidence of AOM is highest during winter months, which coincide with the seasonal peak of URIs. Risk factors for AOM include congenital defects such as cleft palate and Down syndrome, young age (highest incidence in children below age 2), family history, and children who attend day care or are relatives of children in day care. The following risk factors have also been associated, however inconsistently, with an increased risk of AOM: male sex, exposure to secondhand smoke, allergies, and lack of exclusive breast-feeding for the first 6 months of life (Hoberman et al., 2002).

OME is thought to result from prolonged blockage of the eustachian tube, which in turn causes negative pressure within the middle ear that allows fluid to accumulate and persist, and may result in conductive hearing loss (Pelton, 2012). The presence of effusion does not always correlate to the presence of an infection. In fact, bacterial pathogens are reported in only 20% to 30% of middle ear effusions (Pelton, 2012).

Otitis Externa

OE is a cellulitis of the ear canal skin and subdermis with or without infection (Rosenfeld et al., 2013). Children, adolescents, and adults are all at risk for developing this infection. This condition may occur as a result of many different factors. The most common predisposing factor is swimming, especially in freshwater. Additional OE risk factors include eczema or seborrhea resulting in excessive itching, trauma from cerumen removal, use of hearing aids, chronic otorrhea, and immunocompromised states such as diabetes (Schaefer & Baugh, 2012). Disruption of the ear canal homeostasis from prolonged periods of water exposure (head immersion), loss of protective cerumen barrier, and disruption of the epithelium all result in varied pH and compromised local immune defenses, which allows bacteria and other pathogens to harbor infection.

Resistance

The increasing rates of antimicrobial resistance are a major cause and concern for treatment failure of AOM. The increasing incidence warrants the judicious use of antibiotics. Mechanisms of resistance include alteration of drug binding sites and the production of antibiotic inactivating enzymes, for example, beta-lactamases. Organisms such as *H. influenzae* and *M. catarrhalis* can produce these enzymes, which essentially render many beta-lactam antibiotics useless. It is for this reason that antibiotics that remain stable in the presence of beta-lactamase–producing enzymes must be chosen to ensure treatment success. A detailed discussion of treatment options is discussed in the management section of this chapter.

Drug-resistant *S. pneumoniae* (DRSP) remains a threat in the treatment of AOM. Penicillin, historically, has been the mainstay of treatment against *S. pneumoniae.* However, the increasing prevalence of penicillin-intermediate and penicillin-resistant strains has discouraged the use of penicillin and its derivatives. Furthermore, penicillin-resistant strains may also confer resistance to other antibiotics such as macrolides, trimethoprim–sulfamethoxazole, and clindamycin. The mechanism of penicillin-resistant *S. pneumoniae* is the alteration of the penicillin-binding site resulting in elevated minimum inhibitory concentration (MIC). This may be overcome by administering high-dose amoxicillin if deemed intermediate susceptibility based on the MIC. It should be noted that infections caused by penicillin-resistant *S. pneumoniae* have mostly been reported in children younger than age 2.

Beta-lactamase production is the mechanism by which organisms such as *H. influenzae* and *M. catarrhalis* develop resistance. Beta-lactamase inhibitors in combination with beta-lactam therapy, such as amoxicillin–clavulanic acid or beta-lactamase stable cephalosporins (i.e., cefixime, cefpodoxime), can overcome this mechanism of resistance. Therefore, these agents should be recommended for treatment if these organisms are suspected, specifically in the setting of treatment failure or recurrent infection.

Diagnostic Criteria and Clinical Presentation

Acute Otitis Media

The presentation of AOM includes abrupt onset of symptoms such as fever, otalgia, irritability, and tugging on the affected ear; the tympanic membrane (TM) appears bulging, erythematous, and immobile to pneumatic otoscopy upon inspection indicating middle ear effusion. The averbal infant may express otalgia by tugging, rubbing, or holding the affected ear, excessive crying, fever, or changes in sleep or behavior pattern. The diagnosis of AOM requires abrupt onset of symptoms (less than 48 hours), presence of middle ear effusion, and signs or symptoms of middle ear inflammation, including erythema of the TM, hearing loss, and otalgia (Lieberthal et al., 2013). Otorrhea may also be present and will affect management (Table 18.2).

TABLE 18.2 Diagnostic Criteria for Acute Otitis Media

1. History of acute onset of signs/symptoms
2. Presence of middle ear effusion (indicated by one of the following)
   a. Bulging of TM
   b. Limited or absent TM mobility
   c. Otorrhea
   d. Air–fluid level behind TM
3. Signs and symptoms of middle ear inflammation
   a. Erythema of TM
   b. Otalgia

The absence of acute inflammatory signs and symptoms presumes a diagnosis of OME. Patients with OME are usually asymptomatic but may complain of a full sensation in the ear and hearing loss. Upon examination, the TM may not appear bulging, but air–fluid levels may be apparent. AOM and OME require differentiation since OME should not be treated with antibiotics due to probable viral etiology or result of AOM resolution.

Tympanocentesis, the process by which fluid is drained from the middle ear, is recommended for recurrent treatment failure to ensure proper diagnosis of the causative organism and determine the presence of bacterial resistance. This process relieves pressure

in the middle ear cavity and promotes drainage, but it is reserved for treatment failures due to the potential risk of permanent hearing loss and facial paralysis.

Initiating Drug Therapy

Goals of Drug Therapy

The goals of therapy for AOM include symptomatic pain relief, appropriate use of antibiotics to prevent complications, and judicious use of antibiotics to prevent future antimicrobial resistance. Symptomatic pain relief can be achieved with the use of acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen. Antibiotics are utilized to eradicate the infecting organism and prevent complications such as mastoiditis and hearing impairment. Antibiotic use is not without concerns, such as resistance and adverse effects. For these reasons, clinicians should avoid unnecessary use of antibiotics.

Over-the-Counter Therapy

Acetaminophen and NSAIDs should be offered early to relieve pain regardless of antibiotic use, unless hypersensitivity exists. Local topical anesthetics containing benzocaine or procaine may provide brief additional pain relief for children over 5 years of age.

Observational Therapy

The decision to manage AOM with antibiotics is based on patient-specific characteristics such as age, bilateral involvement, presence of otorrhea, and severity of illness (Lieberthal et al., 2013). All patients with suspected AOM who are younger than age 6 months should receive antibiotics. For patients with nonsevere, unilateral AOM without otorrhea who are older than age 6 months, the role of antibiotics is unclear, and the decision to provide symptomatic relief with close observation can be made. The decision to observe and withhold antibiotics is based on the high rate of spontaneous resolution (approximately 80%) and overlap of nonspecific AOM symptoms with viral URIs (Hersh et al., 2013). In addition, judicious antibiotic prescribing reduces the risk of resistance and reduces common adverse effects associated with antibiotic therapy.

Patients with otorrhea or severe symptoms (i.e., toxic-appearing child, persistent otalgia more than 48 hours, temperature ≥102.2°F in the past 48 hours, or uncertain access to follow-up after visit) require antibiotic therapy regardless of age. Bilateral AOM requires antibiotic therapy only if the patient is less than 2 years of age. Patients 2 years old or greater with bilateral AOM without otorrhea or severe symptoms may initially be managed with observation therapy after a discussion with the child's family to understand the decision. Observation therapy requires implementation of follow-up within 48 to 72 hours to ensure antibiotics can be initiated if the child's condition worsens or fails to improve. The technique for observational therapy is controversial: observe with or without a prescription with instructions to fill after 2 to 3 days if symptoms persist (Chao et al., 2008). This decision should be based on the prescriber's discussion with the caregiver and assessment of likelihood to adhere to the plan.

Penicillins

First-line therapy for AOM is high-dose amoxicillin for adequate middle ear penetration and to overcome intermediate-resistant *S. pneumoniae* (Lieberthal et al., 2013; Figure 18.1; Table 18.3). If the child has received amoxicillin in the past 30 days and has concurrent purulent conjunctivitis or allergy to penicillin, amoxicillin may not be appropriate. Recent receipt of amoxicillin or failure to improve while on amoxicillin raises concern of resistant organisms causing the infection, such as *M. catarrhalis* and *H. influenzae*. Therefore, the addition of beta-lactamase inhibitor to beta-lactam is necessary. Amoxicillin–clavulanate is a combination product commercially available in the United States in various concentrations of the oral suspension, chewables, tablets, and extended-release tablets. The major difference among these formulations is the ratio of clavulanate to amoxicillin and therefore may not be interchanged. The most common adverse effect of amoxicillin–clavulanate is diarrhea, which is dependent on the dosage of clavulanate (Block et al., 2006). Since high-dose amoxicillin is recommended for AOM treatment, use of amoxicillin–clavulanate standard ratio (clavulanate to amoxicillin, 1:7) would result in excess exposure of clavulanate and diarrhea. Therefore, the ES formulation for oral

suspension (ratio 1:14) or XR formulation for tablets (ratio 1:16) should be recommended to limit excess exposure to clavulanate and therefore reduce the incidence of diarrhea.

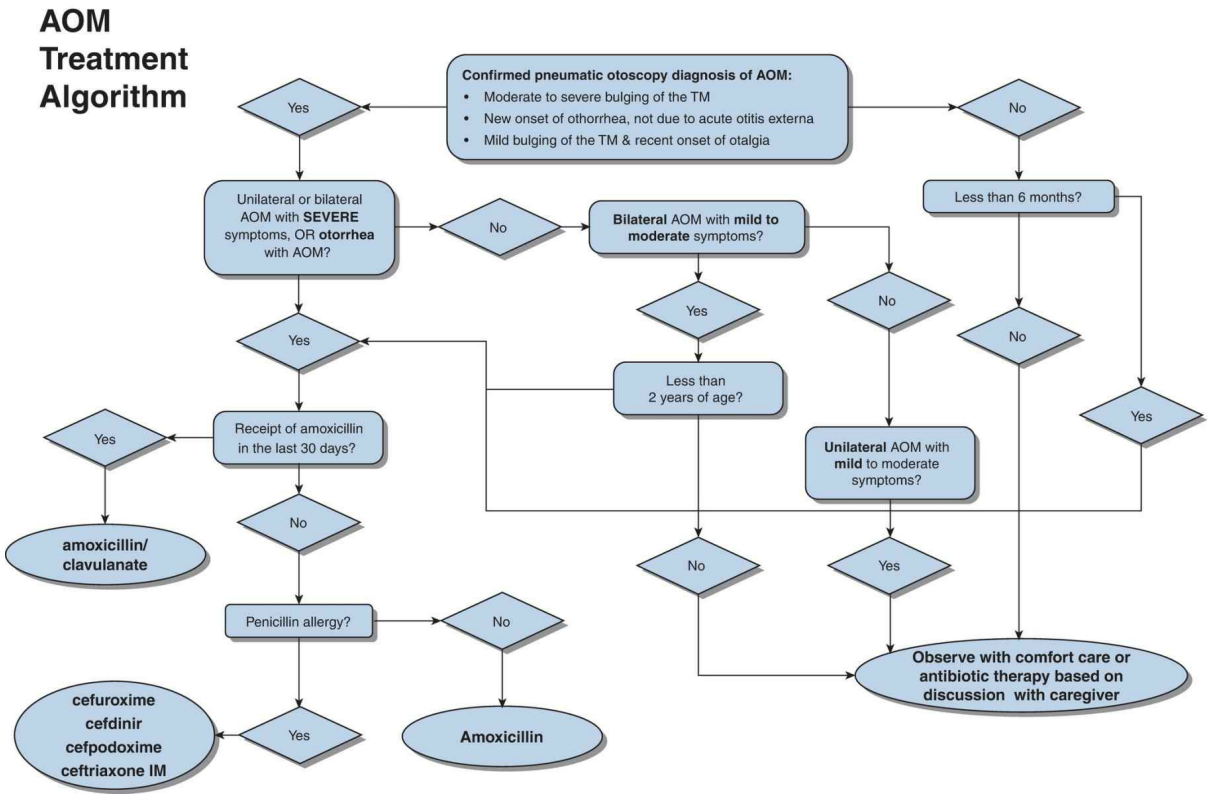

FIGURE 18.1 Treatment algorithm for acute otitis media.

TABLE 18.3 Overview of Antibiotics for Acute Otitis Media

Generic (Trade) Name	Usual Pediatric Daily Dose	Usual Adult Daily Dose	Adverse Effects	Dosage Formulations
amoxicillin (various)	80–90 mg/kg/d PO divided into 2 doses per day	2–3 g/d PO divided into 2 to 3 doses per day	Abnormal taste, diarrhea, headache, skin rash	Suspension, oral: 125 mg/5 mL, 250 mg/5 mL, 400 mg/mL Chewable, oral: 125 mg, 200 mg, 250 mg, 400 mg Tablet, oral: 500 mg, 875 mg Capsule: 250 mg, 500 mg
amoxicillin–clavulanate (Augmentin)	80–90 mg/kg/d based on amoxicillin component PO divided into 2 doses per day	250–500 mg PO every 8 h; or 875 mg PO every 12 h	Abnormal taste, diarrhea, headache	Suspension, oral: amoxicillin* 200 mg/5 mL, 250 mg/5 mL, 400 mg/5 mL; Augmentin ES-600†: 600 mg/5 mL Chewable, oral:* amoxicillin 200 mg, 400 mg Tablet, oral:‡ 250 mg, 500 mg, 875 mg Augmentin XR§ 1,000 mg
ceftriaxone (Rocephin)	50 mg/kg/d IM once daily for 1 or 3 d	1 g IM once daily for 1 or 3 d	Skin rash, injection site reactions	IM: 250–350 mg/mL with lidocaine
cefdinir (Omnicef)	14 mg/kg/d PO divided into 2 doses per day	300 mg PO twice a day	Skin rash and GI upset but otherwise generally well tolerated	Suspension, oral: 125 mg/5 mL, 250 mg/5 mL Capsule, oral: 300 mg
cefpodoxime (Vantin)	10 mg/kg/d PO once daily	200 mg PO twice a day	Skin rash and GI upset but otherwise generally well tolerated	Suspension, oral: 50 mg/5 mL, 100 mg/5 mL Tablet, oral: 100 mg, 200 mg
cefuroxime (Ceftin)	30 mg/kg/d PO divided into 2 doses per day	250–500 mg PO twice a day	Skin rash and GI upset but otherwise generally well tolerated	Suspension, oral: 125 mg/5 mL, 250 mg/5 mL Tablet, oral: 250 mg, 500 mg
clindamycin (various)	30 mg/kg/d PO divided into 3 doses per day	300–450 mg PO every 6–8 h	Diarrhea, *C. difficile*–associated diarrhea, rash	Suspension, oral: 75 mg/5 mL Capsule, oral: 75 mg, 150 mg, 300 mg

*Standard ratio of clavulanate to amoxicillin of 1:7.

†ES ratio of clavulanate to amoxicillin of 1:14.

‡Standard 125 mg of clavulanate per tablet.

§XR ratio of clavulanate to amoxicillin of 1:16.

Cephalosporins

If the presence of a penicillin allergy is elicited from the patient or caregiver, the type of reaction should be assessed. Fortunately, the cross-reactivity between penicillins and most second-generation and third-generation cephalosporins is low due to distinct chemical structures (Pichichero, 2005). Therefore, oral formulations of cefdinir and cefpodoxime, which are third-generation cephalosporins, and cefuroxime, which is a second-generation cephalosporin, are recommended for penicillin-allergic patients, regardless of reaction type (both anaphylactic and urticarial reaction) (Table 18.3).

Patients who are persistently vomiting or cannot tolerate oral medication for other reasons, ceftriaxone, a third-generation cephalosporin, administered as intramuscular injection, is an option for initial or repeat antibiotic treatment due to treatment failure.

Macrolides

Historically, macrolides including azithromycin and erythromycin were recommended for patients with a history of anaphylactic reaction to penicillins. Due to limited macrolide

efficacy against both *S. pneumoniae* and *H. influenzae* and lower rate of cross-sensitivity to cephalosporins among penicillin-allergic patients than previously reported, macrolides are no longer recommended by the AAP (Lieberthal et al., 2013).

Clindamycin

Similar to macrolides, clindamycin historically was an option for patients who had an anaphylactic to penicillin. But again, due to concerns of clindamycin's lack of activity against *H. influenzae* or *M. catarrhalis*, it is no longer recommended. Clindamycin may be used for suspected penicillin-resistant *S. pneumoniae*, but it may not be effective against multi–drug-resistant strains, such as serotype 19A (Kaplan et al., 2015).

Selecting the Most Appropriate Agent

Figure 18.1 outlines the process for selecting the most appropriate agent.

First-Line Therapy

Amoxicillin is considered the first-line treatment for AOM in patients who have severe symptoms and who have not had a course of amoxicillin in the past 30 days. For those patients who had a course of amoxicillin in the recent past, treatment with the combination amoxicillin–clavulanate is indicated. In patients with a penicillin allergy, one of the cephalosporins is indicated as the first-line treatment.

Second-Line Therapy

After 48 to 72 hours of persistent patient's symptoms under observation therapy, antibiotic therapy should be initiated. Upon the decision to initiate antibiotic therapy, the same antibiotic decision algorithm applies as discussed earlier (Figure 18.1). Patients who received antibiotics for more than 72 hours and severe symptoms persist are deemed treatment failure. Treatment failure may be due to the presence of a resistant organism, a viral infection, which is unresponsive to antibiotic therapy, inadequate concentration of antibiotic in the middle ear, or noncompliance with the prescribed regimen. Treatment failure requires escalation to the next step in management and is highly dependent on the initial therapy. If the patient does not improve with high-dose amoxicillin treatment, therapy should be switched to amoxicillin–clavulanate. If a patient fails amoxicillin–clavulanate, an oral cephalosporin (i.e., cefpodoxime, cefuroxime, cefdinir), or 1-dose ceftriaxone intramuscular injection should receive a 3-day course of intravenous ceftriaxone (Leibovitz et al., 2000). Tympanocentesis is an option for patients who have repeatedly failed therapy for bacteriologic diagnosis. The effusion is sent for Gram stain, culture, and antibiotic susceptibility testing to tailor therapy to the causative organism.

Monitoring Patient Response

The standard duration of antibiotic therapy is 10 days for patients younger than 2 years of age or to manage severe AOM. Patients 2 years old or greater should be treated with a 7-day course of antibiotics. Patients age 6 years and older may benefit from a shorter, 5-day course of therapy (Lieberthal et al., 2013). Symptoms of AOM should improve within 2 to 3 days, and the patient should achieve complete resolution of symptoms after 7 days, although asymptomatic MEE may persist if inspected by pneumatic otoscope. The patient or caregiver must be counseled to continue antibiotic therapy even if symptoms resolve before completion of the entire therapy course to prevent recurrence.

Recurrent Acute Otitis Media

Recurrent AOM is defined as more than three episodes within 6 months or four episodes within 12 months, with one episode in the preceding 6 months. Recurrence is most commonly due to relapse (infection with the same organism) or reinfection (infection with a different organism). Management of recurrent AOM remains controversial. Antibiotic prophylaxis is no longer recommended due to risk outweighing the benefit, as mentioned below, and evidence supporting placement of tympanostomy tubes is limited. The American Academy of Otolaryngology: Head and Neck Surgery Foundation published guidelines state tympanostomy should be ordered to children with bilateral OME for 3 months or longer with documented hearing difficulties (Rosenfeld et al., 2013). An additional indication is for children at increased risk of speech, language, or learning problems from OME due to baseline sensory, physical, cognitive, or behavioral factors. Hearing assessment in infants and children requires varying tools depending on age to detect hearing loss (mean response greater than 20 dB), including evoked optoacoustic emissions, auditory brainstem response, visual reinforcement audiometry, play audiometry, or conventional audiometry (Harlor et al., 2009). Myringotomy and insertion of tympanostomy tubes improve AOM symptoms by allowing drainage of the effusion. These tubes maintain a disease-free state typically in the first 6 months after insertion; however, the benefit thereafter is unknown (McDonald et al., 2008). Complications of tube placement include otorrhea, myringosclerosis, perforation, and tissue granulation as seen on otoscopic examination (Vlastarakos et al., 2007).

Prophylaxis and/or Prevention

Use of antibiotic prophylaxis for recurrent AOM is controversial due to lack of supporting evidence. Cost, adverse effects, and contribution to bacterial resistance emergence do not outweigh the small reduction in frequency of AOM with long-term antibiotic prophylaxis. Therefore, antibiotic prophylaxis is no longer recommended for children with recurrent AOM (Leach & Morris, 2006).

The Centers for Disease Control and Prevention's (CDC) recommended schedule for vaccines should be followed to reduce preventable diseases. The vaccines pertinent to the prevention of AOM are the pneumococcal, *H. influenzae* type B, and influenza vaccine. Please refer to the prevention section of this chapter for a detailed discussion on target vaccine groups and current recommendations.

Otitis Externa

Diagnostic Criteria and Clinical Presentation

OE presents with symptoms of ear canal inflammation such as ear pain, itching, or fullness; signs of ear canal inflammation such as tenderness of tragus and/or pinna; and erythematous ear canal with occasional otorrhea. Hearing is usually unaffected unless pressure and fullness in the ear exist, producing occasional conductive or sensorineural hearing loss. Jaw pain may also be present. Acute OE diagnosis requires rapid onset of signs and symptoms within 48 hours in the past 3 weeks. Differentiation from other possible causes of otalgia, otorrhea, and inflammation of the ear canal, such as AOM, is important due to overlapping pathologies that require alteration in treatment.

Patient evaluation should include history of symptoms, water exposure, local trauma, past medical history of inflammatory skin disorders or diabetes, and history of ear surgeries or local radiotherapy. Otoscopic examination of the ear canal and TM may require cerumen or debris removal for visualization. If the TM is bulging or erythematous, the patient should be worked up for OM. Examination of pinna and adjacent skin for regional lymphadenitis and cellulitis is included as well. Otomycosis, fungal OE, presents with intense pruritus, aural fullness, clear otorrhea, and fluffy, cotton-like debris in the external ear canal upon examination (Kesser, 2011). Necrotizing OE diagnosis is confirmed with a raised erythrocyte sedimentation rate and abnormal computed tomography or magnetic resonance imaging scan to detect a skull base osteomyelitis (Rosenfeld et al., 2013).

Initiating Drug Therapy

Goals of Drug Therapy

The goals of OE treatment are similar to OM, which are eradicating the causative organisms and decreasing the accompanying pain. This can be accomplished with direct ototopical application of antimicrobial agents and systemic analgesic and/or anti-inflammatory drugs.

Management of OE begins with clearing any obstructing debris or excess cerumen from the canal (i.e., aural toilet) and checking the integrity of the TM to determine if extension beyond the ear canal is present. Topical therapy is the mainstay of OE treatment (i.e., antibiotics, steroids, or combination treatments). Topical antimicrobials are preferred over systemic administration to achieve high concentration at the site of infection while reducing systemic adverse effects to the patient. Selection of the appropriate product must include evaluation of the patient's infection, predisposing factors, adherence, and medication costs (Boyce, 2012).

Pain relief can be achieved with orally administered acetaminophen or NSAIDs given alone or in combination with an opioid for mild to moderate pain (Rosenfeld et al., 2013). Topical anesthetic drops, such as benzocaine otic solution, are not recommended due to potential masking of underlying disease states and lack of FDA approval for OE indication.

Antibiotic Therapy

If edema prevents application of the drops, a compressed cellulose ear wick can be placed into the ear to facilitate drug delivery. The medication should be applied to the wick until inflammation subsides and the wick falls out or is removed as instructed by a clinician (usually within 24 to 48 hours). Ototopical antimicrobials for OE include aminoglycosides, polymyxin B, and quinolones. Ototopical selection is based on several factors including TM condition (e.g., perforation, tympanostomy tubes), risk of adverse effect, adherence issues, cost, patient preference, and physician experience/preference (Table 18.4). Systemic antimicrobials are not recommended for uncomplicated, acute OE, but for infections extending beyond the ear canal or when certain factors are present such as uncontrolled diabetes, immunocompromised, history of radiotherapy, or inability to deliver topical antibiotics. Otomycosis requires debridement and topical antifungal therapy, such as a powdered mixture of Chloromycetin, sulfanilamide, Fungizone, and hydrocortisone (Kesser, 2011). Necrotizing OE is managed with surgical debridement and systemic, prolonged antipseudomonal and antistaphylococcal antibiotics.

TABLE 18.4 Overview of Treatment for Otitis Externa

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
polymyxin B sulfate, neomycin, and hydrocortisone Children: 3 drops into ear canal three to four times daily for maximum of 10 d Adults: 4 drops into ear canal three to four times daily for maximum of 10 d	Superinfection, contact dermatitis, ototoxicity with prolonged use	Herpes simplex, fungal, tubercular, or viral otic infections Perforated eardrum Prescribe with caution in pregnancy (category C drug) and in breast-feeding patients	Use otic drops for a maximum of 10 d
ofloxacin (Floxin) Children 1–12 y: 5 drops into ear canal bid for 10 d Children >12 y and adults: 10 drops bid for 10 d	Pruritus, site reaction, dizziness, earache, vertigo, taste perversion, paresthesia, rash	Not recommended for patients <1 y, perforated eardrum Prescribe with caution in pregnancy (category C drug) and in breast-feeding patients	Use otic drops for a maximum of 10 d

Fluoroquinolones

The fluoroquinolone antibiotics, that is, ciprofloxacin and ofloxacin, are often used to treat infections associated with OE, due to its ideal antipseudomonal activity. Higher bacteriologic and clinical cure rates have been observed with quinolone-containing otic drops compared to nonquinolone therapy (Mösges et al., 2011). In addition, these agents may be more tolerable compared to neomycin/polymyxin B due to frequent administration, less adverse effects (e.g., stinging), and lower risk of hypersensitivity. This information must be balanced with the high cost of quinolone otic preparations. Ciprofloxacin 0.3%/dexamethasone 0.1% (Ciprodex) and ofloxacin (Floxin Otic) are commercially available fluoroquinolone formulations. (See Table 18.4 for dosage and adverse effect information.) The addition of a corticosteroid to the antibiotic formulation is controversial. The anti-inflammatory effects potentially include reduced pain, swelling, and itching. Dohar (2003) reported on a controlled study suggesting that the addition of

hydrocortisone decreases the duration of pain by about 1 day. However, additional studies have not been conducted to confirm this point. The risk of local immunosuppression and potential hypersensitivity reactions should be studied in light of potential benefits. Of note, the Floxin Otic preparation does not contain a corticosteroid.

Aminoglycoside Antibiotics

The combination product neomycin sulfate/polymyxin B/hydrocortisone acetate (Cortisporin) has historically been used for OE. The combination of the gram-positive coverage of the aminoglycoside neomycin and the antipseudomonal activity of polymyxin has made this combination the gold standard of treatment in the past. The same controversy regarding the addition of a corticosteroid exists with this combination. Concerns associated with the side effect profile, particularly the hypersensitivity reactions related to neomycin (and possibly the preservative), and frequency of dose administration must be weighed against the low cost for the generic product. Furthermore, ototoxicity with neomycin has been reported, although the number of reports is low and the data are speculative. Due to concerns of ototoxicity, aminoglycosides should not be used if the TM is not intact since the risk of injury outweighs the benefit and efficacious, nonototoxic antibiotics are available (i.e., quinolones) (Haynes et al., 2007).

Selecting the Most Appropriate Agent

First-Line Therapy

OE with intact or nonintact TM is treated initially with a fluoroquinolone antibiotic. The selection of ciprofloxacin versus ofloxacin depends on the formulary status of the agents as well as the clinician's experience with added corticosteroids (Table 18.5).

TABLE 18.5 Recommended Order of Treatment for Otitis Externa

Order	Agents	Comments
First line	Fluoroquinolone drops	Floxin is not recommended for patients <1 y Use all otic drops for a maximum of 10 d
Second line	Combination neomycin/polymyxin B drops	Vosol is not recommended for patients <3 y All drops are contraindicated in cases of perforated eardrum
Third line	Antifungal drops Systemic antipseudomonal or antistaphylococcal agent	Considered if a patient fails to respond to initial topical antibiotic therapy Consider if ear canal obstruction cannot be relieved or if infection extends beyond the ear canal

Second-Line Therapy

Neomycin/polymyxin B combinations are considered second-line agents, primarily due to their side effect profile and precaution against use for nonintact TM OE. The lower cost of these agents, however, warrants consideration, particularly in patients without insurance or other means of paying for the more expensive fluoroquinolones.

Third-Line Therapy

Antifungals can be considered if a patient fails to respond to initial topical antibiotic therapy (e.g., clotrimazole, miconazole, bifonazole, ciclopirox olamine, tolnaftate) (Vennewald et al., 2010). Systemic antibiotic therapy with *P. aeruginosa* and *S. aureus* coverage is recommended if ear canal obstruction cannot be relieved or if infection extends beyond the ear canal.

Special Population Considerations

Children with tympanostomy tubes placed within 1 year of an acute OE episode are assumed to have nonintact TM and therefore should not receive an ototoxic antibiotic. Historical concerns of fluoroquinolone use in children are not relevant due to the minimal systemic absorption and small dose administered ototopically.

Monitoring Patient Response

Symptom improvement should occur within 48 to 72 hours after appropriate treatment initiation, but complete symptom resolution may take up to 2 weeks. Reassessment of patients who fail initial therapy may include addressing patient adherence with therapy, re-examination of the ear canal and TM, a culture of the ear canal to identify causes of infection and target therapy, and consideration of underlying dermatologic disorders.

Prevention

Prevention is the key and plays a significant role in reducing the overall burden of illness (e.g., office visits, antibiotic expenditures, severity of illness). Vaccination programs have been shown to have a favorable outcome on decreasing the overall incidence of the AOM, namely, those caused by *S. pneumoniae*, influenza virus, and *H. influenzae*.

The introduction of the heptavalent pneumococcal polysaccharide conjugate vaccine (PCV-7, Prevnar-7; serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F) decreased the overall incidence of invasive pneumococcal disease by 69% in children younger than age 2 from 1998 to 1999 and 2001 (Pichichero & Casey, 2007). Specifically, reductions in OM office visits and severity of illness have been observed since the introduction of the vaccine (Black et al., 2000). The serotypes in the 7-valent vaccine when brought to the market in 2000 represented approximately 70% of the serotypes found in AOM. Unfortunately, after PCV-7 introduction, otopathogenic *S. pneumoniae* serotype 19A had been identified as resistant to all FDA-approved antibiotics for children with AOM (Pichichero & Casey, 2007). A 13-valent pneumococcal conjugate vaccine (PCV-13, Prevnar-13; serotypes 1, 3, 4, 5, 6A, 6B, 7F, 19A, in addition to the 7 serotypes of PCV-7) approved by the U.S. FDA in 2010 contains the 6 serotypes responsible for 63% of invasive pneumococcal disease and has replaced PCV-7 in the childhood vaccination schedule (CDC, 2015).

Pneumococcal vaccination includes two formulations: PCV and polysaccharide (PPSV) for infants younger than age 2 and children older than age 2 with comorbidities, respectively. PPSV contains 23 pneumococcal serotypes indicated for children age 2 and older with chronic disease such as chronic lung disease or congenital heart disease and not indicated in infants younger than age 2 due to poor immunogenicity (Committee on Infectious Disease, 2010).

Administration of the influenza and *H. influenzae* type B (HiB) vaccines are also routinely recommended in children to decrease potential infections caused by them. The HiB vaccine is a polysaccharide, conjugated protein carrier indicated for infants age 6 weeks and older. The influenza vaccine is recommended for all children ages 6 months to 18 years, but the selection of the correct formulation is dependent on the age of the patient. Influenza vaccine is available as a trivalent inactivated IM injection and live attenuated vaccine as an intranasal administration, which is indicated in infants older than age 6 months and children older than age 2 who are not immunocompromised or pregnant or have exacerbative pulmonary diseases, respectively (CDC, 2015).

For up-to-date Advisory Committee on Immunization Practices (ACIP) vaccine administration schedules, check the CDC Web site at www.cdc.gov/vaccines (CDC, 2015).

Patient Education

Drug Information

Administration of ototopical products requires patient education and potentially an assistant to administer the drops for them as self-administration may be difficult. Ototopicals should be warmed to body temperature before instillation to avoid dizziness. To warm the otic solution, the patient should hold or roll the bottle in the hand for 1 to 2 minutes. To instill drops, the patient should lie with the affected ear upward, administer enough drops to fill the ear canal (or saturate the ear wick if in place), gently tug the auricle to help expel trapped air and assist drug delivery, and remain in this position for about 5 minutes to help the solution penetrate into the ear canal.

Nutrition/Lifestyle Changes

The use of hypoallergenic ear canal molds when swimming or showering is controversial for the prevention of OE. Drying the ears with a cool hair dryer to aid removal of fluid after swimming may be beneficial. The patient should avoid trying to remove ear wax mechanically with cotton-tipped swabs to prevent trauma. It is important for the patient to avoid water in the ear until the infection clears (usually 5 to 7 days) and for 4 to 6 weeks afterward. To accomplish this, hair can be washed in a sink instead of a shower or tub, and the patient can use a shower cap when bathing.

Complementary and Alternative Medications

"Home remedies" of a 1:1 solution of white vinegar and rubbing alcohol have never been evaluated or substantiated and therefore are not recommended for OE. In addition, ear candles are not efficacious and may be harmful (e.g., hearing loss).

Case Study*

C.J., age 17, is on his high school swim team. He presents with sudden onset of right ear pain that worsens at night. He says that the pain intensifies when he touches his ear and that he has a feeling of fullness in the ear. On examination, the auditory canal is edematous and erythematous, with yellow crusting. His temperature is 97.8°F, and his TM is pearly gray with landmarks intact.

Diagnosis: Otitis Externa

1. What drug therapy would you prescribe? Why?
2. What are the parameters for monitoring success of the therapy?
3. Discuss specific patient education based on the prescribed therapy.
4. List one or two adverse reactions for the selected agent that would cause you to change therapy.
5. What would be the choice for second-line therapy?
6. What over-the-counter and/or alternative medications would be appropriate for C.J.?
7. What lifestyle changes would you recommend to C.J.?
8. Describe one or two drug–drug or drug–food interaction for the selected agent.

* Answers can be found online.

UNIT 4
Pharmacotherapy for Cardiovascular Disorders

19 Hypertension

Kelly Barrangern ■ Diane E. Hadley

Hypertension or high blood pressure (BP) is one of the common chronic conditions managed by primary care providers and other health practitioners. It increases the risk for cardiovascular disease and chronic kidney disease (CKD). Heart disease is a prevalent cause of death in the United States, thus making management of a patient's BP crucial. Approximately, 70 million Americans or one out of three adults in the United States has hypertension. The total costs associated with hypertension in 2011 in the United States were approximately $46 billion in health care services, medications, and missed days of work (Mozzafarian et al., 2015). Despite these alarming numbers, many people are unaware that they have hypertension because the disease can be asymptomatic; therefore, the disease is appropriately nicknamed "the silent killer."

The prevalence of hypertension continues to grow due to the increasing age of our population, obesity, and high dietary salt intake. According to the Centers for Disease Control and Prevention (CDC), approximately 69% of adults 20 years and older are overweight and 35% of adults age 20 years and older are obese. Obesity, impaired renal function, and diabetes mellitus are all associated with resistant hypertension (Vongpatanasin, 2014).

Hypertension increases with age and affects all ethnic groups. However, blacks suffer disproportionately from hypertension and its effects, leading to high rates of cardiovascular morbidity and mortality. Hypertension in blacks occurs at an earlier age, is more severe, and results in organ damage such as coronary heart disease, stroke, and end-stage renal disease more often than it does in whites.

Causes

Hypertension is classified as primary or essential, secondary, or idiopathic when there is no identifiable cause for elevation in BP. Approximately 95% of adults have primary or essential hypertension, and the exact cause of primary hypertension is not known. Environmental factors (excess salt, obesity, and sedentary lifestyle) and genetic factors (inappropriately high activity of the renin–angiotensin–aldosterone system [RAAS] and the sympathetic nervous system) are hypothesized contributing factors and are being studied. An additional cause of hypertension is secondary to aorta artery stiffening secondary to increasing age. This is referred to as isolated or predominant systolic hypertension. It is characterized by high systolic blood pressure (SBP) with normal diastolic blood pressure (DBP) and is found primarily in elderly people.

Secondary hypertension, where the cause of high BP can be identified, accounts for 5% of all hypertensions. The main types of secondary hypertension are CKD (anemia, low GFR, small kidney), renovascular hypertension (abdominal bruit, elevated plasma renin activity, greater than 30% elevation of creatinine with starting BP-lowering agents), hypothyroidism (elevated TSH), hyperparathyroidism (elevated calcium), pheochromocytoma, sleep apnea, and primary aldosteronism (hypokalemia, ratio serum aldosterone/plasma renin activity greater than 25:30).

Furthermore, medications can serve as a factor that may increase BP. Examples include oral contraceptives, nicotine, steroids, appetite suppressants, tricyclic antidepressants, the antidepressant venlafaxine (Effexor), cyclosporine (Sandimmune), nonsteroidal anti-inflammatory drugs (NSAIDs), and some nasal decongestants (which include over-the-counter preparations). Herbal products that affect BP include capsicum, goldenseal, licorice root, ma huang (Ephedra), Scotch broom, witch hazel, and yohimbine.

Pathophysiology

Role of the Nervous System

The central and autonomic nervous systems play a key dual role in regulating BP. Centrally located presynaptic beta receptors stimulate the release of norepinephrine, while alpha-2 receptors inhibit norepinephrine release. Receptors located in the periphery also regulate BP. These receptors are located on effector cells that are innervated by sympathetic neurons. Stimulation of alpha-1 receptors located on arterioles and venules causes vasoconstriction, while activation of the beta-2 receptors on these vessels produces vasodilation. Beta-1 receptors, which are located in the heart and kidneys, regulate heart rate and contractility, which ultimately impacts cardiac output. Because BP is the product of cardiac output and peripheral resistance, any reduction in cardiac output results in a decrease in BP. Therefore, blockade of beta-1 receptors decreases cardiac output, peripheral resistance, and BP.

Baroreceptors, which are nerve endings located in large arteries such as the aortic arch and carotids, additionally play a significant role in regulating BP. These receptors are sensitive to changes in BP. When BP drops drastically, the baroreceptors send an impulse to the brain stem, which results in vasoconstriction and increased heart rate and contractility. In contrast, elevation in BP increases baroreceptor activity, which results in vasodilation and decreased heart rate and contractility.

Peripheral autoregulatory components also play a role in controlling BP. Normally, rises in BP result in sodium and water elimination by the kidney. In turn, plasma volume, cardiac output, and BP decrease. Dysfunction of this mechanism can raise plasma volume and BP.

Role of the Renal System

RAAS regulates sodium, potassium, and fluid balance in the body. Renin, an enzyme secreted by the juxtaglomerular cells on the afferent arterioles of the kidney, is released in response to changes in BP caused by reduced renal perfusion, decreased intravascular volume, or increased circulation of catecholamines. Renin catalyses the conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to the potent vasoconstrictor angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II causes direct vasoconstriction and stimulation of the sympathetic nervous system. Angiotensin II also stimulates release of aldosterone from the adrenal gland, which results in the retention of sodium and water. In normal physiology, angiotensin II directly inhibits further release of renin through a negative feedback system. If the negative feedback system fails, BP rises. Hyperinsulinemia is another contributing factor to hypertension by causing sodium retention and stimulating the sympathetic nervous system.

Diagnostic Criteria

Hypertension is defined as an elevation in SBP and/or DBP. As suggested by the 2014 Eighth Report of the Joint National Committee (JNC 8) guidelines, hypertension is defined as a BP of 150/90 mm Hg or higher in adults 60 years and older. The guidelines also highlights that a BP of 140/90 or higher in adults younger than 60 is defined as hypertension. Two studies within the primary literature, SHEP and Syst-EUR, used placebo-controlled approaches to evaluate people over the age of 60 with systolic hypertension and the HYVET study evaluated patients over the age of 80. The JNC 8 panel could not recommend a lower threshold value for those over 60 since no evidence existed that less than 140 mm Hg was better than less than 150 mm Hg for protecting patients from harm. Additionally, the ASH (American Society of Hypertension) and ISH (International Society of Hypertension) recommend an SBP of less than 150 (as opposed to less than 140 mm Hg) be used only in those over 80 years of age.

The biggest difference between JNC 7 and JNC 8 were the defined BP treatment goals. Additionally, another difference between JNC 7 and JNC 8 is that prehypertension was not addressed in JNC 8. This was well defined in JNC 7 as SBP ranging from 120 to 139 mm Hg and DBP ranging from 80 to 89 mm Hg and therefore remains valid. Another distinct difference was the use of very specific compelling indications within JNC 7 while JNC 8 used broader compelling indications. Finally, JNC 8 guidelines are more evidence based utilizing randomized controlled trials and have clear target ranges.

Hypertension is not diagnosed on an initial reading; rather, it is confirmed after three readings at least 1 week apart. BP measurements should be obtained after the patient has had time to relax for at least 5 minutes. Patients should be seated in a chair, back supported, rather than on an examination table, with feet on the floor, uncrossed, and arm supported at heart level. Patients should avoid smoking cigarettes 30 minutes before the reading, should not exercise heavily immediately before the reading, should not drink caffeine during the hour preceding the reading, and should avoid adrenergic stimulants, such as phenylephrine. For an accurate reading, the appropriate-size sphygmomanometer cuff should be used. The cuff should encompass 80% of the arm, and the width of the cuff should be at least 40% of the length of the upper arm (Screening for high blood pressure, 2007). At the initial evaluation, BP should be measured in both arms. If the readings are different, the arm with the higher reading should be used for measurements thereafter. It is preferable to take two readings, 1 to 2 minutes apart and use the average of these measurements. In older people, it is useful to obtain standing BP, after 1 minute and again after 3 minutes, to check for postural effects.

The diagnosis of hypertension should be confirmed at an additional patient visit, usually 1 to 4 weeks after the first measurement. On both occasions, the SBP and DBP should be higher than recommendations listed above per age. The U.S. Preventive Services Task Force (USPSTF) recommends BP monitoring in adult patients over the age of

eighteen. If the BP is very high (SBP greater than 180), initiate the appropriate triage and treatment should occur. If available resources are not adequate to permit a convenient second visit, the initial diagnosis can be made and treatment can be started.

Ambulatory BP monitoring (ABPM) is recommended for patients with suspected variable BP. Contributing factors can include "white coat hypertension," episodic hypertension, hypertension resistant to increasing medication regimens, hypotensive symptoms while taking antihypertensive medications, and autonomic dysfunction. Patients with "white coat hypertension" have a persistently elevated BP in the doctor's office but a persistently normal BP at other times. ABPM readings correlate better with target organ damage than clinical measurements. ABPM also identifies patients in whom BP does not drop significantly during sleep. More aggressive treatment may be necessary for these patients, who are known to be at higher cardiovascular risk. An elevated systolic BP is a more potent cardiovascular risk factor than an elevated diastolic BP.

Physical Examination

A thorough examination should be performed including a personal history, first-degree family history of cardiovascular disease, poor dietary habits, and a history of prescription medications, smoking/tobacco product use, daily caffeine intake (if applicable), ETOH consumption, over-the-counter medications, and herbal products. For patients with documented hypertension, lifestyle should be evaluated and other cardiovascular risk factors or concomitant disorders should be identified to determine the extent of target organ damage and to assess the patient's overall cardiovascular risk status. Most prevalent target damage concern is concentrated to the cardio, cerebral, and renal tissue.

Physical examination includes two or more measured seated BP readings with verification in the contralateral arm; weight and height; body mass index (BMI) (calculated as weight in kilograms divided by the square of height in meters); waist circumference; muscle strength; funduscopy exam; auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; thorough examination of the heart and lungs; examination of the abdomen for enlarged kidneys, enlarged liver, masses, and abnormal aortic pulsation; palpation of the lower extremities for edema and pulses; and neurologic assessment for sign of previous stroke.

Diagnostic Tests

The following laboratory tests should be routinely performed: electrocardiogram, blood glucose, hemoglobin, hematocrit, complete urinalysis, and complete chemistry panel especially serum potassium, creatinine, estimated glomerular filtration rate, liver function tests, calcium and magnesium, glycosylated hemoglobin (hemoglobin A1c), and fasting lipid panel (9- to 12-hour fast), which includes total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides. Further testing should be performed based on clinical findings.

Initiating Therapy

Goals of Drug Therapy

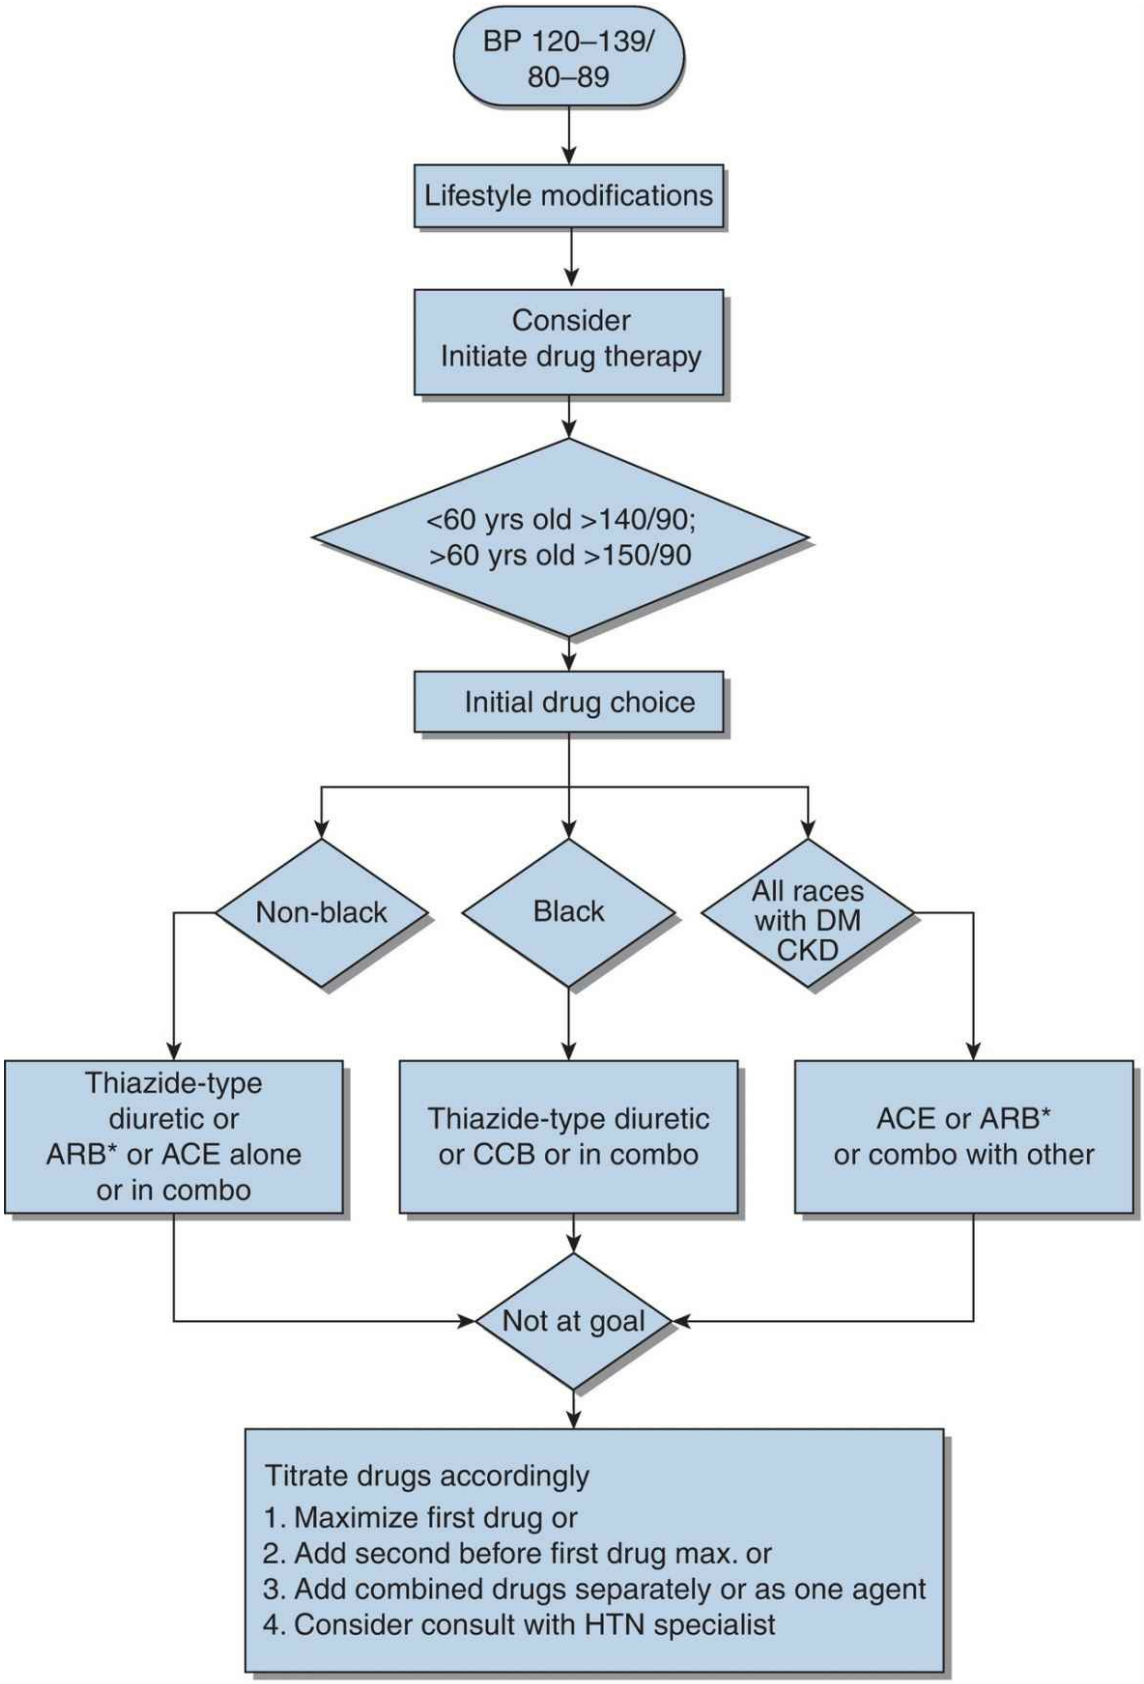
Treatment guidelines are cumbersome due to the different classifications of hypertensive patients with or without comorbidities of diabetes and/or CKD and also elderly versus nonelderly patients. Per JNC 8 guidelines, treatment should be initiated when BP is 140/90 or higher in adults younger than 60 and treated to a goal of less than 140/90 mm Hg. Similarly, the National Institute for Health and Care Excellence (NICE) 2013 guidelines support the same BP goal; however, they recommend this for patients 80 and younger. In adult patients with hypertension and diabetes, pharmacologic treatment should be initiated when BP is 140/90 mm Hg or higher, regardless of age, per the JNC 8 guidelines and the American Diabetes Association (ADA) 2015 Standards of Medical Care in Diabetes guidelines. The JNC 8 goal for diabetic patients, regardless of race, is less than 140/90 mm Hg. The ADA guidelines state as a caveat, however, that younger patients can be considered for a more aggressive BP target of ≤130/80 mm Hg if this can be achieved without side effects. The American College of Cardiology (ACC), American Heart Association (AHA), and the CDC also recommend a BP goal of less than 140/90 mm Hg for diabetic patients (Go et al., 2014).

Furthermore, the National Kidney Foundation (KDOQI) 2012 commentary on the 2012 KDIGO clinical practice guidelines for nondiabetic patients with hypertension and CKD with normal to mild albuminuria states the BP goal is ≤140/90 mm Hg. However, for severe albuminuria patients, the BP goal is ≤130/80 mm Hg. Thus, BP treatment per the KDOQI guidelines would be initiated at the respective targets listed above (Taler et al., 2013). The current 2014 JNC 8 guidelines recommend treatment in adult CKD patients with BP of 140/90 mm Hg or higher and their goal is a BP less than 140/90 mm Hg. Lastly, for elderly patients, JNC 8 recommends treatment for BP of 150/90 mm Hg or higher in adults 60 years and older to aim at a BP goal of less than 150/90 mm Hg. In contrast, the NICE guidelines from 2013 state that for patients above the age of 80 years old, their BP goal is less than 150/90 mm Hg.

The goal of antihypertensive therapy is to manage hypertension and reduce cardiovascular disease (including lipid disorders, glucose intolerance or diabetes, obesity, and smoking) and renal disease. The treatment goal of SBP is less than 140 mm Hg and DBP less than 90 mm Hg with special note of higher goals for elderly patients as listed above. In the past, guidelines have recommended treatment values of less than 130/80 mm Hg for patient with diabetes, CKD, and coronary artery disease. However, evidence to support this lower target is lacking and recent guidelines, such as JNC 8, have increased the BP target goal. For instance, the ACCORD trial, BP trial arm, demonstrated that aggressive reduction of BP target (less than 120/80 mm Hg) in type 2 DM patients did not reduce combined cardiovascular and renal outcomes compared with usual care (target BP

less than 140/90 mm Hg) (Cushman et al., 2010). Among secondary outcomes, strokes were reduced by the lower BP goals but at the expense of twice as many serious side effects. Several meta-analyses have demonstrated that lowering BP to below 130 mm Hg systolic does not reduce mortality rates or most cardiovascular outcomes (Mancia et al., 2013). It is important to inform patients that the treatment of hypertension is usually expected to be a lifelong commitment and can be dangerous for them to terminate treatment without first consulting their provider.

Figure 19.1 summarizes widely used guidelines for hypertension treatment.



*Do not combine ACE and ARB
ARB = angiotensin receptor blocker
ACE-I = angiotensin converting enzyme
CCB = calcium channel blocker

Nonpharmacological Antihypertensive Treatment

All patients diagnosed with hypertension should be counseled about the benefits and a way to implement a combination of dietary and lifestyle modifications for BP reduction. Patients are encouraged to maintain appropriate body weight (BMI of 19.5 to 24.9) and adopt the Dietary Approaches to Stop Hypertension (DASH) diet, USDA Food Pattern diet, or the AHA diet. These diets focus on a high quantity of fruits, vegetables, and low-fat dairy products. They specifically focus on reduction of saturated and total fat. Other recommended lifestyle modifications include restriction of dietary sodium to less than 2.4 g daily, encouragement of physical activity (at least 120 minutes/week of aerobic activity), and reduction in alcohol consumption (Eckel et al., 2014). Patients classified as prehypertensive are ideal candidate for aggressive dietary and lifestyle changes to lower BP and prevent onset of overt hypertension. All patients diagnosed with hypertension should be utilizing lifestyle modifications as a backbone to treatment.

Overview of Pharmacological Antihypertensive Agents

Diuretics

There are five classes of diuretics: carbonic anhydrase inhibitors (which are not used for hypertension because of their weak antihypertensive effects), thiazides, thiazide-like diuretics, loop diuretics, and potassium-sparing diuretics. Diuretics decrease BP by causing diuresis, which results in decreased plasma volume, stroke volume, and cardiac output (see Table 19.1). During chronic therapy, their major hemodynamic effect is reduction of peripheral vascular resistance. As a result of drug-induced diuresis, adverse effects of hypokalemia and hypomagnesemia may lead to cardiac arrhythmias. Patients at greatest risk are those receiving digitalis therapy, those with LVH, and those with ischemic heart disease.

TABLE 19.1 Overview of Selected Antihypertensive Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Selected Diuretics			
THIAZIDE AND THIAZIDE-LIKE			
chlorthalidone 12.5–100 mg qd	Hyperuricemia, hypokalemia, hypomagnesemia, hyperglycemia, hyponatremia, hypercalcemia, hypercholesterolemia, hypertriglyceridemia, rashes, and other allergic reactions	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Preferred in patients with creatinine clearance >30 mL/min
hydrochlorothiazide (Microzide) 12.5–25 mg qd	Same as chlorthalidone	Same as chlorthalidone	Same as chlorthalidone
indapamide (Lozol) 1.25–5 mg qd	Same as chlorthalidone	Same as chlorthalidone	Same as chlorthalidone
metolazone (Zaroxolyn) 2.5–5 mg qd	Less or no hypercholesterolemia		
LOOP DIURETICS			
bumetanide (Bumex) 0.5–5 mg bid–tid	Dehydration, circulatory collapse, hypokalemia, hyponatremia, hypomagnesemia, hyperglycemia, metabolic alkalosis, and hyperuricemia (short duration of action, no hypercalcemia)	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Effective in patients with creatinine clearance <30 mL/min
ethacrynic acid (Edecrin) 25–100 mg bid–tid	Same as bumetanide (only nonsulfonamide diuretic, ototoxicity)	Same as bumetanide	Same as bumetanide
furosemide (Lasix) 20–320 mg qd	Same as bumetanide	Same as bumetanide	Same as bumetanide
torsemide (Demadex) 5–20 mg qd	Short duration of action and no hypercalcemia	Same as bumetanide	Same as bumetanide
POTASSIUM-SPARING DIURETICS			
amiloride (Midamor) 5–10 mg qd–bid	Hyperkalemia, GI disturbances, and rash	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Effective in patients with creatinine clearance <30 mL/min
spironolactone (Aldactone) 12.5–100 mg qd–bid**	Hyperkalemia, GI disturbances, rash, gynecomastia, hirsutism, and menstrual irregularities	Same as amiloride	Ideal in patients with heart failure; in GFR <.30, use is not recommended.
eplerenone (Inspra) 50 mg qd to 50 mg bid**	Same as amiloride	Same as amiloride	Not recommended in CrCl < 30 mL/min
triamterene (Dyrenium) 50–150 mg qd–bid	Hyperkalemia, GI disturbances, and nephrolithiasis	Same as amiloride	Effective in patients with creatinine clearance <30 mL/min
*** Also known as an aldosterone receptor antagonist*			
Beta-Adrenergic Blocking Agents			
SELECTED BETA-BLOCKERS			
atenolol (Tenormin) 25–100 mg qd	Fatigue, depression, bradycardia, decreased exercise tolerance, congestive heart failure, aggravates peripheral arterial insufficiency, bronchospasm, masks signs and symptoms of hypoglycemia, Raynaud phenomenon, insomnia, vivid dreams or hallucinations, acute mental disorder, and impotence; sudden withdrawal can lead to exacerbation of angina and MI.	Contraindicated in first trimester of pregnancy and heart failure (except carvedilol, bisoprolol, and metoprolol succinate); relatively use in caution with patients with asthma (prefer low-dose cardioselective agents).	Abrupt cessation should be avoided; taper the dose of beta-blocker over a 2-wk period. Advantageous in patients with angina, tachycardia, and acute MI; hypertensive patients with left ventricular hypertrophy

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
bisoprolol (Zebeta) 2.5–10 mg qd	Same as atenolol	Same as atenolol	Same as atenolol
metoprolol tartrate (Lopressor) 50–100 qd–bid	Same as atenolol	Same as atenolol	Same as atenolol
nadolol (Corgard) 40–120 mg qd	Same as atenolol	Same as atenolol	Same as atenolol
propranolol (Inderal, Inderal LA) 40–160 mg bid and 60–180 mg bid	Same as atenolol	Same as atenolol	Same as atenolol
metoprolol succinate (Toprol-XL) 50–100 mg qd–bid	Same as atenolol	Same as atenolol	Same as atenolol; one of the agents recommended for heart failure patients
pindolol (Visken) 10–40 mg bid	Same as atenolol, but with less resting bradycardia and lipid changes	Same as atenolol	Same as atenolol
acebutolol (Sectral) 200–800 mg bid	Same as atenolol, but with less resting bradycardia and lipid changes; positive antinuclear antibody test and occasional drug-induced lupus	Same as atenolol	Same as atenolol
ALPHA- AND BETA-BLOCKERS			
carvedilol (Coreg) 12.5–50 mg bid	Similar to atenolol but more postural hypotension and bronchospasm	Same as atenolol	Same as atenolol; one of the agents recommended for heart failure patients
labetalol (Trandate) 200–800 mg bid	Hepatotoxicity	Same as atenolol	Same as atenolol; does not affect serum lipids
Angiotensin-Converting Enzyme (ACE) Inhibitors			
SELECTED ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS			
benazepril (Lotensin) 10–40 mg qd–bid	Common: cough; hypotension, particularly with a diuretic or volume depletion; hyperkalemia; rash; loss of taste; leukopenia; angioedema; neutropenia, and agranulocytosis in <1% of patients	Contraindicated in pregnancy; avoid in patients with bilateral renal artery stenosis or unilateral stenosis.	First line in hypertensive diabetic patients with proteinuria; congestive heart failure patients with systolic dysfunction
captopril (Capoten) 25–100 mg bid–tid	Same as benazepril; rash in 10% of patients; loss of taste	Same as benazepril	Same as benazepril
enalapril maleate (Vasotec) 2.5–40 mg qd–bid	Same as benazepril	Same as benazepril	Same as benazepril
fosinopril (Monopril) 10–40 mg qd	Same as benazepril	Same as benazepril	Same as benazepril
lisinopril (Prinivil, Zestril) 10–40 mg qd	Same as benazepril	Same as benazepril	Same as benazepril
moexipril (Univasc) 7.5–30 mg qd	Same as benazepril	Same as benazepril	Same as benazepril
quinapril (Accupril) 10–80 mg qd	Same as benazepril	Same as benazepril	Same as benazepril
ramipril (Altace) 2.5–20 mg qd	Same as benazepril	Same as benazepril	Same as benazepril
trandolapril (Mavik) 1–4 mg qd	Same as benazepril	Same as benazepril	Same as benazepril

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Angiotensin II Receptor Blockers			
**Selected agents are listed.*			
losartan (Cozaar) 25–100 mg qd–bid	Similar to ACE inhibitors but causes cough rarely; angioedema (very rare) and hyperkalemia		
valsartan (Diovan) 80–320 mg qd			
candesartan cilexetil (Atacand) 8–32 mg qd			
irbesartan (Avapro) 150–300 mg qd			
telmisartan (Micardis) 20–80 mg qd			
eprosartan (Teveten) 400–800 mg qd–bid			
olmesartan (Benicar) 20–40 mg qd			
Calcium Channel Blocking Agents			
**Selected agents are listed.*			
NONDIHYDROPYRIDINES			
diltiazem HCl (Cardizem SR, Cardizem CD, Dilacor XR, Tiazac) 180–420 mg qd and (Dilta XR) 120–480 mg qd	Dizziness, headache, edema, and constipation (especially verapamil); lupus-like rash with diltiazem; conduction defects, worsening of systolic dysfunction, and gingival hyperplasia (nausea, headache)	Avoid in patients with AV node dysfunction (second- or third-degree heart block) or left ventricular (systolic) dysfunction.	Swallow whole; do not chew, divide, or crush.
verapamil HCl (Isoptin SR, Calan SR, Verelan) 120–480 mg qd	Constipation	Same as diltiazem	Swallow whole; do not chew, divide, or crush.
DIHYDROPYRIDINES			
amlodipine (Norvasc) 2.5–10 mg qd	Dizziness, headache, rash, peripheral edema, flushing, headache, and gingival hypertrophy		Swallow whole; do not chew, divide, or crush. Elderly patients with isolated systolic hypertension
felodipine (Plendil) 2.5–20 mg qd	Same as amlodipine		Swallow whole; do not chew, divide, or crush.
isradipine (DynaCirc) 2.5–10 mg bid and (DynaCirc CR) 5–10 mg bid	Same as amlodipine		Swallow whole; do not chew, divide, or crush.
nicardipine (Cardene SR) 60–120 mg bid	Same as amlodipine		Swallow whole; do not chew, divide, or crush.
nifedipine (Procardia XL) 30–60 mg qd	Same as amlodipine		Swallow whole; do not chew, divide, or crush. Do not use sublingually.
nisoldipine (Sular) 10–40 mg qd	Same as amlodipine		Swallow whole; do not chew, divide, or crush.
Alpha-Blockers			
doxazosin (Cardura) 1–16 mg qd	First-dose phenomenon, postural hypotension, lassitude, vivid dreams, depression, headache, palpitations, fluid retention, weakness, priapism, and drowsiness		Administer initially at bedtime; start with low dose and titrate slowly. Ideal for hypertensive patients with benign prostatic hypertrophy

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
prazosin (Minipress) 2–20 mg bid–tid	Same as doxazosin		Same as doxazosin
terazosin (Hytrin) 1–20 mg qd–bid	Same as doxazosin		Same as doxazosin
Central Agonists			
clonidine (Catapres) 0.1–0.8 mg bid–tid	Sedation, dry mouth, bradycardia, withdrawal hypertension, bradycardia, and heart block	Avoid prescribing for noncompliant patients.	Do not stop therapy abruptly without consulting health-care provider first.
transdermal (Catapres TTS) one patch weekly (0.1–0.2 mg/d)			
guanabenz (Wytensin) 4–64 mg bid	Similar to clonidine	Similar to clonidine	Tolerance of alcohol may decrease.
guanfacine (Tenex) 0.5–2.0 mg qd	Similar to clonidine	Similar to clonidine	Take at bedtime.
methyldopa (Aldomet) 250–1000 mg bid	Drowsiness, sedation, fatigue, depression, dry mouth, orthostatic hypotension, bradycardia, heart block, and autoimmune disorders, including colitis, hepatitis and hemolytic anemia <1% of patients		Urine may darken after voiding when exposed to air.
Direct Vasodilators			
hydralazine (Apresoline) 25–100 mg bid	Tachycardia, aggravation of angina, headache, dizziness, fluid retention, lupus-like syndrome, dermatitis, drug fever, hepatitis, and peripheral neuropathy		Beneficial use in black patients with heart failure
minoxidil (Loniten) 2.5–80 mg qd–bid	Tachycardia, aggravation of angina, dizziness, fluid retention, and hypertrichosis	Avoid in patients taking nitrates.	Restrict to patients with refractory hypertension.
Adrenergic Antagonists			
guanadrel (Hylorel) 10–75 mg bid	Postural hypotension, exercise hypotension, diarrhea, weight gain, syncope, and retrograde ejaculation		Restrict to patients with refractory hypertension.
guanethidine (Ismelin) 10–50 mg qd	Similar to guanadrel, but greater incidence of diarrhea	Relatively contraindicated in depression	Maximal effect not seen for 2–4 wk. Avoid doses above 0.25 mg daily in patients with depression.
reserpine (Serpasil) 0.5–0.25–0.1 mg qd	Nasal stuffiness, drowsiness, GI disturbances, bradycardia, and nightmares with high doses		

Thiazide Diuretics

Mechanism of Action

Thiazide diuretics work by increasing the urinary excretion of sodium and chloride in equal amounts (see Table 19.1). They inhibit the reabsorption of sodium and chloride in the thick ascending limb of the loop of Henle and the early distal tubules. The antihypertensive action requires several days to produce effects. The duration of action of the thiazides requires a single daily dose to control BP. Thiazide diuretics cause an increase potassium and bicarbonate excretion and decrease calcium excretion. Additionally, they cause uric acid retention; therefore, caution should be used in patients with a history of gout. Diuretic-induced hyperuricemia may produce gouty arthritis or uric acid stones.

Contraindications

Thiazide diuretics are not recommended in patients with a creatinine clearance of less than 30 mL/min and are contraindicated in those who have renal decompensation or are hypersensitive to thiazides or sulfonamides.

Adverse Events

Side effects include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, and hyperglycemia. As a result of drug-induced diuresis, hypokalemia occurs in 15% to 20% of patients taking low-dose thiazide diuretics; therefore, potassium supplements can be utilized by some patients. Combination therapy with thiazide and potassium-sparing diuretics (e.g., hydrochlorothiazide [Microzide] and triamterene [Dyrenium]) may be prudent when potassium levels are less than 4.0 mEq/L and the patient is taking a thiazide diuretic or when a low potassium level may potentiate drug toxicity, as in patients concurrently taking digoxin (Lanoxin). Other side effects include tinnitus, paresthesia, abdominal cramps, nausea, vomiting, diarrhea, muscle cramps, weakness, and sexual dysfunction.

Loop Diuretics

Mechanism of Action

Loop diuretics are indicated in the presence of edema associated with congestive heart failure, hepatic cirrhosis, and renal disease (see Table 19.1). This class of drug is useful when greater diuresis is desired compared to thiazide diuretics. In general, loop diuretics should be reserved for hypertensive patients with chronic renal insufficiency and/or need more severe diuresis.

Furosemide and ethacrynic acid inhibit the reabsorption of sodium and chloride, not only in proximal and distal tubules but also in the loop of Henle. In contrast, bumetanide is more chloruretic than natriuretic and may have an additional action in the proximal tubule.

Contraindications

Loop diuretics are contraindicated in patients who are anuric, in patients hypersensitive to these compounds or to sulfonylureas, and in patients with hepatic coma or in states of severe electrolyte depletion. Ethacrynic acid is contraindicated in infants.

Adverse Events

Loop diuretics may cause the same side effects as thiazides, although the effects on serum lipids and glucose are not as significant, and hypocalcemia may occur instead (see Table 19.1). The metabolic abnormalities, such as hyperlipidemia and hyperglycemia, usually occur with high doses of diuretics and can be avoided by using low doses of the drug. Loop diuretics may lead to electrolyte and volume depletion more readily than thiazides; they have a short duration of action, but the thiazide diuretics are more effective than loop diuretics in reducing BP in patients with normal renal function. Therefore, loop diuretics should be reserved for hypertensive patients with renal dysfunction (serum creatinine of more than 2.5).

Potassium-Sparing Diuretics

In the kidney, potassium is filtered at the glomerulus and then absorbed parallel to sodium throughout the proximal tubule and thick ascending limb of the loop of Henle, so that only minor amounts reach the distal convoluted tubule. As a result, potassium appearing in urine is secreted at the distal tubule and collecting duct. The potassium-sparing diuretics interfere with sodium reabsorption at the distal tubule, thus decreasing potassium secretion (see Table 19.1). This drug can be used as a possible agent for HTN; however, its true benefit is indicated within heart failure. Secondary to the Randomized Spironolactone Evaluation Study (RALES), in 1999, showed the benefits of low-dose spironolactone (Aldactone) to improve morbidity and mortality rates in patients with severe heart failure (Pitt et al., 1999). Potassium-sparing diuretics have the potential for causing hyperkalemia and hyponatremia, especially in patients with renal insufficiency or diabetes and in patients receiving concurrent treatment with an ACE inhibitor (ACEI), NSAIDs, or potassium supplements.

Contraindications

Contraindications are the same as for the diuretic class. Additionally, aldosterone antagonists and potassium-sparing diuretics can cause hyperkalemia and hyponatremia and should be avoided in patients with serum potassium levels of more than 5 mEq/L.

Adverse Events

Side effects include gynecomastia, hirsutism, and menstrual irregularities.

Beta-Adrenergic Blockers

Mechanism of Action

Beta-1 receptors, located predominantly in the heart and kidney, regulate heart rate, renin release, and cardiac contractility (see Table 19.1). Beta-2 receptors, located in the lungs, liver, pancreas, and arteriolar smooth muscle, regulate bronchodilation and vasodilation. Beta-blockers reduce BP by blocking central and peripheral beta receptors, which results in decreased cardiac output and sympathetic outflow.

Despite several pharmacologic differences in the available beta-blockers, they are all effective in treating hypertension. Beta-blockers that mostly bind to beta-1 receptors are referred to as *cardioselective* because they do not significantly block beta-2 receptors. These agents include metoprolol tartrate (Lopressor), metoprolol succinate (Toprol-XL), atenolol (Tenormin), nebivolol (Bystolic), and bisoprolol (Zebeta) and may be safer than nonselective beta-blockers for patients with asthma, chronic obstructive pulmonary disease, and peripheral vascular disease. At higher doses, however, selective beta-blockers lose cardioselectivity and may aggravate a pre-existing condition.

Some beta-blockers possess intrinsic sympathomimetic activity (ISA); these agents are partial beta-receptor agonists that reduce heart rate and contractility during excessive sympathetic outflow. In resting states, heart rate and contractility are maintained. Typical medications include pindolol (Visken) and acebutolol (Sectral).

Studies suggest that beta-blockers may decrease sympathetic activity involved with the progression of heart failure (see Chapter 22, Heart Failure). For example, carvedilol (Coreg) and metoprolol succinate (Toprol-XL) decreased mortality rates in patients with heart failure and decreased ventricular remodeling (which results in LVH). Beta-blockers should be used only in patients with stable congestive heart failure and be temporarily discontinued if the patient has an acute decompensation. Practitioners should refer any patient with heart failure to a cardiologist for evaluation of therapy.

Patients should be cautioned not to discontinue therapy abruptly. The dose of beta-blockers should be tapered gradually over 14 days to prevent withdrawal symptoms, which include unstable angina, myocardial infarction (MI), or even death in patients with underlying cardiovascular disease. Patients without coronary artery disease may experience sinus tachycardia, palpations, increased sweating, and fatigue.

Contraindications

Beta-blockers should be avoided in patients who have sinus bradycardia, asthma (if needed, low-dose cardioselective beta-blockers are preferred), chronic obstructive pulmonary disease, second- or third-degree heart block, or overt cardiac failure. Non-ISA beta-blockers are the preferred agents for treating hypertension in patients with coexisting coronary artery disease and especially in patients after MI. Beta-blockers should be used cautiously, but not

avoided, in patients with resting ischemia or severe claudication secondary to peripheral vascular disease, reactive airway disease, systolic congestive heart failure, diabetes mellitus, or depression.

Adverse Events

The most common side effects of beta-blockers are fatigue, drowsiness, dizziness, bronchospasm, nausea, and vomiting. Serious side effects include bradycardia, atrioventricular (AV) conduction abnormalities, and the development of congestive heart failure. In diabetic patients beta-blockers can mask all of the symptoms of hypoglycemia (low blood sugar) with the exception of sweating.

ACE Inhibitors

Mechanism of Action

ACEIs such as captopril (Capoten), enalapril (Vasotec), and lisinopril (Zestril, Prinivil) exert an antihypertensive effect by the inhibiting ACE enzyme, which converts angiotensin I to angiotensin II, which is a potent vasoconstrictor (see Table 19.1). ACEIs also inhibit the degradation of bradykinin and increase the synthesis of vasodilating prostaglandins. ACEIs decrease morbidity and mortality rates in patients with congestive heart failure, post-MI, and systolic dysfunction.

Contraindications

ACEIs should be avoided in patients with bilateral renal artery stenosis or unilateral stenosis because of the risk of acute renal failure. They are not recommended to be used in combination with an angiotensin II receptor blocker (ARB) or a renin inhibitor due to all of these agents working on the RAAS system and increasing the incidence of side effects. They are also contraindicated in patients who have experienced angioedema and during pregnancy because of their teratogenic effects.

Adverse Events

The most common side effects associated with ACEIs include chronic dry cough, rashes (most common with captopril [Capoten]), and dizziness. Hyperkalemia can occur but is at a higher risk in patients with renal disease or diabetes. Angioedema is a rare but dangerous side effect that occurs most frequently in blacks; it is reversible on discontinuation of the agent. Laryngeal edema, another rare adverse effect, is life-threatening and requires immediate medical attention.

Angiotensin II Receptor Blockers

Mechanism of Action

ARBs block the vasoconstriction and aldosterone-secreting effects of angiotensin II by selectively blocking the binding of angiotensin II to the angiotensin II receptor found in many tissues (see Table 19.1). They are indicated for patients with hypertension, nephropathy in type 2 diabetes, and heart failure and those who cannot tolerate the side effects associated with ACEIs.

The results of the Losartan Intervention For Endpoint reduction in hypertension study (LIFE), from 2002, suggest that losartan is more effective than atenolol in reducing cardiovascular morbidity and mortality in diabetic patients with hypertension and left ventricular hypertrophy (Dahlöf et al., 2002). Available ARBs are losartan (Cozaar), valsartan (Diovan), candesartan (Atacand), telmisartan (Micardis), eprosartan (Teveten), olmesartan (Benicar), and irbesartan (Avapro). The incidence of cough and hyperkalemia associated with this class of drugs is lower than with ACEIs but still may occur.

Contraindications

Caution should be used in patients with renal and hepatic function impairment. Angioedema can also be seen with ARB therapy, but with much less frequency than with ACEIs. There should be some justification (heart failure or proteinuric nephropathy) for the use of ARBs in patients having experienced ACEI–related angioedema. Like ACEIs, ARBs are contraindicated in pregnancy. Combination with ACEI and/or renin inhibitors is not recommended.

Adverse Events

Adverse reactions include dizziness, upper respiratory tract infections, cough, viral infection, fatigue, diarrhea, pain, sinusitis, pharyngitis, and rhinitis. Angioedema is less likely; however, it can occur with these agents. There is some cross-reactivity between ACEIs and ARBs; therefore, if angioedema occurs in a patient on an ACEI, the risk is still present with an ARB.

Renin Inhibitors

Mechanism of Action

Renin inhibitors block the conversion of angiotensinogen to angiotensin I. Angiotensin I suppression decreases the formation of angiotensin II (see Table 19.1). Angiotensin II functions within the RAAS as a negative inhibitory feedback mediator within the renal parenchyma to supress the further release of renin. The reduction in angiotensin II levels suppresses this feedback loop, leading to further increased plasma renin concentrations and subsequent low plasma renin activity. The first effective oral direct renin inhibitor, aliskiren (Tekturna), was approved by the U.S. Food and Drug Administration in March 2007. Aliskiren lowers BP to a degree comparable to most other agents. There are no clinical trial data of aliskiren on outcomes in hypertension, diabetes, or CVD.

Contraindications

This drug is not recommended in combination with ACEI and ARB therapy due to similar mechanisms of action. This medication should be avoided during pregnancy secondary to directly acting on the renin–angiotensin system can cause fetal and neonatal morbidity.

Adverse Events

Significant adverse events include diarrhea and angioedema (rare).

Calcium Channel Blockers

Mechanism of action

Calcium channel blockers (CCBs) share the ability to inhibit the movement of calcium ions across the cell membrane (see Table 19.1). The effect on the cardiovascular system is muscle relaxation and vasodilation. Nondihydropyridines, such as verapamil (Calan) and diltiazem (Cardizem), decrease heart rate and slow cardiac conduction at the AV node. The dihydropyridines (amlodipine [Norvasc], felodipine [Plendil], nifedipine [Procardia XL], nicardipine [Cardene SR], nisoldipine [Sular], and isradipine [DynaCirc]) are potent vasodilators. CCBs are effective as monotherapy and are especially effective in black patients. CCBs are indicated for treating hypertension associated with ischemic heart disease. CCBs are similar in antihypertensive effectiveness but differ in other pharmacodynamic effects. In addition, for use in HTN, these agents are recommended specifically for Prinzmetal angina treatment.

Contraindications

First-generation CCBs such as verapamil and diltiazem may accelerate the progression of congestive heart failure in a patient with cardiac dysfunction; therefore, these agents are not first line.

Diltiazem and verapamil should also be avoided in patients with AV node dysfunction (second- or third-degree heart block) or left ventricular (systolic) dysfunction when the ejection fraction measures less than 45%. Short-acting nifedipine should not be used for treating essential hypertension or hypertensive emergencies because of its association with causing inconsistent fluctuations in BP and reflex tachycardia.

Adverse Events

The dihydropyridine agents (nifedipine, nicardipine, isradipine, felodipine, nisoldipine, and amlodipine) produce symptoms of vasodilation, such as headache, flushing, palpations, and peripheral edema. Other side effects of nifedipine include dizziness, gingival hyperplasia, mood changes, and various gastrointestinal (GI) complaints. Nifedipine may cause reflex tachycardia as a result of stimulating the baroreceptors in response to an acute drop in BP. Diltiazem and verapamil can cause GI upset, peripheral edema, and hypotension. Rare side effects include bradycardia, AV block, and congestive heart failure. Verapamil can cause constipation in the elderly.

Peripheral Alpha-1 Receptor Blockers

Mechanism of Action

Doxazosin (Cardura), prazosin (Minipress), and terazosin (Hytrin) are selective alpha-1 receptor blockers that are effective in patients with benign prostatic hypertrophy and not usually prescribed solely for HTN treatment (see Table 19.1). Peripheral alpha-1 receptor blockers act peripherally by dilating both arterioles and veins, causing relaxation of smooth muscle.

Contraindications

In the presence of cardiovascular disease, alpha-1 receptor blockers should be avoided, as the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) study, in 2003, showed that these patients had an increase in mortality (Papademetriou et al., 2003). The use of tadalafil (Cialis), sildenafil (Viagra), and vardenafil (Levitra) is not recommended to be taken concurrently with alpha-1 receptor blockers due to an increased risk of symptomatic hypotension. If both agents are prescribed, a washout window of at least 4 to 6 hours is recommended.

Adverse Events

The most common side effect associated with this class of antihypertensive medications is the first-dose phenomenon, which consists of dizziness or faintness, palpitations, or syncope. These agents should be administered initially at bedtime and the dosage should be adjusted slowly. With chronic administration, even at low doses, fluid and sodium accumulate, requiring concurrent diuretic therapy. Other side effects include vivid dreams and depression.

Central Alpha-2 Receptor Agonists

Mechanism of Action

Central alpha-2 agonists stimulate alpha-2 adrenergic receptors in the brain, resulting in decreased sympathetic outflow, cardiac output, and peripheral resistance (see Table 19.1). These agents may cause fluid retention, and in most cases, combination with a diuretic can be considered. Clonidine (Catapres), methyldopa (Aldomet), guanabenz (Wytensin), and guanfacine (Tenex) should not be used as initial monotherapy. Abrupt cessation of alpha-2 agonist therapy may result in a compensatory increase in the norepinephrine level, therefore increasing BP.

Contraindications

Central agonists should be used cautiously in patient with severe coronary insufficiency, conduction disturbances, recent MI, cerebrovascular disease, and renal failure. Abrupt cessation should be avoided.

Adverse Events

These agents may cause fluid retention, sedation, and dry mouth. Also, the first-dose effect of dizziness and syncope is possible.

Direct Vasodilators

Mechanism of Action

The direct vasodilators hydralazine (Apresoline) and minoxidil (Loniten) cause arteriolar smooth muscle relaxation, resulting in BP reduction (see Table 19.1). Direct vasodilators should be reserved for patients with essential or severe hypertension. Both hydralazine and minoxidil may cause fluid retention and reflex tachycardia, which can be treated with a concurrent diuretic and a beta-blocker or other agent (clonidine, diltiazem, or verapamil) that slows the heart rate.

Contraindications

Hydralazine should be used with caution in patients with coronary artery disease and mitral valvular rheumatic heart disease. Minoxidil is contraindicated in patients with pheochromocytoma, acute MI, and dissecting aortic aneurysm.

Adverse Events

Hydralazine is associated with a lupus-like syndrome that is dose related at dosages greater than 300 mg/d. Other adverse reactions include dermatitis, drug fever, and peripheral neuropathy. Minoxidil may cause a drug-induced hirsutism, which is unfavorable to most female patients.

Adrenergic Antagonists

Mechanism of Action

Reserpine (Serpasil), guanethidine (Ismelin), and guanadrel (Hylorel) inhibit the sympathetic system by depleting norepinephrine stores in the central nervous system (see Table 19.1). This results in a decrease in peripheral vascular resistance and a reduction in BP. In patients who use these agents, depression may result from decreased catecholamine and serotonin levels in the central nervous system.

Adverse Effects

Reserpine's use is limited because of its side effect profile, which includes depression, impotence, diarrhea, bradycardia, drowsiness, and nasal stuffiness. Guanadrel and guanethidine also produce numerous adverse effects, such as diarrhea, impotence, orthostatic hypotension, and syncope. They should be used with caution.

Selecting the Most Appropriate Agent

First-line therapy should be influenced by the age, ethnicity/race, and other conditions (diabetes, coronary disease, etc.). Long-acting drugs that need to be taken once daily are preferred to shorter acting drugs because this will reduce nonadherence. For this reason, when more than one drug is prescribed, combination products can simplify treatment. However, combination products can be more expensive.

According to the JNC 8 guidelines, for black patients with hypertension, with or without diabetes, CCB or thiazide diuretics are recommended. For all other ethnicities, according to JNC 8, HTN treatment options include ACEIs or ARB, thiazide diuretics, or CCB. Additionally, per the JNC 8 guidelines, all adult CKD patients regardless of having diabetes are recommended either an ACEI or an ARB for hypertension therapy. This is in contrast to JNC 7, which recommended using diuretics as monotherapy in preference of other antihypertensive agents.

If a diuretic is chosen, the longer acting and more potent agent chlorthalidone should be considered as first-line treatment given that it has the highest level of clinical trial evidence supporting its use. Recent data support that monotherapy with a β-blocker (in particular atenolol because of excess risks of strokes) or an α-blocker (caused by excess risks of CHF events by doxazosin in the ALLHAT study) should be discouraged because they are less effective than most other agents (Law et al., 2009), although β-blockers might be effective in the secondary prevention of ischemic heart disease and meta-analyses suggest that β-blockers are inferior in the prevention of strokes (Bangalore et al., 2007).

Studies have shown that isolated systolic hypertension (SBP greater than 160 mm Hg with DBP less than 90 mm Hg) is a potent risk factor for strokes and CVD. Among patients older than 50 years, SBP levels are more strongly related to CVD and renal disease than DBP. Treatment of isolated systolic hypertension leads to improved CVD outcomes regardless of achieved DBP. Although there have been long-standing concern and debate about the risks of the "J-curve," whereby excessive reductions in DBP may lead to increased risk for CHD events, the overall evidence supports that this effect is limited to high-risk patients with established CAD. Treatment-induced reduction in SBP to less than 140 mm Hg provides a greater overall event reduction and is offset by any adverse effect of excessive lowering of DBP (Mancia et al., 2013). Nevertheless, careful monitoring of certain individuals in this scenario is warranted, including those older than 80 years, patients with active angina worsened by BP lowering, and people with excessively low DBP (less than 65 mm Hg) or orthostatic hypotension.

Additionally, the Avoiding Cardiovascular events through Combination therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial demonstrated a significant 20% reduction in combined cardiovascular events in patients treated with a combination of an ACEI plus CCB (benazepril + amlodipine) compared with patients

treated with an ACEI plus a thiazide diuretic (benazepril + hydrochlorothiazide) (Jamerson et al., 2008). Furthermore, the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) study demonstrated that combined ACEI + ARB therapy did not prevent cardiovascular events more than monotherapy. In fact, it showed that renal outcomes were worsened by this combination and higher risk of adverse events (Yusuf et al., 2008).

If the patient is not at goal, the ACC/AHA/CDC recommends that physicians increase the dose of the medications and/or add a drug from a different class. Similarly, JNC 8 states if the target BP is not reached within one month after initiating pharmacologic therapy, the dose of the initial medication should be increased or a second medication should be added. If the BP goal is not reached using two drugs, it is recommended adding a third drug. Should the patient still not be at goal, physicians should question patient adherence, request readings from home, or consider secondary causes of hypertension. A hypertension specialist should be considered if the patient still fails to get to goal, after being on multiple medications, since the patient may have resistant hypertension.

For select individuals, it was concluded that some alternative treatments, notably resistance and isometric exercise, device-guided slow breathing, and certain meditation techniques, can serve as effective and helpful adjuvants to lower BP. Whether or not patients are able to adhere to these nonpharmacologic lifestyle treatments to control BP over several years remains uncertain.

Special Population Considerations

Pediatric Patient Population

The current JNC 8 guidelines address adult BP goals not pediatric BP goals. Instead, hypertension diagnosis and treatment of hypertension is managed by the fourth report from the National High Blood Pressure Education Working Group for Hypertension Management Children and Adolescents. This guideline highlights diagnosis based on the child's age and goal ranges of the SBP and/or DBP falls into percentiles. Treatment regimens are recommended to be individualized and starting doses of antihypertensive agents between adults and children are not equivalent.

Geriatric Patient Population

The Trial of Nonpharmacological Interventions in the Elderly (TONE) showed that in older patients with hypertension, BP can be reduced by low-sodium diets and weight loss. In some instances, patients could discontinue their antihypertensive medications or reduce the number of medications required to remain normotensive (Sander, 2002).

Elderly patients are very sensitive to medications that cause sympathetic inhibition and are at greater risk of becoming volume depleted than their younger patients. Decreased renal and hepatic function complicates hypertension treatment and increases the risk of adverse events in this population. Antihypertensive medications should be started at low doses and titrated slowly. If choosing to use beta-blockers in the elderly, it is prudent to use the newer beta-blockers such as nebivolol and carvedilol as they may provide a better safety profile and better morbidity and mortality outcome (Kaiser et al., 2014). According to the SHEP trial, patients with isolated systolic hypertension should start hypertensive therapy with a diuretic due to decrease in stroke incidence unless there is a compelling reason to avoid its use. The long-acting dihydropyridine CCBs are also effective and are an alternative in these patients. Clinical trials have demonstrated that in older patients with isolated systolic hypertension, low diastolic BP was associated with a higher mortality rate for any given level of systolic BP. Postural hypotension should also be closely monitored in this population.

Women Patient Population

There are no significant differences in BP response between genders. Women taking oral contraceptives may have an increase in BP, and the risk of hypertension may increase with the duration of oral contraceptive use. If hypertension develops as a result of oral contraceptive use, an alternate contraception method should be used. Because of the risk of stroke associated with oral contraceptive use and cigarette smoking, women taking oral contraceptives should be encouraged not to smoke cigarettes, and women older than age 35 should not take oral contraceptives if they continue to smoke.

Women diagnosed with hypertension before pregnancy should continue taking antihypertensive agents throughout pregnancy. Few are safe for use, however, during pregnancy. ACEIs, rennin inhibitors, and ARBs should be avoided during pregnancy because they are teratogenic. Beta-blockers should also be avoided during early pregnancy because of the risk of fetal growth retardation. Methyldopa is recommended for women who are diagnosed with hypertension during pregnancy. Consultation with a woman's OB-GYN specialty practitioner regarding an antihypertensive recommendation should occur in all cases.

Black Patient Population

The incidence of hypertension and hypertension-related complications is believed to be higher in blacks than in any ethnic group. Some blacks experience hypertension before age 10, which was attributed to two major risk factors: obesity and inactivity. Other risk factors include a diet high in sodium and low in potassium. This has resulted in the greatest incidence of stroke, end-stage renal disease, cardiovascular disease, and death in this population. Blacks who are diagnosed and treated have a lower incidence of complications.

Blacks have physiologic characteristics that contribute to this risk, including low circulating renin levels with excessive levels of angiotensin II, endothelial dysfunction as a result of reduced bradykinin and nitric oxide, abnormal sympathetic nervous system activation, and higher levels of intracellular calcium stores. Blacks are more responsive to monotherapy with diuretics. Results from the ALLHAT found that chlorthalidone and amlodipine were superior to ACEIs in treating blacks (Papademetriou et al., 2003). Alpha-blockers should not be used as initial monotherapy per the conclusions of this trial (Papademetriou et al., 2003). ACEIs may induce angioedema, which occurs two to four times more frequently in blacks.

Diabetic Patient Population

The coexistence of hypertension and diabetes mellitus is very common. Hypertension increases cardiovascular risks in diabetic patients. Current guidelines recommend lowering BP to less than 140/90. This is a consensus among the following guidelines: the American Heart Association/American College of Cardiology, the American Society of Hypertension/International Society of Hypertension, the American Diabetes Association (ADA) 2015 standards of care guidelines, and the Eighth Joint National Committee. The American Diabetes Association, 2015 standard of care guidelines recommend that hypertensive diabetic patients be treated if they have a DBP greater than 80 or an SBP greater than 140 with a target BP of less than 140/80.

All patients should be encouraged to modify their lifestyle, to limit sodium intake, lose weight, and exercise for 150 minutes/week. All major antihypertensive drug classes, RAAS blockers, beta blockers, diuretics, and calcium blockers are useful in diabetic patients. ACEI and ARBs are considered the cornerstone of therapy. Studies have shown these classes to be

beneficial in reducing overall cardiovascular risk, nephropathy, renal failure, and retinopathy. Combination therapy consisting of two RAAS blockers or the use of ACEI and an ARB in combination is not recommended because of the risk of causing renal impairment, hypotension, and hyperkalemia.

Hypertensive Emergency/Hypertensive Urgency

Hypertensive crisis or malignant hypertension is defined as an extremely high SBP and/or DBP according to JNC 7. Hypertensive emergency was not addressed by JNC 8 guidelines. Hypertensive crisis is further divided into two categories based upon evidence of target organ damage. If end organ damage is present, the condition is classified as hypertensive emergency. Hypertensive crisis without evidence of organ damage is classified as hypertensive urgency. In hypertensive emergencies, the therapeutic goal is to protect remaining end organ function, reduce risk of complications, and improve outcomes. BP reduction should be made in a controlled fashion and not aimed at normalizing the BP quickly as this can exacerbate target organ damage. The BP itself may not be as important as the rate of elevation. Patients with a chronic history of hypertension can tolerate high levels than that of a normotensive patient. Hypertensive urgencies are severe elevation of BP with no target organ dysfunction. A majority of these patients present as a result of noncompliance or inadequate treatment.

In hypertensive emergencies, presenting symptoms may include chest pain, dyspnea, and neurologic deficits. The physical examination must include serial BP measurements in both arms, lung and heart auscultation, renal artery auscultation, neurologic evaluation, and funduscopic evaluation. Imaging studies should be obtained if the patient presents with chest or back pain and unequal pulses in the upper extremities. Electrocardiogram and cardiac enzymes are part of the initial workup for shortness of breath or chest pain and echocardiogram is useful if heart failure is suspected.

Immediate treatment with an intravenous antihypertensive agent(s) is needed to salvage viable tissue. The marked elevation in BP results in arteriolar fibrinoid necrosis, endothelial damage, platelet and fibrin deposition in the media of smooth muscle, and loss of autoregulatory function. This results in end organ ischemia such as encephalopathy, MI, unstable angina, pulmonary edema, eclampsia, stroke, intracranial hemorrhage, life-threatening arterial bleeding, or aortic dissection. These patients require hospitalization and parenteral drug therapy.

The drug of choice to treat hypertensive emergencies depends on the clinical situation. BP control can be achieved over several hours (24 to 48 hours) with either IV or oral medications depending on the urgency of the situation. Commonly used medications include direct vasodilators (hydralazine), nitrates (sodium nitroprusside, nitroglycerin), CCBs (nicardipine, clevidipine), sympathoplegic agents (labetalol, esmolol), alpha-I blockers (phentolamine), and ACEIs (enalaprilat). After the BP is lowered, the patient's drug regimen should be assessed to determine possible causes of the hypertensive emergency/urgency such as medication nonadherence, adverse effects that interfere with the patient's lifestyle, and/or a complex medication regimen that could be simplified.

Monitoring Patient Response

Follow-Up and Monitoring

BP should be measured at every routine visit. The patients' efforts and lifestyle modifications should be discussed at each visit. Referral to a hypertension specialist may be indicated if the BP goal is not achieved despite several medications, if resistant hypertension is suspected, or if clinical consultation is needed for the more complicated patients. Serum creatinine and potassium levels should be monitored once or twice a year in patients taking antihypertensive medications once the levels have proven to be stable. When initially adding medication or increasing doses of drugs that have electrolyte abnormalities as an adverse effect, frequent monitoring is warranted.

The importance of adhering to the drug regimen cannot be overemphasized. The practitioner needs to be alert for signs of nonadherence and should ask patients about their experiences or problems with adhering to the drug regimen. Side effects should be discussed, and changes in medications may or may not be considered at each visit.

Patient Education

Patient education is a vital part of hypertension treatment. Because most patients are free of symptoms, they must be educated about the disease, the importance of adhering to therapy, and the consequences of uncontrolled hypertension. Patient education booklets are available from most well-known organizations such as the AHA, which may be used to reinforce the information provided by the practitioner.

Because each antihypertensive medication has some side effects, the patient needs to be informed about what they are, what actions to take to relieve minor side effects, and what to do about intolerable or dangerous side effects. Adherence to hypertensive medication regimen should be assessed at each office encounter. Since the objective of drug therapy is to lower BP without intolerable effects, the patient needs to know which adverse reactions should be reported to the practitioner and which ones may be relieved by switching to an alternative drug in a different class. The patient also needs to know that several different agents may be tried before finding the one that best controls his or her BP with minimal or no side effects. Other important teaching involves information about lifestyle changes and the consequences of uncontrolled hypertension.

Nutrition/Lifestyle Changes

As described above, it is important to remind hypertensive patients about the key role of a lifestyle effects on BP. Patients should follow a healthy diet, restrict sodium, and quit smoking (if applicable) and alcohol consumption. Patients should also be reminded to maintain a healthy weight and get regular exercise for better control of BP.

Complementary and Alternative Medications

To date, there is no evidence that alternative medications reduce BP.

Conclusion

As you can see, hypertension is a complex chronic disease in terms of both pathophysiology and treatment. Successful treatment of high pressure can help prevent several negative outcomes.

Case Study*

R.S., a 65-year-old black man, was referred to the hypertension clinic for evaluation of high BP noted on an initial screening. He reports having headaches and nocturia. He states that he has gained 8 pounds over the last year.

- Past medical history
  - Appendectomy 30 years ago
  - Peptic ulcer disease 10 years ago
  - Type 2 diabetes mellitus for 10 years
  - Gout
- Family history
  - Father had hypertension; died of myocardial infarction at age 55
  - Mother had diabetes mellitus and hypertension; died of cerebrovascular accident at age 60
- Physical examination
  - Height 69 in, weight 90 kg
  - BP: 140/89 mm Hg (left arm), 138/82 mm Hg (right arm)
  - Pulse: 84 beats/minute, regular
  - Funduscopic examination: mild arterial narrowing, sharp discs, no exudates or hemorrhages
- Laboratory findings
  - Blood urea nitrogen: 24 mg/dL
  - Serum creatinine: 1.1 mg/dL
  - Glucose: 95 mg/dL
  - Potassium: 4.0 mEq/L
  - Total cholesterol: 201 mg/dL
  - High-density lipoprotein cholesterol: 30 mg/dL
  - Triglycerides: 167 mg/dL
  - Urinalysis: within normal limit (no proteinuria)
  - Electrocardiogram and chest radiograph: mild left ventricular hypertrophy
- Social history
  - Tobacco: 35 pack years
  - Alcohol: 1 pint of vodka/week

Coffee: 2 cups/day

Diagnosis: Stage 1 hypertension

1. List specific goals for treating R.S.'s hypertension.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for R.S.?
8. What lifestyle changes would you recommend to R.S.?
9. Describe one or two drug–drug or drug–food interaction for the selected agent.*

*Answers can be found online.

20 Hyperlipidemia

John Barron ■ Vincent J. Willey

Hyperlipidemia is a blood disorder characterized by elevations in blood cholesterol levels. The term is often used synonymously with *dyslipidemia* and *hypercholesterolemia*. Hyperlipidemia is one of the major contributing risk factors in the development of coronary heart disease (CHD). It is estimated that approximately 15.5 million people in the United States have CHD, with approximately 375,000 deaths each year (American Heart Association, 2015). In addition, approximately $215 billion is spent each year on direct and indirect costs from CHD.

Informed estimates indicate that approximately greater than 100 million adults aged 20 and older had total cholesterol levels above 200 mg/dL using data from 2009 to 2012, representing approximately 47% of adults in the United States (American Heart Association, 2015). However, data from the National Health and Nutrition Examination Survey (NHANES) suggest that the percentage of patients with elevated cholesterol may be decreasing.

Numerous large studies have shown that reducing elevated cholesterol levels reduces morbidity and mortality rates in patients with and without existing CHD (Downs et al., 1998; Frick et al., 1987; Heart Protection Study Collaborative Group, 2002; Lewis et al., 1998; Long-Term Intervention With Pravastatin in Ischaemic Disease [LIPID] Study Group, 1998; Ridker et al., 2008; Scandinavian Simvastatin Survival Study Group, 1994; Shepherd et al., 1995). Although these and other trials have clearly shown the benefits of treating high cholesterol levels and other preventive measures, including the use of aspirin, beta-blockers, and angiotensin-converting enzyme inhibitors in the treatment of patients with coronary artery disease, long-term use of these medications across the population is still suboptimal (Newby et al., 2006).

Causes

In hyperlipidemia, serum cholesterol levels may be elevated as a result of an increased level of any of the lipoproteins. (See the section on Pathophysiology: Lipoproteins and Lipid Metabolism.) The mechanisms for hyperlipidemia appear to be genetic (primary) and environmental (secondary). In fact, the most common cause of hyperlipidemia (95% of all those with hyperlipidemia) is a combination of genetic and environmental factors.

Some individuals are genetically predisposed to elevated cholesterol levels. They may inherit defective genes that lead to abnormalities in the synthesis or breakdown of cholesterol. These may include abnormalities in low-density lipoprotein (LDL) receptors and mutations in apolipoproteins that lead to increased production of cholesterol or decreased clearance of cholesterol from the bloodstream. (See the section on Pathophysiology: Lipoproteins and Lipid Metabolism.)

Secondary factors may include medications (e.g., beta-blockers and oral contraceptives), concomitant disease states or other conditions (e.g., diabetes mellitus and pregnancy), diets high in fat and cholesterol, lack of exercise, obesity, and smoking (Box 20.1).

BOX 20.1 Secondary Causes of Hyperlipidemia

- Disease States
- Acute hepatitis
- Diabetes mellitus
- Hypothyroidism
- Nephrotic syndrome
- Primary biliary cirrhosis
- Systemic lupus erythematosus
- Uremia

- Drugs
- Alcohol
- Beta-blockers
- Glucocorticoids
- Oral contraceptives
- Progestins
- Thiazide diuretics

Pathophysiology

The major plasma lipids are cholesterol, triglycerides, and phospholipids. Cholesterol is a naturally occurring substance that is required by the body to synthesize bile acids and steroid hormones and to maintain the integrity of cell membranes. Although cholesterol is found predominantly in the cells, approximately 7% circulates in the serum. It is this serum cholesterol that is implicated in atherosclerosis. Triglycerides are made up of free fatty acids and glycerol and serve as an important source of stored energy. Phospholipids are essential for cell function and lipid transport. Because these lipids are insoluble in plasma, they are surrounded by special fat-carrying proteins, called *lipoproteins*, for transport in the blood.

Lipoproteins are produced in the liver and intestines, but endogenous production of lipoproteins occurs primarily in the liver. Lipoproteins consist of a hydrophobic (water-insoluble) inner core made of cholesterol and triglycerides and a hydrophilic (water-soluble) outer surface composed of apolipoproteins and phospholipids. Apolipoproteins are specialized proteins that identify specific receptors to which the lipoprotein will bind. They are thought to play a role in the development or prevention of hyperlipidemia because they control the interaction and metabolism of the lipoproteins.

Lipoproteins and Lipid Metabolism

The major lipoproteins are named according to their density. They include chylomicrons, very–low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), LDLs, and high-density lipoproteins (HDLs).

Chylomicrons

Chylomicrons, the largest lipoproteins, are composed primarily of triglycerides. Chylomicrons are produced in the gut from dietary fat and cholesterol that has been solubilized by bile acids (exogenous pathway). Chylomicrons normally are not present in the blood after a 12- to 14-hour fast.

Very–Low-Density Lipoproteins

VLDLs are primarily composed of cholesterol and triglycerides and are the major carrier of endogenous triglycerides. On secretion into the bloodstream, lipoprotein lipase and hepatic lipase hydrolyze the triglyceride core by a mechanism similar to that which occurs with chylomicrons. As the triglyceride content decreases, the lipoprotein becomes progressively smaller with a higher percentage of cholesterol; it is now referred to as an IDL. IDL is a short-lived lipoprotein that is converted to LDL or is taken up by LDL receptors on the liver. LDL, the final product of the metabolism of VLDL, contains the most cholesterol by weight of all the lipoproteins. It is estimated that 60% to 75% of the total cholesterol is contained in LDLs (Talbert, 1997).

Approximately 50% of LDL is taken up by the liver, and the remaining 50% is taken up by peripheral cells. Increased levels of LDL cholesterol are directly related to the probability that atherosclerosis will develop. Thus, LDL cholesterol is usually referred to as "bad" cholesterol.

High-Density Lipoproteins

HDL particles are produced in the liver and intestine. The primary function of HDL cholesterol is to remove LDL cholesterol from the peripheral cells and to remove triglycerides that result from the degradation of chylomicrons and VLDL particles. The HDL then transports these particles to the liver for metabolism. This process is termed *reverse cholesterol transport*. For this reason, HDL is often referred to as "good" cholesterol.

Pathogenesis of Atherosclerosis

Atherosclerosis is characterized by the development of lesions resulting from accumulations of cholesterol in the blood vessel wall. Atherosclerosis primarily affects the larger arteries, including the coronary arteries.

The atherogenic process begins with the accumulation of LDL cholesterol under the endothelial lining of the innermost arterial layer, the intima. As LDLs accumulate, circulating monocytes attach to the endothelial lining and penetrate between the endothelial cells into the subendothelial space. On entry into the subendothelial space, the monocytes form into macrophages, which then ingest the LDLs. Macrophages, in particular, have a high affinity for modified (oxidized) LDL. As the macrophages ingest the modified LDL, they are converted into foam cells and form the *fatty streak*, which is the initial lesion in the atherogenic process. These lesions commonly affect the coronary arteries. Formation begins in the midteens, and the lesions grow as the person ages.

Once the fatty streak forms, the oxidized LDL and macrophages act in other ways that promote the progression of the atherogenic lesion. Oxidized LDL appears to act as a chemotactic agent, recruiting other circulating monocytes and preventing macrophages from leaving the subendothelial space. Macrophages also produce chemotactic factors as well as growth factors. The growth factors cause proliferation of smooth muscle cells from the media into the fatty streak, leading to the formation of a fibrous plaque (Ross & Glomset, 1976). Fibrous plaques are usually raised and protrude into the lumen of the artery, thereby compromising blood flow.

As the foam cells grow, the endothelium stretches and may become damaged. This leads to platelet aggregation and clot formation. In many instances, these fissures heal and incorporate the thrombi inside the plaque. This process may occur dozens of times and eventually may produce a complicated lesion. The formation of complicated lesions is the major cause of acute cardiovascular (CV) events. However, in some instances, rupture of a small, unstable plaque may also cause the formation of a single large clot that totally occludes the vessel. The fibrous plaques that are most likely to rupture are those that have large lipid cores and a thin fibrous cap, a layer of smooth muscle cells directly over the lipid core. Large plaques with a strong fibrous cap may be more stable and less likely to rupture (Cooke & Bhatnagar, 1997; McKenney & Hawkins, 1995).

The primary symptom associated with atherosclerosis is chest pain known as *angina*. Symptoms occur when the lesion compromises blood flow in the vessel lumen. A lesion that occludes approximately 50% of the lumen usually causes symptoms when more blood flow is required (i.e., exercise-induced angina). As the lesions grow and occlude more than 70% of the vessel, anginal symptoms may occur even when the person is resting (Cooke & Bhatnagar, 1997).

Risk Assessment

In 2013, the American College of Cardiology and the American Heart Association released guidelines on the assessment of CV risk (2013 ACC/AHA CV risk guidelines). While these guidelines encompass more than just assessment based on lipid levels, lipids are still an important part of the overall CV risk assessment for a patient. The workgroup echoed a well-established but important framework that the intensity of an intervention should be proportional to the individual's absolute risk for having a future atherosclerotic cardiovascular disease (ASCVD) event (Box 20.2). Health care practitioners can then utilize this framework by assessing a patient's ASCVD risk, discussing benefits and risks associated with potential therapies, and reviewing the patient's goals and preferences for treatment.

The 2013 ACC/AHA CV risk guidelines recommend assessment of traditional ASCVD risk factors in patients age 20 to 79 without a history of CVD every 4 to 6 years. In addition to lipid levels, these traditional risk factors include age, gender, systolic blood pressure, antihypertensive therapy use, presence of diabetes, and smoking status. While for the estimation of 10-year risk for ASCVD only total and HDL cholesterol levels are required, a full lipid panel, which also contains LDL cholesterol and triglycerides, should be obtained to fully evaluate a patient's ASCVD risk. A past medical history should also be obtained to determine if the patient has already had an ASCVD event such as an MI or thromboembolic stroke. Those patients with a past medical history of ASCVD, labeled as secondary prevention patients, are at a higher risk for a future ASCVD event than are those without a history of ASCVD, labeled as primary prevention.

To quantify the ASCVD risk in a primary prevention patient, the 2013 ACC/AHA CV risk guidelines recommend the use of the Pooled Cohort Equations that are race and gender specific. This risk assessment tool estimates the 10-year ASCVD risk for patients 40 to 79 years of age and the lifetime ASCVD risk for patients 20 to 59 years of age. The Pooled Cohort Equations are based off of multiple studies beyond the original Framingham study and were hoped to be an improvement on the Framingham risk calculator because the equations were developed in a broader population, including African Americans, and a fuller definition of ASCVD was utilized (CHD death, nonfatal MI, and fatal/nonfatal stroke). Patients with a 10-year ASCVD risk ≥7.5% are considered at elevated risk for a future ASCVD event. Some individuals have criticized the accuracy of the results the Pooled Cohort Equations generate for some patients and the use of a cut point for elevated risk of ≥7.5%. In order to potentially improve the ASCVD risk assessment in patients with borderline risk based on the traditional risk factors and to help inform treatment decisions, the 2013 ACC/AHA CV risk guidelines also addressed the use of several novel risk markers. Although the workgroup responsible for the development of these guidelines reviewed multiple novel risk markers, they identified the following four that were considered to show promise for clinical utility: family history of CVD, high-sensitivity C-

reactive protein (hs-CRP), coronary artery calcium (CAC) score, and ankle–brachial index (ABI). hs-CRP is a marker for inflammation, and levels ≥2 mg/L have been associated with an increased risk of ASCVD.

TABLE 20.1 Four Major Statin Benefit Groups

Statin Benefit Group	Statin Dose Intensity
1. Have clinical ASCVD	High intensity ages ≤75 Moderate intensity >75 y
2. No ASCVD but have LDL-C values ≥190 mg/dL	High intensity unless contraindicated or unable to tolerate
3. No ASCVD and 40–75 y old with type 1 or type 2 diabetes mellitus and have LDL-C values of 70–189 mg/dL	Moderate-intensity statin if 10-year ASCVD risk is <7.5% High-intensity statin if 10-year ASCVD risk is ≥7.5%
4. No ASCVD or diabetes mellitus and are 40–75 y old with LDL-C values of 70–189 mg/dL and have a 10-year risk of ASCVD of ≥7.5%	Moderate-intensity statin if 10-year ASCVD risk is ≥7.5%.

Lifestyle Modification

In 2013, the American College of Cardiology and the American Heart Association also released guidelines on lifestyle management to reduce CV risk (2013 ACC/AHA lifestyle guidelines). These guidelines focused primarily on dietary therapy, exercise, weight loss, moderation of alcohol intake, and smoking cessation.

Diet

The guidelines recommend a diet that is high in fruits, vegetables, whole grains, low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts. It also recommends limiting sweets, sugar-sweetened beverages, and red meats. Individuals should try to limit caloric intake of saturated fat to no more that 5% to 6% of total calories. Additionally, it is recommended to limit intake of trans fats. Diets that are recommended include the Dietary Approaches to Stop Hypertension (DASH) dietary pattern, the USDA Food Pattern, or the AHA Diet.

In addition, overweight patients should attempt to lose weight. The ability to lose weight depends on the amount of calories consumed and the amount of calories burned. The goal for overweight patients should be a realistic, gradual, and steady loss of weight. Once an ideal weight is achieved, caloric intake is adjusted to maintain that weight.

Exercise

Regular physical exercise may provide several benefits in patients with hyperlipidemia.

The guidelines encourage individuals to participate in aerobic physical activity three to four times a week, with each session averaging about 40 minutes. As mentioned, it should be used along with dietary therapy to promote weight loss. Exercise may benefit the lipid profile by reducing triglycerides and raising HDL levels. Exercise may also improve control of diabetes and coronary blood flow.

Moderation of Alcohol Intake and Smoking Cessation

Excessive alcohol intake may elevate serum lipid levels, specifically triglyceride levels, but in moderation (no more than one drink per day for women and two drinks per day for men), alcohol may improve HDL levels and has been associated with lower ASCVD rates (Brien et al., 2011). Despite these benefits, alcohol should not be recommended for ASCVD prevention because the consequences associated with excessive alcohol use outweigh any benefits.

Cigarette smoking is an independent risk factor in the development of ASCVD (Huxley & Woodward, 2011). Although smoking minimally affects cholesterol levels, it contributes to the development of ASCVD by damaging the vascular endothelium and promoting platelet aggregation, which results in increased risk of clot formation. Smoking

cessation can reduce this risk and should be encouraged by all health care professionals. The risk of developing ASCVD decreases by approximately 50% within 1 to 2 years of smoking cessation.

Initiating Drug Therapy

The 2013 ACC/AHA treatment guidelines recommend use of HMG-CoA reductase inhibitors (statins) for ASCVD prevention in four groups of patients, termed "statin benefit groups." The statin benefit groups include individuals who are (1) ≥21 years of age and have clinical ASCVD or (2) do not have ASCVD but have LDL-C values ≥190 mg/dL or (3) are 40 to 75 years old with type 1 or type 2 diabetes mellitus and have LDL-C values of 70 to 189 mg/dL, or (4) are 40 to 75 years old with LDL-C values of 70 to 189 mg/dL and have a 10-year risk of ASCVD of ≥7.5% (Table 20.1).

BOX 20.2 Atherosclerotic Vascular Disease (ASCVD)

Coronary Heart Disease (CHD)
Myocardial infarction
Significant myocardial ischemia (angina pectoris)
History of coronary artery bypass graft
History of coronary angioplasty
Angiographic evidence of lesions
Peripheral Vascular Disease
Claudication
Carotid Artery Disease
Thrombotic stroke
Transient ischemic attack

The recommended statin and dose to use are based upon the expected reduction in LDL-C levels. High-intensity statins are those that can lower LDL-C by 50% or more, on average. Moderate-intensity statins reduce LDL-C by about 30% to 49%, and low-intensity statins typically reduce LDL-C by less than 30%. Specific medications and doses for each category are listed in Table 20.2.

TABLE 20.2 Statin Dose Intensity (Daily Dose)

Generic Name (Trade Name)	High Intensity	Moderate Intensity	Low Intensity
atorvastatin (Lipitor)	40–80 mg	10–20 mg	NA
rosuvastatin (Crestor)	20–40 mg	5–10 mg	NA
simvastatin (Zocor)	NA	20–40 mg	10 mg
lovastatin (Mevacor)	NA	40 mg	20 mg
pravastatin (Pravachol)	NA	40–80 mg	10–20 mg
fluvastatin (Lescol)	NA	80 mg	20–40 mg
pitavastatin (Livalo)	NA	2–4 mg	1 mg

In individuals with clinical ASCVD, a high-intensity statin is recommended in those ≤75 years of age, unless contraindicated (known hypersensitivity, active liver disease, women who are pregnant or may become pregnant, or nursing mothers) or unable to tolerate dose, in which a moderate-intensity statin should be used. For individuals with ASCVD who are greater than 75 years of age, a moderate-dose statin is recommended.

Individuals who do not have ASCVD but whose LDL-C is ≥190 mg/dL should receive high-intensity statin, unless contraindicated or unable to tolerate high-intensity statin.

A moderate-intensity statin is recommended for individuals aged 40 to 75 years old who have diabetes mellitus and have LDL-C between 70 and 189 mg/dL. High-intensity statin is recommended for patients meeting these criteria whose 10-year ASCVD risk is ≥7.5%. For diabetic patients aged less than 40 or greater than 75 years old, it is recommended to evaluate 10-year ASCVD risk to determine whether or not statin therapy should be considered.

For patients aged 40 to 75 years old without ASCVD, without diabetes mellitus, and whose LDL-C is between 70 and 189 mg/dL, treatment with a moderate-intensity statin is indicated when 10-year ASCVD risk is ≥7.5%.

Goals of Statin Therapy and Monitoring

The 2013 guidelines do not provide a specific recommendation on target cholesterol levels. However, they do recommend obtaining a fasting lipid panel within 1 to 3 months after initiating treatment for the purpose of evaluating medication adherence. For individuals whose response is less than expected, providers should assess reasons for nonadherence, including intolerance to the statin. Inadequate response would include an LDL-C reduction of less than 50% for those on high-intensity statin, and less than 30% LDL-C reduction in those on moderate-intensity statin. If intolerance to the statin is not an issue, providers should reinforce the need for adherence. For individuals who do have the expected response, they should be monitored every 3 to 12 months for continued assessment. If response continues to be lower than expected, then consider adding a nonstatin medication. Decreasing the statin dose could also be recommended in patients whose LDL-C decreases to less than 40 mg/dL.

Statin Intolerance

The statins are well tolerated by most patients and long-term therapy does not appear to have any serious risks. The most common complaint with statin use is muscle-related symptoms, including pain, tenderness, weakness, and fatigue. These symptoms combined with a creatine phosphokinase (CPK) level 10 times above the upper normal limits are consistent with a diagnosis of myopathy. If severe symptoms occur, the patient should be evaluated for rhabdomyolysis, a severe breakdown of muscle cells that leak into the urine and can result in renal failure. If suspected, the statin should be discontinued and should have creatinine kinase, serum creatinine, and urinalysis performed.

If individuals develop mild to moderate muscle-related symptoms, it is reasonable to discontinue the statin and see if the symptoms resolve. If symptoms resolve after discontinuation, and patient has no other contraindications, it is recommended to restart the same statin at a lower dose or start a different statin at a lower intensity dose. If patient is able to tolerate the lower dose statin, the dose can gradually be increased to recommended dose as tolerated. Individuals who are unable to achieve recommended statin dose or tolerate statins all together should consider use of nonstatin medications.

HMG-CoA Reductase Inhibitors (Statins)

Statins primarily block the conversion of HMG-CoA to mevalonate, which is the rate-limiting step in the production of cholesterol in the liver. Blocking the production of cholesterol in the liver leads to an increase in the number of LDL cholesterol receptors on the liver. As a result, a larger amount of LDL cholesterol is taken up by the liver, thereby decreasing the amount of LDL cholesterol in the bloodstream (Figure 20.1).

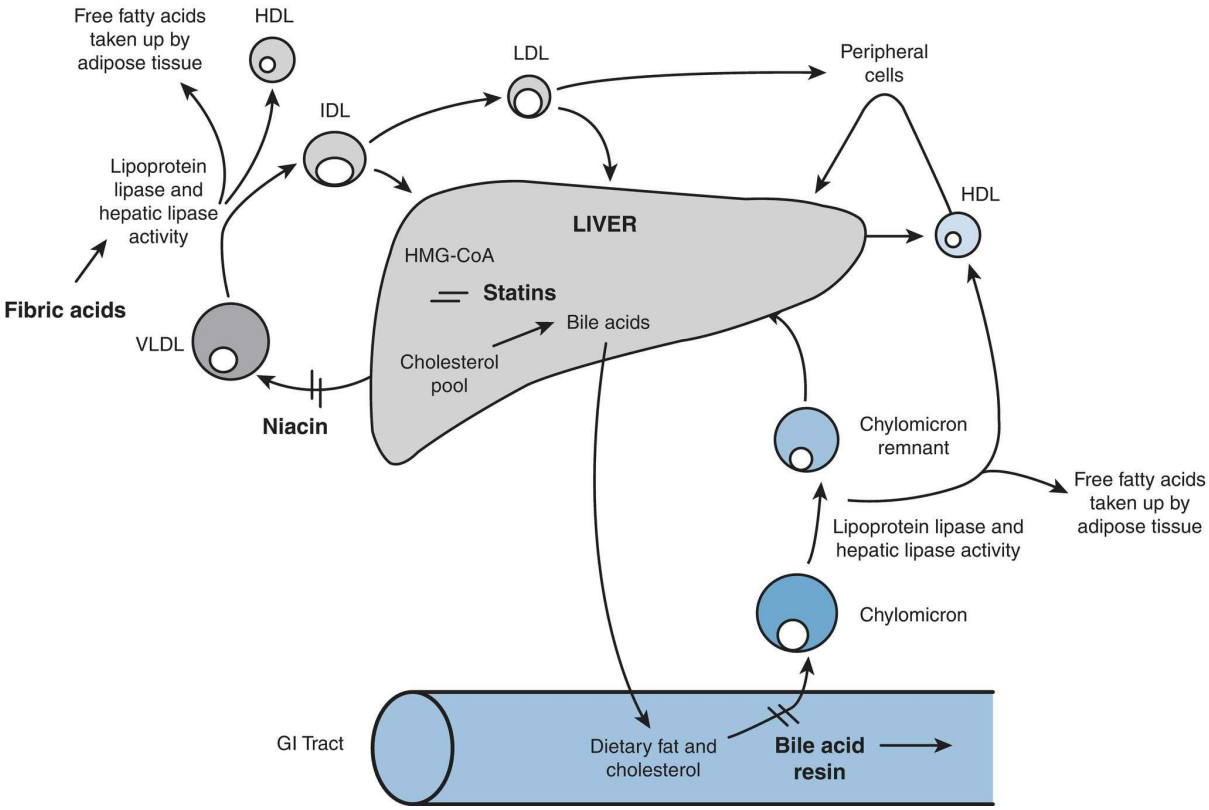

FIGURE 20.1 How lipid-lowering drugs work. The statins work in the liver by blocking the conversion of HMG-CoA to mevalonate, which is involved in producing cholesterol. The bile acid resins bind bile acid in the intestines for excretion in the feces so that lipids are not absorbed by the intestinal tract and returned to the liver. Niacin works to decrease circulating triglyceride and LDL cholesterol and fibric acid derivatives appear to lower triglyceride levels and stimulate lipoprotein lipase, which enhances the breakdown of VLDL to LDL cholesterol.

LDL receptors are also involved with the uptake of VLDL and IDL, thus leading to a decrease in triglyceride levels. In addition, modest increases in HDL tend to occur. Despite having the same mechanism of action, there are differences between the agents, including the magnitude of their cholesterol lowering (Table 20.2). For example, fluvastatin (Lescol) can lower LDL cholesterol levels up to approximately 36% with the maximum dose, whereas atorvastatin (Lipitor) and rosuvastatin (Crestor) can lower LDL cholesterol levels up to 60% at maximum doses.

Maximum effects usually are seen after 4 to 6 weeks of therapy. For this reason, dosage adjustments should not be made more frequently than every 4 weeks.

Contraindications

There are several instances when statins are contraindicated or should be used with caution. Although no studies have been conducted in pregnant women, lovastatin causes skeletal malformations in rats, so statins are contraindicated during pregnancy. These agents should

be used with extreme caution in women who are breast-feeding because they may be excreted in breast milk.

Statins are also contraindicated in patients with active liver disease or with unexplained elevated aminotransferase levels. They should be used with caution in patients who consume large amounts of alcohol or have a history of liver disease.

Adverse Events

The statins are well tolerated by most patients and long-term therapy does not appear to have any serious risks, although statin intolerance is still an important issue. As mentioned previously, the most common cause of statin intolerance is due to myopathies. Gastrointestinal (GI) complaints and headache are typically among the most commonly reported adverse events, but they are usually mild and transient. Asymptomatic elevations in liver function test (LFT) values may also occur. Traditionally, LFTs were recommended to be monitored at baseline (before starting therapy), at 6 and 12 weeks after starting or titrating therapy, and periodically thereafter. However, after decades of use and data from numerous clinical trials, these monitoring parameters have been relaxed. The 2013 ACC/AHA cholesterol treatment guidelines recommend that transaminase (ALT) levels should be performed before initiating statin therapy and during therapy only as clinically indicated if hepatotoxic symptoms present. This approach is consistent with most of the package insert recommendations for the statins.

Interactions

The risk of myopathy is most common when using statins at high doses or in combination with drugs that can also cause myopathy (including other lipid-lowering agents) or that can affect the metabolism of the statins (e.g., cyclosporine, erythromycin, azole antifungals). Moreover, myopathy may occur at any time during therapy. Patients should be instructed to report any unusual muscle pain or weakness during therapy.

The practitioner should encourage the patient to take the statins in the evening or at bedtime because a significant amount of cholesterol production seems to occur during sleep. By taking the medication before bedtime, peak concentrations of medication occur during sleep. Exceptions are lovastatin, which has an increased bioavailability when taken with food and is usually taken with the evening meal, and atorvastatin and rosuvastatin, which can be taken at any time during the day because of their long half-lives.

Cholesterol Absorption Inhibitors

Currently, there is only one cholesterol absorption inhibitor on the market, ezetimibe (Zetia). Ezetimibe appears to act at the brush border of the small intestine and inhibits the absorption of cholesterol, leading to a decrease in the delivery of intestinal cholesterol to the liver. This causes a reduction of hepatic cholesterol stores and an increase in clearance of cholesterol from the blood; this distinct mechanism is complementary to that of HMG-CoA reductase inhibitors.

Zetia, introduced in April 2003, is indicated for use as monotherapy or as combination therapy with a statin. LDL cholesterol levels are reduced by up to 18% with monotherapy and up to an additional 25% when added to ongoing statin therapy. Together with a statin, LDL cholesterol reductions of more than 50% have been noted. The recommended dosage of ezetimibe is 10 mg daily. If taken with a bile acid sequestrant, ezetimibe should be taken 2 hours before or 4 hours after the bile acid (Table 20.3).

TABLE 20.3 Doses and Lipid-Lowering Ability of Other Available Agents

Class	Generic Name (Trade Name)	Usual Daily Dose	LDL*	HDL*	Triglycerides*
Bile acid resins	cholestyramine (Questran, Questran Light, Prevalite)	4–16 g	↓13%–32%	↑3%–5%	↑0%–15%
	colesevelam (Welchol)	3.75 g	↓15%–18%	↑3%	↑9%–10%
Cholesterol absorption inhibitors	ezetimibe (Zetia)†	10 mg	↓16%–19% ↓33%–60%	↑3%–4% ↑8%–11%	↓5% ↓19%–40%
Niacin‡	niacin (various)	1.5–3.0 g	↓12%–21%	↑18%–30%	↓15%–44%
Fibric acid derivatives	gemfibrozil (Lopid)	600 mg bid	0	↑6%	↓31%
	fenofibrate (various)	48–200 mg qd	↓20%	↑11%	↓38%
Combination products	lovastatin/niacin	20/500 to 40/2,000 mg	↓30%–42%	↑20%–30%	↓32%–44%
simvastatin/ezetimibe		10/10 to 80/10 mg	↓45%–60%	↑6%–10%	↓23%–31%

*Effects on lipid levels are dose dependent.

†Results in first line are those seen when used as monotherapy (Bays et al., 2001). Second results are those seen when used with statin therapy (Kerzner et al., 2003 [lovastatin]; Davidson et al., 2002 [simvastatin]; Ballantyne et al., 2003 [atorvastatin]).

‡Dose must be titrated slowly (usually weekly) to avoid side effects.

The Ezetimibe and Simvastatin Hypercholesterolemia Enhances Atherosclerosis Regression (ENHANCE) trial, which evaluated the impact of adding ezetimibe to simvastatin, found no significant change in carotid artery intima–media thickness (a marker for atherosclerosis progression) despite significant decreases in LDL cholesterol and CRP levels (Kastelein et al., 2008). However, the more recent Improved Reduction in Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) showed that the addition of ezetimibe 10 mg to simvastatin 40 mg reduced CV events compared to simvastatin alone. While the magnitude of the results were not large (5.8% relative risk reduction, 2.0% absolute risk reduction—both statistically significant), they were very important in that it was the first trial to demonstrate incremental benefit in ASCVD event reduction with a nonstatin added to a statin compared to the statin alone.

Contraindications

Ezetimibe is contraindicated in patients who have a hypersensitivity to any component of the medication. The combination of ezetimibe with an HMG-CoA reductase inhibitor is contraindicated in patients with active liver disease or unexplained persistent elevations in serum transaminases. There are no adequate, controlled studies of ezetimibe in pregnant women, so use during pregnancy is indicated only if the potential benefit outweighs any potential risk to the fetus.

Adverse Events

Adverse events with ezetimibe are minimal. Adverse events noted in clinical trials include headache, diarrhea, and abdominal pain. In addition, myopathy and rhabdomyolysis have been noted when given in combination with statins. The incidence of elevated liver enzymes was similar to placebo.

Bile Acid Resins

Bile acid resins decrease cholesterol absorption through the exogenous pathway. These agents are not absorbed from the GI tract. They act to bind bile acids in the intestines, forming an insoluble complex that is excreted in the feces. This decreases the return of cholesterol to the liver. The body responds to this by increasing LDL receptors on the liver, which in turn increases the amount of LDL cholesterol taken up by the liver and thus decreases LDL cholesterol levels in the bloodstream (see Figure 20.1). Unfortunately, this process also leads to increased production of VLDL particles. As a result, triglyceride levels rise, especially in patients with elevated baseline triglyceride levels. Bile acid resins can decrease LDL cholesterol levels by 15% to 30%, increase HDL levels by approximately 3%, and increase triglyceride levels by up to 15% (Table 20.3). As with the statins, these effects are dose related.

Maximum effects of cholesterol lowering are seen in approximately 3 weeks. Bile acid resins are indicated as adjunct therapy for patients who do not respond to dietary therapy alone. Because of their safety with long-term use, they are extremely useful in young adult men and premenopausal women who are at relatively low CV risk. These agents are contraindicated in patients with biliary obstruction or chronic constipation.

Contraindications

Bile acid resins should not be used in patients whose fasting triglyceride levels are ≥ 300 mg/dL, as it may lead to a severe increase in triglyceride levels. They can be used with caution in patients whose baseline triglycerides are between 250 and 299 mg/dL, with monitoring every 4 to 6 weeks.

Adverse Events

Bile acid resins are not absorbed, and therefore, systemic adverse events are minimal. Monitoring for abnormal LFT values is not required. The most common adverse events are GI related and include flatulence, bloating, abdominal pain, heartburn, and constipation. For these reasons, some patients, such as elderly patients, may not be good candidates for bile acid resins.

Interactions

Because bile acid resins block the absorption of cholesterol from the GI tract, they should be taken with meals to maximize effectiveness. These agents are usually administered once or twice daily but can be taken up to four times a day. If taken once a day, a bile acid resin should be taken with the largest meal. The two major agents in this class are cholestyramine (Questran, Questran Light, Prevalite) and colesevelam (Welchol).

Cholestyramine is available as a powder and colestipol is available as granules or tablets.

The powder and granules should be mixed with water, noncarbonated beverages, soups, or pulpy fruits such as applesauce. The tablets should be swallowed whole with water or other fluids. These agents should not be taken dry because they can cause esophageal distress. Patients should avoid taking these agents with carbonated beverages because it may result in increased GI discomfort. Medications taken concomitantly, such as thyroid hormones, antibiotics, and fat-soluble vitamins, should be taken at least 1 hour before or 4 hours after the bile acid resin because of their potential to bind to other medications and decrease their bioavailability.

Niacin

Niacin (nicotinic acid) is a naturally occurring B vitamin that can improve cholesterol levels when used at doses 100 to 300 times the recommended daily allowance as a vitamin. Niacin's mechanism of action is uncertain, but the substance appears to decrease VLDL synthesis in the liver, inhibit lipolysis in adipose tissue, and increase lipoprotein lipase activity. This results in decreased triglyceride and LDL cholesterol levels in the bloodstream (see Figure 20.1). LDL cholesterol levels can be decreased by 15% to 25% and triglycerides by up to 50%, whereas HDL cholesterol levels may be increased by up to 35% (see Table 20.3). Although niacin is one of the most effective agents in improving cholesterol levels, most patients cannot tolerate the adverse events associated with its use (see Adverse Events). Additionally, there is very little evidence to suggest that it can reduce ASCVD events further when added to statin therapy.

Dosage

Doses of immediate release products are at least 1.5 g niacin daily are usually required to achieve beneficial effects on lipid levels. However, to minimize adverse events, dosages need to be titrated gradually. The usual starting dose for immediate release products is 50 to 100 mg two or three times a day. The dose can be increased every 1 to 2 weeks until a dosage of 1.0 to 1.5 g daily is reached; this should take approximately 4 to 5 weeks. This dosage range provides significant increases (15% to 30%) in HDL cholesterol levels and decreases (20% to 30%) in triglyceride levels. However, for maximal LDL cholesterol lowering, dosages of 3 g/d or more may be necessary. Niacin is available in both immediate-release and sustained-release formulations. Maximum effects usually are seen after 4 to 6 weeks of therapy on the aforementioned dosages.

Contraindications

Niacin is contraindicated in patients with hepatic dysfunction, severe hypotension, persistent hyperglycemia, acute gout, new-onset atrial fibrillation, or active peptic ulcers. In addition, niacin can elevate uric acid levels and worsen glucose control. Therefore, niacin is not a first-line treatment agent in patients with gout or diabetes mellitus, and it should be used cautiously in these populations.

Adverse Events

Niacin use has been limited primarily because of its extensive adverse events. Although it is one of the most effective agents for improving lipid profiles, many patients cannot tolerate the adverse events. The most common adverse events are attributed to an increase in prostaglandin activity and include pruritus and flushing of the face and neck. A dose of aspirin, 325 mg, taken 30 minutes before the niacin dose may decrease the severity. As mentioned earlier, niacin can also increase uric acid levels and worsen glucose control and

should be used cautiously, if at all, in patients with a history of gout or diabetes mellitus. Baseline glucose and uric acid levels should be checked in all patients starting niacin therapy.

Other adverse events include GI side effects (it is contraindicated in patients with an active peptic ulcer), rash, hepatotoxicity, and, rarely, acanthosis nigricans (hyperpigmentation of the skin, usually in the axilla, neck, or groin). Unlike statins, LFTs are still recommended to be monitored at 6 and 12 weeks after initiating or titrating therapy and periodically thereafter.

Fibric Acid Derivatives

Fibric acid derivatives class of lipid-lowering drugs mainly affects triglyceride and HDL cholesterol levels. The exact mechanism of action of fibric acid derivatives is unclear, but the principal effect of triglyceride lowering appears to result from the stimulation of lipoprotein lipase, which enhances the breakdown of VLDL to LDL cholesterol (see Figure 20.1).

These agents may also inhibit hepatic VLDL production, and they lower triglyceride levels up to 60% and increase HDL cholesterol by up to 30%. Although gemfibrozil and clofibrate (Atromid-S) have minimal effects on LDL cholesterol lowering, fenofibrate (TriCor) has been shown to decrease LDL cholesterol by up to 20%. Fibric acid derivatives are primarily indicated in patients who have severely elevated triglyceride levels and who have not responded to dietary therapy (see Table 20.3).

Gemfibrozil and fenofibrate are the currently available fibric acid derivatives.

Dosage

Gemfibrozil is given in 600-mg doses twice daily with breakfast and dinner. No titration of dose is necessary, although some patients may respond at lower doses. Fenofibrate therapy is initiated at 43 to 67 mg/d (depending upon formulation). The dosage can be increased to a maximum of 200 mg/d. Because its absorption is increased when taken with food, fenofibrate should be taken with meals.

Contraindications

Fibric acid derivatives are contraindicated in patients with a history of gallstones and in those with severe hepatic or renal dysfunction. No studies have been conducted in pregnant women, so therefore, these agents should be used only if the benefits clearly outweigh any risks to the fetus.

Adverse Events

The fibric acid derivatives usually are well tolerated. The most common adverse events are GI related and include epigastric pain, nausea and vomiting, dyspepsia, flatulence, and constipation. Myopathy may occur and the incidence is increased when fibric acid derivatives are used with lovastatin and simvastatin and, to a lesser degree, other statins and niacin. As with the other systemic lipid-lowering agents, hepatotoxicity can occur, and LFTs should be monitored at 6 and 12 weeks and periodically thereafter. If LFT values increase to more than three times the upper normal limits, the fibric acid derivative should be discontinued. Other adverse events include rhabdomyolysis, cholestatic jaundice, gallstones, and, rarely, leukopenia, anemia, and thrombocytopenia.

Interactions

As mentioned previously, the incidence of myopathy is increased when fibric acids, especially gemfibrozil, are used in combination with lovastatin and simvastatin and, to a lesser degree, other statins and niacin. In fact, the combination of gemfibrozil and simvastatin is contraindicated. Fenofibrate should be used with caution in patients taking anticoagulant therapy because it can increase the effects of the anticoagulant. Doses of the anticoagulant should be lowered and levels monitored closely if fenofibrate therapy is initiated.

Omega-3 Fatty Acids

Similar to fibric acids, omega-3 fatty acids are not considered a major class of lipid-lowering drugs due to a lack of LDL cholesterol lowering. In some cases, omega-3 fatty acids may increase LDL cholesterol levels. Additionally, there have been no studies showing reduced CV morbidity and mortality. There are numerous over-the-counter dietary supplements that contain omega-3 fatty acids, and omega-3-acid ethyl esters by prescription. These agents are all indicated as an adjunct to diet for the treatment of severe hypertriglyceridemia. Patients should be on a lipid-lowering diet before treatment with any omega 3 fatty acids or omega-3-acid ethyl esters is initiated.

Dosage

All prescription Omega 3 products are given as a once- or twice-daily dose. Patients can take either 4 g (four capsules) daily or 2 g (two capsules) twice daily. There is no dose titration.

Contraindications

Any omega 3 fatty acids is contraindicated in patients with a known hypersensitivity to the drug. To date, there is no evidence to suggest that patients who have fish allergies are at an increased risk for an allergic reaction with these agents. There are no studies that have included pregnant women, so it should only be used if the benefits outweigh any potential risks to the fetus.

Adverse Events

Omega-3 fatty acids are generally well tolerated. Some of the side effects noted in clinical trials include flulike symptoms, belching, taste changes, upset stomach, and back pain.

Interactions

There has been some evidence to suggest that omega-3 fatty acids prolong bleeding time, but no studies have been performed to determine if there is an interaction with concomitant use of anticoagulants.

Medications for Familial Homozygous Hypercholesterolemia

Familial homozygous hypercholesterolemia (FH) is a rare genetic disorder characterized by dysfunctional LDL cholesterol receptors on the liver, which leads to severely elevated cholesterol levels (LDL cholesterol levels greater than 600 mg/dL) and ASCVD at an early age. Due to the lack of function of the LDL cholesterol receptors, many lipid-modifying agents including statins show significantly reduced effects on LDL cholesterol reduction in this clinical setting. In 2013, mipomersen and lomitapide were approved in the United States for the treatment of FH. Mipomersen (Kynamro) and lomitapide (Juxtapid) have been shown to reduce LDL cholesterol levels by 25% and 40%, respectively, on top of what had been achieved with maximum tolerated statin doses. Due to the extremely small overall patient population affected by FH, ASVCD event reduction studies will not be possible. Severe liver toxicity is associated with these agents. Due to this, specific FDA-mandated training is required before prescribing these medications, which should only be used in patients with FH.

Two new medications, alirocumab (Praulent) and evolocumab (Repatha), which are monoclonal antibodies that target proprotein convertase subtilisin/kexin type 9 (PCSK9) were approved by the FDA in late 2015. These agents, which are injectables, provide LDL-C lowering of up to 60% or more when used alone or when added on to statin therapy, though no studies have been completed to date to determine if these reductions in cholesterol result in fewer CV events. Initial indications for use are adjunct to maximally tolerated statin therapy in adults with heterozygous and/or homozygous familial hypercholesterolemia or clinical ASCVD.

Combination Therapy

In the past, it was thought that it would be beneficial for patients to be prescribed combination lipid-lowering therapy to achieve desired cholesterol levels, particularly those with severe hypertriglyceridemia or severely elevated LDL cholesterol levels who do not respond adequately to a statin alone or are intolerant to statin doses needed to attain desired LDL-C reduction. Statin/niacin and statin/gemfibrozil have been used together for patients with severely elevated LDL cholesterol, low HDL cholesterol, and hypertriglyceridemia. Currently, there are two products available that include a statin and niacin in a single formulation: lovastatin/niacin (Advicor) and simvastatin/niacin (Simcor). However, to date, there have been no studies showing an increased benefit in reducing CV morbidity and mortality from either of these combinations. Combining statins with a cholesterol absorption inhibitor has shown added benefits in reducing both LDL cholesterol and ASCVD event rates. As previously mentioned, this is the only lipid medication combined with a statin to show incremental benefits in ASCVD event rates. Bile acid resins can be used safely and effectively with statins, niacin, and fibric acid derivatives to enhance LDL cholesterol lowering. The only concern with using bile acid resins in combination is ensuring that the concomitant medications are taken at least 1 hour before or 4 hours after the resin to ensure adequate GI absorption.

Alternative Therapy

Antioxidant therapy has been a major focus of studies on preventing ASCVD, but its preventive benefits have yet to be determined. In theory, antioxidants block the conversion of LDL cholesterol to a modified (oxidized) LDL in the vascular endothelium. As mentioned previously, modified LDL cholesterol appears to be more atherogenic than nonoxidized LDL cholesterol. Thus, blocking the production of oxidized LDL cholesterol may slow the atherogenic process. The major antioxidants that have been studied include vitamin E, vitamin C, and beta carotene, a precursor of vitamin A. Most of the beneficial evidence has been seen with the use of vitamin E, but there is no strong evidence to support vitamin E use.

Other alternatives include garlic, vinegar, and fish oils. Although some evidence suggests that these may be beneficial, no conclusive evidence exists to support their use.

Selecting the Most Appropriate Therapy

Choosing which drug to use in which order is individualized and based on the patient's clinical status, the impact on heart health by the surrogate marker of cholesterol lowering, and an assessment of patient compliance. Factors that affect compliance include side effects, cost of therapy, health beliefs supporting the need to lower cholesterol levels, and the understanding that this is a lifelong treatment. In a study by Wei et al. (2013), the primary reasons for discontinuation of statins are muscle pain (60%), cost of therapy (16%), and perceived lack of efficacy (13%). Further, the Statin Intolerance Panel (2014) recommends that a patient-centered approach is important to reduce statin intolerance; true intolerance is estimated at a rate of approximately 10%. See Table 20.4 and Figure 20.2 for further guidance in drug selection.

TABLE 20.4 Selecting the Most Appropriate Agent

	Agents	Comments
First line	Statins	Most experts agree that the benefits of treatment with statins are a class-wide effect. Choice of agent and dose is dependent upon the statin benefit group that an individual is classified.
Second line	Cholesterol absorption inhibitors	Cholesterol absorption inhibitors can be used alone or in combination with statins. When used in combination, LDL cholesterol lowering of ~60% has been shown, resulting in fewer ASCVD events.
	Niacin and bile acid resins	Niacin has beneficial effects on each of the lipoproteins, but most patients cannot tolerate the side effects of the drug.
		Bile acids are not systemically absorbed and can be used in patients who cannot tolerate the effects of statins or in combination with statins for patients who are unable to reach LDL goal on a statin alone.
Third line	Fibric acid derivatives	Fibric acid derivatives are reserved for patients with very high triglyceride levels (>1,000 mg/dL) who do not respond to dietary interventions or in combination with other agents for patients with elevated triglyceride levels that cannot be controlled with other agents.

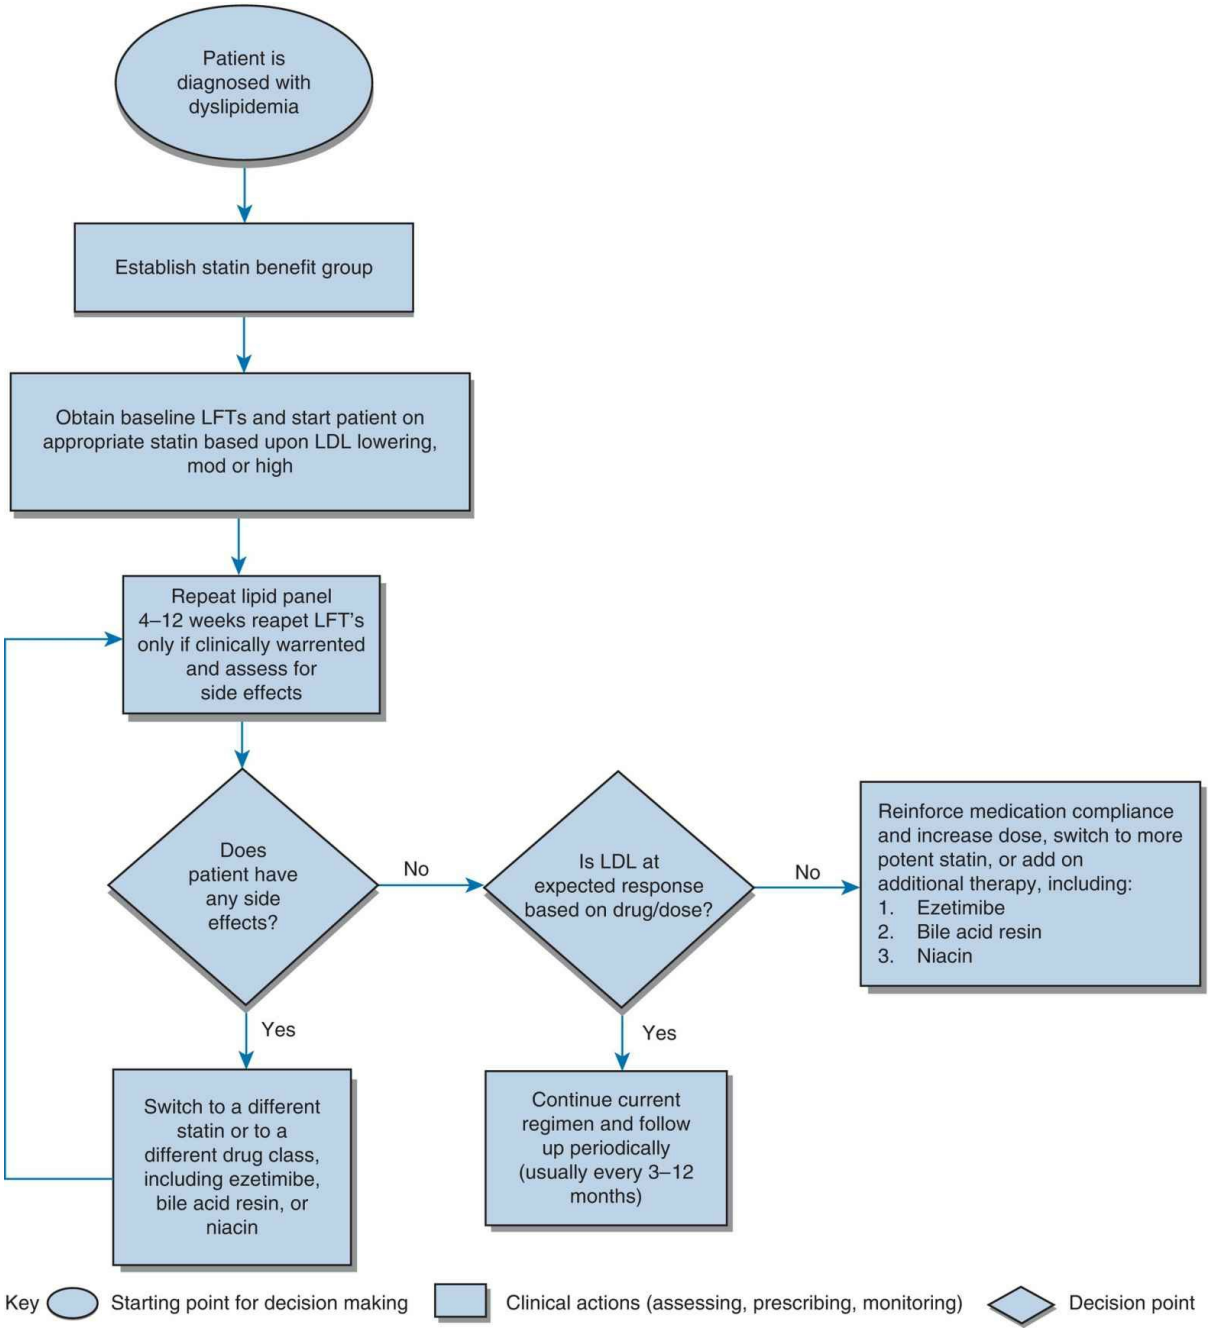

FIGURE 20.2 Treatment algorithm for initiating cholesterol-lowering therapy.

Special Population Considerations

Pediatric

Pharmacologic therapy may be considered in children older than age 10 if lifestyle modifications cannot adequately lower cholesterol levels. Use in children younger than age 10 usually is not recommended because atherosclerotic lesions are not thought to develop before this age. A consultation with a lipid specialist is recommended for any child with elevated cholesterol levels.

Geriatric

Though there have not been a large number of patients over the age of 75 included in most randomized clinical trials, evidence does support continuation of use of statins in individuals who have been taking them. If statins are used, it is recommended to use a moderate-intensity statin.

Women

Statins are classified as category X by the U.S. Food and Drug Administration and should not be used by pregnant women because of the potential for fetal abnormalities. Most other agents are classified as category C, meaning that tests have not been performed in humans.

Patient Education

Patient education consists of a thorough explanation of the value of modifying habits and making lifestyle changes (diet, exercise) to avoid or enhance drug therapy in reducing lipid levels. Equally important is thorough teaching about the need for regular laboratory tests to evaluate the effect of drug therapy on body systems and organs, such as the liver. Such education will encourage the patient to cooperate with the therapeutic plan.

Two websites that provide useful information for patients are www.americanheart.org (American Heart Association) and www.nhlbi.nih.gov (Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute). On the latter site, the patient can calculate his or her 10-year risk of having a heart attack.

Cholesterol screening should begin at age 20 and should be done every 5 years if it is normal unless there has been a significant lifestyle change, such as significant weight gain. Children should be screened if their parents have a cholesterol level greater than 240 or they have grandparents age 55 or younger with overt ASCVD.

Drug Information

Grapefruit juice may increase the potency of all statins except pravastatin. Patients taking statins should report any new muscle pain, since these drugs can cause myopathy and, rarely, rhabdomyolysis.

Nutrition

The patient should eat a diet low in saturated fats and cholesterol. The diet can include up to 35% daily fats, but no more than 7% saturated fats.

Case Study*

J.J., age 55 white male, has come in for his annual physical. He has hypertension and type 2 diabetes mellitus. His blood pressure is controlled with lisinopril 20 mg daily and amlodipine 5 mg daily (BP 132/82 mm Hg). His most recent HbA1c was 7.2% while taking metformin. His father died at age 55 of a myocardial infarction, and his brother, age 57, just underwent angioplasty. J.J. eats fast food at least five times a week because of his work schedule. He weighs 245 lb and stands 5-foot-11. His blood pressure is 134/80. His total cholesterol is 237 (LDL, 162; HDL, 35; triglycerides, 200).

1. Does J.J. fall into any of the statin risk categories? If so, which one?
2. What drug therapy and dose would you prescribe, and why?
3. What are the parameters for monitoring the success of the therapy?
4. List one or two adverse reactions for the drug therapy that you prescribed for J.J. that would cause you to change therapy.
5. When rechecked, J.J.'s total cholesterol is 174 (LDL, 100; HDL, 38), but he is complaining of muscle pain. How would you manage J.J.'s treatment?* Answers can be found online.

21 Chronic Stable Angina

Andrew M. Peterson ■ Christopher C. Roe

Cardiovascular disease was responsible for nearly 40.6% of deaths recorded in 2014, making it the leading cause of death in the United States (Go et al., 2014). Angina is a clinical syndrome caused by coronary heart disease (CHD) and affects nearly 10.2 million Americans. In 2010, the cost of cardiovascular disease was estimated to be nearly $315.4 billion (Go et al., 2014).

Fortunately, the overall mortality rate from CHD has been declining. The reason for this decline is the improved treatments for cardiovascular disease, including angina. Despite this hopeful note, angina remains a significant challenge for primary care management. Successful management depends on an in-depth understanding of the pathologic process, diagnosis, and treatment of this symptom complex.

Angina is a syndrome—a constellation of symptoms—that results from myocardial oxygen demand being greater than the oxygen supply (myocardial ischemia). By definition, angina is associated with reversible ischemia, so it does not result in permanent myocardial damage. Myocardial infarction (MI) is the result of irreversible ischemia when myocardial tissue is permanently damaged.

Patients with angina may report left-sided chest pain, discomfort, heaviness, or pressure, and the sensation may radiate to the back, neck, jaw, and throat or arms. Usually, these sensations last 1 to 15 minutes. Patients may also experience shortness of breath or fatigue. It is important to note, however, that not all patients present with "angina" in a typical fashion. For example, dyspnea on exertion may be the only presenting symptom. If a patient presents with unique symptoms, his or her group of symptoms associated with identified ischemia is called that patient's "anginal equivalent." Box 21.1 lists common and unique terms used to describe angina.

BOX 21.1 Words Patients Use to Describe Angina

Ache, toothache-like, dull
Burning, heartburn, soreness, bursting, searing indigestion
Choking, strangling, compressing, constricting, tightness, viselike
Discomfort, fullness, swelling, heaviness, pressure, weight, uncomfortable

Angina is called *stable* when the paroxysmal chest pain or discomfort is provoked by

physical exertion or emotional stress and is relieved by rest and/or nitroglycerin (NTG). Stable angina exists when the stimulating factors or activities and the degree and duration of discomfort have not changed for the past 60 days.

Anginal episodes that increase in frequency, duration, or severity are referred to as *unstable*. Unstable angina is experienced when the patient is at rest or if the episode is prolonged or progressive. Unstable angina has also been called *preinfarction angina*, *crescendo angina*, or *intermittent coronary syndrome*. It is differentiated from stable angina by the fact that symptoms may be triggered by minimal physical exertion or may be present at rest. Patients who experience unstable angina are at high risk for developing an MI.

Other types of angina include variant (or Prinzmetal) angina, nocturnal angina, angina decubitus, and postinfarction angina. Stable angina is frequently managed in the primary care setting and is the focus of this chapter.

Causes

The development of angina is directly related to the risk factors that have been identified for CHD. Nonmodifiable risk factors for CHD cannot be altered or improved by the patient; they include age, family history, and gender. Modifiable risk factors may be controlled or treated by lifestyle modifications or pharmacologic therapy to reduce the risk of morbidity or mortality from CHD. Modifiable risk factors include cigarette smoking, hypertension, dyslipidemia, diabetes, obesity, and physical inactivity. Box 21.2 lists the risk factors for chronic stable angina.

BOX 21.2 Risk Factors for Chronic Stable Angina

Nonmodifiable Risk Factors

Age
Heredity
Gender

Modifiable Risk Factors

Cigarette smoking
Hypertension
Dyslipidemia
Diabetes
Obesity
Physical inactivity

Nonmodifiable Risk Factors

Age

It is uncommon for men younger than age 40 and premenopausal women to have symptomatic CHD, but the incidence increases with age and is increased in women after menopause. More than 80% of patients who die of CHD are over age 65 (American Heart Association, 2010). This increasing incidence of CHD with age is likely linked to age-related changes in the vasculature and the higher prevalence of other CHD risk factors among older persons.

Heredity

A family history of premature CHD in a first-degree relative (i.e., mother, father, sister, or brother) is a strong predictor for CHD in an individual. Premature CHD is defined as occurring in a man younger than age 55 or in a woman younger than age 65. The strong association between family history and the development of CHD has been consistently demonstrated in several studies. Furthermore, race has been shown to be a factor. Data show that 44% of African Americans have high blood pressure versus 27.4% of Whites, thus increasing their risk of a cardiovascular event (Go et al., 2014). Therefore, individuals with a family history of CHD should be carefully screened for other CHD risk factors and managed appropriately.

Gender

In general, the risk of CHD is higher for men than women. Male gender is considered a nonmodifiable risk factor for CHD. Differences for CHD susceptibility diminish, however, when comparing postmenopausal women and older men. In fact, after age 65, the incidence of CHD increases in women, but it does not reach that of men.

Modifiable Risk Factors

Cigarette Smoking

Cigarette smoking increases the risk of CHD by at least twofold to threefold. Smoking increases the incidence of atherosclerosis by a mechanism that is not clearly understood. It is thought to increase the release of catecholamines, which leads to elevated blood pressure due to an increased workload of the heart caused by an increase in the heart rate and peripheral vascular constriction. Catecholamines also increase the release of free fatty acids, which increases the amount of lipids in the blood. Smoking lowers high-density lipoprotein (HDL) levels and increases low-density lipoprotein (LDL) levels, and is thought to promote platelet activation, which increases the risk of clot formation in the arteries. All patients with CHD risk factors or established disease should be instructed to stop smoking. See Chapter 53 for a more detailed discussion of smoking cessation.

Hypertension

It is estimated that over 77.9 million Americans have elevated blood pressure (Go et al., 2014). Hypertension is a major risk factor for CHD and can lead to vascular complications that increase morbidity and mortality. Additionally, the higher the blood pressure, the higher the risk of MI and other cardiovascular events.

Atherosclerotic changes in the vasculature are exacerbated by increased pressure. Increased blood pressure alone also causes injury to the inner lining of the arteries, resulting in atherosclerotic changes and thrombus formation. As the arteries become stiff and narrow, the blood flow that normally increases during physical activity is restricted to a greater degree, resulting in ischemic symptoms. Chapter 19 provides further discussion of drug therapy for hypertension.

Dyslipidemia

Nearly half of the American population has high cholesterol (American Heart Association, 2010). Cholesterol plays a substantial role in the pathophysiology of atherosclerosis and CHD. High levels of LDL cholesterol and low levels of HDL cholesterol are associated with an increased risk of cardiovascular disease and occurrence of MI or other poor cardiovascular outcomes. Treatment of dyslipidemia in patients with CHD using pharmacologic and nonpharmacologic means has been shown in multiple large-scale studies to reduce the risk of cardiovascular death. In 2014, a new guideline was released outlining the diagnosis and treatment of dyslipidemia in adults. See Chapter 20 for more detailed information on the treatment of dyslipidemia.

Diabetes

Cardiovascular disease is the most common cause of death in patients with diabetes. In fact,

patients with diabetes have the same risk of having an MI as a patient who already has a history of an MI. Although data have not shown a clear or conclusive link between glucose control and cardiovascular risk reduction, an effort should be made to prevent or treat diabetes in these patients. For a complete discussion of diabetes treatment, see Chapter 45.

Obesity

In the United States, 68.2% of the population is considered overweight or obese (Go et al., 2014). The increasing incidence of obesity has been attributed to poorer nutrition and a more sedentary lifestyle.

Obesity is a risk factor for CHD in both men and women. Hypertension, dyslipidemia, and diabetes are more common in patients who are obese, but obesity also increases cardiovascular risk independent of these other risk factors by a mechanism that is not well understood. Even modest weight loss can improve blood pressure, hypertension, and insulin resistance and reduce cardiovascular risk. Weight loss is discussed in Chapter 54.

Physical Inactivity

A sedentary lifestyle predisposes patients to CHD. Regular physical exercise reduces blood pressure, maintains a healthy weight, and improves dyslipidemia, but it also reduces the risk of CHD independent of these changes. Patients should be carefully screened and counseled before beginning an exercise program. Exercise may include walking, running, cycling, or formalized aerobic exercise routines. It is recommended that patients get 30 to 60 minutes of aerobic exercise every day at least 5 days per week. Resistance training on 2 day/week may also be of benefit.

Pathophysiology

Angina is a symptomatic manifestation of reversible myocardial ischemia, which occurs when demand for oxygen in the myocardium exceeds available supply. This imbalance between oxygen supply and demand is caused by limited blood supply due to narrowing of the blood vessels that supply the heart muscle. The most common cause of this narrowing of the coronary arteries is atherosclerotic disease. Rarely, vasospasm of the coronary arteries narrows the arteries, thereby limiting the blood supply to the heart muscle. Other even more uncommon sources of anginal symptoms are thrombosis, aortic stenosis, primary pulmonary hypertension, and severe hypertension.

Atherosclerotic Disease

The pathophysiology of angina involves atherosclerosis, a disorder of lipid metabolism resulting in the deposit of cholesterol in the blood vessel. Over time, this causes a reactive endothelial injury that eventually results in a narrowing of the vessels by episodes of acute thrombosis. The narrow arteries impair the ability of oxygen and nutrients to reach the myocardium. This reduction in blood supply, or ischemia, impairs myocardial metabolism. The myocardial cells remain alive but cannot function normally. Once the blood supply is restored, cardiac function returns to normal. If the ischemia is caused by complete occlusion of the coronary artery, an MI (cell death) occurs.

Regardless of the risk factors that cause the development of atherosclerosis and resulting restriction of coronary blood supply, the pathophysiologic process is essentially the same. The three layers of the arterial wall—intima, media, and adventitia—are affected by structural changes that lead to CHD. The intima is a single layer of endothelial cells, constituting the innermost surface of the artery. It is impermeable to the substances in the blood. The media is the middle layer of the artery and is made up almost entirely of smooth muscle. The outer layer, or adventitia, consists mainly of smooth muscle cells, fibroblasts (which are normally only in this layer), and loose connective tissue. Atherosclerotic changes in the artery occur in stages. Normally, the intima is thin and contains only an occasional muscle cell. As a person ages, the intima slowly increases in thickness and muscle cells proliferate.

Atherosclerosis primarily affects the intima of the arterial wall. It normally takes years to develop, and clinical manifestations do not occur until the disorder is well advanced. CHD progresses through three developments—the fatty streak, the fibrous plaque, and the complicated lesion.

The Fatty Streak

Thought to begin in childhood, the fatty streak is caused by the development of fatty, lipid-rich lesions that result from macrophages adhering to the intact endothelial surface. The macrophages take in lipids, which leads to a thickening of the intimal layer. Smooth muscle cells migrate to the intima and become lipid laden. The lesions at this stage do not obstruct the artery. However, on examination, fatty streaks appear in the coronary arteries as early as age 15. They continue to enlarge through the third decade of life and appear to be a precursor to plaque formation, although the process is not clearly understood.

The Fibrous Plaque

The raised fibrous plaque is a white, elevated area on the surface of the artery. It signals the beginning of progressive changes in the arterial wall, including protrusion of the lesion into the lumen of the artery. These more advanced lesions begin to develop at approximately age 30 in most patients. The major change in the arterial intima during this phase is the

migration and proliferation of smooth muscle cells and the formation of a fibrous cap over a deeper deposit of extracellular lipid and cell debris. The lipid accumulation directly or indirectly reduces the blood supply. The decrease in blood supply is permanent and results in cell necrosis and cell debris.

The Complicated Lesion

A complicated lesion contains a fibrous plaque, calcium deposits, and a thrombus formed by hemorrhage into the plaque. The complicated lesion results from continuing cell degeneration. As the complicated lesion, with its lipid, necrotic center, becomes larger, it calcifies. The intimal surface may develop open or ruptured areas that degenerate into an ulcer. The damage is most likely to occur in areas where blood flow creates the greatest amount of stress in the vessel, such as at branches and bifurcations. The damaged surface allows blood from the artery lumen to enter the lipid core. Then, platelets adhere and thrombus formation begins. The thrombus expands and distorts the plaque, which becomes larger and begins to block the lumen of the artery. The blockage impedes the blood flow needed to supply extra oxygen and nutrients to meet the increased workload of the heart. The result is cardiac ischemia and anginal symptoms. These symptoms are relieved when either the workload of the heart is decreased or administration of vasodilating drugs increases blood flow to the myocardium. Complete blockage can cause permanent myocardial death because the cells are entirely deprived of oxygen and blood flow cannot be restored in time to revive the cardiac cells, resulting in an MI.

Coronary Artery Vasospasm

A less common cause of restricted coronary blood supply may be coronary vasospasm, a narrowing of the coronary artery lumen. This narrowing is produced by an arterial muscle spasm and limits the blood supply to the myocardium. The exact cause is unknown, but it is thought to occur when the smooth muscles of the coronary arteries contract in response to neurogenic stimulation. Cigarette smoking and hyperlipidemia appear to play a role in this type of angina because they interfere with normal neurogenic control of the arterial intima.

Spasm is suspected of playing a role in acute MI, as well as in triggering anginal episodes. Coronary artery spasm also can occur with abrupt nitrate withdrawal, cocaine use, and direct mechanical irritation from cardiac catheterization. However, the exact mechanisms leading to spasm are still unclear.

Activation of Ischemic Episodes

Regardless of the existing pathophysiologic process, ischemic episodes that result in anginal pain are usually activated by two situations occurring simultaneously or independently: (1) ambient factors that increase myocardial oxygen demand and (2) circumstances that decrease oxygen supply. For example, the person with atherosclerosis (noncompliant arteries) climbs a flight of stairs. The activity increases the workload of the heart, and the myocardium needs more oxygen. The damaged arteries are unable to meet this demand. In some situations, the arteries may be so constricted that they are unable to deliver an adequate amount of oxygen even if the person is in a resting state. Therapy is directed at resolution or control of these situations so that the heart can receive the oxygen it needs to meet the physical demands of the body. Control of the blood flow to the heart by increasing it when necessary prevents the pathophysiologic process responsible for the myocardial ischemia.

Diagnostic Criteria

Health History

The health history is an important part of the diagnosis and management of angina. The chief complaint for most patients is usually chest pain or discomfort, but other symptoms may predominate, such as neck or jaw pain or shortness of breath. The patient should be asked to describe the duration, quality, location, severity, and radiation of the pain. Additionally, the practitioner should inquire about potential triggers of the pain and any accompanying symptoms, such as dyspnea, diaphoresis, nausea, or palpitations. The practitioner also should explore what interventions relieved the patient's pain or symptoms, such as rest or NTG.

For all patients with angina, an assessment of CHD risk factors should be performed to determine an individual patient's risk for CHD and to better target pharmacologic and nonpharmacologic management. Practitioners should ask patients about both nonmodifiable and modifiable risk factors, including family history, cigarette smoking, hypertension, dyslipidemia, diabetes, and physical inactivity. A past history of cerebrovascular disease or the presence of peripheral vascular disease also increases a patient's risk of CHD.

Physical Findings

Most commonly, practitioners will not have the opportunity to examine a patient during an acute anginal episode. In that case, the physical examination should focus on the assessment of risk factors and the cardiovascular system as a whole. For example, the practitioner should assess a patient for obesity during the physical examination. Additionally, the vasculature may be evaluated by looking for funduscopic changes or decreased peripheral pulses. Hypertension may be evident from taking the patient's blood pressure, and clinical signs and symptoms of heart failure may include murmurs, gallops, changes in the heart sounds, edema, rales, or organomegaly. Patients with dyslipidemia may exhibit xanthomas or cholesterol nodules.

If a physical exam is performed during an episode of anginal pain, a variety of findings may be present. These may include extra heart sounds, mild hypertension, tachycardia, or tachypnea. A paradoxical split of S_2 may indicate altered left ventricular (LV) heart function associated with the ischemic discomfort.

Diagnostic Tests

Before therapy for angina can be properly prescribed, diagnostic testing is necessary to identify a cardiac cause of the patient's chest pain. Diagnostic testing includes electrocardiography, echocardiography, exercise tolerance testing, radioisotope imaging, and coronary artery angiography.

Patients with new, current, or recent chest pain should have an electrocardiogram (ECG) to detect signs of cardiac ischemia. During an acute anginal episode, ST segment depressions with or without symmetric T-wave inversions may be noted in the leads that correspond to the myocardium affected. During pain-free intervals, however, the ECG reverts to baseline. ECG changes that may be present in the patient with chronic CHD include evidence of a prior MI, LV hypertrophy, and repolarization abnormalities.

Echocardiography is recommended if valvular disease or heart failure is suspected, if the patient has a history of MI, or if the patient experiences ventricular arrhythmias. Most patients with intermittent episodes of chest pain should undergo an exercise tolerance test with ECG monitoring (also called a *stress test*) to evaluate the risk of future cardiac events. Those suspected of having coronary ischemia based on the presence of anginal symptoms should undergo testing within 72 hours of symptoms (Fihn et al., 2012). One notable exception would be patients with a high probability of CHD, such as a patient with known coronary disease and classical angina symptoms; these patients should be referred to a specialist for potential advanced interventional therapies. Further testing with radioisotope perfusion testing or coronary artery angiography may be indicated for subgroups of patients. If diagnostic testing confirms cardiac ischemia as the cause of anginal symptoms, drug therapy is warranted.

Initiating Drug Therapy

The treatment goals for the management of angina include relieving the acute anginal episode, preventing additional anginal episodes, preventing progression of CHD, reducing the risk of MI, improving functional capacity, and prolonging survival. These goals should be accomplished while maintaining the patient's quality of life and avoiding adverse events associated with therapy.

Nonpharmacologic therapy is the cornerstone of treatment for patients with angina. The practitioner must assess the patient's modifiable risk factors and work with him or her to reduce the risk for CHD. Practitioners should counsel patients on smoking cessation at each clinic visit and provide support and access to pharmacologic treatment if necessary. Patients should be instructed to maintain a normal weight by consuming a low-fat, low-cholesterol diet, and practitioners should provide dietary counseling and refer interested patients to dietitians for further support. Finally, practitioners should encourage patients to engage in regular aerobic exercise. Further details on these lifestyle modifications are provided in Chapters 19, 20, 53, and 54.

The practitioner should emphasize to the patient that nonpharmacologic therapy and lifestyle modifications supplement drug therapy and should continue indefinitely.

Goals of Drug Therapy

After the patient has been properly instructed on nonpharmacologic therapy for angina, appropriate drug therapy may be initiated. A summary of selected agents is provided in Table 21.1. Several classes of medications are used to treat angina, including angiotensin-converting enzyme (ACE) inhibitors, nitrates, beta-blockers, calcium channel blockers, and antiplatelet agents.

TABLE 21.1 Overview of Agents Used to Treat Chronic Stable Angina

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Selected Angiotensin-Converting Enzyme Inhibitors			
captopril (Capoten) Start: 6.25 mg or 12.5 mg tid Therapeutic range: 25–100 mg tid	Common: cough; hypotension, particularly with a diuretic or volume depletion; hyperkalemia, loss of taste, and leukopenia; angioedema, neutropenia, and agranulocytosis in <1% of patients; rash in >10% of patients	Contraindicated in pregnancy; avoid in patients with bilateral renal artery stenosis or unilateral stenosis	Renal impairment related to ACE inhibitors is seen as an increase in serum creatinine and azotemia, usually in the beginning of therapy. Monitor BUN, creatinine, and K levels when starting.
enalapril (Vasotec) Start: 2.5 mg qd or bid Range: 5–20 mg qd or bid daily	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
fosinopril (Monopril) Start: 10 mg qd Range: 10–40 mg qd	Same as above	Same as above	Same as above Use only 5 mg/d in patient with impaired renal function or hyponatremia.
lisinopril (Zestril, Prinivil) Start: 5 mg qd Range: 5–20 mg qd	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
quinapril (Accupril) Start: 5 mg bid Range: 20–40 bid	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
ramipril (Altace) Start: 1.25 mg twice daily Range: 1.25–5 mg twice daily	Same as above	Same as above	Same as above
Selected Angiotensin Receptor Blockers (ARBs)			
losartan (Cozaar) Start: 12.5 mg/d Range: 50–100 mg/d	Dyspnea, hypotension, hyperkalemia	Angioedema secondary to ACE inhibition	May be used in patients experiencing cough due to ACE inhibitor
valsartan (Diovan) Start: 80 mg/d Range: 80–160 mg twice daily	Same as above	Same as above	Same as above
Short-Acting Nitrates			
nitroglycerin (Nitrostat, NitroQuick) 0.4 mg SL prn	Headache, dizziness, tachycardia, hypotension, edema	Combination with phosphodiesterase-5 inhibitors (e.g., sildenafil, vardenafil, and tadalafil)	For acute treatment of anginal episodes
isosorbide dinitrate (ISDN; Isordil, Sorbitrate) 5 mg SL prn	Above notes also apply	Above notes also apply	Above notes also apply
Long-Acting Nitrates			
nitroglycerin	Above notes also apply	Above notes also apply	For chronic prevention of anginal episodes
Topical ointment (Nitro-Bid) ½–1 in bid–tid	Local irritation and erythema with topical application		Use nitrate-free interval to reduce risk of nitrate tolerance.
Transdermal patch (Minitran, Nitro-Dur, Nitrol, Transderm-Nitro) 0.2–0.8 mg/h			Potential hypotensive effect with vasodilators Tapering is recommended after long-term use. Onset of action with transdermal application is ~60 min.
isosorbide mononitrate (ISMN) Immediate release (Ismo, Monoket) 5–20 mg bid Extended release (Imdur) 30–120 mg bid	Above notes also apply	Above notes also apply	Above notes also apply Extended-release formulations should be swallowed whole.
Beta-Blockers			
propranolol Immediate release (Inderal) 40–160 mg bid Extended release (Inderal LA) 80–240 mg qd	Fatigue, dizziness, decreased exercise tolerance, bradycardia, hypotension, dyspnea	Use with caution in patients with reactive airway disease. Bradycardia (heart rate <45 beats per minute) Acutely decompensated heart failure	Abrupt cessation of beta-blocker therapy should be avoided. Extended-release formulations should be swallowed whole.
atenolol (Tenormin) 25–100 mg qd	Above notes also apply	Above notes also apply	Above notes also apply Dose adjustment needed in chronic kidney disease
metoprolol Immediate release (metoprolol tartrate, Lopressor) 25–200 mg tid Extended release (metoprolol succinate, Toprol-XL) 50–100 mg qd	Above notes also apply	Above notes also apply	Toprol-XL tablets may be split, but should not be chewed or crushed.
Calcium Channel Blockers			
amlodipine (Norvasc) 2.5–10 mg qd	Headache, dizziness, flushing, edema, gingival hyperplasia	Severe conduction abnormalities Use with caution in patients with preexisting bradycardia or CHF.	Useful for patients with isolated systolic hypertension
nifedipine (extended release, Adalat CC, Procardia XL) 30–60 mg qd	Above notes also apply	Above notes also apply	Should be swallowed whole
diltiazem (extended release, Cardizem CD, Dilacor XR, Tiazac) 180–420 mg qd	Headache, nausea, conduction abnormalities, gingival hyperplasia	Above notes also apply	Should be swallowed whole
verapamil Immediate release (Calan, Isoptin) 80–320 mg bid Extended release (Calan SR, Isoptin SR) 120–480 mg qd	Above notes also apply Constipation	Above notes also apply	Extended-release formulations should be swallowed whole.
Antiplatelet Agents			
aspirin 81–325 mg qd	Nausea, dyspepsia	Allergy to aspirin Bleeding disorders Allergy to clopidogrel	For primary and secondary prevention of cardiovascular events
clopidogrel (Plavix) 75 mg qd	Nausea	Bleeding disorders	Alternative antiplatelet agent for aspirin-intolerant or aspirin-allergic patients
Ranolazine			
ranolazine (Ranexa) 500–1,000 mg qd	Dizziness, nausea, constipation	Patients taking strong inhibitors of CYP3A4 and/or severe hepatic impairment	Should be swallowed whole

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

The 2012 Guideline for the Diagnosis and Management of Patients with Stable Ischemic Heart Disease recommends that patients with ejection fractions of less than 40% or those with hypertension, diabetes, or kidney disease be placed on an ACE inhibitor unless contraindicated (Fihn et al., 2012). When patients cannot take an ACE inhibitor, an angiotensin receptor blocker (ARB) may be used (Fihn et al., 2012). ACE inhibitors include captopril (Capoten), ramipril (Altace), enalapril (Vasotec), quinapril (Accupril), benazepril (Lotensin), perindopril (Aceon), and lisinopril (Prinivil, Zestril). ARBs include losartan (Cozaar), valsartan (Diovan), candesartan (Atacand), telmisartan (Micardis), eprosartan (Teveten), olmesartan (Benicar), and irbesartan (Avapro).

Mechanism of Action

ACE inhibitors affect the enzyme responsible for the conversion of angiotensin I to angiotensin II. ARBs block the vasoconstriction and aldosterone-secreting effects of angiotensin II by selectively blocking angiotensin II from binding to angiotensin II receptors found in many tissues. Angiotensin II is a potent vasoconstrictor and also stimulates aldosterone secretion. Blocking the production of angiotensin II results in reduced vasoconstriction and sodium and water retention, thus reducing preload, afterload, and ejection fraction. These benefits are helpful in chronic stable angina, heart failure (Chapter 22), and hypertension (Chapter 19).

Dosage

ACE inhibitors and ARBs should be initiated at low doses and followed by gradual dosage increases if the lower doses are well tolerated. Renal function and serum potassium should be assessed within 1 to 2 weeks of starting therapy and periodically thereafter, especially in patients with preexisting diabetes or those receiving potassium supplementation. Table 21.1 shows the doses of some common ACE inhibitors and ARBs when used to treat chronic stable angina.

Contraindications

ACE inhibitors are contraindicated in pregnancy and should be avoided in patients with bilateral renal artery stenosis or unilateral stenosis.

Adverse Effects

Side effects of ACE inhibitors are uncommon but may include an irritating cough and excessive drops in blood pressure, particularly in hypovolemic patients or those already on diuretics. Hyperkalemia may also occur; however, the incidence is less with ARBs than with

ACE inhibitors. A serious adverse effect with ACE inhibitors is angioedema, which usually occurs early in treatment. Angioedema secondary to an ACE inhibitor is a contraindication to further ACE inhibitor use, but an ARB may be used cautiously in its place. Other adverse effects include rash, loss of taste, neutropenia, and agranulocytosis.

Interactions

Due to the effects on angiotensin II and aldosterone, ACE inhibitors contribute to potassium retention as sodium is preferentially excreted. This raises the possibility of a hyperkalemia state for the patient and must be monitored routinely. Similarly, patients taking lithium are at increased risk for lithium toxicity due to its decreased renal excretion. Other important ACE inhibitor interactions can be found in Chapter 19, Table 22.3.

Nitrates

The nitrates are one of the original medications used for controlling angina, and they are still commonly used to halt an acute anginal attack, to prevent predictable episodes, and for chronic treatment to prevent anginal episodes.

Mechanism of Action

Nitrates and their analogs are potent agents and have profound effects on vascular smooth muscle. The nitrates cause dilation throughout the vasculature—in the peripheral arteries and veins as well as the coronary arteries. When dilated, the veins return less blood to the heart, thereby reducing LV filling volume and pressure (preload). This decreases the workload of the heart. Another primary effect of the nitrates is coronary arterial dilation, which results in increased blood flow and oxygen supply to the myocardium. Nitrates do not directly influence the chronotropic or inotropic actions of the heart, so their administration does not affect or alter cardiac function but rather decreases the work of the heart and increases myocardial oxygenation. Nitrates are moderately effective in lessening coronary vasospasm.

Rapid-Acting Nitrates

The sublingual forms of NTG are rapid acting. (See Table 21.1.) These medications are used for acute attacks of angina. Short-acting nitrates are also used for prophylaxis of angina in situations when an anginal episode can be reasonably predicted by the patient, such as during walking, climbing stairs, or sexual activity. To be effective, NTG must be administered sublingually to avoid hepatic first-pass metabolism, which would inactivate the medication.

Sublingual NTG (Nitrol, Isordil, others) remains the first-line therapy for managing acute angina episodes. NTG may be adequate treatment for patients who experience angina no more frequently than once a week. NTG usually relieves anginal symptoms within 1 to 5 minutes and provides short-term (up to 30 minutes) relief. NTG tablets or spray (0.3 to 0.6 mg) is used sublingually for immediate symptomatic treatment of anginal episodes. The practitioner instructs the patient to rest at the time of pain, take a single dose, repeat the dose if the pain does not resolve within 5 minutes, and call emergency medical services if the pain is not relieved with three doses.

Patients should be instructed to mark the date they open a bottle of NTG tablets or first use an NTG spray canister. Tablets in an opened glass bottle of NTG retain efficacy for only 1 year and should be discarded after that time period. NTG canisters retain their efficacy for up to 3 years.

The main advantage of rapid-acting nitrates is their ability to halt an episode of angina once it has begun. Generally, the adverse effects of short-acting nitrates are related to their vasodilatory effects; however, patients may also experience burning under the tongue with

sublingual preparations.

Long-Acting Nitrates

Due to their short duration of action, short-acting nitrates such as sublingual NTG are not suitable for maintenance therapy; long-acting nitrates must be used for chronic prophylaxis of anginal episodes. Long-acting nitrates act to maintain vasodilation, thereby continuously decreasing the workload of the heart and maintaining blood flow to the heart. The most prescribed long-acting nitrates are isosorbide dinitrate (ISDN; oral [Cedocard SR, Isordil, others]), isosorbide mononitrate (ISMN; oral [Imdur, Ismo, Monoket, others]), and long-acting transdermal NTG preparations (transdermal [Minitran, Nitro-Dur, Transderm-Nitro, others], topical [Nitro-Bid, others]).

Isosorbide Dinitrate (Oral)

Single oral doses of 20 to 40 mg significantly improve hemodynamic parameters and exercise tolerance, and the effect continues for several hours. The starting dose should be low (e.g., ISDN 5 mg three times a day) and the dosage should be advanced slowly in small increments every 1 to 2 weeks to minimize side effects. The dose is increased until control is obtained, side effects become intolerable, systolic blood pressure falls to 100 mm Hg or below, resting heart rate increases more than 10 beats per minute, or postural hypotension occurs.

Intestinal absorption with ISDN is unpredictable, especially when taken with food, so oral nitrates should be taken on an empty stomach, 1 hour before or 2 hours after food intake. A drawback to ISDN products is the short half-life (approximately 2 to 4 hours) and duration of action, which necessitates multiple doses during the day.

Isosorbide Mononitrate (Oral)

ISMN is a long-acting metabolite derivative of ISDN. Formulated in extended-release tablets, ISMN can be administered in fewer doses (Imdur, once daily; other products, twice daily). A common twice-daily starting regimen is 20 mg (immediate release) orally at 7 AM and 3 PM, allowing for a nitrate-free period to reduce the risk of nitrate tolerance. A starting dose using extended-release ISMN (Imdur) is 30 to 60 mg orally in the morning. Like ISDN, ISMN should also be taken on an empty stomach. Extended-release formulations of ISMN must be taken whole, without crushing or chewing the tablet.

Nitroglycerin (Transdermal)

Transdermal NTG is long-acting and effective for treating and preventing anginal pain. Two percent (2%) NTG ointment may be applied to the skin as an adjunct to isosorbide therapy for nocturnal pain or, with repeated daily dosing, used alone for anginal treatment. One half to one inch of the ointment is applied to a clean, hairless area of the torso before bed. Alternatively, the ointment may be applied every 4 to 6 hours while awake, allowing

for an 8- to 12-hour nitrate-free interval. Measurement guides are provided with the product to assist in dosing. The dose is increased by a half inch at a time until pain relief is achieved.

Transdermal NTG patches may also be used as a long-acting nitrate. Therapy is typically initiated with a 5-mg (0.2 mg/h) or 10-mg (0.4 mg/h) patch, which should be left in place for 12 to 14 hours and then removed to prevent nitrate tolerance. Nitrate patches should be applied to the torso intact, since cutting a patch destroys the drug delivery system. Care should be taken to ensure that a previously applied patch is removed before applying a new patch.

Nitrate Tolerance

A drawback to the use of nitrates to treat angina is the potential for the development of nitrate tolerance. Nitrate tolerance refers to the loss of ability of the smooth muscles to respond to the action of the nitrates. Tolerance develops to both the peripheral and coronary vasodilator effects of nitrates. This phenomenon occurs with continuous nitrate use over prolonged periods. Tolerance is both dose and time dependent. Nitrate tolerance can be seen after as few as 7 to 10 days of continuous administration. Nitrate tolerance may also develop with frequent sublingual administration of nitrates, if the oral tablets are given four times daily in evenly spaced intervals or if the transdermal patches are left on the skin for 24-hour periods.

Prevention of nitrate tolerance is based on a treatment plan that provides for rapid changes in blood nitrate levels over a given time, usually 24 hours. To prevent nitrate tolerance, one 10- to 12-hour nitrate-free interval per day is necessary. In this manner, the intervals between doses need not be equal. For example, the patch can be applied in the morning and removed in the evening. The same schedule can be developed for patients taking oral medications. The medication is given three times during the day when the patient is awake. The patient does not receive any medication during the night to minimize the risk of nitrate tolerance. Combination antianginal therapy (e.g., a beta-blocker plus a long-acting nitrate) should be used for patients whose anginal symptoms are not controlled during the nitrate-free interval.

Adverse Events

The common side effects of the nitrates are related to their vasodilatory effects: headache, flushing, dizziness, weakness, and orthostatic hypotension. Additionally, since all segments of the vascular system relax in response to nitrates, reflex tachycardia often results as the heart compensates for the blood pressure drop to maintain cardiac output. Transdermal nitrate products may also cause irritation of the skin at the site of application.

Most of the side effects associated with nitrates abate or disappear with continuation of therapy. By starting therapy at a low dose and slowing titrating the dose upward, side effects are minimized and may not present at all. However, starting with a high dose can

produce severe side effects (especially headache), and if side effects are intolerable, the patient may self-discontinue the medication.

If a patient has been receiving nitrate therapy long term, it should not be abruptly discontinued because of the risk of rebound hypertension and angina. If discontinuation of nitrate therapy is required, it should be done by tapering the dose over a period of time.

Caution should be exercised when using nitrates in combination with vasodilators due to additive hypotensive effects. Concurrent use of nitrates and phosphodiesterase-5 inhibitors such as sildenafil (Viagra), vardenafil (Levitra), or tadalafil (Cialis) is contraindicated due to the potential for severe hypotension.

Beta-Blockers

Beta-blockers are very effective in managing angina. They reduce the workload of the heart and decrease overall myocardial oxygen demand and consumption through antagonism of adrenergic receptors. This is accomplished by a reduction in the heart rate and myocardial contractility, both at rest and during periods of normal exercise. As such, they are particularly beneficial for treating exertional angina.

Nitrates and beta-blockers have complementary effects on myocardial oxygen supply and demand and therefore are often used together. Because beta-blockers reduce the heart rate, they can be used to control the reflex tachycardia that sometimes occurs with the administration of nitrates. This reduction in heart rate also allows more time for coronary artery filling and therefore myocardial perfusion during diastole.

Mechanism of Action

Beta-blockers can be categorized according to their cardioselectivity, that is, the degree of preferential affinity for $beta_1$ receptors, which predominate in the heart and are the principal target of these medications. Beta antagonists that block only $beta_1$ receptors are considered *cardioselective* beta-blockers. Those that block both $beta_1$ and $beta_2$ receptors are *nonselective*. There are many beta-blockers available, all of which block $beta_1$ receptors. However, many agents also block $beta_2$ receptors, which predominate in the lungs.

$Beta_1$-receptor blockade is desirable in a patient with angina because it causes a slowing of the heart rate and a reduction in myocardial contractility. These effects reduce myocardial oxygen demand and therefore improve and prevent anginal symptoms.

Blockage of $beta_2$ receptors can lead to bronchoconstriction; therefore, nonselective beta-blockers should be used with caution in patients with uncontrolled or unstable reactive airway disease. At low to intermediate doses, cardioselectivity is demonstrated by atenolol (Tenormin) and metoprolol (Lopressor). Propranolol (Inderal) is an example of a nonselective beta-blocker. However, even cardioselective beta-blockers show nonselective action at high doses.

Propranolol is a nonselective beta-blocker with a short half-life (4 to 6 hours). Immediate-release formulations of propranolol must be dosed multiple times per day, but sustained-release preparations for once-daily dosing are also available. Other nonselective beta-blockers include nadolol and timolol.

Atenolol and metoprolol are selective $beta_1$ antagonists. These drugs, which preferentially block $beta_1$ receptors, were developed to eliminate the unwanted bronchoconstriction effect of the agents that also block $beta_2$ receptors. These agents may be a better choice for patients with severe or uncontrolled asthma or chronic obstructive pulmonary disease (COPD). However, when these agents are prescribed at high dosage

levels, they lose their cardioselective properties. Atenolol has a long duration of action and therefore may be dosed once daily. Atenolol is renally cleared; therefore, dose adjustments must be made based on the patient's eGFR. Immediate-release metoprolol tartrate (Lopressor) must be given two to three times daily, but extended-release metoprolol succinate (Toprol-XL) is given only once daily. Both atenolol and metoprolol tartrate are available in generic forms and are relatively inexpensive. A generic form of metoprolol succinate is now available; however, it remains expensive when compared to the immediate-release preparation.

Pindolol and acebutolol are beta-blockers that also possess some agonist activity. They are not completely blockers in that they have the ability also to stimulate weakly both $beta_1$ and $beta_2$ receptors, possessing so-called *intrinsic sympathomimetic activity* (ISA). Drugs possessing ISA can stimulate the beta receptor to which they are bound, yet, as antagonists, they block the activation of the receptor by the more potent endogenous catecholamines, epinephrine and norepinephrine. Because of the agonist action, there is a diminished effect on cardiac rate and cardiac output. Patients who cannot tolerate the other beta-blockers because of preexisting bradycardia or heart block may tolerate these agents.

Contraindications

Beta-blockers are relatively contraindicated and therefore should be used cautiously in patients with preexisting bradycardia because beta blockade may lower the heart rate further. Additionally, beta-blockers should not be used if a patient is experiencing an acute episode of decompensated heart failure. The addition of a beta-blocker in this situation has the potential to negatively impact the patient by further reducing heart rate and contractility. Finally, as discussed above, beta-blockers should be used with caution in patients with reactive airway disease. In patients with stable or controlled asthma or COPD, a selective beta-blocker may be a better choice to minimize the risk of bronchospasm.

Adverse Events

Beta-blockers have the potential to adversely affect cardiac function. These effects include slowing the sinoatrial node and atrioventricular (AV) conduction, leading to symptomatic bradycardia and heart block. Sinus arrest is possible. If the patient has preexisting cardiac conduction system disease, a preparation with some intrinsic beta-agonist activity may be chosen to minimize these adverse events. These patients require close and frequent monitoring to ensure that early conduction system disease is managed promptly. Beta-blockers should not be given to patients with a slow heart rate at baseline due to the potential for severe bradycardia.

Since beta-blockers attenuate the "fight or flight" response, the clinical manifestations of hypoglycemia may be masked. Therefore, patients with diabetes should be instructed to more closely monitor their serum glucose to avoid severe hypoglycemic reactions. Typical

symptoms of hypoglycemia, including tachycardia, tremor, or sweating, may be decreased or absent when these patients are taking a beta-blocker.

Abrupt withdrawal of beta-blockers can precipitate an acute withdrawal syndrome that may be manifested by tachycardia, hypertensive crises, angina exacerbation, acute coronary insufficiency, or even MI (Antman & Sabatine, 2013). For this reason, beta-blocker therapy should always be tapered. Withdrawal is of particular concern in the anginal patient on large doses of beta-blockers who is faced with an emergency situation that makes it impossible to continue taking the prescribed beta-blocker for more than 48 hours.

Beta-blockers may also cause adverse central nervous system effects, including drowsiness and depression. These effects may occur more frequently in the elderly or in patients with preexisting depression or psychiatric disorders. In these patients, careful monitoring of mood, sleep pattern, and sexual and cognitive functioning is necessary.

Calcium Channel Blockers

Calcium channel blockers are effective in managing angina because they exert vasodilatory effects on the coronary and peripheral vessels. Depending on the specific agent, they have the potential to depress cardiac contractility, heart rate, and conduction, which may mediate their antianginal effects. These drugs are effective in relieving coronary constriction associated with vasospastic angina.

Mechanism of Action

Calcium plays a major role in the electrical excitation and contraction of cardiac and vascular smooth muscle cells. The calcium channel blockers inhibit the entrance of calcium into smooth muscle cells of the coronary and systemic arterial vessels, which inhibits muscular contraction and therefore causes vasodilation. These vasodilatory effects are more pronounced on arteries than veins because of the relatively large amount of smooth muscle found in the arteries. Because calcium channel blockers do not cause substantial venous dilation, they do not reduce preload. Nondihydropyridine calcium channel blockers reduce heart rate by slowing conduction through the sinoatrial and AV nodes, and they depress cardiac contractility.

Two major groups of calcium channel blockers are available: the dihydropyridines and the nondihydropyridines.

Dihydropyridines

The dihydropyridine calcium channel blockers are potent dilators of the coronary and peripheral arteries. Due to the vasodilatory effect of these agents, they may cause reflex tachycardia due to a reduction in systemic blood pressure. Since dihydropyridines do not alter conduction, they do not slow the sinus rate.

There are many dihydropyridine calcium channel blockers available. Nifedipine is an example of a first-generation dihydropyridine; nicardipine, felodipine, isradipine, and amlodipine are second-generation dihydropyridines. In general, the second-generation agents are better tolerated than the first-generation agents.

All of these agents are administered orally, and they have relatively short half-lives. Doses should be titrated upward slowly to minimize orthostasis or other adverse events. Several dihydropyridines (e.g., nifedipine, nicardipine) must be administered as multiple daily doses unless the sustained formulations are used. Amlodipine is administered once daily.

Nondihydropyridines

Although diltiazem and verapamil are both nondihydropyridine calcium channel blockers, they display different effects on the cardiovascular system. Verapamil has a pronounced

effect on cardiac conduction, reducing the rate of electrical conduction through the AV node. Verapamil also exerts negative inotropic and chronotropic effects, suppressing contractility, reducing heart rate, and therefore causing a reduction in oxygen demand. However, due to this effect, verapamil should be used with caution in those patients with depressed cardiac function or AV conduction abnormalities. Immediate-release formulations of verapamil must be administered as divided doses, but sustained-release products are administered once daily.

Like verapamil, diltiazem reduces the heart rate but to a lesser extent. Diltiazem also has a less potent effect than verapamil on conduction and contractility, but it is a more potent vasodilator. Diltiazem has immediate- and sustained-release formulations. The immediate-release formulation usually is taken four times a day before meals; the sustained-release formulation is taken daily on an empty stomach.

Contraindications

Before a calcium channel blocker can be selected for treating angina, a careful assessment must be done to determine a patient's LV and conduction system function. Nondihydropyridine calcium channel blockers with negative inotropic properties may worsen preexisting LV dysfunction. Patients with conduction system disease are poor candidates for nondihydropyridine calcium channel blocker therapy because of the risk of bradyarrhythmias.

The nondihydropyridine calcium channel blockers are contraindicated in patients with heart block because of the significant depression of AV node conduction. Additionally, calcium channel blockers should be used with caution in patients with sick sinus syndrome and hypotension.

Adverse Events

In general, adverse events accompanying the dihydropyridine calcium channel blockers are more common with the first-generation than the second-generation agents. Leg edema, a common problem, results from vasodilation, which causes fluid to pool in the legs. In some cases, the edema may be so severe that new-onset heart failure may be suspected. In this situation, dosage reduction or drug discontinuation may be considered. Other common side effects of the calcium channel blockers include fatigue, dizziness, headache, flushing, and gingival hyperplasia. Verapamil is associated with constipation much more often than the other calcium channel blockers.

Antiplatelet Therapy

Antiplatelet drugs inhibit platelet aggregation through a variety of mechanisms. Aspirin inhibits platelet activation through irreversible enzyme antagonism to block prostaglandin synthesis, and clopidogrel reduces ADP-induced platelet activation. Aggregation is a normal process that causes disease when the platelets adhere to vessel walls, causing thrombus formation. Antiplatelet therapy limits the formation of the thrombus, thereby decreasing the risk of progressive CHD. When antiplatelet medications are used to treat patients with angina, the chances of having an MI are reduced.

In patients with stable angina, the risk of MI can be lowered with daily aspirin therapy. Aspirin acts by blocking prostaglandin synthesis, which prevents formation of the platelet-aggregating substance thromboxane A_2. Current angina recommendations suggest that all patients with acute or chronic ischemic heart disease receive aspirin 75 to 162 mg daily as primary or secondary prevention of cardiovascular disease (Fihn et al., 2012). Doses of aspirin greater than 162 mg have been shown to increase the risk of adverse events without any enhanced benefit.

Adverse events associated with aspirin use include dyspepsia, bruising, and bleeding. Enteric-coated aspirin may be prescribed to minimize gastrointestinal symptoms. Aspirin is contraindicated in patients with a known aspirin hypersensitivity.

Clopidogrel is another antiplatelet agent that may be used in patients with angina. It reduces ADP-induced platelet activation by antagonizing the platelet ADP receptors. Clopidogrel is recommended for prevention of MI in angina patients who have contraindications to aspirin. Like aspirin, clopidogrel has been shown to reduce the incidence of morbidity and mortality in patients with established cardiovascular disease.

The dose of clopidogrel is 75 mg daily. Bleeding events associated with clopidogrel are similar to aspirin, although it typically exhibits better gastrointestinal tolerance. However, clopidogrel is metabolized to its active component, in part by the CYP2C19 system, which in certain patients shows significant genetic variation. Data have shown that this genetic variation may play a role in the effectiveness of this agent, particularly in those who have a slow metabolism. For further discussion of antiplatelet agents, refer to Chapter 49.

Ranolazine

Ranolazine (Ranexa) is a unique antianginal agent that can be used alone or in combination with nitrates, beta-blockers, calcium channel blockers, or ACE inhibitors. Currently, its primary role is as an adjunctive agent for patients who are not achieving adequate symptom relief with other agents.

Mechanism of Action

The mechanism of action of ranolazine is not well understood, but it is thought to block

late-phase sodium channels, which often remain open during hypoxic or ischemic events. An increase in intracellular sodium during late phase affects sodium-dependent calcium channels, thus increasing the amount of calcium entering the cell and causing a calcium overload. This overload can lead to further or continued contraction of the myocardium, increasing oxygen demand. By blocking late-phase sodium channels, ranolazine decreases calcium overload and breaks the cycle of ischemia.

Dosage

Ranolazine is taken orally at 500 mg twice daily and can be titrated up to a maximum of 1,000 mg twice daily. Ranexa tablets should be swallowed whole, not crushed or split. There may need to be a dose reduction in patients taking CYP3A4 inhibitors, such as diltiazem and verapamil.

Contraindications

Ranolazine is contraindicated in patients taking ketoconazole, itraconazole, clarithromycin, and other strong CYP3A4 inhibitors.

Adverse Events

Ranolazine prolongs the QTc interval in a dose-related manner; however, in long-term studies, there has been no association with an increased risk of proarrhythmia or sudden death. Regardless, caution should still be used because there is little experience with doses greater than 1,000 mg twice daily. Dose-related dizziness, headache, constipation, and nausea are common adverse effects. Other adverse events include palpitations, vertigo, dry mouth, peripheral edema, hypotension, and, less commonly, angioedema and renal failure.

Interactions

As noted earlier, patients taking potent CYP3A4 inhibitors should not take ranolazine, and less potent inhibitors warrant monitoring. Conversely, agents that induce the CYP3A4 system, such as rifampin, carbamazepine, phenytoin, and St. John's wort, may decrease plasma concentrations of ranolazine. Ranolazine, through the P-glycoprotein system, may increase digoxin levels.

Selecting the Most Appropriate Antianginal Therapy

Choosing the appropriate medications for treating a patient with angina can be challenging. The primary goal is to design a regimen that will reduce the frequency and severity of anginal episodes. Subsequent adjustments are made empirically based on the patient's response to treatment, disease progression, risk factor modification, and patient satisfaction and adherence (Figure 21.1).

FIGURE 21.1 Treatment algorithm for angina.

Acute Treatment of Anginal Episodes

All patients with angina should be provided a short-acting nitrate for acute treatment of anginal episodes. Additionally, patients with infrequent episodes of angina can be managed effectively with short-acting nitrates alone. They are a good choice for the patient who has infrequent attacks or predictable pain on exertion.

Chronic Prevention of Anginal Episodes

Patients with repeated episodes of angina should receive long-acting therapy for chronic prophylaxis. All patients should be receiving aspirin. In addition, there are three classes of agents that may be used for chronic antianginal therapy: beta-blockers, calcium channel blockers, and long-acting nitrates. The initial choice of an antianginal agent should be based on the patient's specific characteristics, such as physical exam findings and coexisting medical conditions. Treatment with a single agent is generally used for initial antianginal therapy, whereas combination therapy is instituted for patients who fail monotherapy.

First-Line Therapy

In the absence of contraindications, beta-blockers are the agents of choice for prevention of acute anginal episodes in patients with or without a history of MI. Beta-blockers reduce the frequency and likelihood of anginal episodes and reduce CHD-related morbidity and mortality. Additionally, beta-blockers are useful as antihypertensive and antiarrhythmic agents. Beta-blockers are particularly useful in patients whose anginal symptoms are related to physical exertion.

For patients whose anginal symptoms have been linked to coronary vasospasm, a calcium channel blocker may be considered for initial treatment. See Table 21.2 for more information.

TABLE 21.2 Recommended Order of Treatment for Angina

Order	Agents	Comments
For all patients	Short-acting nitrate aspirin (if not contraindicated)	For acute treatment of anginal episodes May be used to prevent predictable episodes May be used alone in patients with infrequent episodes
Chronic prevention of anginal episodes		
First line	Beta-blocker	Reduces workload of heart by decreasing overall myocardial oxygen consumption
	Calcium channel blocker	Useful for patients who cannot tolerate a beta-blocker
Second line	Combination therapy	If monotherapy fails, add another agent from a different class: beta-blocker, calcium channel blocker, long-acting nitrate (e.g., beta-blocker and long-acting nitrate)

Second-Line Therapy

For patients who do not respond sufficiently to therapy with a single antianginal agent, combination therapy should be attempted. When initial treatment with a beta-blocker is not successful, either a calcium channel blocker or a long-acting nitrate may be added to beta-blocker therapy.

A long-acting nitrate/beta-blocker regimen is safe, effective, and low in cost. Nitrates and beta-blockers are well tolerated, and their effects are complementary. Reflex tachycardia caused by nitrates is blunted by a beta-blocker. The control of reflex tachycardia is beneficial because a decrease in heart rate lowers myocardial oxygen demand. The combination of nitrates and beta-blockers is an accepted treatment of angina, and they are often used together.

A beta-blocker plus a calcium channel blocker is another typical combination. Patients who have anginal symptoms that cannot be controlled by beta-blocker or calcium channel blocker monotherapy often respond to a combination of the two. However, a beta-blocker plus nondihydropyridine calcium channel blocker combination should be used with caution. When drugs from these two classes are given together, the additive effect is potent suppression of AV conduction, which may be problematic in patients with preexisting cardiac conduction abnormalities. It is best to start with low doses of each drug and monitor each dosage increase so that side effects can be identified early.

Nitrates are often combined with a nondihydropyridine calcium channel blocker, such as diltiazem or verapamil, or a second-generation dihydropyridine calcium channel blocker, such as amlodipine. Since nitrates and first-generation dihydropyridine calcium channel blockers are potent vasodilators, they should be used together with extreme caution and only if no other treatment option is available.

Third-Line Therapy

In patients who are refractory to a two-drug regimen, a three-drug regimen of a calcium channel blocker, beta-blocker, and a long-acting nitrate may be used. In general, patients whose anginal symptoms do not respond to two antianginal agents should be referred to a specialist's care.

Monitoring Patient Response

In patients with angina, monitoring is important to evaluate for progression or stability of the disease, response to therapy, and presence or absence of adverse events.

Patient monitoring begins when a stress test is performed to confirm the diagnosis of angina. Once the diagnosis is made, stress tests may be repeated if there is a change in the pattern of anginal symptoms. Additionally, patients with stable angina should have an ECG if the history or physical examination changes or if the practitioner suspects new myocardial ischemia or development of a conduction abnormality (Fihn et al., 2012).

Routine follow-up depends on the frequency and severity of the patient's complaints. Stable patients should be seen every 2 to 6 months, but visits should be more frequent if the patient's symptoms change or become more severe or more frequent. Medication initiation and adjustment also require more office visits. At each office visit, vital signs should be taken and a complete physical examination performed. The patient should be questioned about anginal pain and associated symptoms and side effects of the drug regimen. Additional monitoring parameters should be determined by the specific drug regimen. Ideally, a patient's antianginal regimen should make him or her symptom-free.

Patient Education

For optimal control of anginal symptoms, the patient should be educated on his or her disease and medications. Patients should be informed of the seriousness of coronary artery disease and the potential consequences of leaving their angina untreated. Education about lifestyle modification strategies should be provided to all patients as often as possible. Additionally, patients need to know how to recognize worsening or escalating symptoms so they know when to seek emergency care.

Drug Information

There are many sources of information relating to the treatment of angina. Several therapeutic guidelines are available to the practitioner, including those from the American College of Cardiology and American Heart Association, the American College of Chest Physicians, the European Society of Cardiology, and many other organizations. Specific questions relating to pharmacologic agents used in the treatment of angina may be addressed using the *Physician's Desk Reference, Drug Facts and Comparisons, Epocrates*, or another drug reference. Finally, information regarding ongoing clinical trials for angina and other conditions may be obtained from a Web site provided by the National Institutes of Health (www.clinicaltrials.gov).

Patient-Oriented Information Sources

Practitioners may provide disease- and treatment-related information to patients with information from a variety of sources. The Web site for the American Heart Association (www.americanheart.org) has many resources available to explain cardiovascular disease and angina in a fashion that patients will understand. Also, the American Academy of Family Physicians (www.familydoctor.org) provides on its Web site a variety of resources under the heading of "Patient Ed." Finally, the National Heart, Lung, and Blood Institute describes for patients the disease of angina, its causes, and appropriate treatments under the "Diseases and Conditions Index" (http://www.nhlbi.nih.gov/health/dci/Diseases/Angina/Angina_WhatIs.html).

Complementary and Alternative Medications

Although there are a variety of complementary medications, such as Coenzyme Q10 and vitamin E, that allege to provide symptom relief for patients with angina, no herbal or supplement medication has been shown to have efficacy similar to that of the traditional agents described above. Chelation therapy also has anecdotal reports of anginal symptom improvement, but there are no randomized controlled trials that support its use (Fihn et al., 2012). If at all possible, practitioners should counsel patients to adhere to treatment regimens that have shown efficacy in the treatment of angina.

Patients should be educated on each of the medications they are provided. They should know the importance of taking their medications as prescribed. They should be informed of each medication's indication and possible side effects, and what to do if they miss one or more doses of a scheduled medication, such as a long-acting nitrate. Additionally, practitioners should educate patients about the proper storage of all medications.

Case Study*

E.H. is a 45-year-old African American man who recently moved to the community from another state. He requests renewal of a prescription for a calcium channel blocker, prescribed by a physician in the former state. He is unemployed and lives with a woman, their son, and the woman's 2 children. His past medical history is remarkable for asthma and six "heart attacks" that he claims occurred because of a 25-year history of drug use (primarily cocaine). He states that he used drugs as recently as 2 weeks ago. He does not have any prior medical records with him. He claims that he has been having occasional periods of chest pain. He is unable to report the duration or pattern of the pain.

Before proceeding, explore the following questions: What further information would you need to diagnose angina (substantiate your answer)? What is the connection between cocaine use and angina? Identify at least three tests that you would order to diagnose angina.

Diagnosis: Angina

1. List specific goals of treatment for E.H.
2. What dietary and lifestyle changes should be recommended for this patient?
3. What drug therapy would you prescribe for E.H. and why?
4. How would you monitor for success in E.H.?
5. Describe one or two drug–drug or drug–food interactions for the selected agent.
6. List one or two adverse reactions for the selected agent that would cause you to change therapy.
7. What would be the choice for the second-line therapy?
8. Discuss specific patient education based on the prescribed first-line therapy.
9. What over-the-counter and/or alternative medications would be appropriate for E.H.?

22 Heart Failure

Andrew M. Peterson ■ Melody D. Randle ■ Troy L. Randle

Heart failure (HF), one of the most serious consequences of cardiovascular disease, has rapidly become one of the most important health problems in cardiovascular medicine. Nearly 5 million Americans have HF today, with an incidence approaching 20 per 1,000 among persons older than age 65 (Go et al., 2013). At age 40, the lifetime risk of developing HF for both men and women is 1 in 5. The incidence of HF increases with age (Go et al., 2013). HF is more common in men than in women, due to the higher incidence of ischemic heart disease in men. Approximately 75% of all ambulatory patients with HF are age 60 or older (Go et al., 2013). As the population is aging, the number of people with HF will significantly increase in the future. In people diagnosed with HF, the mortality rates remain approximately 50% within 5 years of diagnosis (Go et al., 2013). Health care disparities place African Americans at highest risk for HF (Bahrami et al., 2008).

In the United States, HF incidence has largely remained stable over the past several decades, with more than 650,000 new HF cases diagnosed annually. HF incidence increases with age, rising from approximately 20 per 1,000 individuals 65 to 69 years of age to greater than 80 per 1,000 individuals among those 85 years of age or older. Approximately 5.1 million persons in the United States have clinically manifest HF, and the prevalence continues to rise, and 7% of all cardiac deaths are due to HF.

The economic impact of HF also is significant. The large number and often high complexity of hospitalizations for HF make this diagnosis very costly. The total cost of HF hospitalizations in the United States has been estimated at $8 billion. After hypertension, HF is the second most common indication for physician office visits. The estimated direct and indirect cost of HF in the United States for 2009 was $37.2 billion (Go et al., 2013). Consequently, improved quality of life is considered a worthy health care goal, and the therapeutic approach to HF is directed toward increasing the patient's ability to maintain a positive quality of life with symptom-free activity and to enhance survival. Vasodilator therapy, especially with the angiotensin-converting enzyme (ACE) inhibitors, has made significant contributions toward achieving this goal.

Causes

The development of HF may be related to many etiologic variables. Coronary artery disease, hypertension, and idiopathic cardiomyopathy are the most frequently cited risk factors for HF. Acute conditions that may result in HF include acute myocardial infarction (MI), arrhythmias, pulmonary embolism, sepsis, and acute myocardial ischemia. Gradual development of HF may be caused by liver or renal disease, primary cardiomyopathy, cardiac valve disease, anemia, bacterial endocarditis, viral myocarditis, thyrotoxicosis, chemotherapy, excessive dietary sodium intake, and ethanol abuse.

Drugs also can worsen HF. Drugs that may cause fluid retention, such as nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, hormones, antihypertensives (e.g., hydralazine [Apresoline], nifedipine [Procardia XL]), sodium-containing drugs (e.g., carbenicillin disodium [Geopen]), and lithium (Eskalith, others), may cause congestion. Beta-blockers, antiarrhythmics (e.g., disopyramide [Norpace], flecainide [Tambocor], amiodarone [Cordarone], sotalol [Betapace]), tricyclic antidepressants, and certain calcium channel blockers (e.g., diltiazem [Cardizem], nifedipine, verapamil [Calan]) have negative inotropic effects and further decrease contractility in an already depressed heart. Direct cardiac toxins (e.g., amphetamines, cocaine, daunorubicin [DaunoXome], doxorubicin [Adriamycin], and ethanol) also can worsen or induce HF.

Pathophysiology

HF is a pathophysiologic state in which abnormal myocardial function inhibits the ventricles from delivering adequate quantities of blood to metabolizing tissues at rest or during activity. It results not only from a decrease in intrinsic systolic contractility of the myocardium but also from alterations in the pulmonary and peripheral circulations (Braunwald, 2015). The cardiac dysfunction is either in ventricular contraction/ejection (systolic) or ventricular filling/relaxation (diastolic).

When the heart fails as a pump and cardiac output (the volume of blood pumped out of the ventricle per unit of time) decreases, a complex scheme of compensatory mechanisms to raise and maintain cardiac output occurs. These compensatory mechanisms include increased preload (volume and pressure or myocardial fiber length of the ventricle prior to contraction [end of diastole]), increased afterload (vascular resistance), ventricular hypertrophy (increased muscle mass), and dilatation, activation of the sympathetic nervous system (SNS), and activation of the renin–angiotensin–aldosterone system (RAAS).

Although initially beneficial for increasing cardiac output, these compensatory mechanisms are ultimately associated with further pump dysfunction. In effect, the consequence of activating the compensatory systems is worsening HF. This is often referred to as the *vicious cycle of HF* (Figure 22.1). Without therapeutic intervention, some of the compensatory mechanisms continue to be activated, ultimately resulting in a reduced cardiac output and a worsening of the patient's symptoms. An understanding of the compensatory mechanisms makes it clear why one goal in treating HF is to interrupt this vicious cycle and why various drugs are used in managing patients with HF.

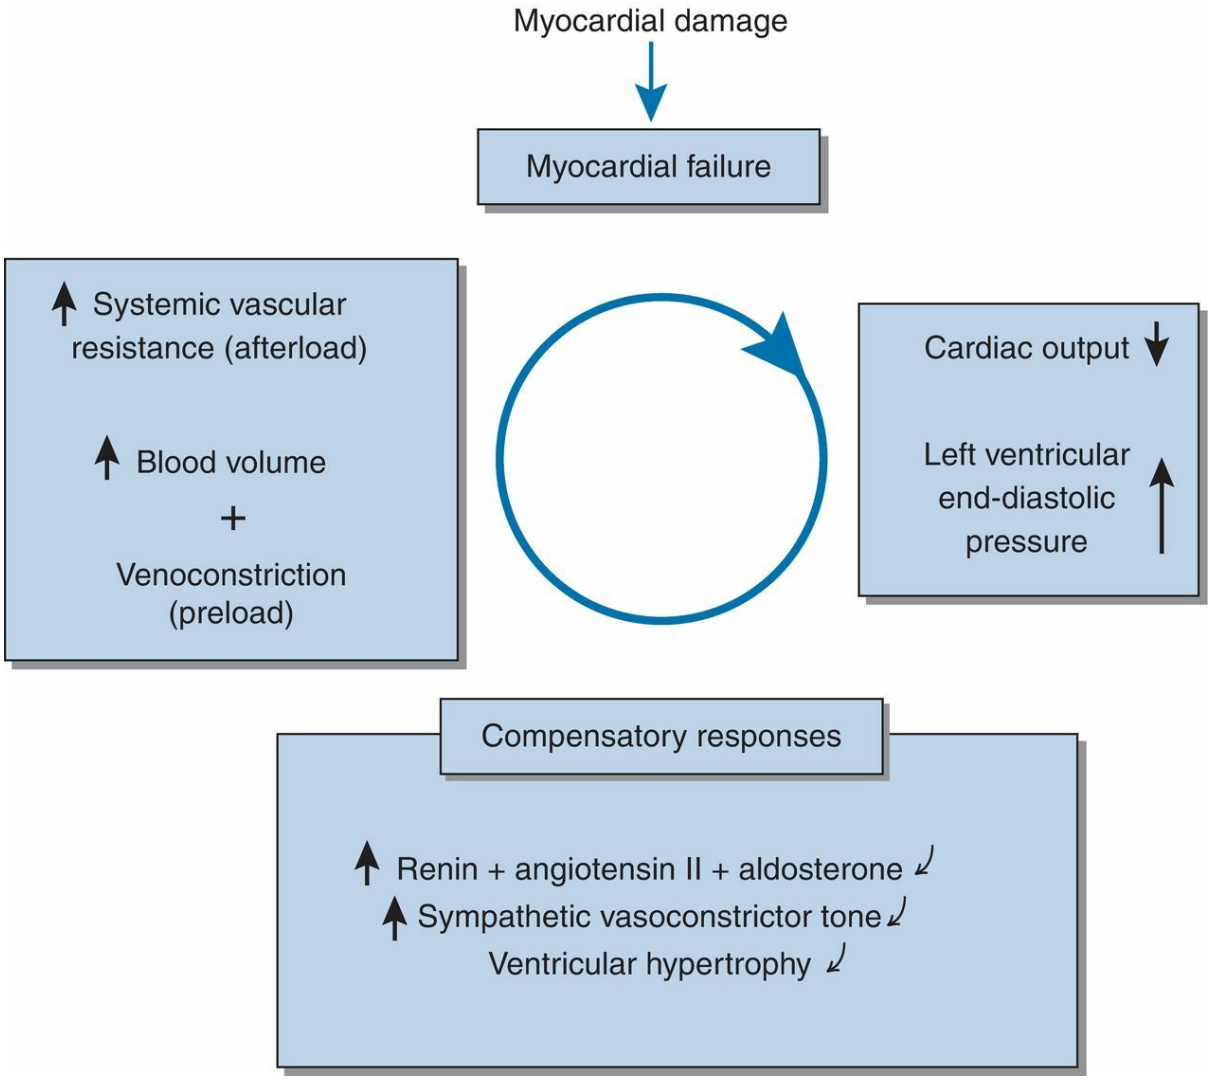

FIGURE 22.1 Vicious circle of heart failure.

Diagnostic Criteria

The signs and symptoms of HF are useful in diagnosing and assessing a patient's clinical response to therapy. The clinical manifestations of HF are in part due to pulmonary or systemic venous congestion and edema. When the left ventricle malfunctions, congestion initially occurs proximally in the lungs. When the right ventricle functions inadequately, congestion in the supplying systemic venous circulation results in peripheral edema, liver congestion, and other indicators of right HF (Box 22.1). Both pulmonary and systemic congestion eventually develop in most patients with left HF. In fact, the chief cause of right HF is left HF.

BOX 22.1 Clinical Manifestations of Heart Failure

Left Ventricular Failure—Pulmonary Congestion

Symptoms: Cough, dyspnea, dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, nocturia

Signs:

Cardiomegaly, S_3 heart sound, bibasilar rales, signs of pulmonary edema, tachycardia, increased respiratory rate

Right Ventricular Failure—Systemic Congestion

Symptoms: Peripheral pitting edema, abdominal pain, anorexia, bloating, constipation, nausea, vomiting

Signs:

Hepatomegaly, distention of the jugular veins, hepatojugular reflex, signs of portal hypertension, ascites, splenomegaly

Decreased Cardiac Output

Peripheral cyanosis, fatigue, decreased tissue perfusion, decrease in metabolism and renal elimination of drugs, decreased appetite, angina, increased risk for thromboembolism

Depressed ventricular function may be confirmed by echocardiography, radionuclide ventriculography, magnetic resonance imaging, or cardiac catheterization. Abnormalities in the electrocardiogram (ECG) are common and include arrhythmias, conduction delays, left ventricular (LV) hypertrophy, and nonspecific ST–T changes, which typically reflect the underlying etiology. Laboratory findings from liver function or other tests disclose such abnormalities as elevated blood urea nitrogen (BUN) and creatinine levels, hyponatremia, and elevated serum enzymes of hepatic origin. The circumstances in which the symptoms

of HF occur are also particularly important in determining the severity of disease in a particular patient.

The New York Heart Association (NYHA) classifies the functional incapacity of patients with cardiac disease into four levels depending on the degree of effort needed to elicit symptoms (Table 22.1):

TABLE 22.1 NYHA Functional Classification/ACCF/AHA Stages of HF

Class	Definition	Class	Definition
None		A	At high risk for HF without structural heart disease or symptoms of HF
I	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue or dyspnea.	B	Structural heart disease but without signs or symptoms of HF
II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue or dyspnea	C	Structural heart disease with prior or current symptoms of HF
III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue or dyspnea		
IV	Unable to carry on any physical activity without symptoms. Symptoms are present even at rest. If any physical activity is undertaken, symptoms are increased.	D	Refractory HF requiring specialized interventions

- *Class I:* Patients may have symptoms of HF only at levels that would produce symptoms in normal people.
- *Class II:* Patients may have symptoms of HF on ordinary exertion.
- *Class III:* Patients may have symptoms of HF on less than ordinary exertion.

- *Class IV:* Patients may have symptoms of HF at rest.

The American College of Cardiology/American Heart Association (ACC/AHA) has developed a classification system that categorizes the progression of HF and is intended to complement the NYHA classification (Table 22.1):

- *Stage A:* Patients who are at high risk for developing HF but have no structural heart disease
- *Stage B:* Patients with structural heart disease who have never had symptoms of HF
- *Stage C:* Patients with past or current symptoms of HF associated with underlying structural heart disease
- *Stage D:* Patients with end-stage disease who require specialized treatment strategies, such as mechanical circulatory support, continuous IV inotrope infusions, cardiac transplantation, or hospice care

Initiating Drug Therapy

In the past, digitalis, glycosides, and diuretics were the mainstays of therapy for HF. However, the concept of HF has changed dramatically from a narrow focus on the weakened heart to a broadened view of the systemic pathophysiologic state, with peripheral as well as myocardial factors playing important roles. Individualization of pharmacologic therapy is a cornerstone of care and now based on the stage of HF. The goals of therapy are to improve the quality of life, decrease mortality, and reduce the compensatory mechanisms causing the symptoms. Three general approaches are used:

1. An underlying cause of HF is treated if possible (e.g., surgical correction of structural abnormalities/valvular heart disease or medical treatment of conditions such as hypertension, diabetes mellitus, or dyslipidemia).
2. Precipitating factors that produce or worsen HF are identified and minimized (e.g., fever, anemia, arrhythmias, medication noncompliance, or drugs).
3. After these two steps, drug therapy to control the HF and improve survival becomes important.

Nonpharmacologic management techniques should be used along with pharmacologic therapy in patients with HF. In the past, reduced activities and bed rest were considered a standard part of the care of patients with HF. However, it has been determined that short periods of bed rest result in reduced exercise tolerance and aerobic capacity. There is insufficient evidence to recommend a specific type of training program or the routine use of supervised rehabilitation programs. Although most patients should not participate in heavy labor or exhausting sports, aerobic activity should be encouraged (except during periods of acute decompensation). For example, according to the Agency for Healthcare Research and Quality (AHRQ), regular exercise (e.g., walking or cycling) is recommended for patients with stable class I to III disease.

Goals of Drug Therapy

Pharmacologic management of patients with HF is critical in reducing symptoms and decreasing mortality. In most cases, drug therapy is long term and consists of ACE inhibitors and beta blockers for class I indications. Diuretics, aldosterone antagonists, hydralazine, nitrates, digoxin (Lanoxin), and others medications are also used. Table 22.2 provides an overview of drugs used to treat HF.

TABLE 22.2 Overview of Selected Agents Used to Treat Heart Failure

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Selected Angiotensin-Converting Enzyme Inhibitors			
captopril (Capoten) Start: 6.25 mg or 12.5 mg tid Therapeutic range: 25–100 mg tid	Common: cough; hypotension, particularly with a diuretic or volume depletion; hyperkalemia, loss of taste, leukopenia; angioedema, neutropenia, and agranulocytosis in <1% of patients; rash in >10% of patients	Contraindicated in pregnancy Avoid in patients with bilateral renal artery stenosis or unilateral stenosis.	Renal impairment related to ACE inhibitors is seen as an increase in serum creatinine and azotemia, usually in the beginning of therapy. Monitor BUN, creatinine, and K levels when starting.
enalapril (Vasotec) Start: 2.5 mg qd or bid Range: 5–20 mg qd or bid daily	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
fosinopril (Monopril) Start: 10 mg qd Range: 10–40 mg qd	Same as above	Same as above	Same as above Use only 5 mg/d in patient with impaired renal function or hyponatremia.
lisinopril (Zestril, Prinivil) Start: 5 mg qd Range: 5–20 mg qd	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
quinapril (Accupril) Start: 5 mg bid Range: 20–40 bid	Same as above	Same as above	Same as above Use only 2.5 mg/d in patient with impaired renal function or hyponatremia.
ramipril (Altace) Start: 1.25 mg twice daily Range: 1.25–5 mg twice daily	Same as above	Same as above	Same as above
trandolapril (Mavik) Start: 0.5–1 mg daily Target dose: 4 mg	Same as above	Same as above	Same as above
Selected Thiazide and Thiazide-like Diuretics			
chlorthalidone (Hygroton) 12.5–50 mg qd	Hyperuricemia, hypokalemia, hypomagnesemia, hyperglycemia, hyponatremia, hypercalcemia, hypercholesterolemia, hypertriglyceridemia, pancreatitis, rashes and other allergic reactions	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Thiazide diuretics preferred in patients with CrCl >30 mL/min
hydrochlorothiazide (HydroDIURIL, Microzide) 12.5–50 mg qd	Same as chlorthalidone	Same as chlorthalidone	Same as chlorthalidone
metolazone (Zaroxolyn) 2.5–10 mg qd	Less or no hypercholesterolemia	Same as chlorthalidone	Same as chlorthalidone
Loop Diuretics			
bumetanide (Bumex) 0.5–5 mg qd–bid	Dehydration, circulatory collapse, hypokalemia, hyponatremia, hypomagnesemia, hyperglycemia, metabolic alkalosis, hyperuricemia (short duration of action, no hypercalcemia)	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Effective in patients with CrCl <30 mL/min Monitor BUN, creatinine, and K levels when starting and with dosage changes.
ethacrynic acid (Edecrin) 25–100 mg bid–tid	Same as bumetanide (only nonsulfonamide diuretic, ototoxicity)	Same as bumetanide	Same as bumetanide

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
furosemide (Lasix) 20–320 mg bid–tid	Same as bumetanide	Same as bumetanide	Same as bumetanide
torsemide (Demadex) 5–20 mg qd–bid	Short duration of action, no hypercalcemia	Same as bumetanide	Same as bumetanide
Potassium-Sparing Diuretics			
amiloride (Midamor) 5–20 mg qd–bid	Hyperkalemia, GI disturbances, rash	High doses are relatively contraindicated in patients with hyperlipidemia, gout, and diabetes.	Same as bumetanide
spironolactone (Aldactone) 12.5–100 mg qd–bid	Hyperkalemia, GI disturbances, rash, gynecomastia	Same as amiloride	Spironolactone ideal in patients with heart failure
triamterene (Dyrenium) 50–150 mg qd–bid	Hyperkalemia, GI disturbances, nephrolithiasis	Same as amiloride	Same as bumetanide
Other Agents			
digitalis/digoxin (Lanoxin) 0.25 mg qd	Ventricular tachycardia, paroxysmal atrial tachycardia, fatigue, anorexia, nausea	Allergy, ventricular tachycardia, ventricular fibrillation, heart block, sick sinus syndrome, idiopathic hypertrophic subaortic stenosis, acute MI, renal insufficiency, electrolyte abnormalities Use with caution in pregnancy and lactation.	Check potassium levels before starting. Check serum levels once a year.
hydralazine (Apresoline) 25–75 mg tid	Postural hypotension, tachycardia	Coronary artery disease, aortic stenosis	Advise patient to avoid rapid changes in position. Patient can be started on 10 mg tid if elderly, with severe heart failure, or hypotensive.
isosorbide dinitrate (ISDN) (Isordil) 10–40 mg tid	Headache, dizziness, tachycardia, retrosternal discomfort, blurred vision, rash, flushing	Hypersensitivity to nitrates, closed-angle glaucoma, early MI, head trauma, pregnancy (category C)	Advise patient to avoid rapid changes in position.
Beta-Blockers			
bisoprolol (Zebeta) Start: 5 mg daily Range: 5–20 mg daily	Bradycardia, congestive heart failure, atrioventricular block, postural hypotension, vertigo, fatigue, depression, bronchospasm, impotence, insomnia, decreased exercise tolerance, impaired peripheral circulation, generalized edema, sinusitis	Sinus bradycardia, second- or third-degree heart block, asthma, liver abnormalities	Advise patient to avoid abrupt cessation of therapy. Observe for signs of dizziness for 1 h when dose is increased.
carvedilol (Coreg) 3.125–50 mg bid	Same as above	Same as above	Same as above
metoprolol Start: 6.25 mg 2–3 times daily Range: 50–100 mg 2–3 times daily	Same as above	Same as above	Same as above

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Selected Angiotensin Receptor Blockers			
losartan (Cozaar) Start: 12.5 mg/d Range: 50–100 mg/d	Dyspnea, hypotension, hyperkalemia	Angioedema secondary to ACE inhibition	May be used in patients experiencing cough due to ACE inhibitor
valsartan (Diovan) Start: 80 mg/d Range: 80–160 mg twice daily	Same as above	Same as above	Same as above
Other Agents			
dobutamine (Dobutrex) 2–5 mcg/kg/min intravenously	Elevated blood pressure, increased heart rate, angina, hypotension	Idiopathic hypertrophic subaortic stenosis	May increase insulin requirements
ivabradine (Corlanor) 2.5–7.5 mg bid	Bradycardia, HTN, atrial fibrillation, visual disturbances	Severe hepatic impairment, sick sinus syndrome, SA block without pacemaker, resting HR <60, atrial fibrillation, BP <90/50	Avoid grapefruit.

In patients with a history and reduced ejection fraction (EF), ACE inhibitors (ACE-I) or angiotensin receptor blockers (ARBs) should be used to prevent HF. In patients with an MI and reduced EF, beta-blockers should be used to prevent HF and a statin also given.

Angiotensin-Converting Enzyme Inhibitors (ACE-I)

Patients who have HF resulting from LV systolic dysfunction and who have an LV EF less than 35% to 40% should be given a trial of ACE inhibitors, unless they cannot tolerate treatment with these drugs. The ACE inhibitors may be considered therapy in the subset of patients who present with fatigue or mild dyspnea on exertion and who do not have any other signs or symptoms of volume overload. In patients with evidence for, or a prior history of, fluid retention, ACE inhibitors are usually used together with diuretics. (See section on Selecting the Most Appropriate Agent.) ACE inhibitors are also recommended for use in patients with LV systolic dysfunction who have no symptoms of HF. The clinical and mortality benefits of the ACE inhibitors have been shown in numerous uncontrolled and controlled, randomized clinical trials.

ACE inhibitors (ACE-I) have a positive effect on cardiac function (i.e., reduced preload and afterload, increased cardiac index, and EF) and the signs and symptoms of HF (e.g., dyspnea, fatigue, orthopnea, and peripheral edema). As a result, exercise capacity is increased, NYHA functional classification is significantly improved, and morbidity and mortality rates in patients with HF, including those who have suffered an MI, are reduced because these drugs can attenuate ventricular dilation and remodeling.

Captopril (Capoten), enalapril (Vasotec), fosinopril (Monopril), lisinopril (Zestril), quinapril (Accupril), trandolapril (Mavik), ramipril (Altace), and perindopril (Aceon) are the ACE inhibitors currently indicated for treating HF (see Table 22.2). The ACE inhibitors that are approved for use in patients with LV dysfunction, and have been shown to prolong survival, are enalapril, captopril, and lisinopril. Quinapril and fosinopril are labeled for symptom reduction in HF, but data are lacking as to their effect on mortality rates.

Mechanism of Action

"Balanced" vasodilators, including the ACE inhibitors and angiotensin II receptor blockers, cause vasodilation on both the venous and arterial sides of the heart and therefore provide the hemodynamic and clinical benefits of both preload and afterload reduction.

Activation of the RAAS is an important compensatory mechanism in HF (Figure 22.2). ACE catalyzes the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor and stimulant of aldosterone secretion. ACE inhibitors are uniquely effective in managing HF by interrupting stimulation of the RAAS, inhibiting the contributions of this system to the downward spiral of HF. The pharmacodynamic properties of ACE inhibitors involve specific competitive binding to the active site of ACE.

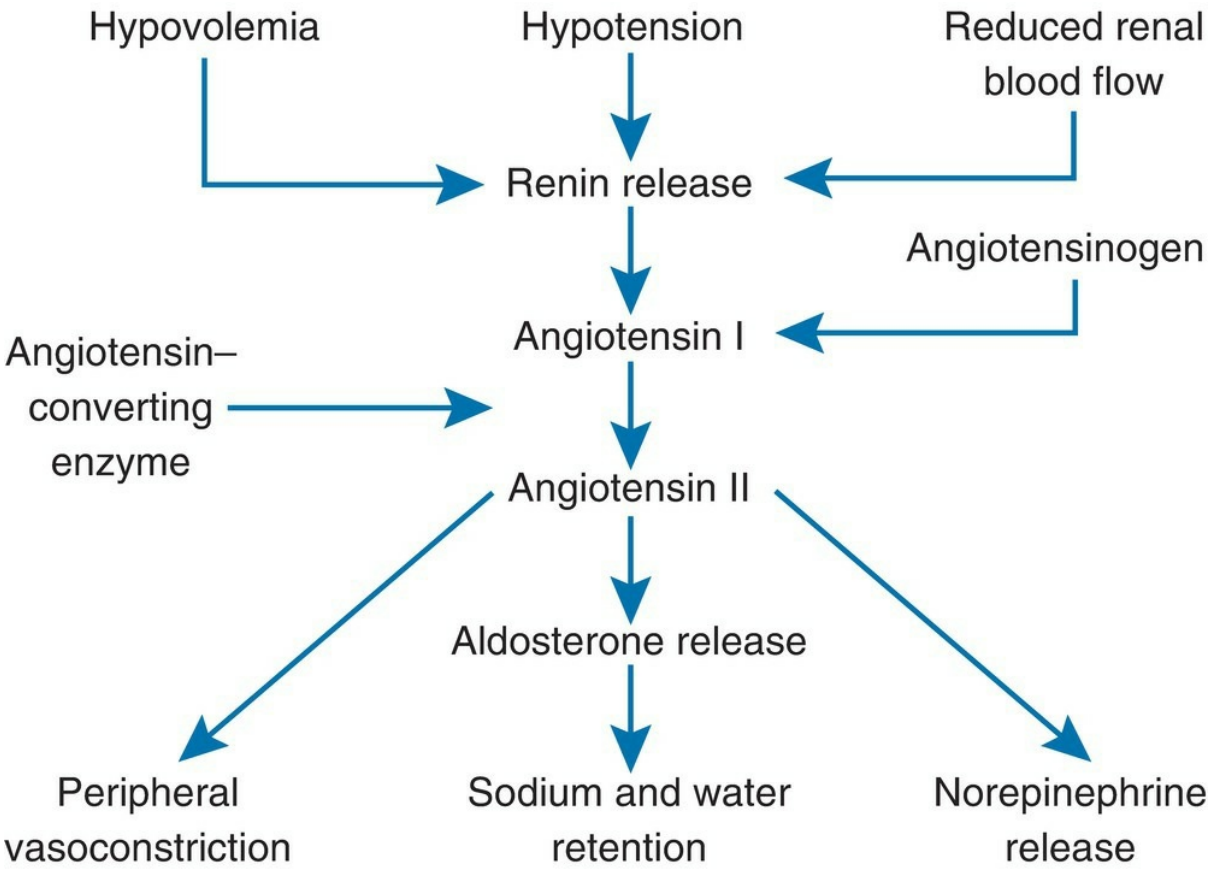

FIGURE 22.2 The renin–angiotensin–aldosterone (RAA) syndrome.

Angiotensin II interacts with at least two known membrane receptors, type 1 and type 2 (AT_1 and AT_2). By blocking formation of angiotensin II, ACE inhibitors indirectly produce vasodilation and a decrease in systemic vascular resistance (LV afterload). In addition, because angiotensin II stimulates aldosterone secretion by the adrenal cortex and provides negative feedback for plasma renin, inhibition of angiotensin II may lead to decreased aldosterone and increased renin activity. This prevents aldosterone-mediated sodium and water retention and may produce a small increase in serum potassium levels. The reduction in volume expansion due to ACE inhibition decreases ventricular end-diastolic volume (i.e., preload). Because ACE (kininase II) is involved in the breakdown of bradykinin, a vasodilator, a decrease in kininase II activity by an ACE inhibitor could increase bradykinin as well as prostaglandin production, either of which can lead to vasodilation.

ACE inhibitors produce vasodilation, inhibit fluid accumulation, and increase blood flow to vital organs, such as the brain, kidney, and heart, without precipitating reflex tachycardia. The hemodynamic effects of ACE inhibitors in HF include decreased preload, afterload, and mean arterial pressure, as well as increased cardiac output. EF is also improved. Clinical benefits to patients with HF include improvement in exercise duration, NYHA functional class, dyspnea/fatigue focal index, and signs and symptoms of HF, as

well as increased survival.

Dosage

ACE inhibitors should be initiated at low doses followed by gradual dosage increases if the lower doses have been well tolerated. Renal function and serum potassium should be assessed within 1 to 2 weeks of starting therapy and periodically thereafter, especially in patients with preexisting hypotension, hyponatremia, diabetes, or azotemia, or if they are receiving potassium supplementation. Doses should be titrated as tolerated by the patient to the target doses shown in clinical trials to decrease morbidity and mortality (e.g., 150 mg/d in divided doses of captopril; 20 mg/d of enalapril or lisinopril). The doses of ACE inhibitors can be increased to these effective doses unless the patient cannot tolerate high doses. The practitioner should provide the following information to patients taking ACE inhibitors:

- Adverse effects may occur early in therapy but do not usually prevent long-term use of the drug.
- Symptomatic improvement may not be seen for several weeks or months.
- ACE inhibitors may reduce the risk of disease progression even if the patient's symptoms have not responded favorably to treatment (Savarese et al., 2013).

Captopril, lisinopril, ramipril, and trandolapril have been shown to reduce mortality rates in patients who have had an MI and who have HF symptoms. The indications for these ACE inhibitors in this population vary slightly, and the dosing in patients after MI differs from the dosing for patients with chronic HF. Captopril is indicated to improve survival after MI in clinically stable patients with LV dysfunction manifested as an EF of 40% or less and to reduce the incidence of overt HF and subsequent hospitalizations for HF. Captopril may be initiated with a single dose of 6.25 mg. If the patient tolerates this dose, the dose should be titrated in increments to a maximum of 50 mg three times a day as long as tolerated (systolic blood pressure greater than 100 mm Hg). Other post-MI therapies (e.g., thrombolytics, aspirin, and beta-blockers) may be used concurrently.

Lisinopril has been shown to decrease mortality rates in both acute and post-MI patients. Lisinopril also is indicated for treating hemodynamically stable patients within 24 hours of an acute MI to improve survival. Patients should receive, as appropriate, the standard recommended treatments, such as thrombolytics, aspirin, and beta-blockers. The first 2.5-mg dose of lisinopril may be given to hemodynamically stable patients within 24 hours of the onset of symptoms of acute MI. The dose of lisinopril should be titrated as tolerated to a dose of 10 mg daily. Dosing should be continued for 6 weeks. At that time, the patient should be assessed for signs and symptoms of HF, and therapy should be continued if necessary. The dose should be decreased to 2.5 mg in patients with a low systolic blood pressure (below 120 mm Hg) when treatment is started or during the first 3 days after the MI. If hypotension occurs (systolic blood pressure below 100 mm Hg), a daily maintenance dose of 5 mg may be given with temporary reductions to 2.5 mg if

needed. If prolonged hypotension occurs (systolic blood pressure below 90 mm Hg for at least 1 hour), lisinopril therapy should be discontinued. Patients who develop symptoms of HF should receive the usual effective dose of lisinopril for HF, with a goal of 20 mg/d.

Ramipril has also been approved for stable patients who have shown clinical signs of HF within the first few days after an acute MI. It is used to decrease the risk of death (principally cardiovascular death) and to decrease the risks of HF-related hospitalization and progression to severe or resistant HF. The starting dose is 2.5 mg twice daily. A patient who becomes hypotensive at this dose may be switched to 1.25 mg twice daily, but all dosages should then be titrated, as tolerated, toward a target dose of 5 mg twice daily. In patients with a creatinine clearance less than 40 mL/min/1.73 m^2 (serum creatinine level of less than 2.5 mg/dL), the dose should be decreased to 1.25 mg once daily. The dosage may be increased to 1.25 mg twice daily up to a maximum dose of 2.5 mg twice daily, depending on clinical response and tolerability.

Trandolapril also is approved for use in stable patients who have evidence of LV systolic dysfunction (identified by wall motion abnormalities) or who have symptoms of HF within the first few days after an acute MI. This drug has proved beneficial for the treatment of LV dysfunction after MI and has been found considerably important in treatment of patients with comorbid diabetes. It also reduces the progression to proteinuria in high-risk patients (Diaz & Ducharme, 2008). The recommended starting dose is 1 mg once daily. Dosages should be titrated, as tolerated, toward a target dose of 4 mg/d. If the 4-mg dose is not tolerated, patients can continue therapy with the highest tolerated dose.

Contraindications

Patients should not receive an ACE inhibitor if they have experienced life-threatening adverse effects (e.g., angioedema or anuric renal failure) during previous exposure or if they are pregnant. Angioedema is a potentially fatal allergic reaction that may cause sudden difficulty in breathing, speaking, and swallowing accompanied by obvious swelling of the lips, face, and neck. Patients should receive an ACE inhibitor with caution if they have any of the following:

- Very low systemic blood pressure (systolic blood pressure less than 80 mm Hg)
- Markedly increased serum creatinine levels (above 3 mg/dL)
- Bilateral renal artery stenosis (previously considered a contraindication)
- Elevated serum potassium levels (above 5.5 mmol/L)

In addition, ACE inhibitors should not be given to hypotensive patients who are at immediate risk for cardiogenic shock and who require intravenous (IV) pressor support (e.g., dobutamine [Dobutrex] or epinephrine [Adrenalin, others]). These patients should receive treatment for their pump failure first; then, once they are stabilized, the HF should be reevaluated.

When taken by pregnant women during the second and third trimesters, ACE

inhibitors can cause injury and even death to the fetus. When pregnancy is detected, the ACE inhibitor should be discontinued immediately due to the teratogenic effects.

Adverse Events

The most common adverse reactions of ACE inhibitors are dizziness, headache, fatigue, diarrhea, cough, and hypotension. Angioedema of the face, extremities, lips, tongue, glottis, or larynx also has been reported in patients treated with ACE inhibitors. Angioedema associated with throat or laryngeal edema may be fatal because of airway blockage, which causes suffocation. Patients should be advised about this possible adverse effect and told to go to an emergency department immediately if they experience any of the symptoms suggesting angioedema.

Hypotension may occur with any of the ACE inhibitors and is usually observed after the first dose. It is more common in patients who are sodium or volume depleted, such as those treated vigorously with diuretics or those on dialysis, and in patients with severe HF. Hypotension can be minimized by starting with a very low dose and then increasing it slowly (usually every 3 to 7 days based on response) to the highest clinically effective level that does not produce hypotension. The diuretic dose may also need to be decreased or discontinued before starting the ACE inhibitor. Blood pressure should be followed closely after the first dose (until the blood pressure is stabilized), for the first 2 weeks of therapy, and whenever the dose of the ACE inhibitor or diuretic is increased. Hypotension, an anticipated problem among older patients with HF because of blunted baroreceptor reflexes, is no more common in the elderly than in other age groups.

Changes in renal function may occur in susceptible patients (i.e., patients with hyponatremia; those taking high doses of diuretics; those with low cardiac output, diabetes mellitus, severe HF, or preexisting renal impairment) because of inhibition of the RAAS. Patients with bilateral or unilateral renal artery stenosis should receive ACE inhibitors with extreme caution and should be monitored closely because renal failure may occur. The increases in serum creatinine and BUN that may occur are usually reversible by adjusting the dose of the ACE inhibitor, diuretic, or both. Furthermore, an increase in serum creatinine not exceeding 30% of the basal value is now being viewed as an indicator that the drug is working (i.e., there is adequate ACE inhibition) and not that it has caused renal failure and the drug may be continued in these patients. However, the initial dose of an ACE inhibitor should be reduced with increasing severity of HF, and the titration period should be monitored carefully. Age-related declines in renal function may slow the elimination of ACE inhibitors and thus increase the level and duration of their effects. Therefore, it may be necessary to reduce the initial dose of ACE inhibitors in the elderly or in patients with a serum creatinine level of 2.5 mg/dL or more. These patients may not tolerate as high a dose as other patients with HF but should be titrated to the highest possible dose.

Diuretic-induced potassium loss (hypokalemia) may be reduced when an ACE

inhibitor is used in combination with a diuretic. However, hyperkalemia may occur in patients with renal impairment or in those receiving a potassium-sparing diuretic, a potassium supplement, or potassium-containing salt substitutes. ACE inhibitors should be administered cautiously if hypokalemia exists and discontinued if hyperkalemia exists. Frequent monitoring of serum potassium levels should be performed.

A cough is a common adverse event associated with ACE inhibitor therapy, occurring in 5% to 20% of patients. It is thought to be due to increased production of bradykinins or substance P, both of which lower the cough reflex. The cough is described as an annoying, ticklish, dry cough that is reversible on discontinuation of the ACE inhibitor. In patients with HF, cough is rarely severe enough to require discontinuation of therapy. Patients who experience cough should be questioned to determine whether this symptom is due to the ACE inhibitor or to pulmonary edema. The ACE inhibitor should be implicated only after other causes have been excluded. In most cases, the patient and family can be advised that if the cough is bothersome but not intolerable, the benefits of ACE inhibitor therapy outweigh this adverse effect. However, if the cough is persistent and troublesome, the clinician can suggest withdrawing the ACE inhibitor and trying alternative medications (e.g., an ARB or a combination of hydralazine and isosorbide dinitrate [HYD/ISDN]).

Because HF is common among the elderly and increases in prevalence with age, safety and efficacy in this population are important. When ACE inhibitors first became available, many experts believed that because elderly patients tend to have low plasma renin activity, these agents would be relatively ineffective. Furthermore, the physiologic consequences of aging may alter the absorption, distribution, and elimination of drugs, as well as the sensitivity of the patient to drugs. Thus, it was recognized that safety and efficacy studies should be conducted in this important patient population. A number of studies have been completed, and they document that ACE inhibitors are well tolerated and effective for elderly patients with HF. Studies have not yet identified differences in response between the elderly and younger patients. However, greater sensitivity of some older patients cannot be ruled out. Older patients receiving ACE inhibitors do not experience more adverse effects than do younger patients (Masoudi et al., 2004).

Interactions

The ACE inhibitors have been associated with very few significant drug–drug interactions. One or all of the ACE inhibitors have been used in combination with digoxin, methyldopa (Aldomet), prazosin (Minipress), hydralazine, beta-blockers, nitrates, and calcium channel blockers. The drug interactions that should be kept in mind are listed in Table 22.3.

TABLE 22.3 Drug Interactions Associated with the Angiotensin-Converting Enzyme Inhibitors

Interacting Agent	Potential Effect
antacids	Decrease the bioavailability of captopril; therefore, separate administration times by 2 h.
aspirin	Decreases hemodynamic response of ACE inhibitor
capsaicin	Triggers or exacerbates the coughing that is associated with ACE inhibitor treatment
lithium	In combination with ACE inhibitor, causes increased serum lithium levels and symptoms of lithium toxicity
nonsteroidal anti-inflammatory drugs	In combination with ACE inhibitor, promotes sodium and water retention and diminishes control of hypertension and heart failure
potassium supplements/potassium-sparing diuretics/salt substitutes	In combination with ACE inhibitor, increases risk of hyperkalemia
rifampin	Reduces the pharmacologic effects of enalapril
tetracycline	In combination with quinapril, tetracycline undergoes decreased absorption (28%–37%), possibly from the high magnesium content in quinapril.

Diuretics

During initial evaluation, the clinician should determine whether the patient manifests symptoms (e.g., orthopnea, paroxysmal nocturnal dyspnea, or dyspnea on exertion) or signs (e.g., pulmonary rales, a third heart sound, or jugular venous distention) of volume overload. Patients with HF and significant volume overload should be started immediately on a diuretic in conjunction with an ACE inhibitor and a beta-blocker (see Table 22.2).

Mechanism of Action

Diuretics cause an increase in sodium and water excretion by the kidney by inhibiting the reabsorption of sodium or chloride. Thiazide diuretics work at the distal tubule of the kidney. Loop diuretics (bumetanide, furosemide, or torsemide) exert their effect at the loop of Henle as well as the proximal and distal tubules. Thus, loop diuretics are more potent in inhibiting sodium, chloride, and water excretion. Diuretics decrease preload by reducing the volume overload. An immediate effect (extrarenal) is an increase in venous capacity, with resultant redistribution of venous blood away from the lungs toward the periphery, which results in a decrease in pulmonary capillary pressure.

Dosage

Therapy is commonly initiated with low doses of a diuretic (e.g., furosemide [Lasix] 20 to 40 mg/d), and the dose is increased until urine output increases and weight decreases, usually by 0.5 to 1.0 kg daily. Increases in the dose of the diuretic may be required to sustain the loss of weight. The goal is to reduce symptoms as well as eliminate physical signs of fluid retention by restoring jugular venous pressures toward normal, by eliminating edema, or both. Patients with persistent volume overload despite initial medical management may require one of the following:

- More aggressive administration of the current diuretic (e.g., IV administration)
- A combination of diuretics (e.g., loop diuretic and metolazone [Zaroxolyn])
- Short-term use of drugs that increase renal blood flow (e.g., dopamine [Intropin])

Although patients are commonly prescribed a fixed dose of diuretic, the dose of these drugs should be adjusted ideally on a daily basis. This can be accomplished in most cases by having the patient record his or her weight daily and allowing the patient or an appropriately trained health professional to adjust the dosage if the weight increases or decreases beyond a specified range for that patient. Thus, the most useful approach for practitioners to select the dose of, and monitor the response to, diuretic therapy is by measuring body weight, preferably on a daily basis. Practitioners should educate patients on the importance of weighing themselves and contacting a health care professional when weight increases or symptoms return. This may help to avoid hospitalization of the patient with HF.

Patients with pulmonary edema or with marked volume overload should be given an IV loop diuretic initially. Diuretics should then be titrated to achieve resolution or improvement of signs and symptoms of volume overload. There is no standard target dose. Excessive diuresis should be avoided before starting an ACE inhibitor. Volume depletion may lead to hypotension or renal insufficiency when ACE inhibitors are started.

Spironolactone (Aldactone) has taken a larger, but controversial, role in the treatment of HF. In the Randomized Aldactone Evaluation Study (RALES), study of spironolactone use in HF revealed a decrease in morbidity and mortality (Pitt et al., 1999). A more recent global study of spironolactone did not support the findings of RALES supported (Pitt et al., 2014). Spironolactone lacked efficacy within patient subgroups who also had comorbid problems of blood pressure and diabetes. The researchers speculated this variance could be explained by different treatments around the world. However, in the absence of any other similar drug, cardiology experts still support the use of spironolactone. Spironolactone acts to competitively bind at the aldosterone receptor site of the distal convoluted renal tubules, which causes increased amounts of water and sodium to be excreted. Therefore, low doses (25 to 50 mg/d) of spironolactone merit consideration in patients with recent or current NYHA class IV symptoms. The efficacy and safety of aldosterone antagonists in patients with mild or moderate HF remain unknown.

Adverse Events

Potassium depletion commonly occurs when patients are treated chronically with diuretics, except with the use of spironolactone. However, ACE inhibitors decrease renal potassium losses and raise serum potassium levels, so many patients with HF who are treated with both agents may not have potassium depletion. Concomitant administration of ACE inhibitors alone or in combination with potassium-sparing agents (e.g., spironolactone) can prevent electrolyte depletion in most patients with HF. Diuretics may also cause magnesium depletion, which often accompanies potassium depletion. If high doses of diuretics are used, magnesium levels should be followed and oral supplementation given when needed (Mg 1.5 mEq/L).

Interactions

NSAIDs (including aspirin) may blunt the natriuretic effect of diuretics. Therefore, patients receiving daily therapy with NSAIDs may need an increase in the dose of the diuretic to compensate for fluid retention. Diuretics may decrease lithium clearance, which may raise lithium levels into the toxic range. Lithium levels should be monitored in patients receiving both drugs. Patients may be at an increased risk of ototoxicity when high doses of loop diuretics and other ototoxic drugs (e.g., aminoglycosides) are used concomitantly.

Angiotensin II Type 1 Receptor Blockers (ARBs)

These antagonists were developed to offer the advantages of increased selectivity and specificity and to maintain blockade of the circulating and tissue RAAS at the AT_1 receptor level, without the adverse reactions associated with ACE inhibitors. ARBs do not block the degradation of vasoactive substances (e.g., bradykinin, enkephalins, and substance P) and may not cause the adverse effects, such as cough, related to ACE inhibitor–induced bradykinin accumulation.

Of the currently approved ARBs, losartan (Cozaar) has been the most extensively studied in patients with HF. Losartan lowers blood pressure, systemic vascular resistance, pulmonary capillary wedge pressure, and heart rate and raises the cardiac index. Dyspnea on exertion and HF exacerbation decrease with losartan. Compared with the ACE inhibitor enalapril, losartan shows no significant difference in terms of altered exercise capacity (6-minute walk test), clinical status (dyspnea–fatigue index), neurohumoral activation (norepinephrine, N-terminal atrial natriuretic factor), laboratory evaluation, or incidence of adverse effects. Comparisons with another ACE inhibitor, captopril, show that losartan has the same incidence of persistent renal dysfunction and no difference in the incidence of death or HF hospital admissions. Further studies with other ACE inhibitors in various patient populations are needed to determine whether losartan reduces morbidity and mortality to a greater degree than the ACE inhibitors. The initial studies of losartan for treating HF seem promising. In addition, studies of the combination of ARBs and ACE inhibitors are also being conducted. Although combination therapy with an ACE inhibitor and ARB has been shown to be of benefit in the Val-HeFT and CHARM trials, there is hesitancy in clinical practice due to effects on renal function. It is reasonable to prescribe ARBs instead of ACE inhibitors only in patients who cannot tolerate ACE inhibitors because of angioedema or intractable cough. Even though the pathways are different, ARBs should be used cautiously (if at all) in patients that developed angioedema with ACE inhibitors.

Mechanism of Action

ARBs block the physiologic effects of angiotensin II by inhibiting receptor stimulation. The currently marketed ARBs—candesartan (Atacand), eprosartan (Teveten), losartan (Cozaar), olmesartan (Benicar), telmisartan (Micardis), valsartan (Diovan), and irbesartan (Avapro)—are approved by the US Food and Drug Administration (FDA) for the management of hypertension. These antagonists were developed to offer the advantages of increased selectivity and specificity and to maintain blockade of the circulating and tissue RAAS at the AT_1 receptor level, without the adverse reactions associated with ACE inhibitors. ARBs do not block the degradation of vasoactive substances (e.g., bradykinin, enkephalins, and substance P) and may not cause the adverse effects, such as cough, related to ACE inhibitor–induced bradykinin accumulation.

When ARBs were introduced into practice, there was a theoretical consideration that reducing the production of angiotensin II with an ACE inhibitor and blocking the remaining angiotensin II with an ARB would be better than either therapy alone. However, the Val-HeFT study showed that adding an ARB to ACE inhibitor therapy is not beneficial.

Dosage

The doses of these agents vary. Table 22.2 lists selected ARBs and their doses, but a more complete review of these agents can be found in Chapter 19. Regardless of which agent is selected, the practitioner should monitor the patient's renal function and blood pressure.

Adverse Events

ARB therapy may be associated with hypotension. This usually occurs with the first dose but may also occur during upward titration or when clinical status worsens. This situation is most common among patients with hyponatremia, hypovolemia, low baseline blood pressure, renal impairment, and high baseline levels of renin or aldosterone. Potentiation of the vasodilator effects of bradykinin and prostaglandins appears to contribute to this hypotension. Theoretically, ARBs, which do not interfere with the degradation of these peptides, should result in fewer episodes of first-dose hypotension. However, this beneficial effect remains to be proven in clinical trials. In addition, specific ARBs could block the deleterious effects of angiotensin II produced by non–ACE-dependent pathways that are not blocked by ACE inhibitors.

The most common adverse events with losartan include dyspnea, worsening of HF, hypotension, dizziness, cough, and upper respiratory tract infection. The ARBs appear as likely as the ACE inhibitors to produce hypotension, worsening renal function, and hyperkalemia. Also, like ACE inhibitors, these agents are contraindicated in pregnancy, especially during the second and third trimesters.

Beta-blockers

Historically, beta-blockers have been contraindicated for treating HF. The negative inotropic effect, bradycardic effect, and peripheral constriction of the beta-blockers can all exacerbate HF. However, observations from experimental studies and controlled clinical trials indicate that prolonged activation of the SNS can accelerate the progression of HF. The studies also determined that the risks of such progression can be substantially decreased through the use of pharmacologic agents that interfere with the actions of the SNS on the heart and peripheral blood vessels. Thus, the use of beta-blockers is gaining acceptance as a treatment for HF.

The new recommendations strongly advocate using beta-blockers for treating patients with HF. As stated previously, the recommendations state that all patients with stable NYHA class II to class IV HF due to LV systolic dysfunction should receive a beta-blocker unless they have a contraindication to its use or have shown to be unable to tolerate treatment with the drug. Beta-blockers should not be used in unstable patients or in acutely ill patients ("rescue" therapy), including those who are in the intensive care unit with refractory HF requiring IV support. Beta-blockers can be initiated once patients are clinically compensated. Also, if a patient is already on a beta-blocker, it can be continued as long as the patient is hemodynamically stable. Beta-blockers are recommended to improve symptoms and clinical status and to decrease the risk of death and hospitalization in patients with mild to moderate (NYHA class II) or moderate to severe (NYHA class III) HF who have an LV EF of less than 35% to 40%. Beta-blockers should be added to preexisting treatment with diuretics and an ACE inhibitor and may be used together with digitalis or vasodilators.

Carvedilol, a nonselective beta-adrenergic receptor blocker with vasodilating action (through alpha-adrenergic blocking action) previously approved for the management of essential hypertension, has become the first beta-blocker approved in the United States for treating HF. It is intended to reduce the progression of disease as evidenced by cardiovascular death, cardiovascular hospitalization, or the need to adjust other HF medications. Similarly, the extended-release formulation of metoprolol, metoprolol succinate, was shown to be superior to placebo in decreasing mortality in HF patients. Bisoprolol (Zebeta) is also a beta-blocker used in the treatment of HF that decreases mortality.

Mechanism of Action

Catecholamines can cause peripheral vasoconstriction that can exacerbate loading conditions in the failing heart and may precipitate myocardial ischemia and ventricular arrhythmias. In addition, activation of the SNS can increase heart rate, which may adversely affect the relation between myocardial supply and demand and more importantly may exacerbate the abnormal force–frequency relation that exists in HF. In addition,

catecholamines activate cellular pathways that can lead to the loss of myocardial cells by a process of programmed cell death (apoptosis), which has been implicated in the progression of HF.

In experimental models of HF, pharmacologic interference with the SNS can favorably alter the natural history of the disease, similar to the manner in which antagonism of the RAAS by ACE inhibitors can modify the course of HF. Extensive research implicating the target mechanism, increased adrenergic drive, as being unfavorable to the natural history of systolic dysfunction and the HF clinical syndrome has been done. This has led to the conclusion that the primary mechanism of action of beta-blockers in chronic HF is to prevent and reverse adrenergically mediated intrinsic myocardial dysfunction and remodeling. This occurs through a time-dependent, biologic effect involving inhibition of beta-adrenergic mechanisms directly or indirectly responsible for the development of cellular contractile dysfunction and remodeling (Doughty et al., 2004). In addition, one of the beta-blockers used in patients with HF, carvedilol, has direct antioxidant effects that may decrease the role played by apoptosis in the progression of HF (Dandona, 2007).

Studies have shown that carvedilol and metoprolol improve LV function, hemodynamic parameters, and various symptoms of HF. Carvedilol also improves submaximal exercise tolerance and NYHA classification. In multicenter clinical trials, carvedilol was associated with a highly significant 65% reduction in the risk of death versus placebo (all patients received conventional therapy in addition to carvedilol or placebo). This was due to a decrease in both death due to pump failure and sudden death. In addition, carvedilol decreases the risk of hospitalization for cardiovascular causes and the combined risk of all-cause mortality and cardiovascular hospitalization (Pasternak et al., 2014).

Dosage

Adverse effects with carvedilol usually occur early in therapy and are more frequent and severe with higher doses. Because of this, the starting dose of carvedilol is 3.125 mg twice daily, and each dose titration should be done slowly over a 2-week period, doubling the dose each time. At initiation of each new dosage, the patient should be observed for 1 hour for signs of dizziness or light-headedness. In addition, blood pressure should be monitored. The maximum recommended dosage is 25 mg twice daily in patients weighing less than 85 kg and 50 mg twice daily in patients weighing 85 kg or greater. In addition, patients should be seen in the office during titration and evaluated for symptoms of worsening HF, vasodilation (i.e., dizziness, light-headedness, and symptomatic hypotension), or bradycardia to determine their tolerance for carvedilol. Treatment with metoprolol starts at 6.25 mg two or three times daily, and the dose is titrated slowly up to a target of 100 mg two or three times daily.

Initiation of therapy with a beta-blocker may produce fluid retention, which may be severe enough to cause pulmonary or peripheral congestion and worsening symptoms of

HF. Increases in body weight may occur after 3 to 5 days of starting treatment and if untreated may lead to worsening symptoms within 1 to 2 weeks. For this reason, practitioners should ask patients to weigh themselves daily. The amount of weight gain then guides the practitioner in prescribing an increase in the diuretic dosage until the patient's weight is restored to pretreatment levels. The dose of carvedilol may also have to be decreased; occasionally, the drug must be temporarily discontinued.

Excessive vasodilation may occur with initiation of therapy. It is usually asymptomatic but may be accompanied by dizziness, light-headedness, or blurred vision. Vasodilatory adverse effects are usually seen within 24 to 48 hours of the first dose or increments in dose but usually subside with repeated dosing without any change in the dose of carvedilol or other medications. The risk of hypotension may be minimized by taking the beta-blocker, ACE inhibitor, or vasodilator (if used) at different times during the day. Practitioners can work with patients to develop a regimen that is convenient and minimizes adverse effects. The practitioner may need to reduce the dose of the ACE inhibitor or vasodilator if hypotension is excessive. If the patient's heart rate decreases to less than 50 beats per minute or second- or third-degree heart block occurs, the patient should contact the practitioner, who may then decrease the dose of the beta-blocker. Practitioners should evaluate the patient's concomitant medications for drug interactions that also may decrease heart rate or cause heart block (e.g., diltiazem or flecainide).

Contraindications

Beta-blockers should not be used in patients with bronchospastic disease, symptomatic bradycardia, or advanced heart block (unless treated with a pacemaker). Patients should receive a beta-blocker with caution if they have asymptomatic bradycardia (heart rate below 60 beats per minute). Despite concerns that beta blockade may mask some of the signs of hypoglycemia, patients with diabetes mellitus may be particularly likely to experience a reduction in morbidity and mortality with beta-blocker therapy. The GEMINI trial showed that carvedilol improved insulin resistance, maintained glycemic control, and reduced progression to microalbuminuria.

Adverse Events

The adverse effect profile of beta-blockers in patients with HF is consistent with the pharmacology of the drug and the health status of the patient. The most common adverse effects are dizziness, fatigue, and worsening of HF. Other adverse reactions that occur less frequently include bradycardia, hypotension, generalized edema, dependent edema, sinusitis, and bronchitis. Rare cases of liver function abnormalities have been reported in patients receiving carvedilol, but no deaths due to these abnormalities have been reported. Mild hepatic injury related to carvedilol has been reversible and has occurred after short- and long-term therapy. Carvedilol should be discontinued if a patient has laboratory evidence of liver function abnormalities or jaundice.

Practitioners should advise patients receiving therapy with carvedilol or other beta-blockers of the following:

- Adverse effects may occur early in therapy but usually do not prevent long-term use of the drug.
- Symptomatic improvement may not be seen for 2 to 3 months.
- Beta blockade may reduce the risk of disease progression even if the patient's symptoms have not responded favorably to treatment.

Digoxin

Digoxin can prevent clinical deterioration in patients with HF due to LV systolic dysfunction and can improve these patients' symptoms. However, it does not decrease the mortality rate. The latest large trial, the Digitalis Investigation Group (DIG) study, showed that survival was not changed by use of digoxin (0.125 to 0.5 mg) in NYHA class II and III patients with HF who were taking diuretics and ACE inhibitors. However, digoxin significantly decreased the number of hospitalizations compared with placebo. This effect seemed to be more pronounced in patients with the lowest EFs and the most enlarged hearts. However, digoxin increased the risk of non-HF causes of cardiac death from presumed arrhythmia or MI (Digitalis Investigation Group, 1997).

The ACTION HF organization recommends digoxin to improve the clinical status of patients with HF due to LV systolic dysfunction and recommends that it should be used in conjunction with diuretics, an ACE inhibitor, and a beta-blocker. In addition, digoxin is recommended in patients with HF who have rapid atrial fibrillation, even though beta-blockers may be more effective in controlling the ventricular response during exercise. If a patient is receiving digoxin but not an ACE inhibitor or a beta-blocker, treatment with digoxin should not be withdrawn, but appropriate therapy with the neurohormonal antagonists should be instituted. Patients should not receive digoxin if they have significant sinus or atrioventricular (AV) block, unless the block has been treated with a permanent pacemaker. Digoxin should be used cautiously in patients receiving other drugs that can depress sinus or AV nodal function (e.g., amiodarone or a beta-blocker), although these patients usually tolerate digoxin without difficulty. In addition, digoxin is not indicated for the stabilization of patients with acutely decompensated HF (unless they have rapid atrial fibrillation). There are no data to recommend using digoxin in patients with asymptomatic LV dysfunction (NYHA class I).

Mechanism of Action

Digoxin produces a mild inotropic effect by inhibiting cell membrane sodium–potassium adenosine triphosphatase activity and thereby enhancing calcium entry into the cell. Calcium enhances contractile protein activity, allowing for a greater force and velocity of contraction.

Dosage

Loading doses of digoxin usually are not needed in patients with HF. The typical dosage of 0.25 mg daily may be initiated if there is no evidence of renal dysfunction. Patients who have reduced renal function, who have baseline conduction abnormality, or who are small or elderly should be started on 0.125 mg daily or lower (such as every other day). Levels of 0.9 to 1.2 ng/mL are considered therapeutic, but levels as high as 2.5 ng/mL may be tolerated. It is not clear whether the beneficial effects of digoxin are greater at higher serum

levels. Although it has been suggested that serum levels may be used to guide the selection of an appropriate dose of digoxin, there is no evidence to support this approach (Packer & Cohn, 1999).

Steady state is reached in approximately 1 week in patients with normal renal function, although 2 to 3 weeks may be required in patients with renal impairment. When steady state is achieved, the patient should be evaluated for symptoms of toxicity. In addition, an ECG, serum digoxin level, serum electrolytes, BUN, and creatinine should be obtained. It is not clear whether regular serum digoxin monitoring is necessary, but levels should be checked once a year after a steady state is achieved. In addition, levels should be checked if HF status worsens, renal function deteriorates, signs of toxicity develop (e.g., confusion, nausea, anorexia, visual disturbances, arrhythmias), or additional medications are added that could affect the digoxin level.

Adverse Events

Signs of digoxin toxicity develop in approximately 20% of patients, and up to 18% of digoxin-toxic patients die from the arrhythmias that occur. Noncardiac symptoms are related to the central nervous system (CNS) and gastrointestinal (GI) tract. Anorexia is often an early manifestation, with nausea and vomiting following. The CNS adverse effects include headache, fatigue, malaise, disorientation, confusion, delirium, seizures, and visual disturbances. The noncardiac symptoms do not always precede the cardiac symptoms. Cardiac toxicity manifested by arrhythmias can take the form of almost every known rhythm disturbance (e.g., ectopic and re-entrant cardiac rhythms and heart block).

Digoxin should be discontinued (often with consideration of reinstitution at a lower dose after 2 to 3 days if the patient is benefiting from therapy) if any of the following is noted:

- Elevated digoxin level
- Substantial reduction in renal function
- Symptoms of toxicity
- Significant conduction abnormality (e.g., symptomatic bradycardia due to second- or third-degree AV block or high-degree AV block in atrial fibrillation)
- An increase in ventricular arrhythmias

Practitioners should counsel patients about the potential adverse effects of digoxin. They also should stress the importance of taking digoxin exactly as it is prescribed to avoid toxicity or a subtherapeutic effect.

Interactions

The medications that most often cause an increase in digoxin levels are quinidine (Cardioquin, others), amiodarone, flecainide, propafenone (Rythmol), spironolactone, and verapamil. It may be necessary to decrease the dose of digoxin when treatment with these

drugs is initiated. Antibiotics may decrease gut flora and prevent bacterial inactivation of digoxin, and anticholinergic agents may decrease intestinal motility. Both of these drug classes also may increase digoxin levels. Antacids, cholestyramine (Questran), neomycin (Mycifradin Sulfate), and kaolin–pectin (Kaopectate) may inhibit the absorption of digoxin and decrease digoxin levels. Patients should be advised to take digoxin at least 2 hours before these medications. Diuretics can enhance digoxin toxicity by decreasing renal clearance of digoxin and by causing electrolyte changes, including hypokalemia, hypomagnesemia, and hypercalcemia (thiazides). Before any new medications are added to a patient's regimen, the prescriber should determine whether the medication interacts with digoxin.

Hydralazine/Isosorbide Dinitrate

The HYD/ISDN combination of vasodilators is an appropriate alternative in African American patients with contraindications to or intolerance of ACE inhibitors. The combination should not be used for treating HF in patients who have not tried ACE inhibitors and should not be substituted for ACE inhibitors in patients who are tolerating ACE inhibitors without difficulty. No studies have specifically addressed the use of HYD/ISDN for patients who cannot take or tolerate ACE inhibitors, and the FDA has not approved HYD/ISDN for use in patients with HF. Isosorbide mononitrate also is not approved for HF and has not been studied for treating HF. HYD/ISDN is not as beneficial as the ACE inhibitor enalapril in reducing mortality rates during the first 2 years of treatment. However, this combination has been shown to achieve an absolute reduction in mortality rates compared with placebo during the first 3 years of treatment. The combination increases exercise capacity as much as enalapril, but adverse effects are a significant problem.

Mechanism of Action

Vasodilators may be classified by their mechanism of action or their site of action (venodilators, arteriolar dilators, or "balanced" vasodilators). ISDN is a venodilator that redistributes blood volume to the venous side of the heart to the systemic circulation, away from the lungs, which decreases the ventricular blood volume (preload). Hydralazine, along with prazosin and minoxidil (Loniten), which are not used for treating HF, is an arteriolar dilator. Hydralazine decreases the resistance the heart encounters during contraction (afterload), which allows for increased stroke volume (volume of blood leaving the heart) and increased cardiac output. Balanced vasodilators, including the ACE inhibitors and ARBs, cause vasodilation on both the venous and arterial sides of the heart and therefore provide the hemodynamic and clinical benefits of both preload and afterload reduction (as discussed in other sections).

Dosage

Isosorbide dinitrate usually should be initiated at 10 mg three times a day and increased weekly to 40 mg three times a day as tolerated (up to 160 mg/d). Hydralazine should be initiated at 25 mg three times a day and increased weekly to 75 mg three or four times a day (up to 300 mg/d). Patients with low blood pressure, severe HF, or advanced age can be started on 10 mg three times a day for both agents.

Adverse Events

Adverse events include reflex tachycardia, headache, flushing, nausea, dizziness, syncope, nitrate tolerance, and sodium and water retention. Nitrate tolerance can be avoided by providing a nitrate-free period of 10 to 14 hours.

Interactions

Other drugs that lower blood pressure, including diuretics, may cause additive hypotension, and blood pressure should be monitored.

Other Agents

Amiodarone

Amiodarone is approved in the United States for treating refractory life-threatening ventricular arrhythmias. Amiodarone has been studied in patients with HF with ventricular arrhythmias to assess whether it reduces mortality rates. Some studies demonstrated that low-dose amiodarone (300 mg/d) reduced mortality rates, whereas others found no improvement (Doval et al., 1994; Singh et al., 1995). A meta-analysis of 13 randomized, controlled trials of prophylactic amiodarone in patients with recent MI (8 trials) or HF (5 trials) found that amiodarone reduced the rate of arrhythmic/sudden death in high-risk patients with recent MI or HF (Amiodarone Trials Meta-Analysis Investigators, 1997).

The FDA has not approved amiodarone for treating HF. According to the most recent HF guidelines (Yancy et al., 2013), amiodarone is the only antiarrhythmic to have neutral effects on mortality from HF. Further studies are needed to determine whether it is useful for routine prophylactic treatment of patients with ventricular arrhythmias and nonischemic HF. It may be beneficial in patients at high risk for arrhythmic/sudden death, patients with primary cardiomyopathy, or patients with both (Amiodarone Trials Meta-Analysis Investigators, 1997; Gheorghiade et al., 1998). The recommendations suggest that some class III antiarrhythmic agents (e.g., amiodarone) do not appear to increase the risk of death in patients with chronic HF. Such drugs are preferred over class I agents when used for treating atrial fibrillation in patients with LV systolic dysfunction. Because of its known toxicity and equivocal evidence for efficacy, amiodarone is not recommended for general use to prevent death (or sudden death) in patients with HF already treated with drugs that reduce mortality rates (e.g., ACE inhibitors or beta-blockers).

Mechanism of Action

Amiodarone is classified as a Vaughn-Williams class III (potassium channel blocking) antiarrhythmic drug, but it also possesses class I (sodium blocking), class II (beta blocking), and class IV (calcium channel blocking) antiarrhythmic effects. It also has vasodilatory properties. The therapeutic benefit of amiodarone may be due to its beta-blocking effects and not to an antiarrhythmic effect.

Dosage

Before treatment with amiodarone starts, the practitioner should make sure the patient does not have hyperthyroidism or advanced liver disease. In addition, pulmonary function tests, chest radiography, ophthalmologic examination, and neurologic assessment are recommended before initiating therapy. The maintenance dosage should be 200 to 300 mg/d. High doses of amiodarone may cause initial cardiac decompensation with abnormal hemodynamics; therefore, use of high loading doses in patients with very severe forms of

HF should be avoided.

Interactions

Amiodarone interacts with warfarin (Coumadin; increases the international normalized ratio) and digoxin (increases digoxin levels).

Corlanor (Ivabradine)

Corlanor is a relatively new drug in the treatment of HF to reduced risk of hospitalization. It is indicated for patients with stable, symptomatic chronic HF with LVEF ≤35% and in sinus rhythm with resting heart rate greater than or equal to 70 bpm, and taking beta-blockers at the highest dose they can tolerate, or are not taking beta-blockers because there is a medical reason to avoid the use of β-blockers.

Mechanism of Action

Corlanor (ivabradine) is a hyperpolarization-activated cyclic nucleotide-gated channel blocker that reduces the spontaneous pacemaker activity of the cardiac sinus node by selectively inhibiting the I_f current (I_f), resulting in heart rate reduction with no effect on ventricular repolarization and no effects on myocardial contractility.

Dosage

The initial dose is 5 mg orally twice a day with meals, and the maximum dose is 7.5 mg orally twice a day. Dosing is adjusted based on keeping the heart rate between 50 and 60 bpm and the overall tolerability of the drug. In patients who have a resting heart rate greater than 60 bpm, dosing should be increased by 2.5 mg up to the maximum of 7.5 mg twice a day. For patients with resting heart rates between 50 and 60 bpm, the dose should be maintained. Finally, if the resting heart rate is less than 50 bpm, the dose should be decreased by 2.5 mg and tolerability reassessed. If the dose is already 2.5 mg twice a day, then discontinue the drug.

Interaction

Because Corlanor is metabolized by the CYP3A4 pathway of the P450 concomitant, use of CYP3A4 inhibitors will increase the concentration of ivabradine and use of CYP3A4 inducers will decrease the concentration. With increased plasma concentrations, bradycardia and conduction disturbance may be exacerbated. Examples of strong CYPA4 inhibitors include azole antifungals (e.g., ketoconazole, itraconazole), macrolide antibiotics (e.g., clarithromycin), and HIV protease inhibitors. Examples of moderate CYPA4 inhibitors include diltiazem, verapamil, and grape juice. Finally, examples of strong CYPA4 inducers include St. John's wort, rifampicin, barbiturates, and phenytoin.

Contraindications

Corlanor is contraindicated in sick sinus syndrome or AV block (unless a pacemaker is inserted), severe liver disease, worsened HF symptoms, resting heart rate of less than 60, and blood pressure less than 90/50. Corlanor is also contraindicated in COPD, hypotension, or asthma and concomitant use of strong cytochrome P450 3A4 (CYP3A4) inhibitors.

Adverse Events

The most common adverse events in Corlanor are bradycardia, hypertension, atrial fibrillation and phosphenes, and visual brightness. Postmarketing reports of additional reactions include hypotension, angioedema, rash, pruritus, urticaria, vertigo, and diplopia.

Selecting the Most Appropriate Agent

The 2013 ACCF/AHA clinical practice guidelines changed the approach to the management of patients with HF. Instead of digoxin, an ACE inhibitor is now the drug of first choice. Table 22.4 and Figure 22.3 summarize therapeutic regimens. In patients with a history of MI and reduced EF, ACE inhibitors (ACE-I) or ARB should be used to prevent HF. In patients with an MI and reduced EF, beta-blockers should be used to prevent HF and a statin also given.

TABLE 22.4 Recommended Order of Treatment for Heart Failure

Order	Agents	Comments
First line	ACE-I (or ARB) with or without a diuretic (depends on fluid retention)	Monitor patient's response carefully.
Second line	ACE-I (or ARB) and beta-blocker with a diuretic	In patient with mild heart failure, use a potassium-sparing diuretic when serum potassium level is <4.0 mEq/L.
Third line	ARB, beta-blocker, aldosterone agonist, diuretic, and digoxin	

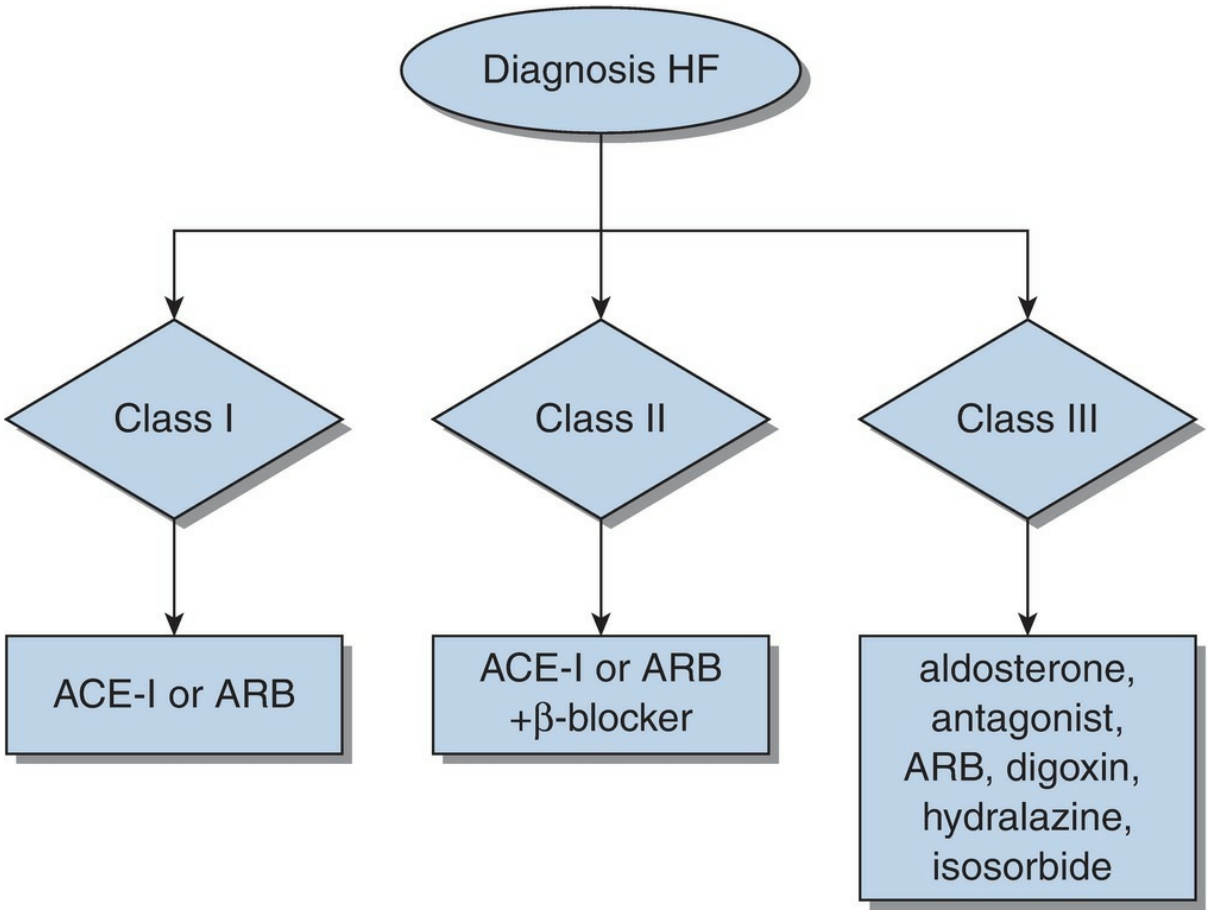

FIGURE 22.3 Treatment algorithm for chronic heart failure. (Adapted with permission from Yancy, C. W., Jessup, M., Bozkurt, B., et al. (2013). 2013 ACCF/AHA guideline for the management of heart failure. *Journal of the American College of Cardiology*, 62 (16), e147–e239. First-Line Therapy

The ACE inhibitors are now considered the first-line choice for routine use in patients with HF. ACE inhibitors may also be considered for treatment of those who are stage A as classified by the ACC/AHA (Yancy et al., 2013). According to the clinical practice guidelines, patients with systolic dysfunction should receive a trial of an ACE inhibitor unless contraindications are present. (See discussion of ACE inhibitors.) The ACE inhibitors may be considered sole therapy in HF patients who have fatigue or mild dyspnea on exertion and who do not have any other signs or symptoms of volume overload. However, if these symptoms persist after the target dose of the ACE inhibitor is reached, a diuretic should be added. (See Second-Line Therapy.) Thus, ACE inhibitor therapy is appropriate for patients in NYHA class I as a means of preventing HF and in patients in NYHA class II to IV with symptoms to decrease mortality rates. (See discussion of ACE inhibitors.) They may be used in conjunction with beta-blockers, which are also considered

first-line therapy.

If the patient is unable to tolerate an ACE inhibitor, an ARB can be used.

Beta-blockers with vasodilating action have been approved for treating HF. (See discussion of beta-blockers.) Beta-blockers are initial therapy.

The recommendations state that all patients with stable NYHA class II or III HF due to LV systolic dysfunction should receive a beta-blocker unless the drug is contraindicated or cannot be tolerated. Beta-blockers should be used with diuretics and ACE inhibitors. Blockers should not be used in unstable patients or in acutely ill patients (rescue therapy), including those who are in the intensive care unit with refractory HF requiring IV support. Studies of beta-blocker therapy in various types of patients with HF are continuing to define their role.

Second-Line Therapy

Diuretics are used to increase sodium and water excretion, correct volume overload (which manifests as dyspnea on exertion), and maintain sodium and water balance. Patients with HF and signs of significant volume overload should be started immediately on a diuretic in addition to an ACE inhibitor. Patients with mild HF or concomitant hypertension may be managed adequately on thiazide diuretics. However, a loop diuretic is preferred in most patients, particularly those with renal impairment or marked fluid retention. A potassium-sparing diuretic or potassium supplement should be used for patients with serum potassium concentrations less than 4.0 mEq/L. Patients with persistent volume overload despite initial medical management may require more aggressive administration of the current diuretic (e.g., IV administration), more potent diuretics, or a combination of diuretics (e.g., furosemide and metolazone, or furosemide and spironolactone).

Third-Line Therapy

The AHRQ clinical practice guidelines state that digoxin should be used in patients with severe HF and should be added to the medical regimen of patients with mild or moderate failure who remain symptomatic after optimal management with ACE inhibitors and diuretics. The ACTION HF recommendations state that digoxin is recommended to improve the clinical status of patients with HF due to LV systolic dysfunction and should be used with diuretics, an ACE inhibitor, and a beta-blocker. Both groups suggest that digoxin may be beneficial in patients with HF when there is a second indication for digoxin therapy (e.g., a supraventricular arrhythmia for which digoxin is specifically indicated). However, there remains a question of whether the benefits of digoxin therapy outweigh its risks.

Fourth-Line Therapy

Fourth-line therapy consists of ARBs, such as losartan, the HYD/ISDN combination of vasodilators, or an aldosterone antagonist, such as spironolactone. A new drug, Corlanor,

can be added to the regime.

According to the AHRQ guidelines and the ACTION HF recommendations, the HYD/ISDN combination is an appropriate alternative in African American patients with contraindications to or intolerance of ACE inhibitors; although, some practitioners continue to use it in all patient populations. There is little evidence to support using nitrates alone or hydralazine alone in treating HF. Spironolactone at a low dosage of 12.5 to 25 mg once daily should be considered for patients who are receiving standard therapy and who have severe HF (with recent or current NYHA class IV standing) caused by LV systolic dysfunction. Patients should have a normal serum potassium level (5.0 mmol/L) and adequate renal function (serum creatinine 2.5 mg/dL).

Special Populations

Pediatric

Children with HF usually have maturational differences in contractile function or congenital structural or genetic heart dysfunction. Drug data for children with HF are not well established. In general, treatment for class I acute HF includes IV inotropes (excluding digoxin) and IV diuretics. For class II failure, digoxin may be added, and for class III, oxygen may be administered. Drug therapy in children is highly individualized according to the child's condition and setting and is usually managed by a specialist in pediatric cardiology.

Geriatric

Because of age-related reductions in renal function, elderly patients may be particularly susceptible to drug-induced decreases in blood pressure, making careful monitoring essential not only at baseline but also when dosage or drug adjustments are instituted. Blood pressure, renal function, and potassium levels should be monitored regularly. Changes in renal function may also affect the elimination of digoxin, and patients should be monitored for digoxin toxicity and educated to recognize its signs and symptoms.

An important issue in drug therapy for elderly patients with HF is therapeutic compliance. In one study, investigators identified the primary reason for hospitalization of elderly patients with HF as noncompliance with diet and medication therapy; moreover, the investigators concluded that up to 40% of readmissions could be prevented by therapeutic compliance and appropriate discharge planning, follow-up, and adequate patient and caregiver education (SOLVD Investigators, 1991).

Women

In pregnant women, ACE inhibitor therapy may pose the risk of congenital birth defects. The same is true for ARB therapy. Corlanor (ivabradine) also has potential for fetal toxicity and appropriate birth control is necessary. For both ACE or ARB inhibitors, and Corlanor if a woman becomes pregnant, the drug should be stopped immediately.

Monitoring Patient Response

A careful history and a physical examination guide outcomes and direct therapy. The patient's symptoms and activities should be explored; any worsening suggests the need to adjust therapy. Although ECG exercise testing is not recommended, repeated testing may be ordered if the patient has a new heart murmur or a new MI or suddenly deteriorates despite compliance with the medication regimen. Serum electrolyte levels, renal function, blood pressure, and diuretic use should be monitored regularly, particularly in patients taking ACE inhibitors. Within 2 weeks of initial ACE inhibitor therapy, serum potassium, creatinine, and BUN measurements should be repeated. If values are stable, monitoring can occur at 3-month intervals or within 1 week of a change in dosage of the ACE inhibitor or diuretic drug.

Response to initial ACE inhibitor therapy should be monitored by blood pressure measurements at 1 to 2 hours (captopril) and 4 to 6 hours for long-acting drugs (enalapril or lisinopril). Blood pressure and heart rate should be monitored for 1 hour after initiating carvedilol to assess tolerance to the drug; clinical reevaluation should occur at each increase in dose and with any worsening of symptoms (increasing fatigue, decreased exercise tolerance, weight gain).

Patients taking spironolactone should have their serum potassium level measured after the first week of therapy, at regular intervals thereafter, and after any change in dose or concomitant medications that may affect potassium balance.

Patient Education

Practitioners must take an active role in patient education to enhance compliance and help prevent medication errors and adverse effects. Patients taking ACE inhibitors, such as captopril and moexipril (Univasc), should take them at least 1 hour before meals. They should also be advised of potential adverse effects, particularly the effects that signal a dangerous reaction: sore throat, fever, swelling of hands or feet, irregular heartbeat, chest pains, and signs of angioedema (swelling of the face, eyes, lips, or tongue; difficulty swallowing or breathing; hoarseness). If these occur, the patient should notify the health care professional at once.

Patients taking diuretics need to know that they can take the medication with food or milk to prevent GI upset and they can schedule administration so that the need to urinate does not interrupt sleep. Because some diuretics cause photosensitivity, patients should use sunblock or avoid extensive exposure to sunlight. The practitioner can show the patient how to rise slowly from a lying or sitting position to avoid orthostatic hypotension.

Patients need to understand how to monitor their symptoms and weight fluctuations, restrict their sodium intake, take their medications as prescribed, and stay physically active.

Patients taking digoxin should understand that discontinuing the medication can be dangerous and that they should consult their health care provider before doing so. They should avoid taking over-the-counter medications, such as antacids, cold and allergy products, and diet drugs. Reportable signs and symptoms are loss of appetite, low stomach pain, nausea, vomiting, diarrhea, unusual fatigue or weakness, headache, blurred or yellow vision, rash or hives, or mental depression.

Women of childbearing age need to know that ACE inhibitors and ARBs should be avoided if pregnancy is a possibility. Patients taking spironolactone should know the signs and symptoms to report (muscle weakness or cramps and fatigue).

Nutrition/Lifestyle Changes

Dietary sodium intake should be limited to 2 or 3 g daily. Although a 2-g daily sodium intake is preferred, patient compliance may be poor because most patients find such a diet unpalatable. Patients with mild or moderate (NYHA class II or III) HF may tolerate 3 g daily. Alcohol decreases myocardial contractility, and therefore, consumption of alcoholic beverages should be discouraged or limited to one drink (i.e., a glass of beer or wine or a cocktail containing 1 ounce or less of alcohol) per day. Patients with HF should avoid excessive fluid intake, but fluid restriction is not advisable unless hyponatremia develops.

Patients should stop smoking because cigarettes cause cardiac injury. In addition to pharmacology therapy and lifestyle, revascularization may be necessitated. Some patients with HF experience severe limitation or repeated hospitalizations despite aggressive drug therapy and intervention; thereby, cardiac transplantation may be a reasonable option.

Case Study*

I.W., aged 62, is a male who is new to your practice. He is reporting shortness of breath on exertion, especially after climbing steps or walking three to four blocks. His symptoms clear with rest. He also has difficulty sleeping at night (he tells you he needs two pillows to be comfortable).

He tells you that 2 years ago, he suddenly became short of breath after hurrying for an airplane. He was admitted to a hospital and treated for acute pulmonary edema. Three days before the episode of pulmonary edema, he had an upper respiratory tract infection with fever and mild cough. After the episode of pulmonary edema, his blood pressure has been consistently elevated. His previous physician started him on a sustained-release preparation of diltiazem 180 mg/d. His medical history includes moderate prostatic hypertrophy for 5 years, adult-onset diabetes mellitus for 10 years, hypertension for 10 years, and degenerative joint disease for 5 years. His medication history includes hydrochlorothiazide (HydroDIURIL) 50 mg/d, atenolol (Tenormin) 100 mg/d, controlled-delivery diltiazem 180 mg/d, glyburide (DiaBeta) 5 mg/d, and indomethacin (Indocin) 25 to 50 mg three times a day as needed for pain. While reviewing his medical records, you see that his last physical examination revealed a blood pressure of 160/95 mm Hg, a pulse of 95 bpm, a respiratory rate of 18, normal peripheral pulses, mild edema bilaterally in his feet, a prominent S3 and S4, neck vein distention, and an enlarged liver.

Diagnosis: Heart Failure Class II

1. List specific goals of treatment for I.W.
2. What drug(s) would you prescribe? Why?
3. What are the parameters for monitoring the success of your selected therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. Describe one or two drug–drug or drug–food interactions for the selected agent(s).
6. List one or two adverse reactions for the selected agent(s) that would cause you to change therapy.
7. What would be the choice for the second-line therapy?
8. What over-the-counter or alternative medications would be appropriate for this patient?
9. What dietary and lifestyle changes should be recommended for I.W.?

23 Arrhythmias

Cynthia A. Sanoski ■ Andrew M. Peterson

Cardiac arrhythmias are abnormal cardiac rhythms, including tachyarrhythmias (an increase in heart rate) and bradyarrhythmias (a decrease in heart rate). Arrhythmias may be asymptomatic or symptomatic, causing palpitations, weakness, loss of consciousness, heart failure (HF), and sudden death. Searching for a reversible cause of the arrhythmia is the first step in patient care. However, in many cases, antiarrhythmic drugs (AADs) are necessary to permit stabilization until the underlying condition is normalized. Many patients require chronic drug therapy for an arrhythmia due to an underlying disease condition that makes them chronically susceptible to cardiac arrhythmias that are associated with high morbidity and mortality rates.

Causes

Arrhythmias may result from structural or electrical/conduction system changes in the heart that may compromise cardiac function and cardiac output. Conditions that give rise to arrhythmias include myocardial ischemia, chronic HF, hypertension, valvular heart disease, hypoxemia, thyroid abnormalities, electrolyte disturbances, drug toxicity, excessive caffeine or ethanol ingestion, anxiety, and exercise. Some of these conditions are reversible, and some cause structural changes that are not reversible.

Pathophysiology

Basic Electrophysiology

Electrically active myocardial cells (non–pacemaker-type cells) at rest maintain a potential difference between their intracellular fluid and the extracellular fluid. When excited, these cells manifest a characteristic sequence of transmembrane potential changes called the *action potential*. The resting membrane potential is –90 mV with respect to the extracellular fluid. The activity of the sodium–potassium pump and the permeability of the membrane to sodium, potassium, and calcium ions determine the membrane potential of a cardiac cell at any given time. Permeability is defined by the diffusion of ions across the membrane through various ion-selective channels. The phases of the action potential correspond to the excitation state of a myocardial cell (Box 23.1).

BOX 23.1 Phases of the Action Potential

- Phase 0 is when rapid depolarization occurs due to the rapid influx of Na^+.
- Phase 1 is a brief initial repolarization period. Inactivation of the inward Na^+ current and activation of the outward K^+ current cause this brief but rapid phase of repolarization.
- Phase 2 is a plateau period during which there is little change in membrane potential. The outward K^+ current and the influx of Ca^{2+} through calcium channels typify the plateau period. The offsetting effect of these currents creates only a small net change in potential, thus creating a plateau.
- Phase 3 is a period of repolarization that is characterized primarily by K^+ efflux.
- Phase 4 is a gradual depolarization of the cell, with Na^+ gradually leaking into the intracellular space, balanced by decreasing efflux of K^+. As the cell is slowly depolarized during this phase, an increase in Na^+ permeability occurs, which again leads to phase 0.

Arrhythmias can result from disorders of impulse formation and/or impulse conduction. Several factors are believed to be involved in precipitating arrhythmias. There may be a defect in the normal mechanism of spontaneous phase 4 depolarization or an increased automaticity of pacemaker cells. In addition, ectopic pacemakers in normally quiescent tissue are responsible for arrhythmias originating from disorders of impulse formation. Impulse conduction defects occur when the impulse is slowed or blocked because of functional unidirectional block, a change in conduction velocity, or a change in the refractory period. Furthermore, simultaneous abnormalities of impulse formation and

conduction may occur.

AADs are used to treat abnormal electrical activity of the heart. The drugs outlined in this chapter are used to treat, suppress, or prevent two major mechanisms of arrhythmias—an abnormality in impulse formation (i.e., increased automaticity) or an abnormality in impulse conduction (i.e., reentry).

Automaticity

Automaticity refers to the ability of the cardiac cells to depolarize spontaneously. Three factors determine automaticity: maximum diastolic depolarization, the rate of depolarization, and the level of the threshold potential. Arrhythmias resulting from abnormal automaticity include sinus tachycardia and junctional tachycardia. The sinoatrial (SA) node has the most rapid rate of depolarization during diastole and reaches threshold first. Cells of the atrioventricular (AV) node and His–Purkinje system have automaticity but a slower rate of phase 4 depolarization. The primary role of the SA node is as the pacemaker of the heart. The SA node is sensitive to alterations in autonomic nervous system output and in its biochemical surroundings. Catecholamine stimulation leads to a shorter action potential duration and increases the spontaneous rate of depolarization. Vagal stimulus and endogenous purines such as adenosine increase outward potassium currents, thus inhibiting depolarization. Increased adrenergic innervation produces major changes in ionic current activity in the SA node.

Another mechanism for arrhythmias due to abnormal impulse formation is intracellular calcium overload, called *after-depolarization*. If after-depolarizations reach threshold, a new action potential is generated and propagated in adjacent cells. After-depolarizations may occur in response to hypothermia, electrolyte imbalance, catecholamine excess, or stretch. Late after-depolarizations may also be of particular importance in some of the arrhythmias caused by digoxin toxicity.

Reentry

Reentry involves indefinite propagation of the impulse and continued activation of previously refractory tissue. Reentrant foci occur if there are two pathways for impulse conduction, an area of unidirectional block (prolonged refractoriness) in one of these pathways, and slow conduction in the other pathway. A refractory period occurs when the cell cannot be activated after having already fired. Excitability determines the strength of a stimulus required to initiate a new action potential at any given point during the action potential cycle.

Types of Arrhythmias

Arrhythmias evolve either above or below the ventricles and can be regular or irregular. *Supraventricular arrhythmias* evolve above the ventricles in the atria, SA node, or AV node. These arrhythmias may present with either tachycardia or bradycardia or with regularity or irregularity. *AV nodal arrhythmias* originate at or within the AV node and are caused by delayed or absent SA node conduction to the AV node. Supraventricular and AV nodal arrhythmias are not usually life threatening; however, they may become troublesome and lead to reduced cardiac output related to decreased ventricular filling.

Ventricular arrhythmias originate in the ventricles or the bundle of His. These types of arrhythmias are usually symptomatic and may cause loss of consciousness or death. Therefore, arrhythmias in this category require immediate intervention. Underlying clinical conditions that usually give rise to these arrhythmias are myocardial ischemia/infarction, dilated and hypertrophic cardiomyopathies, electrolyte disorders, hypoxia, hyperthyroidism, valvular diseases, and drug toxicity. Box 23.2 lists arrhythmias by category.

BOX 23.2 Categories of Supraventricular, Junctional, and Ventricular Arrhythmias

Supraventricular Arrhythmias

Sinus tachycardia
PSVT (originates above or within the AV node and conducts to the His–Purkinje system) (e.g., AV nodal reentrant tachycardia, AV reentrant tachycardia)
Sinus bradycardia
AF
AFl
Atrial tachycardia
Premature atrial contractions
WPW syndrome

Junctional Arrhythmias

Nonparoxysmal AV junctional tachycardia (heart rate > 60 beats/min)
Junctional escape rhythm (heart rate 40–60 beats/min)
Premature AV junctional complexes
AV dissociation
First-degree heart block
Second-degree heart block (Mobitz type I [Wenckebach], Mobitz type II)

Third-degree (complete) heart block

Ventricular Arrhythmias

Premature ventricular contractions
VT
VF
TdP (a rapid form of polymorphic VT associated with a long QT interval)

Diagnostic Criteria

The practitioner must first assess the patient via a thorough and sometimes urgent history and physical examination. There may be no symptoms, or the patient may present with symptoms such as chest pain, shortness of breath, decreased level of consciousness, syncope, confusion, diaphoresis, weakness, and palpitations. The practitioner should ask when the symptoms started, how long they have lasted, their frequency, and how the patient tolerated the symptoms.

It also is important to assess the patient's risk factors for development of arrhythmias, such as previous coronary artery disease (CAD), myocardial infarction (MI), dilated or hypertrophic cardiomyopathy, hypertension, valvular heart disease, alcohol or drug abuse, or prescription drug use (e.g., digoxin, AADs). The practitioner should focus the physical examination on heart rate and blood pressure; presence of extra, irregular, or skipped beats; rate, rhythm, amplitude, and symmetry of peripheral pulses; and response to exercise.

Laboratory and diagnostic studies also are vital in diagnosing arrhythmias. The practitioner should examine the 12-lead electrocardiogram (ECG) for evidence of myocardial ischemia; calculation of the PR interval, QRS interval, and QT interval; presence of premature atrial or ventricular contractions; characteristics of Wolff-Parkinson-White (WPW) syndrome; presence or absence of P waves; and relationship between P waves and QRS complexes. Continuous cardiac monitoring is needed for patients who have episodes of life-threatening arrhythmias so that electrical cardioversion and/or AADs can be administered as immediate interventions.

A complete blood count, basic metabolic profile (to assess electrolyte concentrations), thyroid function tests, and a digoxin level should be performed as necessary to determine any underlying causes of the arrhythmia. In addition, an echocardiogram should be performed to assess left ventricular (LV) function. If myocardial ischemia is suspected as a cause of the arrhythmia, the patient should undergo further evaluation with measurement of cardiac enzymes, performance of cardiac stress testing, and, possibly, cardiac catheterization.

Initiating Drug Therapy

During the past several decades, the treatment approach for both atrial and ventricular arrhythmias has been gradually shifting away from the use of AADs toward the use of various nonpharmacological therapies. Several factors have likely contributed to the decline in AAD use over the years. The negative results of the Cardiac Arrhythmia Suppression Trial (CAST) likely had a significant influence on the downward prescribing patterns of class I AADs. In addition, increasing clinical evidence to support the use of nonpharmacological strategies for the treatment of both supraventricular and ventricular arrhythmias has likely contributed to the decline in the use of AADs as a whole. Numerous studies establishing that a rhythm-control regimen does not confer any benefit over a rate-control regimen in patients with persistent atrial fibrillation (AF) may have also contributed to this decline in AAD use.

Treatable conditions may cause the arrhythmia. Identification of treatable causes before administering an AAD is a priority. Conditions that may cause arrhythmias are electrolyte imbalances (e.g., hypokalemia, hypomagnesemia), drug overdose, drug interactions with other medications or herbal supplements, renal failure, thyroid disorders, metabolic acidosis, hypovolemia, MI, pulmonary embolism, cardiac tamponade, tension pneumothorax, dissecting aortic aneurysm, hypoxemia, and valvular or congenital defects in the heart.

Nonpharmacological therapies, such as radiofrequency catheter ablation and implantable cardioverter–defibrillators (ICDs), are also available to treat various arrhythmias. ICDs are used in the management of ventricular arrhythmias, and their benefits have been demonstrated in several clinical trials (Antiarrhythmics Versus Implantable Defibrillators [AVID] Investigators, 1997; Bardy et al., 2005; Buxton et al., 1999; Connolly et al., 2000; Kuck et al., 2000; Moss et al., 1996, 2002). Radiofrequency catheter ablation permanently terminates the arrhythmia by ablating the focal area where the arrhythmia occurs. This procedure can be used for AF, atrial flutter (AFl), and symptomatic drug-refractory ventricular tachycardia (VT).

Goals of AAD Therapy

The overall goals of AAD therapy are to relieve the acute episode of irregular rhythm, establish sinus rhythm (SR), and prevent further episodes of the arrhythmia. Typical agents used to treat arrhythmias include AADs (classes I through IV), digoxin, adenosine, and atropine (Table 23.1).

TABLE 23.1 Overview of Selected Antiarrhythmic Agents

Generic (Trade) Name and Dosage	Selected Adverse Effects	Contraindications	Special Considerations
adenosine (Adenocard) Adult: 6 mg IV push over 1–2 s; repeat with 12 mg IV push if sinus rhythm not obtained within 1–2 min after first dose; may repeat 12-mg dose a second time if no response in 1–2 min	Headache, chest pain, lightheadedness, dizziness, nausea, flushing, dyspnea, blurred vision	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker	Monitor ECG during administration. Use cautiously in patients with asthma (bronchoconstriction may occur). Each dose should be immediately followed with a 10-mL saline flush.
amiodarone (Cordarone, Nexterone, Pacerone) *AF* Adult IV: 5 mg/kg over 30 min, then continuous infusion of 1 mg/min for 6 h, then 0.5 mg/min; convert to PO when hemodynamically stable and able to take PO medications Adult PO: 400 mg bid–tid for 1 wk, until patient receives ~10 g total, then 200 mg PO daily *Pulseless VT/VF* Adult IV: 300 mg IV push/IO; can give additional 150 mg IV push/IO if persistent VT/VF; if stable rhythm achieved, initiate continuous infusion at 1 mg/min for 6 h, then 0.5 mg/min; convert to PO when hemodynamically stable and able to take PO medications (see PO dose under stable VT) *Stable VT (with a pulse)* Adult IV: 150 mg (diluted in 100 mL of D5W or saline) over 10 min; may repeat dose every 10 min, if necessary for breakthrough VT; if stable rhythm achieved, initiate continuous infusion at 1 mg/min for 6 h, then 0.5 mg/min; convert to PO when hemodynamically stable and able to take PO medications Adult PO: 1,200–1,600 mg/d in 2 or 3 divided doses for 1 wk, until patient receives ~15 g total, then 300–400 mg PO daily	IV: hypotension, bradycardia, heart block, phlebitis PO: corneal microdeposits, optic neuritis, nausea, vomiting, anorexia, pulmonary fibrosis, bradycardia, tremor, ataxia, paresthesias, insomnia, constipation, abnormal liver function tests, hypothyroidism, hyperthyroidism, blue-gray discoloration of skin, photosensitivity	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker	Advise patient to apply sunscreen and to minimize areas of exposure to sun. Patients should have chest x-ray performed annually. Liver function and thyroid function tests should be performed every 6 mo. Pulmonary function tests and ophthalmologic exam should be performed if patient becomes symptomatic. A chest x-ray, pulmonary function tests, liver function tests, and thyroid function tests should also be performed at baseline. An ophthalmologic exam should be performed at baseline if the patient has significant visual abnormalities. Monitor for drug interactions (CYP3A4 substrate, CYP3A4, 2C9, 2D6, and P-gp inhibitor).
atropine Adult: 0.5 mg IV every 3–5 min; not to exceed 3 mg total dose	Palpitations, tachycardia, dry mouth, dizziness	Acute angle-closure glaucoma, obstructive uropathy, tachycardia, obstructive disease of GI tract	Administer IV over 1 min. Monitor ECG during administration.

Generic (Trade) Name and Dosage	Selected Adverse Effects	Contraindications	Special Considerations
digoxin (Lanoxin) Adult (LD IV or PO): 0.25–0.5 mg over 2 min; may give 0.125–0.25 mg q8h for 2 more doses for a total dose of 1 mg or 10–15 mcg/kg Adult MD: 0.125–0.25 mg IV or PO daily in normal renal function	Anorexia, nausea, vomiting, diarrhea, headache, dizziness, vertigo, visual disturbances (yellow-green halos), confusion, hallucinations, arrhythmias, AV conduction disturbances (heart block, AV junctional rhythm, bradycardia)	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker	Teach patient how to take pulse. Dose adjustment required in renal impairment. Monitor for drug interactions (P-gp substrate).
diltiazem (Cardizem) Adult IV: 0.25 mg/kg over 2 min, if ventricular rate remains uncontrolled after 15 min, can repeat with 0.35 mg/kg over 2 min; then initiate continuous infusion of 5–15 mg/h Adult PO: Start with 30 mg four times daily and ↑ to 180–480 mg/d in divided doses (SR can be given once daily)	Dizziness, headache, edema, heart block, bradycardia, HF exacerbation, hypotension	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker, LVSD	Teach patient how to take pulse and blood pressure. Monitor for drug interactions (CYP3A4 substrate and inhibitor).
disopyramide (Norpace) Adult (<50 kg): IR: 100 mg PO q6h; SR: 200 mg PO q12h Adult (>50 kg): IR: 150 mg PO q6h; SR: 300 mg PO q12h; may ↑ up to 800 mg/d	Hypotension, HF exacerbation, nausea, anorexia, dry mouth, urinary retention, blurred vision, constipation, ToP	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker, LVSD	Dose adjustment required in renal impairment (CrCl ≤ 40 mL/min; SR form not recommended when CrCl ≤60 mL/min). Monitor for drug interactions (CYP3A4 substrate).
dofetilide (Tikosyn) Adult: 125–500 mcg PO bid	Chest pain, headache, dizziness, insomnia, nausea, diarrhea, dyspnea, ToP	CrCl <20 mL/min, QT interval >440 msec; concomitant use of cimetidine, dolutegravir, hydrochlorothiazide, ketoconazole, megestrol, prochlorperazine, QTc-prolonging drugs, trimethoprim/sulfamethoxazole, or verapamil	Patients must be hospitalized for ≥3 days for therapy initiation. Dose adjustment required in renal impairment (CrCl ≤60 mL/min). Dose must also be adjusted based on QT interval. Monitor for drug interactions.
dronedarone (Multaq) Adult: 400 mg PO bid (with meals)	Nausea, vomiting, diarrhea, HF exacerbation, hepatic impairment, pulmonary toxicity, renal impairment/failure	Permanent AF, NYHA class IV HF, NYHA class II–III HF with recent hospitalization for decompensated HF, 2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker, heart rate <50 beats/min, concurrent use of potent CYP3A4 inhibitors or QTc-prolonging drugs, QT interval ≥500 msec, PR interval >280 msec, severe hepatic impairment, history of amiodarone-induced hepatic or pulmonary toxicity	Instruct patient to report adverse reactions or any signs/symptoms of HF immediately. Monitor for drug interactions (CYP3A4 substrate, CYP2D6, CYP3A4, and P-gp inhibitor).

Generic (Trade) Name and Dosage	Selected Adverse Effects	Contraindications	Special Considerations
esmolol (Brevibloc) Adult: 500 mcg/kg/min IV for 1 min, then maintenance infusion of 50 mcg/kg/min; if inadequate response, retreat with 500 mcg/kg/min for 1 min and ↑ infusion rate by 50 mcg/kg/min; repeat this process until desired response achieved or maximum infusion rate of 300 mcg/kg/min is reached	Hypotension, wheezing, bronchospasm, heart block, bradycardia, HF exacerbation	2nd–/3rd-degree heart block in the absence of a pacemaker, decompensated HF, sinus bradycardia	Use with caution in patients with LVSD.
flecainide Adult: 50 mg PO q12h; up to a maximum of 300 mg/d	Dizziness, headache, lightheadedness, syncope, blurred vision or other visual disturbances, dyspnea, HF exacerbation, arrhythmias	2nd–/3rd-degree heart block in the absence of a pacemaker, recent MI, ischemic heart disease, cardiogenic shock, HF	Dose adjustment required in renal impairment (CrCl ≤ 50 mL/min). Monitor for drug interactions (CYP2D6 substrate).
ibutilide (Corvert) Adult (>60 kg): 0.01 mg/kg IV over 10 min; can repeat with another dose if AF/AFl does not terminate within 10 min after end of initial dose Adult (≤60 kg): 1 mg IV over 10 min; can repeat with another dose if AF/AFl does not terminate within 10 min after end of initial dose	ToP, hypotension, heart block, headache, nausea	Preexisting hypokalemia or hypomagnesemia, QT interval >440 msec	Monitor ECG during administration. Stop infusion if QT interval prolongation or ventricular arrhythmias occur. Correct electrolyte abnormalities before administering.
lidocaine (Xylocaine) *Pulseless VT/VF* Adult: 1–1.5 mg/kg IV push/IO; may give additional 0.5–0.75 mg/kg IV push/IO every 5–10 min, if persistent VT/VF (maximum cumulative dose = 3 mg/kg); if stable rhythm achieved, initiate continuous infusion of 1–4 mg/min *Stable VT (with a pulse)* Adult: 1–1.5 mg/kg IV push; may give additional 0.5–0.75 mg/kg IV push every 5–10 min, if persistent VT (maximum cumulative dose = 3 mg/kg); if stable rhythm achieved, initiate continuous infusion of 1–4 mg/min	Seizures, confusion, stupor, dizziness, bradycardia, respiratory depression, slurred speech, blurred vision, muscle twitching, tinnitus	Hypersensitivity to amide local anesthetics, 2nd–/3rd-degree heart block in the absence of a pacemaker	A lower infusion rate (1–2 mg/min) should be used in older adults or patients with HF or hepatic disease. Monitor for drug interactions (CYP1A2 and CYP3A4 substrate).

Generic (Trade) Name and Dosage	Selected Adverse Effects	Contraindications	Special Considerations
metoprolol (Lopressor) Adult IV: 2.5–5 mg over 2 min; can repeat every 5 min (maximum cumulative dose = 15 mg over 10–15–min period) Adult PO: IR: 25 mg bid; SR: 50 mg daily; may ↑ up to 400 mg/d	Bradycardia, HF exacerbation, heart block, bronchospasm, fatigue, ↓ exercise tolerance, dizziness, hypotension	2nd–/3rd-degree heart block in the absence of a pacemaker, decompensated HF, heart rate <45 beats/min	Use IV with caution in patients with LVSD. Teach patient how to take pulse and blood pressure. Instruct patient to not discontinue drug abruptly (may lead to hypertensive crises, angina, or MI). Use metoprolol succinate (SR) when initiating PO therapy in patients with LVSD.
mexiletine Adult: 200 mg PO q8h; may ↑ up to 400 mg PO q8h	Dizziness, drowsiness, paresthesias, blurred vision, tremor, seizures, confusion, arrhythmias, nausea, vomiting	2nd–/3rd-degree heart block in the absence of a pacemaker, cardiogenic shock	Monitor for drug interactions (CYP1A2 and CYP2D6 substrate).
procainamide Adult: 15–18 mg/kg IV over 60 min, then continuous infusion of 1–4 mg/min	Bradycardia, heart block, hypotension, HF exacerbation, ToP	Hypersensitivity to procaine, 2nd–/3rd-degree heart block in the absence of a pacemaker	Monitor ECG during administration. Stop infusion if QT interval prolongation or ventricular arrhythmias occur. Use with caution, if at all, in renal impairment.
propafenone (Rythmol) Adult: IR: 150 mg PO q8h (up to a maximum of 300 mg PO q8h); SR: 225 mg PO q12h (up to a maximum of 425 mg PO q12h)	Dizziness, drowsiness, HF exacerbation, blurred vision, arrhythmias, heart block, bradycardia, taste disturbances, bronchospasm	2nd–/3rd-degree heart block in the absence of a pacemaker, bradycardia, cardiogenic shock, HF, bronchospastic disorders	Teach patient how to take pulse and blood pressure. Instruct patient to not discontinue drug abruptly (may lead to hypertensive crises, angina, or MI).
propranolol Adult IV: 1 mg over 1 min; may repeat every 5 min up to a total dose of 5 mg Adult PO: 10–20 mg q6–8h; can ↑ to 80–240 mg/d in 2–4 divided doses	Bradycardia, HF exacerbation, heart block, bronchospasm, fatigue, ↓ exercise tolerance, dizziness, hypotension	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker, LVSD Relatively contraindicated in asthma	Teach patient how to take pulse and blood pressure. Instruct patient to not discontinue drug abruptly (may lead to hypertensive crises, angina, or MI).
quinidine Adult: Sulfate: 200–400 mg PO q8h, up to a maximum of 600 mg PO q8h Gluconate: 324 mg PO q8–12h, up to a maximum of 972 mg PO q8–12h	ToP, heart block, hypotension, tinnitus, diarrhea, nausea, vomiting, fever, HF exacerbations, thrombocytopenia	Allergy or sensitivity to quinidine or cinchona derivatives, long QT syndrome (may predispose to ToP)	Instruct patient to take drug with food if GI distress occurs. Monitor for drug interactions (CYP3A4 substrate, CYP2D6 inhibitor).
sotalol (Betapace, Betapace AF) *AF (Betapace AF)* Adult: 80 mg PO bid; up to a maximum of 160 mg PO bid *Ventricular Arrhythmias (Betapace)* Adult: 80 mg PO bid; up to a maximum of 320 mg PO bid	Bradycardia, heart block, HF exacerbation, ToP, bronchospasm	2nd–/3rd-degree heart block in the absence of a pacemaker, bradycardia, HF, asthma, long QT syndrome (may predispose to ToP)	Patients must be hospitalized for ≥3 days for therapy initiation. Teach patient how to take pulse and blood pressure. Dose adjustment required in renal impairment (CrCl ≤ 60 mL/min). Instruct patient to not discontinue drug abruptly (may lead to hypertensive crises, angina, or MI).

Generic (Trade) Name and Dosage	Selected Adverse Effects	Contraindications	Special Considerations
verapamil (Calan) Adult IV: 2.5–5 mg over 2 min; if ventricular rate remains uncontrolled after 15–30 min, can double initial dose and administer over 2 min; then initiate continuous infusion of 5–10 mg/h Adult PO: 240–360 mg/d in 3 divided doses (SR can be given once daily)	Constipation, bradycardia, heart block, HF exacerbation, hypotension, dizziness, peripheral edema	2nd–/3rd-degree heart block or sick sinus syndrome in the absence of a pacemaker, LVSD	Encourage patient to ↑ fluid and fiber intake to combat constipation. Teach patient how to take pulse and blood pressure. Monitor for drug interactions (CYP3A4 substrate and inhibitor).

AF, atrial fibrillation; AFl, atrial flutter; AV, atrioventricular; bid, twice daily; CrCl; creatinine clearance; CYP, cytochrome P-450, D5W, 5% dextrose in water; ECG, electrocardiogram; GI, gastrointestinal; HF, heart failure; IO, intraosseous; IR, immediate-release; IV, intravenous; LD, loading dose; LVSD, left ventricular systolic dysfunction; MD, maintenance dose; MI, myocardial infarction; NYHA, New York Heart Association; P-gp, P-glycoprotein; PO, oral; SR, sustained release; TdP, torsades de pointes; tid, 3 times daily; VF, ventricular fibrillation; VT, ventricular tachycardia.

Drug Classification

AADs are organized into four classes, I (Ia, Ib, Ic), II, III, and IV (Vaughan Williams, 1984). Although the Vaughan Williams classification system is the most widely used method for grouping AADs based on their electrophysiologic actions, using this classification system requires some points of exception to be made. This system is somewhat incomplete, and it excludes certain drugs including digoxin, adenosine, and atropine. In addition, the classification is not pure, and there is some overlapping of drugs into more than one category. For instance, amiodarone and dronedarone have electrophysiologic properties of all four Vaughan Williams classes. Furthermore, this system does not take into account that the active metabolites of AADs may have different electrophysiologic effects than their parent drugs. For example, *N*-acetyl procainamide (NAPA), the major active metabolite of procainamide, blocks outward potassium channels and therefore can be considered a class III AAD. Although procainamide blocks outward potassium channels, it also primarily blocks inward sodium currents, thereby making it a class Ia AAD. Therefore, the overall electrophysiologic effect produced by procainamide depends upon the relative concentrations of procainamide and NAPA that are present in the body, which can vary based on several clinical factors. The Vaughan Williams classification scheme (Box 23.3) identifies drugs that block sodium channels (class Ia, Ib, and Ic), those that are β-blockers (class II), those that block potassium channels (class III), and those that are nondihydropyridine calcium channel blockers (CCBs) (class IV).

BOX 23.3 Classification of Antiarrhythmic Drugs

Class I—Sodium Channel Blockers

Ia (intermediate onset/offset)
disopyramide
procainamide
quinidine
Ib (fast onset/offset)
lidocaine
mexiletine
Ic (slow onset/offset)
flecainide
propafenone*

Class II—b-Blockers

atenolol
esmolol

metoprolol
propranolol

Class III—Potassium Channel Blockers

amiodarone†
dofetilide
dronedarone†
ibutilide
sotalol*

Class IV—Calcium Channel Blockers

diltiazem
verapamil

*Also has β-blocking properties (class II)

†Also has sodium channel blocking (class I), β-blocking (class II), and calcium channel blocking (class IV) properties

Class I AADs

This class of drugs, known as the sodium channel blockers, may be subdivided into classes Ia, Ib, and Ic according to the rate of sodium channel dissociation. These agents vary in the rate at which they bind and then dissociate from the sodium channel receptor. Class Ib AADs bind to and dissociate from the sodium channel receptor quickly ("fast on–off"), while class Ic AADs slowly bind to and dissociate from this receptor ("slow on–off"). The binding kinetics of the class Ia AADs are intermediate between those of the class Ib and Ic agents. In addition, class I AADs possess rate dependence, whereby sodium channel blockade is greatest at fast heart rates (i.e., tachycardia) and least during slower heart rates (i.e., bradycardia) (see Table 23.1).

Class Ia Drugs

Quinidine

Quinidine is a broad-spectrum AAD that may be used to treat supraventricular and ventricular arrhythmias. This drug slows conduction velocity (phase 0), prolongs refractoriness (phase 3), and decreases automaticity (phase 4). Quinidine widens the QRS complex, prolongs the QT interval, and slightly prolongs the PR interval on the ECG. Quinidine has been used in the management of AF, AFl, AV nodal reentrant tachycardia, and VT.

Quinidine has potent anticholinergic properties that affect the SA and AV nodes. Therefore, quinidine can increase the SA nodal discharge rate and AV nodal conduction. Consequently, in patients with AF or AFl, these anticholinergic effects may lead to a more rapid ventricular rate. Therefore, the AV node should be adequately inhibited with the use of an AV nodal blocking drug, such as a β-blocker, nondihydropyridine CCB (e.g., diltiazem or verapamil), or digoxin prior to administering quinidine in these patients. Quinidine also blocks α_1-receptors, which can lead to vasodilation and subsequent dose-related hypotension, especially when administered intravenously.

The most common adverse effects associated with quinidine are gastrointestinal (GI) (nausea, vomiting, and diarrhea). As with other class Ia drugs, quinidine can cause proarrhythmia, specifically torsades de pointes (TdP). Other adverse effects associated with quinidine include thrombocytopenia, hepatitis, cinchonism (tinnitus, blurred vision, headache), worsening of underlying HF, and hemolytic anemia.

Quinidine is a substrate of the cytochrome P-450 (CYP) 3A4 isoenzyme and an inhibitor of the CYP2D6 isoenzyme. Therefore, quinidine can interact with any drug that inhibits or induces CYP3A4 (e.g., inhibitors: ketoconazole, erythromycin, amiodarone, verapamil, diltiazem; inducers: rifampin, phenobarbital, phenytoin) or is a substrate of CYP2D6 (e.g., β-blockers). Quinidine can also significantly increase serum digoxin concentrations.

Procainamide

Procainamide has basically the same electrophysiologic effects as those of quinidine, except that procainamide does not have the anticholinergic activity of quinidine. Procainamide slows conduction velocity (phase 0), prolongs refractoriness (phase 3), and decreases automaticity (phase 4). Procainamide widens the QRS complex, prolongs the QT interval, and slightly prolongs the PR interval on the ECG. NAPA, the major metabolite of procainamide, blocks outward potassium currents and thereby has class III electrophysiologic properties. NAPA prolongs the QT interval. Procainamide is a broad-spectrum AAD and has been used to treat supraventricular and ventricular arrhythmias.

Procainamide is only available in the intravenous (IV) formulation; all of its oral formulations have been discontinued. Therefore, adverse effects that would most likely occur with chronic therapy (e.g., systemic lupus erythematosus, agranulocytosis) should no longer be a concern. Most of the adverse effects associated with IV administration of procainamide include bradycardia, AV block, hypotension, worsening of underlying HF, and TdP.

Procainamide and NAPA can accumulate in patients with renal impairment. Therefore, serum concentrations must be monitored regularly to assess for efficacy and toxicity. The therapeutic ranges of procainamide and NAPA are 4 to 10 mcg/mL and 15 to 25 mcg/mL, respectively.

Disopyramide

Disopyramide slows conduction velocity (phase 0), prolongs refractoriness (phase 3), and decreases automaticity (phase 4). These effects are manifested as a prolonged QT interval and a slightly prolonged QRS complex on the ECG. Disopyramide has direct and indirect effects on the heart rate similar to those of quinidine. Disopyramide is a broad-spectrum AAD and has been used to treat supraventricular and ventricular arrhythmias. However, the clinical use of this agent is limited because of its potent anticholinergic and negative inotropic effects. If disopyramide is used to treat AF or AFl, the practitioner should give an AV nodal blocking agent (e.g., β-blocker, diltiazem, verapamil, or digoxin) to minimize its vagolytic effect.

The primary adverse effects associated with disopyramide are precipitation of HF and anticholinergic effects (e.g., dry mouth, urinary retention, constipation, blurred vision). Disopyramide is contraindicated in patients with HF with reduced ejection fraction (HFrEF) (left ventricular ejection fraction [LVEF] of 40% or less) because it can cause significant depression of myocardial contractility. Disopyramide can also cause TdP.

Class Ib Drugs

The class Ib AADs include lidocaine and mexiletine. These agents decrease automaticity and conduction velocity and shorten refractoriness. These AADs primarily exert their

electrophysiologic effects on the ventricular myocardium since they have little or no effect on atrial tissue.

Lidocaine

Lidocaine is categorized as a class Ib AAD; however, its electrophysiologic effects are different in that it is selective to ischemic tissue, and especially to active fast sodium channels in the bundle of His, Purkinje fibers, and ventricular myocardium. Thus, lidocaine has little effect on conduction in nonischemic tissue and the atrial myocardium. Lidocaine also has very little effect on the automaticity of the SA node. However, lidocaine does suppress the automaticity of ectopic ventricular pacemakers and Purkinje fibers. In normal tissues, the action potential duration is shortened and conduction velocity shows little change with lidocaine. However, in depolarized fibers or in fibers damaged by ischemia, lidocaine prolongs the action potential and slows conduction.

Lidocaine is primarily effective in treating ventricular arrhythmias, especially those associated with acute MI. Prophylactic administration in patients with acute MI demonstrated a decreased incidence of ventricular fibrillation (VF) but no difference in prehospital treatment outcomes of acute MI and no improvement or even higher mortality rates in hospitalized patients. Selective administration of lidocaine to patients with VF associated with MI or cardiac arrest also demonstrated no improvement in survival rates (Wyse et al., 1988). The use of lidocaine as prophylaxis against VT or VF in patients with MI is not warranted. Its use should be reserved for the treatment of ventricular arrhythmias.

Lidocaine is not effective in the treatment of supraventricular arrhythmias such as AF or AFl. However, lidocaine can be used for the treatment of digoxin-induced arrhythmias (atrial and ventricular) because of its selectivity for depolarized myocardium.

Lidocaine is eliminated primarily by hepatic metabolism, with the metabolic rate being proportional to hepatic blood flow. In patients with HFrEF, the volume of distribution in the central compartment is decreased and hepatic blood flow may be reduced if cardiac output is depressed. Hepatic impairment slows lidocaine's clearance rate but does not affect its volume of distribution.

The principal adverse effects associated with lidocaine are central nervous system (CNS) effects (i.e., dizziness, paresthesia, disorientation, tremor, agitation). At higher concentrations, seizures and respiratory arrest may occur with the use of lidocaine. Lidocaine's adverse effects are more frequent in the elderly, in patients with HFrEF or hepatic disease, and during prolonged administration (more than 24 hours). Therefore, these patients should be closely monitored for signs and symptoms of lidocaine toxicity. Lidocaine concentrations should also be closely monitored in these patients. The therapeutic range of lidocaine is 1.5 to 6 mg/L. Lidocaine toxicity is most commonly observed at concentrations greater than 5 mg/L.

Mexiletine

Mexiletine is a structurally related oral analog of and has similar electrophysiologic effects, antiarrhythmic effects, and adverse events to lidocaine. Mexiletine decreases conduction velocity (phase 0) preferentially in ischemic tissue.

Mexiletine is effective in the treatment of VT. Combining mexiletine with a second AAD (class IA or III) is more effective than mexiletine monotherapy for the treatment of refractory VT. However, its clinical use is limited by a high incidence of GI reactions such as nausea and vomiting. CNS adverse effects such as dizziness, confusion, ataxia, and speech disturbances may lead the practitioner to discontinue treatment with this drug. Mexiletine can also cause proarrhythmia, although the incidence is lower when compared to other AADs.

Class Ic Drugs

Flecainide

Flecainide is a potent blocker of sodium channels during phase 0 of the action potential, thereby slowing conduction velocity in the Purkinje fibers and AV node and diminishing automaticity in the Purkinje fibers. Because of the slowed cardiac conduction, increases in the PR interval and QRS duration may be seen on the ECG.

Flecainide is most commonly used in clinical practice for the treatment of supraventricular arrhythmias, such as AF and AFl. Flecainide has very good efficacy in terms of restoring and maintaining SR in patients with AF (Camm et al., 2012; Slavik et al., 2001). Flecainide has been shown to restore SR in 75% to 90% of patients with AF at 8 hours (with single, oral loading doses of 300 mg) as well as maintain SR in up to 77% of patients at 1 year. Although flecainide is approved by the U.S. Food and Drug Administration (FDA) for the treatment of life-threatening sustained VT, it is rarely, if ever, used for this indication, primarily due to its suboptimal efficacy and the potential for proarrhythmic events (Anderson et al., 1983). There may be a resurgence in the use of flecainide for the use of ventricular arrhythmias, as this AAD has been more recently shown to be effective in suppressing exercise-induced ventricular arrhythmias in patients with catecholaminergic polymorphic VT that is refractory to β-blocker therapy (Van der Werf et al., 2011).

The CAST was conducted to determine if suppression of asymptomatic or mildly symptomatic premature ventricular contractions (PVCs) with the class Ic AADs, flecainide, encainide, or moricizine would reduce the incidence of death from arrhythmia in post-MI patients (CAST Investigators, 1989). Despite adequate suppression of ventricular arrhythmias, flecainide significantly increased mortality from arrhythmia or cardiac arrest (presumably due to proarrhythmia) and significantly increased total mortality. Overall, the results of this trial demonstrated that the use of AADs to suppress asymptomatic PVCs in post-MI patients does not improve survival and is most likely detrimental. The use of flecainide should be avoided in patients with any form of structural heart disease (SHD), which includes CAD, HF, or LV hypertrophy.

Adverse effects associated with flecainide include blurred vision, dizziness, headache, tremor, nausea, vomiting, conduction disturbances, and ventricular arrhythmias (sustained VT) that can be quite resistant to cardioversion. Flecainide also has potent negative inotropic effects that may lead to worsening HF.

Propafenone

Propafenone has the same ability to block sodium channels, slow conduction velocity, and diminish automaticity in the AV node and Purkinje fibers as flecainide. However, propafenone also has a mild, nonselective β-blocking effect. Although propafenone is FDA approved for the treatment of life-threatening ventricular arrhythmias, its use in clinical practice has been limited to the management of supraventricular arrhythmias such as AF. Propafenone has been shown to be effective for restoring and maintaining SR in patients with AF (Miller et al., 2000; Roy et al., 2000). The use of single, oral loading doses of propafenone (450 to 600 mg) in patients with recent-onset AF has been associated with conversion rates of 72% to 76% at 8 hours (Slavik et al., 2001). Although propafenone was not evaluated in the CAST and has not been associated with increased mortality in other trials, there still tends to be an overall negative perception of this drug's safety in patients with SHD. Until the safety of propafenone can be demonstrated conclusively in a large, randomized, prospective trial in patients with SHD, its use should be avoided in this population.

Adverse effects associated with propafenone include blurred vision, dizziness, headache, nausea, vomiting, fatigue, bronchospasm, taste disturbances (metallic taste), conduction disturbances (bradycardia, heart block, QRS prolongation), and ventricular arrhythmias (sustained VT) that can be quite resistant to cardioversion. Propafenone also has potent negative inotropic effects that may lead to worsening HF.

Class II AADs

β-Blockers are useful in suppressing ventricular arrhythmias. They also are used for treating many supraventricular arrhythmias because of their ability to block receptor sites in the conduction system and subsequently slow AV nodal conduction and the SA nodal rate, which in turn slows the ventricular rate. Furthermore, β-blockers are helpful when used in combination with other AADs or in treating the underlying cause of some arrhythmias (ischemia, catecholamine excess) (see Table 23.1).

β-Blockers decrease automaticity (decrease the slope of phase 4 depolarization in the sinus node and in the Purkinje fibers) and conduction velocity (phase 0) and prolong refractoriness (phase 3). Changes in the ECG caused by β-blockers are a sinus bradycardia, consisting of a normal or slightly prolonged PR interval and occasional shortening of the QT interval. In addition to being negative chronotropic drugs (decrease AV nodal conduction), β-blockers are also negative inotropic agents (decrease cardiac contractility). Both of these properties enable β-blockers to decrease myocardial oxygen consumption, which is useful especially in patients with underlying CAD. Patients with sinus node dysfunction or AV conduction system defects may have significant sinus bradycardia when a β-blocker is initiated.

In general, β-blockers lower the heart rate and blood pressure, decrease myocardial contractility, decrease oxygen consumption in the myocardium, and lower cardiac output. β-Blockers have a diverse range of uses, including paroxysmal supraventricular tachycardia (PSVT), AF, AFl, and arrhythmias caused by catecholamine excess, ischemia, mitral valve prolapse, hypertrophic cardiomyopathy, and MI. β-Blockers also reduce complex ventricular arrhythmias, including VT. The VF threshold is increased with the use of β-blockers in animal models, and β-blockers have been found to decrease VF in patients with acute MI. β-Blockers reduce myocardial ischemia, which may reduce the likelihood of VF. All β-blockers (without intrinsic sympathomimetic activity) are relatively similar in efficacy for the treatment of supraventricular and ventricular arrhythmias. Selection of a particular β-blocker is usually based on the safety profile of the individual agent.

The adverse effects associated with β-blockers depend on their selectivity for β_1 or β_2 receptors. Bronchospasm may be seen in patients with asthma and chronic obstructive pulmonary disease; this adverse effect is not eliminated by the use of selective β_1-blockers since these agents gradually become nonselective as the dose is increased. HF, hypotension, bradycardia, and depression also are common adverse effects of β-blockers. In addition, patients receiving β-blockers often report fatigue and impotence.

Class III AADs

Class III AADs include amiodarone, dofetilide, dronedarone, ibutilide, and sotalol. Ibutilide and dofetilide are used to treat AF and AFl. Amiodarone and sotalol can be used to treat both supraventricular and ventricular arrhythmias. Dronedarone is FDA approved to reduce the risk of hospitalization from cardiovascular (CV) causes in patients in SR with a history of paroxysmal or persistent AF.

Patients receiving class III AADs should be monitored closely for ECG changes such as increased ventricular ectopy and changes in PR interval, QRS duration, and QT interval. Practitioners should avoid using class III AADs concomitantly with other drugs that can prolong the QT interval to minimize the risk of TdP (see Table 23.1).

Amiodarone

Amiodarone is a unique drug in that it possesses electrophysiologic characteristics of all four Vaughan Williams classes of AADs. While amiodarone is primarily a potassium channel blocker (blocks the rapid and slow components of the delayed rectifier potassium current), it also blocks sodium channels, has nonselective β-blocking activity, and has weak calcium channel blocking properties. As a result, amiodarone reduces automaticity (phase 4) and conduction velocity (phase 0) and prolongs refractoriness (phase 3). When administered intravenously, amiodarone's β-blocking and calcium channel blocking activities are more predominant. Amiodarone has minimal to no negative inotropic effects, which makes it one of the few AADs that can be safely used in patients with HFrEF.

Amiodarone is approved by the FDA for the management of life-threatening recurrent ventricular arrhythmias. However, its off-label use for AF has increased over the past decade not only because of its increased efficacy in maintaining SR as compared to other AADs but also because of it is one of the few AADs proven to be safe in patients with concomitant SHD. Amiodarone is often given IV for the acute treatment of life-threatening ventricular arrhythmias, such as VT or VF. IV amiodarone can also be used to terminate AF acutely. Even though ICDs now play a primary role in the chronic management of ventricular arrhythmias, amiodarone is still used in patients who refuse or are not candidates for these devices. Also, amiodarone (with a β-blocker) can also be used as adjunctive therapy in these patients if frequent ICD discharges occur (Connolly et al., 2006).

Because of amiodarone's poor oral bioavailability, large volume of distribution, and long half-life, its onset of action may not be apparent for several months. To achieve efficacy more quickly, loading doses of oral amiodarone must be initially used to saturate the myocardial stores. Once the patient is appropriately loaded with oral amiodarone, the dose should be reduced to the recommended maintenance dose to minimize the incidence of adverse events.

Because of its extremely large volume of distribution and high lipophilicity, amiodarone has the potential to accumulate and cause adverse effects in numerous organs

with chronic use, with the lungs, thyroid, eyes, heart, liver, skin, GI tract, and CNS being most notably affected. Unlike other amiodarone-induced adverse effects, pulmonary toxicity can be life threatening. Pulmonary toxicity can develop in up to 15% of patients receiving amiodarone (Range et al., 2013). Definitive diagnosis of amiodarone-induced pulmonary toxicity is difficult, since many of the subjective and objective findings are nonspecific. Patients may present with cough, dyspnea, or fever. The chest radiograph may reveal diffuse infiltrates, and pulmonary function tests may demonstrate a reduction in the diffusion capacity. If pulmonary toxicity is detected, amiodarone should be immediately discontinued. Corticosteroids may be needed to treat the pulmonary inflammation. To screen for pulmonary toxicity in patients receiving amiodarone, pulmonary function tests and a chest radiograph should be obtained at baseline. Subsequently, a chest radiograph should be obtained on an annual basis, while pulmonary function tests can be repeated if symptoms develop (Goldschlager et al., 2007).

Because it contains approximately 38% iodine by weight, amiodarone may also cause thyroid abnormalities that can manifest as either hypothyroidism or hyperthyroidism (Bogazzi et al., 2012). Hypothyroidism is the more common form of amiodarone-induced thyroid dysfunction. Although patients often report increased lethargy, the diagnosis of amiodarone-induced hypothyroidism is made upon detection of elevated levels of thyroid-stimulating hormone (TSH). Patients developing amiodarone-induced hypothyroidism can usually be treated with thyroid hormone supplementation (i.e., levothyroxine). The diagnosis of amiodarone-induced hyperthyroidism should be suspected if patients present with new or recurrent arrhythmias. Patients developing hyperthyroidism have abnormally low TSH levels and can usually be treated with antithyroid medications (i.e., methimazole, propylthiouracil). To screen for thyroid dysfunction in patients receiving amiodarone, thyroid function tests should be performed at baseline and then every 6 months throughout therapy (Goldschlager et al., 2007).

Ocular complications induced by amiodarone often manifest as corneal microdeposits, which occur in virtually every patient (Passman et al., 2012). Although these opacities rarely produce visual disturbances, photophobia, halos, and blurred vision have been reported. Because of their relatively benign nature, these opacities do not require routine monitoring or discontinuation of amiodarone when they develop. Chronic amiodarone therapy has also been associated with optic neuritis and optic neuropathy. Since these ocular disturbances are vision threatening, amiodarone must be discontinued once the diagnosis is confirmed. To screen for these complications, ophthalmologic examinations should be performed at baseline only if patients have significant visual abnormalities and then later only if symptoms develop (Goldschlager et al., 2007).

GI adverse effects are relatively common and occur most frequently when amiodarone-loading doses are administered. Typically, patients report nausea, vomiting, loss of appetite, and abdominal pain. Constipation can also occur during long-term therapy. These GI disturbances can be minimized by dividing the total daily dose into 2 to 3 doses and by taking the drug with food. Liver function test abnormalities can also develop. Although

elevations in aspartate aminotransferase and alanine aminotransferase levels are relatively common with amiodarone therapy, overt hepatotoxicity rarely occurs (Babatin et al., 2008). Liver enzyme levels usually return to baseline following reduction of the amiodarone dose or discontinuation of the drug. To screen for these hepatic abnormalities, liver function tests should be performed at baseline and then every 6 months throughout therapy (Goldschlager et al., 2007).

Although laboratory tests cannot detect amiodarone-induced CV, neurologic, and dermatologic toxicities, patients should still be clinically evaluated for these adverse effects on a routine basis. Compared with other AADs, amiodarone produces fewer CV adverse effects. The bradycardia and heart block that can develop merely represent an accentuation of amiodarone's pharmacologic and electrophysiologic properties. Additionally, even though amiodarone markedly prolongs the QT interval, TdP is rare. Neurologic toxicities associated with amiodarone occur frequently and may include tremors, ataxia, peripheral neuropathy, fatigue, and insomnia. The most common dermatologic reactions observed during amiodarone therapy are photosensitivity and a blue-gray skin discoloration (Jaworski et al., 2014). Photosensitivity reactions can range from extremely tanned areas to sunburned areas with erythema and edema. Blue-gray skin discoloration, which often appears on the patient's face and hands, may be related to the cumulative dose and duration of therapy. To prevent these dermatologic toxicities, patients receiving amiodarone should use opaque sunscreens such as zinc oxide while outdoors.

Patients receiving amiodarone also need to be monitored for drug interactions. Amiodarone is a substrate of the CYP3A4 isoenzyme, a potent inhibitor of the CYP3A4, 2C9, and 2D6 isoenzymes and an inhibitor of P-glycoprotein. Amiodarone significantly interacts with digoxin and warfarin, which are commonly used in patients with AF. Amiodarone potentiates the anticoagulant effects of warfarin, which results in an increased international normalized ratio (INR) and an increased risk of bleeding (Sanoski & Bauman, 2002). When amiodarone and warfarin are initiated concurrently or when warfarin is initiated in a patient already receiving amiodarone, warfarin should be started at a dose of 2.5 mg daily. When amiodarone is initiated in a patient already receiving warfarin, the warfarin dose should be empirically reduced by approximately 30% (Sanoski & Bauman, 2002). Amiodarone can also double serum digoxin concentrations. Therefore, the digoxin dose should be empirically reduced by 50% when amiodarone is initiated. Furthermore, to minimize the risk of myopathy or rhabdomyolysis, the doses of simvastatin and lovastatin should not exceed 20 mg/d and 40 mg/d, respectively, when coadministered with amiodarone.

Dronedarone

Like amiodarone, dronedarone is primarily considered a class III AAD, but it exhibits electrophysiological properties of all four Vaughan Williams classes. Although structurally related to amiodarone, dronedarone's structure has been modified through the addition of a methylsulfonyl group and the removal of iodine to potentially limit the risk of toxicity.

Dronedarone also has a considerably shorter half-life (24 hours) when compared with amiodarone (greater than 50 days), which allows for steady state to be achieved in 5 to 7 days without the need for loading doses.

The efficacy and safety of dronedarone have been evaluated in several clinical trials. Dronedarone has been shown to be more effective than placebo in maintaining SR in patients with paroxysmal AF or AFl (Singh et al., 2007). In another trial, the use of dronedarone was associated with a significant reduction in the incidence of hospitalization due to CV events or death when compared to placebo in patients with persistent or paroxysmal AF and at least one additional risk factor for death (Hohnloser et al., 2009). A trial that evaluated the efficacy and safety of dronedarone in patients with New York Heart Association (NYHA) class III or IV HF (LVEF of 35% or less) was terminated prematurely after significantly more patients in the dronedarone group died (primarily because of worsening HF) compared with the placebo group (Køber et al., 2008). Based on the results of this particular trial, dronedarone is contraindicated in patients with advanced HF (NYHA class IV or NYHA class II or III with a recent hospitalization for decompensated HF). Dronedarone has also been shown to be significantly less effective than amiodarone in reducing AF recurrences (Le Heuzey et al., 2010). Another trial that enrolled older adult patients with permanent AF and risk factors for major vascular events was terminated prematurely after significantly more patients in the dronedarone group died (primarily from CV causes), were hospitalized for HF, and suffered a stroke when compared with the placebo group (Connolly et al., 2011). Based on the results of this trial, dronedarone is contraindicated in patients with permanent AF (i.e., those who cannot be restored to SR).

Dronedarone is a substrate of the CYP3A isoenzyme, a moderate inhibitor of the CYP3A and CYP2D6 isoenzymes, and an inhibitor of P-glycoprotein. Because of the potential for significantly increasing dronedarone concentrations, concomitant use of potent CYP3A inhibitors (i.e., ketoconazole, itraconazole, voriconazole, cyclosporine, clarithromycin, and ritonavir) or inducers (e.g., rifampin, phenobarbital, phenytoin, carbamazepine, and St. John's wort) should be avoided. No significant interaction has been observed between dronedarone and warfarin. Dronedarone may significantly increase serum digoxin concentrations by about 2.5-fold. Therefore, when concomitantly using dronedarone with digoxin, the digoxin dose should be empirically reduced by 50%. Dronedarone can also significantly increase dabigatran concentrations. The dose of dabigatran should be reduced to 75 mg twice daily in patients with AF who have a creatinine clearance (CrCl) of 30 to 50 mL/min. Concomitant use with dabigatran should be avoided in patients with AF who have a CrCl less than 30 mL/min. To minimize the risk of myopathy or rhabdomyolysis, the doses of simvastatin and lovastatin should not exceed 10 mg/d when administered concomitantly with dronedarone.

The most common adverse effects associated with dronedarone in the clinical trials were GI disturbances, including nausea, vomiting, and diarrhea. However, postmarketing reports have suggested that more significant organ toxicities, including severe hepatic injury, interstitial lung disease (i.e., pneumonitis, pulmonary fibrosis), and acute kidney

injury, may also be associated with this AAD. Although a prolonged QT interval can occur with dronedarone, TdP is rare.

Sotalol

Sotalol is a class III AAD that also has nonselective β-blocking properties. Sotalol blocks the rapid component of the delayed rectifier potassium current, which prolongs atrial and ventricular refractoriness. Sotalol exhibits reverse-use dependence, whereby its action potential–prolonging effects are lessened at higher heart rates and increased at lower heart rates. Sotalol increases the QT interval by prolonging ventricular repolarization and may give rise to TdP. The QT interval prolongation with sotalol is a dose-dependent effect. The QT interval should be closely monitored during treatment. Sotalol should be discontinued if the QT interval exceeds 550 msec. The practitioner should avoid combining sotalol with other drugs that increase the QT interval.

Sotalol is effective for the treatment of supraventricular and ventricular arrhythmias. Although sotalol is not effective for conversion of AF, it is an effective agent for maintaining SR in patients with AF (Roy et al., 2000). Several trials have been conducted to compare the efficacy of sotalol and amiodarone in patients with AF (Roy et al., 2000; Singh et al., 2005). The results of these trials suggest that amiodarone is more effective than sotalol in restoring SR in patients with AF. Amiodarone is also more effective than sotalol in maintaining patients in SR, except for in those patients with CAD, where the efficacy of these AADs appears to be similar. In patients with an ICD, sotalol has also been shown to significantly reduce arrhythmia recurrence and discharge from the ICD (Pacifico et al., 1999).

Because sotalol is eliminated primarily by the kidneys, the initial dosing regimen must be based on the patient's CrCl. The practitioner should routinely monitor the patient's renal function throughout therapy to determine if any dosing adjustments are necessary. Sotalol should not be used to treat AF if the patient's CrCl is less than 40 mL/min. The practitioner should also routinely monitor electrolytes, especially if the patient is concomitantly receiving diuretics, since hypokalemia and hypomagnesemia can increase the risk of TdP. Because of concern about TdP when initiating therapy with sotalol, patients must be hospitalized and placed on telemetry for at least 3 days.

Most of the adverse effects associated with sotalol can be attributed to its β-blocking activity (e.g., bradycardia, fatigue, dyspnea). The β-blocking effect of sotalol may decrease cardiac contractility; therefore, this drug should be avoided in patients with HFrEF.

Dofetilide

Dofetilide acts as a selective potassium channel blocker, affecting the rapid component of the delayed rectifier potassium current. This results in a prolonged action potential and QT interval. Dofetilide affects the atria more than the ventricles. It also exhibits reverse-use dependence.

Dofetilide is approved for the conversion of AF or AFl to SR and for the maintenance of SR in patients with permanent AF or AFl. In a study comparing the efficacy and safety of dofetilide with those of placebo, patients randomized to dofetilide were more likely to convert to SR with ascending doses (Singh et al., 2000). At 1 year, slightly more than 50% of patients in the group taking 500 mcg of dofetilide remained in SR. Like amiodarone, dofetilide also has been proven to be safe to use in patients with underlying HFrEF (Køber et al., 2000; Torp-Pedersen et al., 1999).

As with other AADs, the main concern with dofetilide is the dose-dependent onset of TdP and other ventricular arrhythmias. Other adverse effects associated with dofetilide include headache and dizziness.

Dofetilide has a number of important drug interactions. The concomitant use of cimetidine, dolutegravir, ketoconazole, hydrochlorothiazide, megestrol, prochlorperazine, trimethoprim–sulfamethoxazole, or verapamil with dofetilide is contraindicated since these drugs can significantly increase plasma concentrations of dofetilide. Additionally, drugs that prolong the QT interval should not be used concomitantly with dofetilide because of the increased risk of a prolonged QT interval and TdP.

Because dofetilide is eliminated primarily by the kidneys, the initial dosage must be based on the patient's CrCl. The dosage of dofetilide should be decreased in patients with renal impairment (CrCl of less than 60 mL/min). The drug should not be given to patients with a CrCl of less than 20 mL/min or a QT interval greater than 440 msec at baseline. Because of concern about TdP when initiating therapy with dofetilide, patients must be hospitalized and placed on telemetry for at least 3 days.

Ibutilide

Ibutilide is structurally related to L-sotalol, but it has no β-blocking activity. It prolongs the action potential by increasing the slow inward sodium current and blocking the rapid component of the delayed rectifier potassium current, which prolongs atrial and ventricular refractoriness. Ibutilide is available only in IV form. It is indicated only for the acute termination of AF or AFl.

Ibutilide restores SR in approximately 50% of patients with AF or AFl. However, it is more effective for restoring SR in patients with AFl than in those with AF (Stambler et al., 1996). Ibutilide also appears to be effective for facilitating direct-current cardioversion (DCC) of AF (Oral et al., 1999). The major adverse effect associated with ibutilide is TdP. Patients with HFrEF or electrolyte abnormalities (e.g., hypokalemia or hypomagnesemia) are especially at risk for developing proarrhythmia with ibutilide.

Class IV AADs

The class IV AADs, verapamil and diltiazem, are nondihydropyridine CCBs used to treat supraventricular arrhythmias, including PSVT, AF, and AFl. By inhibiting the inward movement of calcium through calcium channels located in cell membranes, these drugs slow conduction, prolong refractoriness, and decrease automaticity in the SA and AV nodes. In AF or AFl, these drugs slow conduction through the AV node and thereby slow the ventricular rate. Their cardiac effects are vascular relaxation, a negative inotropic effect, and a negative chronotropic effect. Verapamil has more potent negative inotropic effects than diltiazem.

Because of their potent negative inotropic effects, both verapamil and diltiazem should be avoided in patients with HFrEF because they are likely to precipitate worsening HF symptoms. These drugs also should not be used in patients with an accessory pathway or WPW syndrome because they can shorten the refractory period of the accessory pathway and subsequently increase the ventricular rate, which may lead to VF.

Bradycardia, heart block, headache, flushing, dizziness, and peripheral edema are the most common adverse effects of diltiazem and verapamil. Verapamil can also cause constipation. The practitioner should use caution when using IV verapamil because significant hypotension can occur (Phillips et al., 1997).

The practitioner should be cautious when administering these agents concomitantly with β-blockers, digoxin, or clonidine because of the increased risk of bradycardia and heart block. Since diltiazem and verapamil are substrates and inhibitors of the CYP3A4 isoenzyme, the practitioner should also use caution when concomitantly administering either of these drugs with other agents that are also metabolized by this isoenzyme.

Other AADs

Several other AADs are commonly used to treat abnormal cardiac impulse formation or conduction. Digoxin, adenosine, and atropine are used in the treatment of various cardiac arrhythmias (see Table 23.1).

Digoxin

Digoxin's predominant antiarrhythmic effect is on the AV node of the conduction system. Digoxin affects the autonomic nervous system by stimulating the parasympathetic division, which increases vagal tone. This vagal effect slows conduction through the AV node and prolongs the AV nodal refractory period.

Digoxin is commonly used to slow electrical impulse conduction through the AV node, thus slowing the ventricular rate in supraventricular arrhythmias such as AF or AFl. Digoxin is not effective for converting AF or AFl to SR. Although digoxin is frequently used to control the ventricular rate in patients with HFrEF and concomitant AF or AFl, its use tends to be limited by its relatively slow onset of action and its inability to control the ventricular rate during exercise. Even after an appropriate loading dose is administered, digoxin's peak onset of effect is delayed for up to 6 to 8 hours. Achievement of steady-state concentrations may take up to a week in patients with normal renal function, or even longer in patients with renal impairment. The increased sympathetic tone generated during exercise tends to offset the vagal effects of digoxin, which limits its efficacy under these conditions. In patients with HFrEF and concomitant AF or AFl, digoxin can provide effective ventricular rate control without increasing the risk of worsening HF symptoms because of its additional positive inotropic effects.

Digoxin toxicity can be precipitated by declining renal function, electrolyte disturbances, and drug interactions. Because digoxin is primarily excreted unchanged by the kidneys, a decline in the CrCl can predispose a patient to digoxin toxicity. Hypokalemia, hypomagnesemia, and hypercalcemia can also predispose the myocardium to the toxic effects of digoxin. Concomitant drug therapy with agents such as amiodarone, dronedarone, or verapamil can also increase serum digoxin concentrations. Potential signs and symptoms of digoxin toxicity include heart block, ventricular arrhythmias, visual disturbances (e.g., blurred vision, yellow/green halos), dizziness, weakness, nausea, vomiting, diarrhea, and anorexia. Digoxin has a narrow therapeutic index. The therapeutic range for digoxin in patients with AF and normal LV systolic function (LVEF >40%) is 0.8 to 2 ng/mL. Because of the potential risk of increased mortality with higher serum concentrations, the therapeutic range for digoxin in patients with AF and concomitant HFrEF (LVEF of 40% or less) is 0.5 to 0.9 ng/mL.

Adenosine

Adenosine is an AAD used for converting PSVT to SR. It activates potassium channels and,

by increasing the outward potassium current, hyperpolarizes the membrane potential, decreasing spontaneous SA nodal depolarization. Adenosine may also decrease the inward calcium current by blocking adenylate cyclase, which normally increases the inward calcium current. Automaticity (phase 4) and conduction (phase 0) are inhibited in the SA and AV nodes. The most common adverse effects of adenosine include chest discomfort, dyspnea, flushing, and headache. Sinus arrest can also occur. However, because of adenosine's short half-life of 10 seconds, these adverse effects are short-lived. Adenosine is administered IV because of its short half-life.

Atropine

Atropine is a parasympatholytic drug that enhances both sinus nodal automaticity and AV nodal conduction through direct vagolytic action. Atropine blocks acetylcholine at parasympathetic neuroeffector sites. Atropine is used almost exclusively in the monitored clinical setting for the treatment of symptomatic bradycardia.

Patients who do not experience signs or symptoms of hemodynamic compromise, ischemia, or frequent ventricular ectopy do not require atropine in bradycardic events. Atropine has been reported to be harmful in some patients with AV block at the His–Purkinje level (type II AV block and third-degree AV block with a new wide QRS complex). Atropine can be used in these situations, but the practitioner must monitor the patient closely for paradoxical slowing of the heart rate.

Atropine may induce tachycardia, which may result in poor outcomes in patients with myocardial ischemia or an MI. Therefore, atropine should be used cautiously in these patients.

Selecting the Most Appropriate Agent

Determining the cause and type of the arrhythmia is essential to selecting the most appropriate drug therapy. Figures 23.1 to 23.5, as well as Table 23.1, guide the practitioner in the initial assessment of which drug to use for patients with various types of arrhythmias.

The first main question to ask when selecting drug therapy is whether the slow or fast rate of the arrhythmia makes the patient ill or symptomatic. A symptomatic patient is one with an arrhythmia characterized by low blood pressure, shock, chest pain, shortness of breath, decreased level of consciousness, pulmonary congestion, HF, or acute MI. These patients may require more urgent treatment, perhaps even with nonpharmacological interventions (e.g., DCC, defibrillation) to immediately terminate the arrhythmia. The practitioner should not make clinical decisions based only on the rhythm displayed on the monitor. The practitioner needs to assess the patient's symptoms to determine how urgent the situation is and how quickly treatment needs to be initiated. Treatment of various arrhythmias is discussed in the first-line and second-line therapy sections. Table 23.2 consolidates the various treatment regimens.

TABLE 23.2 Recommended Order of Treatment for Arrhythmias

Order	Agents	Comments
AF/AFl		
First line	Hemodynamically unstable patient: synchronized DCC. Start with 100 J and proceed to 200, 300, and 360 J if not successful in the preceding cardioversions. Hemodynamically stable patient with rapid ventricular rate: • LVEF > 40%: IV diltiazem, IV verapamil, or IV β-blocker • LVEF ≤ 40%: IV β-blocker or IV digoxin	Start with 50 J in patients with AFl. Premedicate whenever possible when performing DCC. IV amiodarone can be used for ventricular rate control in any patient with AF/AFl who is refractory to or has contraindications to β-blockers, diltiazem, or verapamil; avoid using for ventricular rate control if the AF/AFl has been present >48 h as these patients may be at risk for thromboembolic events induced by conversion to SR.
Second line	Patients with 1st episode of arrhythmia (if likely to convert to and remain in SR): Electrical or pharmacological cardioversion can be considered once ventricular rate acutely controlled. For pharmacological cardioversion, the AAD used depends on the presence of SHD. Decision of whether to proceed acutely with cardioversion depends on the duration of the arrhythmia: • <48 h: May proceed with cardioversion without prolonged period of anticoagulation. If patient at high risk of stroke, IV unfractionated heparin, a low molecular weight heparin (subcutaneously at treatment doses), apixaban, dabigatran, edoxaban, or rivaroxaban should be initiated as soon as possible either before or after cardioversion. Anticoagulate with warfarin (INR target range 2.0–3.0), apixaban, dabigatran, edoxaban, or rivaroxaban for ≥4 wk following successful cardioversion in these high-risk patients. While these anticoagulants can also be initiated immediately before or after cardioversion in patients at low risk for stroke, it is also reasonable to not initiate antithrombotic therapy in these patients. Decisions regarding long-term antithrombotic therapy after this time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR. • >48 h or unknown duration: Anticoagulate with warfarin (INR target range 2.0–3.0), apixaban, dabigatran, edoxaban, or rivaroxaban for ≥3 weeks before proceeding with cardioversion. Anticoagulate with warfarin (INR target range 2.0–3.0), apixaban, dabigatran, edoxaban, or rivaroxaban for ≥4 wk following successful cardioversion. Decisions regarding long-term antithrombotic therapy after this time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR. For patients with persistent or recurrent AF, a strategy of ventricular rate control and anticoagulation is a reasonable alternative to rhythm control. Selection of PO drug for ventricular rate control (diltiazem, verapamil, β-blocker, or digoxin) depends on patient's LV function. Antithrombotic therapy should be based on the patient's CHA_2DS_2-VASc risk score.	A TEE can be performed in patients with AF >48 h or unknown duration to exclude the presence of thrombi and to facilitate cardioversion. IV unfractionated heparin or subcutaneous low molecular weight heparin (at treatment doses) should be started at the time the TEE will be performed. If a thrombus is detected, cardioversion should not be performed and the patient should be anticoagulated indefinitely. If no thrombus is detected, cardioversion can be performed within 24 h without the need for the initial 3-wk period of anticoagulation. These patients will still require anticoagulation after cardioversion for ≥4 wk. Decisions regarding long-term antithrombotic therapy after this time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR. For AADs to be used for acute pharmacologic cardioversion, see **Figure 22.2.** Goal heart rate is based on patient's LV systolic function: • LVEF > 40% and no or acceptable symptoms of AF: <110 beats/min (at rest) • LVEF ≤ 40%: <80 beats/min (at rest) PO agents for ventricular rate control: • LVEF > 40%: diltiazem, verapamil, or β-blocker • LVEF ≤ 40%: β-blocker (i.e., carvedilol, metoprolol succinate, or bisoprolol) or digoxin
Order	**Agents**	**Comments**
Third line	Chronic AAD therapy can be considered for patients who remain symptomatic despite having adequate ventricular rate control or for those in whom adequate ventricular rate control cannot be achieved. The AAD used depends on patient's LV function and the type of SHD that may be present. For patients with permanent AF, a strategy of ventricular rate control and anticoagulation should be considered. Selection of PO drug for ventricular rate control (diltiazem, verapamil, β-blocker, or digoxin) depends on patient's LV function. Antithrombotic therapy should be based on the patient's CHA_2DS_2-VASc risk score. Radiofrequency catheter ablation may be considered in patients with symptomatic episodes of recurrent AF who fail or do not tolerate at least one class I or class III AAD.	PO AADs for chronic rhythm control: • No SHD: dofetilide, dronedarone, flecainide, propafenone, or sotalol; amiodarone is considered alternative if patient fails or does not tolerate one of the initial AADs • LVEF ≤ 40%: amiodarone or dofetilide • CAD: dofetilide, dronedarone, or sotalol; amiodarone is considered alternative if patient fails or does not tolerate one of the initial AADs • Significant LV hypertrophy: amiodarone Avoid flecainide and propafenone in patients with *any* form of SHD.
PSVT (due to AVNRT)		
First line	Hemodynamically unstable patient: synchronized DCC (50–100 J, biphasic). Hemodynamically stable patient: vagal maneuvers	Premedicate whenever possible when performing DCC. Examples of vagal maneuvers include unilateral carotid sinus massage, Valsalva maneuver, facial immersion in ice water, and coughing. Carotid sinus massage should be avoided in patients with carotid bruits or history of cerebrovascular disease.
Second line	IV adenosine If persistent PSVT, use IV diltiazem, IV verapamil, or IV β-blocker; if PSVT remains persistent, can use IV procainamide (if LVEF > 40%) or IV amiodarone (for normal or depressed LVEF)	
Third line	If patient continues to have frequent episodes of PSVT or infrequent episodes accompanied by severe symptoms, refer for possible radiofrequency catheter ablation. If patient is not a candidate for or refuses radiofrequency catheter ablation, PO diltiazem, verapamil, β-blocker, or digoxin can be used for chronic therapy.	If PSVT is infrequent and/or accompanied by only mild symptoms, no chronic therapy is needed.
Nonsustained VT		
First line	No SHD: • Asymptomatic or minimal symptoms: No drug therapy • Symptomatic: PO β-blocker Post-MI patients: • LVEF > 40%: PO β-blocker regardless of the presence of symptoms • LVEF ≤ 40%: EP testing; if sustained VT/VF, ICD should be placed; if sustained VT/VF noninducible, PO β-blocker or amiodarone may be used.	Correct reversible causes. Post-MI patients with normal LV systolic function should receive a β-blocker even if they have no or minimal symptoms associated with the nonsustained VT to ↓ mortality associated with the MI. If frequent shocks occur in patients with an ICD, PO amiodarone and β-blocker combination therapy or sotalol monotherapy can be used.
Sustained VT		
First line	Hemodynamically unstable patient: synchronized DCC (100 J, biphasic). Hemodynamically stable patient: IV procainamide, IV amiodarone, or IV sotalol	Premedicate whenever possible when performing DCC. Correct reversible causes.
Second line	Hemodynamically stable patient: IV lidocaine; synchronized DCC should be considered if AAD therapy fails. Once arrhythmia acutely terminated, patient should be considered for ICD placement. If patient refuses or is not a candidate for an ICD, PO amiodarone can be considered.	If frequent shocks occur in patients with an ICD, PO amiodarone and β-blocker combination therapy or sotalol monotherapy can be used.
Order	**Agents**	**Comments**
Pulseless VT/VF		
First line	Start CPR, establish an airway, and deliver one shock (biphasic defibrillator: 120–200 J); immediately resume CPR for 2 min, then check rhythm.	Correct reversible causes.
Second line	If patient remains in pulseless VT/VF, deliver one shock and then immediately resume CPR; if pulseless VT/VF persists after at least one shock and CPR, give vasopressor therapy (epinephrine 1 mg IV push/IO every 3–5 min through pulseless VT/VF episode) (give drug during CPR; do not interrupt CPR to give drug); immediately resume CPR for 2 min, then check pulse.	
Third line	If patient remains in pulseless VT/VF, deliver one shock and then immediately resume CPR; if pulseless VT/VF persists despite defibrillation, CPR, and vasopressor therapy, consider AAD therapy (IV amiodarone; lidocaine may be used as alternative) (give drugs during CPR; do not interrupt CPR to give drugs); immediately resume CPR for 2 min; then check pulse.	
Bradycardia		
First line	Stable: Close observation Signs/symptoms of poor perfusion (e.g., altered mental status, chest pain, hypotension, shock): Immediately administer IV atropine (0.5 mg every 3–5 min, up to 3 mg total dose). If ineffective, transcutaneous pacing or sympathomimetic continuous infusion (dopamine or epinephrine) should be initiated.	Correct reversible causes.
Second line	If drug therapy and transcutaneous pacing are ineffective, transvenous pacing should be utilized.	

AAD, antiarrhythmic drug; AF, atrial fibrillation; AFl, atrial flutter; AVNRT, atrioventricular nodal reentrant tachycardia; CAD, coronary artery disease; CPR, cardiopulmonary resuscitation; DCC, direct-current cardioversion; ICD, implantable cardioverter–defibrillator; INR, international normalized ratio; IV, intravenous; J, joules; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; PO, oral; PSVT, paroxysmal supraventricular tachycardia; SHD, structural heart disease; SR, sinus rhythm; TEE, transesophageal echocardiogram; VF, ventricular fibrillation; VT, ventricular tachycardia.

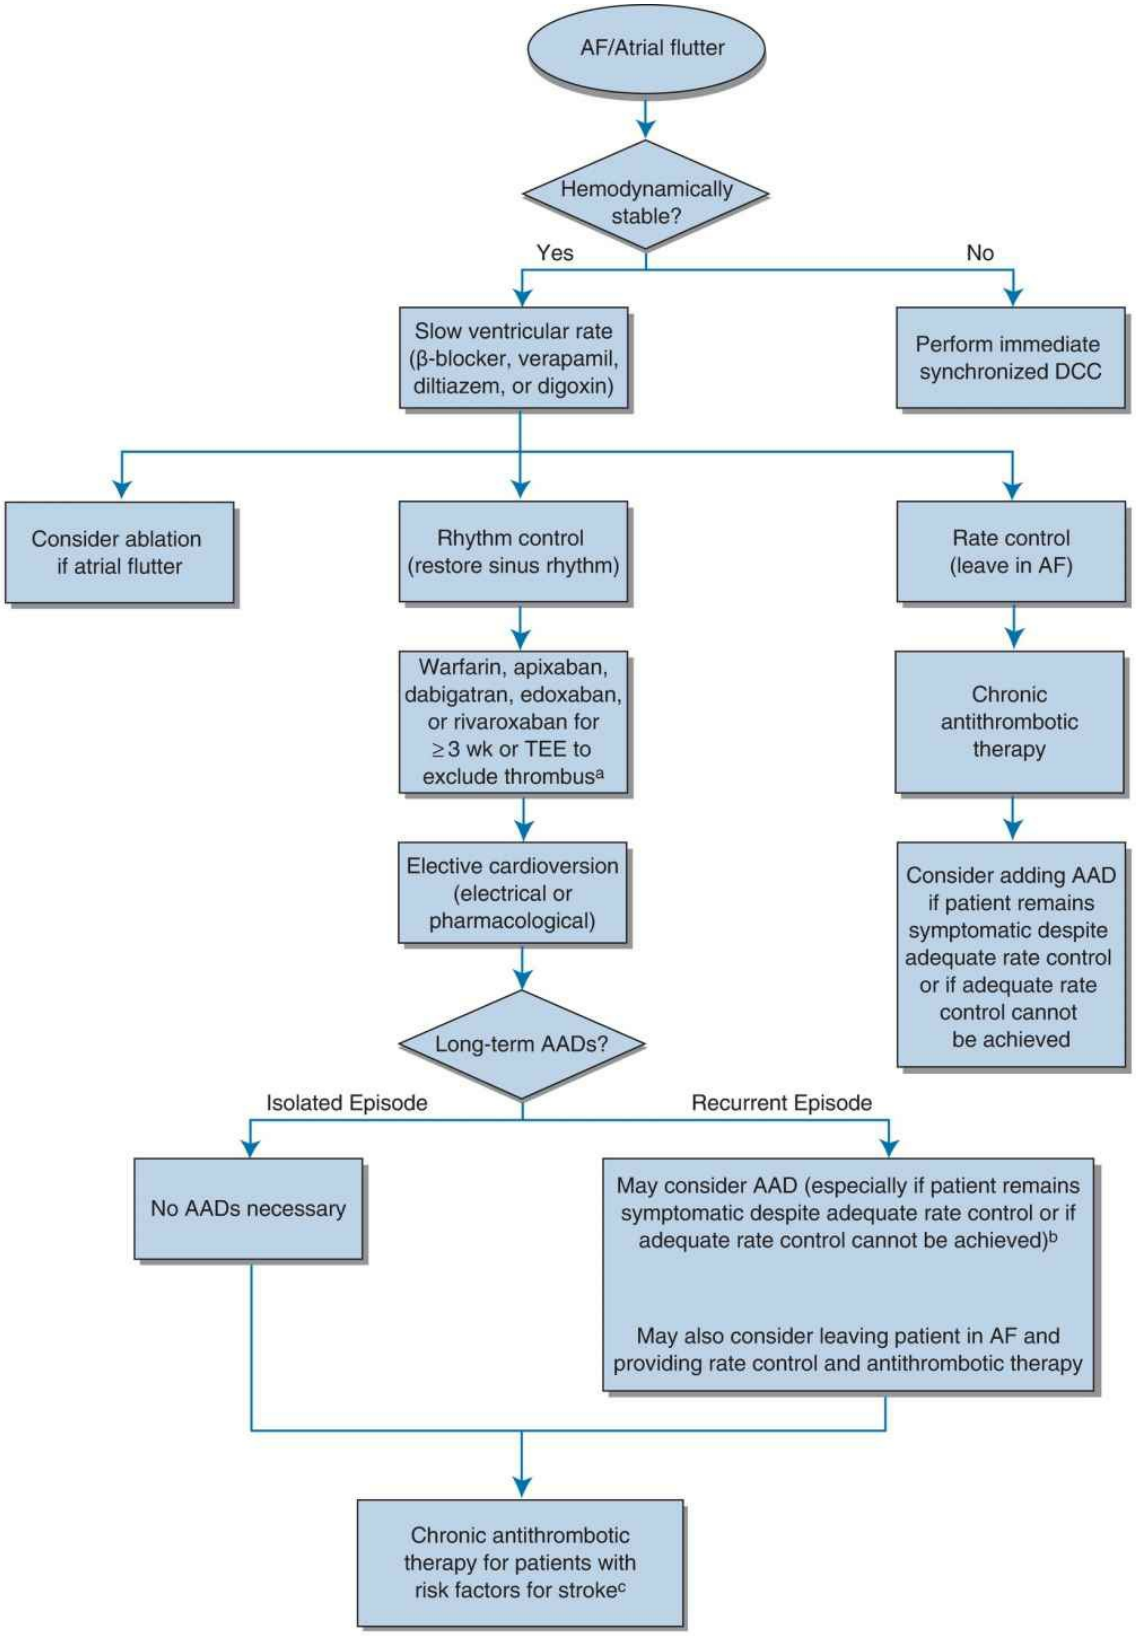
Second, the practitioner must think of treatable conditions that might be causing the arrhythmia. The patient's medical history and laboratory values are important to assess whenever patients present with arrhythmias. Some possible causes of arrhythmias are electrolyte imbalances (i.e., hypokalemia, hypomagnesemia), drug overdose/toxicity, drug interactions, renal failure, hyperthyroidism, metabolic acidosis, hypovolemia, MI, pulmonary embolism, cardiac tamponade, tension pneumothorax, dissecting aortic aneurysm, and hypoxia related to pulmonary disorders, or structural defects in the heart itself. The practitioner may have to correct the cause of the arrhythmia before initiating drug therapy, especially if the patient is asymptomatic. However, time may be a critical factor when treating symptomatic arrhythmias.

Initial vagal maneuvers may serve as both diagnostic and therapeutic purposes for certain arrhythmias. For example, carotid sinus massage may make the flutter waves in AFl more apparent. Appearance of flutter waves allows the practitioner to differentiate AFl from AF, PSVT, or other tachycardias. Examples of vagal maneuvers include unilateral carotid sinus massage, breath holding, facial immersion in ice water, coughing, nasogastric tube placement, gag reflex stimulation by tongue blade or fingers, eyeball massage, squatting, digital sweep of the anus, and bearing down as during a bowel movement. Many patients who have recurrent PSVT with disorders such as mitral valve prolapse often learn how to do these maneuvers to terminate the arrhythmia themselves. It is important to note that eyeball massage should never be taught, encouraged, or performed because it may cause retinal detachment. Unilateral carotid sinus massage (firm massage of the carotid sinus that never lasts for more than 5 to 10 seconds) should be performed only with continuous ECG monitoring and an IV line in place. The procedure should be avoided in older adult patients and should not be performed on patients with carotid bruits because it may occlude already impaired circulation to the brain. Likewise, the practitioner should avoid ice water facial immersion in patients with CAD because of the potential for inducing ischemia.

AF/AFl

AF and AFl may be stable or unstable. Patients presenting with severe hypotension, syncope, HF, or angina would be considered to be hemodynamically unstable and would require more urgent treatment. When the patient is hemodynamically stable, the practitioner should consider conditions that may be causing the AF or AFl. Such conditions include acute MI, hypoxia, pulmonary embolism, electrolyte imbalance (i.e., hypokalemia, hypomagnesemia), drug toxicity (especially digoxin or sympathomimetic agents), thyrotoxicosis, and alcohol intoxication. Since new-onset AF can be due to acute MI, the practitioner should look for ischemic changes on the 12-lead ECG. If acute ischemic changes appear, admission of the patient to the hospital in a monitored bed may be needed. Obviously, treatment and correction of acute causes of AF or AFl should be a priority.

If untreated, AF and AFl can lead to serious hemodynamic and thromboembolic consequences. A rapid ventricular rate can induce angina in patients with underlying CAD or worsening signs and symptoms of HF in patients with HFrEF. A persistently rapid ventricular rate may lead to the development of a tachycardia-induced cardiomyopathy. Loss of synchronized atrial contraction can lead to a significant reduction in cardiac output, which can especially affect patients with underlying HF. In addition, loss of coordinated atrial contraction can lead to the pooling of blood and subsequent thrombus formation. Therefore, AF and AFl can lead to serious thromboembolic complications, particularly ischemic stroke. Overall, the treatment goals for AF and AFl are controlling the ventricular rate, preventing thromboembolic events, and possibly restoring and maintaining SR. Figure 23.1 illustrates an algorithm for the management of AF and AFl.



AAD, antiarrhythmic drug; AF, atrial fibrillation; DCC, direct current cardioversion; TEE, transesophageal echocardiogram

[a] If AF <48 h, 3 wk of anticoagulation prior to cardioversion is unnecessary in patients at high risk for stroke; initiate unfractionated heparin, a low-molecular weight heparin, apixaban, dabigatran, edoxaban, or rivaroxaban as soon as possible either before or after cardioversion.

[b] Radiofrequency ablation may be considered for patients who fail or do not tolerate ≥1 AAD.

[c] Chronic antithrombotic therapy should be considered in all patients with AF and risk factors for stroke regardless of whether they remain in sinus rhythm.

FIGURE 23.1 Treatment algorithm for AF and AFl.

First-Line Therapy

If the patient presenting with AF or AFl is hemodynamically unstable (i.e., severe hypotension, syncope, HF, or angina), immediate DCC is first-line therapy. If the patient is hemodynamically stable and has a rapid ventricular rate, the first priority is to control the ventricular rate. In the acute treatment of AF, the selection of a drug to control the ventricular rate depends on the patient's LV systolic function (January et al., 2014). In patients with normal LV systolic function (LVEF > 40%), IV diltiazem, IV verapamil, or an IV β-blocker is preferred over digoxin because of their relatively quick onset. β-Blockers are especially useful in high adrenergic states (i.e., postoperative patients, hyperthyroidism). The use of digoxin is limited by its relatively slow onset of action and its inability to control heart rate in high adrenergic states (i.e., exercise). In patients with HFrEF (LVEF of 40% or less), an IV β-blocker or IV digoxin is preferred, since these agents also are used to treat HFrEF. Diltiazem or verapamil should be avoided in these patients because their potent negative inotropic effects may precipitate worsening HF symptoms. β-Blockers should be avoided in patients who are exhibiting signs and/or symptoms of decompensated HF. In those patients who are having worsening HF symptoms, IV digoxin or IV amiodarone is recommended as first-line therapy for controlling the ventricular rate. IV amiodarone can also be used for ventricular rate control in any patient with AF who is refractory to or has contraindications to β-blockers, diltiazem, or verapamil. Since amiodarone is a class III AAD, the practitioner should be aware that the patient may convert to SR when using this agent. Patients with AF that has persisted for longer than 48 hours are at risk for thromboembolic events if conversion to SR occurs in the absence of therapeutic anticoagulation. Therefore, in these patients who have not been therapeutically anticoagulated, IV amiodarone should be avoided.

Second-Line Therapy

Once the ventricular rate is acutely controlled, patients should be evaluated for the possibility of restoring SR if AF persists. The results of six landmark clinical trials (Pharmacological Intervention in Atrial Fibrillation [PIAF], Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation [RACE], Atrial Fibrillation Follow-up Investigation of Rhythm Management [AFFIRM], Strategies of Treatment of Atrial Fibrillation [STAF], How to Treat Chronic Atrial Fibrillation [HOT-CAFE], and Atrial Fibrillation and Congestive Heart Failure [AF-CHF]) have provided practitioners with significant insight into the comparative efficacy of rate control (controlling ventricular rate; patient remains in AF) and rhythm control (restoring and maintaining SR) treatment strategies in patients with AF (Carlsson et al., 2004; Hohnloser et al., 2000; Opolski et al., 2004; Roy et al., 2008; Van Gelder et al., 2002; Wyse et al., 2002). The results of all of these trials essentially demonstrated that there were no significant differences in outcomes

between patients who received a rate-control strategy and those who received a rhythm-control strategy. Therefore, based on these findings, a rate-control strategy appears to be a viable alternative to a rhythm-control strategy in patients with persistent or recurrent AF. Consequently, considering the potential toxicities of AADs, it is reasonable to initially consider a rate-control strategy in these patients, including those with concomitant HF. However, a rhythm-control strategy should be considered for those patients who remain symptomatic despite having adequate ventricular rate control or for those in whom adequate ventricular rate control cannot be achieved. The results of the above clinical trials do not necessarily apply to patients experiencing their first episode of AF. If these particular patients are likely to convert to and remain in SR, a rhythm-control strategy may be considered.

If the decision is made to restore SR in hemodynamically stable patients with AF, either electrical (i.e., DCC) or pharmacological (i.e., AADs) cardioversion may be used. The decision to use either of these methods is often based on the practitioner's or patient's preference. DCC is associated with higher success rates than pharmacological cardioversion. However, this method requires sedation or anesthesia and may be rarely associated with complications such as sinus arrest or ventricular arrhythmias. Pharmacological cardioversion is associated with adverse effects (e.g., TdP) and drug interactions.

In those patients in whom it is decided to restore SR, it is important to note that the process of cardioverting the patient from AF to SR may place the patient at risk for a thromboembolic event. Restoration to SR may dislodge thrombi in the atria. This risk is present regardless of whether an electrical or pharmacological method is used to restore SR. In patients undergoing DCC or pharmacological cardioversion, it is imperative to determine how long the patient has been in AF because the risk of thrombus formation increases if the AF duration exceeds 48 hours. If AF has been present for more than 48 hours or for an unknown duration, cardioversion should not be performed acutely because of the risk of thromboembolism. These patients should be therapeutically anticoagulated with warfarin (INR target range 2.0 to 3.0) or one of the target-specific oral anticoagulants (e.g., apixaban, dabigatran, edoxaban, or rivaroxaban) for at least 3 weeks (January et al., 2014). After that time, the patient can undergo DCC or pharmacological cardioversion, which should be followed by therapeutic anticoagulation with warfarin (INR target range 2.0 to 3.0), apixaban, dabigatran, edoxaban, or rivaroxaban for at least 4 weeks. If the 3 weeks of oral anticoagulant therapy prior to cardioversion is not feasible, the patient may alternatively undergo a transesophageal echocardiogram (TEE) prior to cardioversion to look for any thrombi that may be present in the atria or ventricles. If no thrombus is observed on TEE, the patient can undergo cardioversion. In these patients, anticoagulant therapy with either IV unfractionated heparin (target activated partial thromboplastin time 60 seconds; acceptable range 50 to 70 seconds) or low molecular weight heparin (subcutaneously at treatment doses) should be initiated at the time the TEE will be performed (You et al., 2012). Cardioversion should then be performed within 24 hours of the TEE. Alternatively, warfarin therapy (INR target range of 2.0 to 3.0) may be used for at

least 5 days prior to the TEE and cardioversion. If cardioversion is successful, therapeutic warfarin (INR target range 2.0 to 3.0), apixaban, dabigatran, edoxaban, or rivaroxaban should be continued for at least 4 weeks regardless of the patient's baseline risk of stroke (January et al., 2014). Decisions regarding long-term antithrombotic therapy after this 4-week time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR. If a thrombus is seen on TEE, cardioversion should not be performed, and the patient should be anticoagulated indefinitely. If cardioversion is considered in these patients at a later time, a TEE should again be performed.

When the duration of AF is definitively known to be less than 48 hours, a prolonged period of anticoagulation is not necessary prior to proceeding with electrical or pharmacological cardioversion because the risk of thromboembolism is deemed to be low. In those patients who are at high risk for stroke, IV unfractionated heparin (target activated partial thromboplastin time 60 seconds; acceptable range 50 to 70 seconds), a low molecular weight heparin (subcutaneously at treatment doses), apixaban, dabigatran, edoxaban, or rivaroxaban should be initiated as soon as possible either before or after cardioversion (January et al., 2014). If cardioversion is successful in these high-risk patients, therapeutic anticoagulation with warfarin (INR target range 2.0 to 3.0), apixaban, dabigatran, edoxaban, or rivaroxaban should be continued for at least 4 weeks. While the above anticoagulants can also be initiated immediately before or after cardioversion in patients at low risk for stroke, it is also reasonable to not initiate antithrombotic therapy in these patients. Decisions regarding long-term antithrombotic therapy after this 4-week time period should be primarily based on the patient's risk for stroke and not on whether he/she is in SR.

If the practitioner decides to proceed with pharmacological cardioversion as the initial therapy, the selection of drug is primarily based on the presence of SHD (i.e., CAD, HF, LV hypertrophy). Pharmacological cardioversion is most effective when initiated within 7 days of the onset of AF. The AADs with proven efficacy during this time frame include dofetilide, flecainide, ibutilide, propafenone, or amiodarone (oral or IV). The class Ia AADs, disopyramide, procainamide, and quinidine, have limited efficacy or have been incompletely studied for this purpose. Sotalol is not effective for converting AF to SR. Although the use of single, oral loading doses of propafenone or flecainide is effective in restoring SR, these drugs should only be used in patients without underlying SHD. Ibutilide may also be considered in patients without underlying SHD. When utilizing the approach of administering single, oral loading doses of flecainide or propafenone for AF conversion for the first time, patients must be hospitalized to monitor for the development of proarrhythmic adverse effects. If no adverse arrhythmic events occur during this hospitalization, then patients will be educated to self-administer an oral loading dose of flecainide or propafenone at the onset of AF symptoms (e.g., palpitations) in the future. A patient's ventricular rate should be adequately controlled with AV nodal-blocking drugs prior to administering a class Ic (or class Ia) AAD for cardioversion since these AADs can precipitate an increased ventricular response as a result of their vagolytic effects. In patients

with SHD, propafenone, flecainide, and ibutilide should be avoided because of the increased risk of proarrhythmia. Instead, amiodarone or dofetilide should be primarily used in this patient population (January et al., 2014).

If the practitioner does not wish to proceed with cardioversion, an initial management strategy of ventricular rate control and anticoagulation is also reasonable. As previously stated, this strategy, whereby the patient is left in AF, has been shown to be an acceptable alternative to rhythm control for the chronic management of AF. The selection of an oral drug for chronic ventricular rate control is primarily based on the patient's LV systolic function. In patients with normal LV systolic function (LVEF > 40%), an oral β-blocker, diltiazem, or verapamil is preferred over digoxin (January et al., 2014). Digoxin can be added if adequate ventricular rate control cannot be achieved with one of these drugs. In patients with HFrEF (LVEF of 40% or less), an oral β-blocker, or digoxin is preferred because these drugs can also concomitantly be used to treat chronic HF. The nondihydropyridine CCBs should be avoided in patients with HFrEF because of their potent negative inotropic effects. In patients with AF and stable HF symptoms (NYHA class II or III), the β-blockers, carvedilol, metoprolol succinate, or bisoprolol should be used as first-line therapy because of their documented survival benefits in patients with HFrEF. Other β-blockers should be avoided in these patients because their effects on survival in HF are unknown. Digoxin should be used as first-line therapy in patients with AF and decompensated HFrEF (NYHA class IV) because β-blocker therapy may exacerbate HF symptoms. Oral amiodarone may also be considered if adequate ventricular rate control cannot be achieved with or the patient has contraindications to β-blockers or nondihydropyridine CCBs (January et al., 2014). In patients with persistent AF who have no or acceptable symptoms and stable LV systolic function (LVEF greater than 40%), the goal heart rate should be less than 110 beats/min at rest (January et al. 2014; Van Gelder et al., 2010). In patients with LVSD (LVEF of 40% or less), a stricter heart rate goal (less than 80 beats/min) should be considered to minimize the potential harmful effects of a rapid heart rate response on ventricular function.

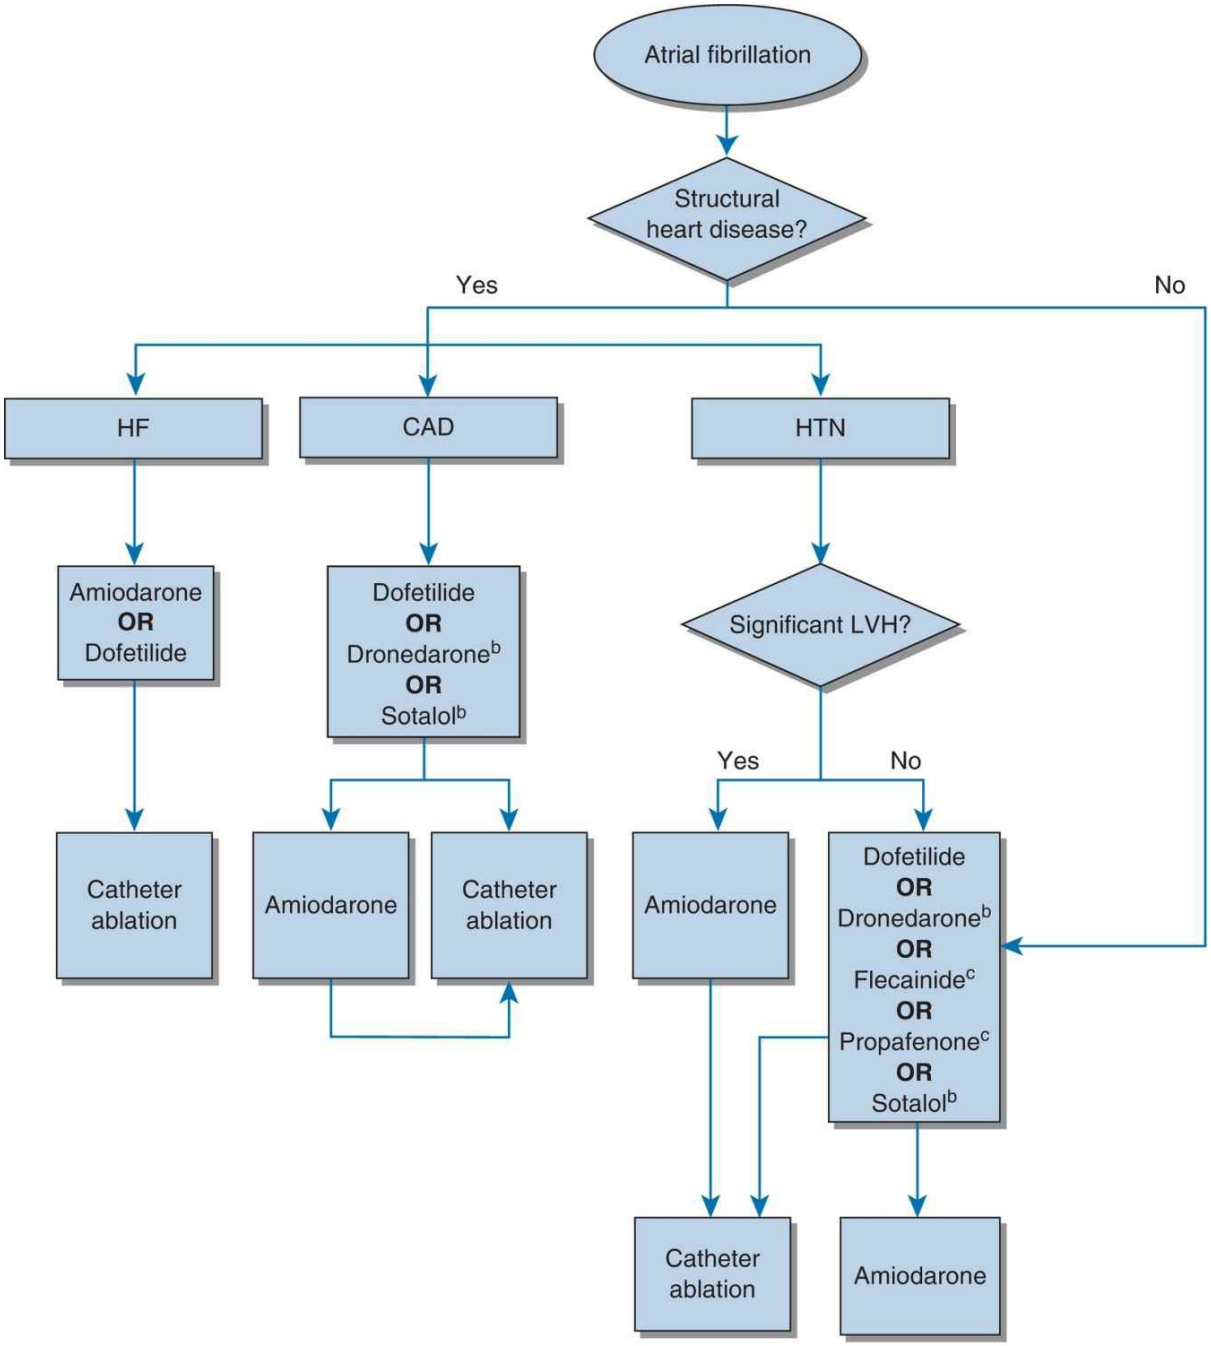
Assessing the patient's risk of stroke becomes important for selecting the most appropriate antithrombotic regimen. The most recent guidelines for the treatment of AF have recommended the CHA_2DS_2-VASc scoring system for stroke risk stratification in patients with AF (January et al., 2014). With this risk index, patients with AF are given 2 points each if they have a history of a previous stroke, transient ischemic attack, or thromboembolism or if they are at least 75 years old. Patients are given one point each for being at least 65 to 74 years old, having hypertension, having diabetes, having congestive HF, having vascular disease (e.g., MI, peripheral arterial disease, or aortic plaque), or being female. (CHA_2DS_2-VASc is an acronym for each of these risk factors.) The points are added up, and the total score is then used to determine the most appropriate antithrombotic therapy for the patient. Patients with a CHA_2DS_2-VASc score of 2 or higher are considered to be at high risk for stroke. In these patients, oral anticoagulant therapy with warfarin (target INR, 2.5; range, 2.0 to 3.0), apixaban, dabigatran, edoxaban,

or rivaroxaban is preferred over aspirin. Patients with a CHA_2DS_2-VASc score of 1 are considered to be at intermediate risk for stroke. In these patients, oral anticoagulant therapy (warfarin [target INR: 2.5; range: 2.0 to 3.0], apixaban, dabigatran, edoxaban, or rivaroxaban), aspirin 75 to 325 mg/d, or no antithrombotic therapy can be selected. Patients with a CHA_2DS_2-VASc score of 0 are considered to be at low risk for stroke. The guidelines state that it is reasonable to not give any antithrombotic therapy to patients who are considered to be at low risk for stroke. Please refer to Chapter 50 for a further discussion of anticoagulation in AF.

The need for antithrombotic therapy should be assessed in all patients with AF regardless of whether a rate-control or rhythm-control strategy is initiated. In addition, if patients are considered candidates for antithrombotic therapy, this regimen should be continued if SR is restored because of the potential for patients to have episodes of recurrent AF.

Third-Line Therapy

For those patients who remain symptomatic despite having adequate ventricular rate control or for those patients in whom adequate ventricular rate control cannot be achieved, it is reasonable to consider AAD therapy to maintain SR once they have been converted to SR. The selection of an AAD to maintain SR is primarily based on the presence of SHD (January et al., 2014) (see Figure 23.2). In patients without SHD, dofetilide, dronedarone, flecainide, propafenone, or sotalol should be considered initially, since these AADs have the best long-term safety profile. Amiodarone can be used as alternative therapy if the patient fails or does not tolerate one of these initial AADs. In patients with any type of SHD, the class Ic AADs, flecainide and propafenone, should be avoided. In these patients, the selection of AAD therapy is based upon the type of SHD present. In patients with LVSD (LVEF of 40% or less), either oral amiodarone or dofetilide can be used. Both dronedarone and sotalol should be avoided in patients with LVSD because of the risk of increased mortality (dronedarone) or worsening HF (sotalol). In patients with CAD, dofetilide, dronedarone, or sotalol can be used as initial therapy. In these patients, sotalol and dronedarone should only be used if their LV systolic function is normal. Amiodarone can be considered as an alternative therapy in these patients if these AADs are not tolerated. In patients with significant LV hypertrophy, amiodarone is the drug of choice. Patients with symptomatic episodes of recurrent AF who fail or do not tolerate at least one class I or III AAD may also be considered for radiofrequency catheter ablation (January et al., 2014).



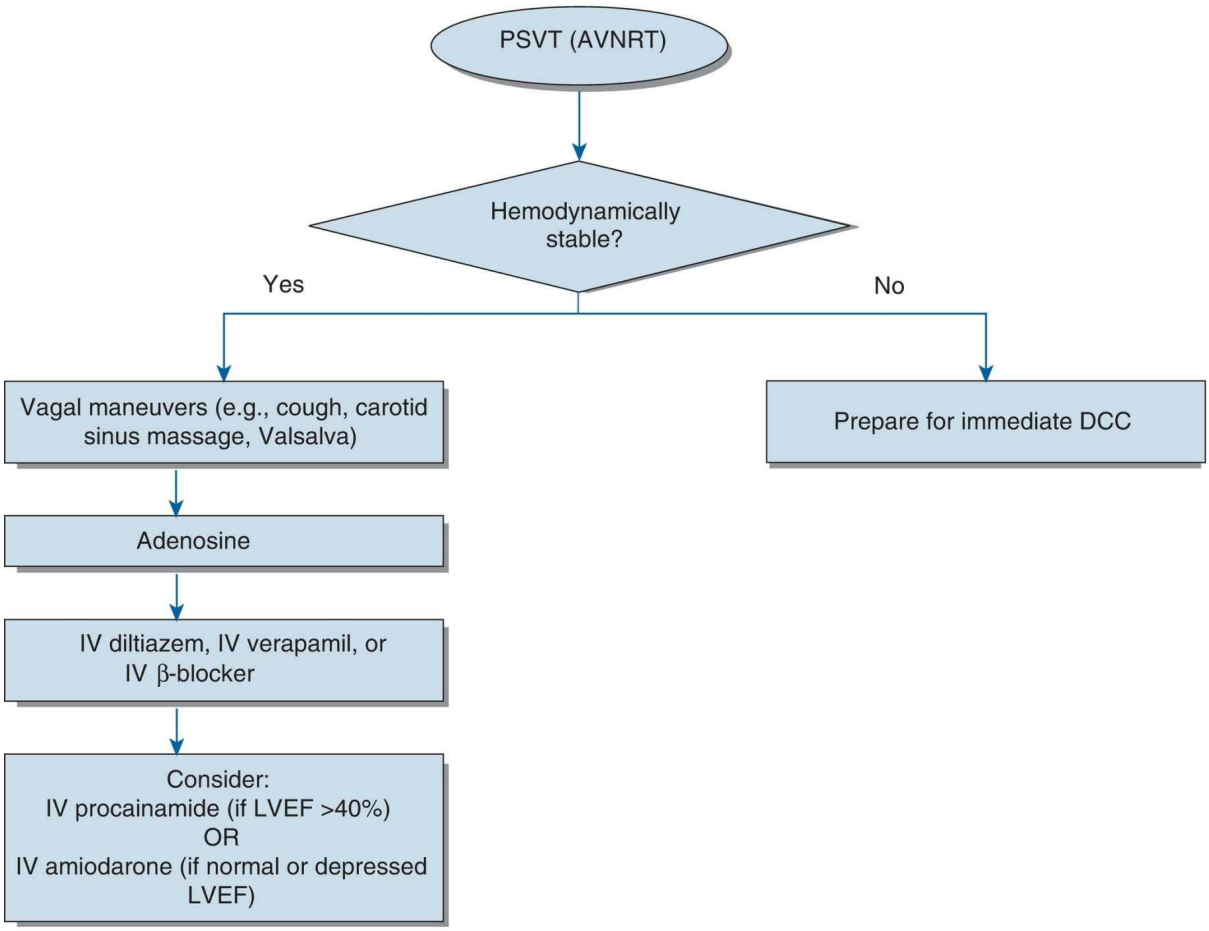
[a] Within each of the boxes, the drugs are listed alphabetically and not in order of suggested use. However, the sequence of the boxes does imply the order of suggested use.
[b] Should only be used if patient has normal left ventricular systolic function.
[c] Should only be used if patient has no other form of structural heart disease.
CAD, coronary artery disease; HF, heart failure; HTN, hypertension; LVH, left ventricular hypertrophy.

FIGURE 23.2 Treatment algorithm for selecting AAD therapy for maintenance of SR in patients with recurrent paroxysmal or persistent AFa. (Adapted from January, C. T., Wann, L. S., Alpert, J. S., et al. (2014). 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *Circulation*, 130, e199–e267.)

PSVT (Due to AV Nodal Reentrant Tachycardia)

First-Line Therapy

Hemodynamically unstable PSVT requires first-line therapy of synchronized DCC to restore SR and correct hemodynamic compromise. Unless contraindicated, patients with mild to moderate symptoms can be initially managed with vagal maneuvers (e.g., unilateral carotid sinus massage, Valsalva maneuver, facial immersion in ice water, and coughing). Figure 23.3 illustrates an algorithm for the management of PSVT due to AV nodal reentrant tachycardia.



AVNRT, atrioventricular nodal reentrant tachycardia; DCC, direct current cardiversion; IV, intravenous; LVEF, left ventricular ejection fraction; PSVT, paroxysmal supraventricular tachycardia.

FIGURE 23.3 Treatment algorithm for PSVT (due to atrioventricular nodal reentrant tachycardia). (Adapted from Neumar, R. W., Otto, C. W., Link, M. S., et al. (2010). Part 8: Adult advanced cardiovascular support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*, 122 (Suppl. 3), S729–S767.)

Second-Line Therapy

If vagal maneuvers are unsuccessful or if PSVT recurs after successful vagal maneuvers, second-line therapy is AADs. The drug of choice for PSVT is adenosine (Neumar et al., 2010). Clinical studies have shown that adenosine is as effective as IV verapamil in initial conversion of PSVT. Adenosine does not produce hypotension to the degree that verapamil does, and it has a shorter half-life. If a total of 30 mg of adenosine does not successfully terminate PSVT, further doses of this agent are unlikely to be effective. Therefore, in patients with persistent PSVT, other AADs will need to be used. In these patients, IV diltiazem, verapamil, or a β-blocker can be used. If PSVT continues despite these treatment measures, the use of IV procainamide (LVEF > 40%) or amiodarone (normal or depressed

LVEF) can also be considered.

Third-Line Therapy

Third-line therapy focuses on the management of chronic PSVT. Chronic preventive therapy is usually necessary if the patient has either frequent episodes of PSVT that require therapeutic intervention or infrequent episodes of PSVT that are accompanied by severe symptoms. Radiofrequency catheter ablation is considered first-line therapy for most of these patients because of its effectiveness in preventing recurrence of PSVT and its relatively low complication rate. Drug therapy with oral diltiazem, verapamil, β-blockers, or digoxin can also be considered if the patient is not a candidate for or refuses to undergo radiofrequency catheter ablation.

Nonsustained VT

VT that spontaneously terminates within 30 seconds is known as nonsustained VT. Given the poor survival of patients who experience cardiac arrest, it is essential to identify the most effective treatment strategies to prevent the initial episode of sustained VT or sudden cardiac death from occurring.

The presence of nonsustained VT in patients without SHD is not associated with an increased risk of sudden cardiac death. Therefore, drug therapy is not necessary in these patients if they are asymptomatic. However, if these patients do become symptomatic, treatment options include a β-blocker, nondihydropyridine CCB, class Ic AAD, or catheter ablation (depending on the underlying etiology) (Pedersen et al., 2014). Post-MI patients (especially those with LVSD) who develop nonsustained VT are at increased risk for sudden cardiac death. For these patients, the selection of therapy is based on the patient's LV systolic function. In patients who experience nonsustained VT due to prior MI, and have an LVEF greater than 40%, drug therapy is not necessary to treat the arrhythmia if they are asymptomatic. However, these patients should still chronically receive a β-blocker specifically to reduce mortality associated with the MI. β-Blockers are also effective if these patients develop significant symptoms associated with the nonsustained VT. In patients who experience nonsustained VT due to prior MI, and have an LVEF of 40% or less, electrophysiologic testing is often performed when asymptomatic nonsustained VT occurs (Pedersen et al., 2014). If sustained VT or VF is induced, an ICD is then recommended (Epstein et al., 2013). If sustained VT or VF is not induced, a β-blocker or amiodarone can be initiated.

Sustained VT

VT that persists for at least 30 seconds or that requires electrical or pharmacological termination because of hemodynamic instability is known as sustained VT. Since sustained VT can degenerate into VF, the treatment goals are to terminate the VT acutely and then prevent recurrence of the arrhythmia.

First-Line Therapy

If the patient is hemodynamically unstable (i.e., severe hypotension, syncope, HF, or angina), immediate synchronized DCC is first-line therapy. If the patient is hemodynamically stable, IV amiodarone, IV procainamide, or IV sotalol can be considered (Neumar et al., 2010). Lidocaine can be used as alternative therapy. Synchronized DCC should be considered if AAD therapy fails.

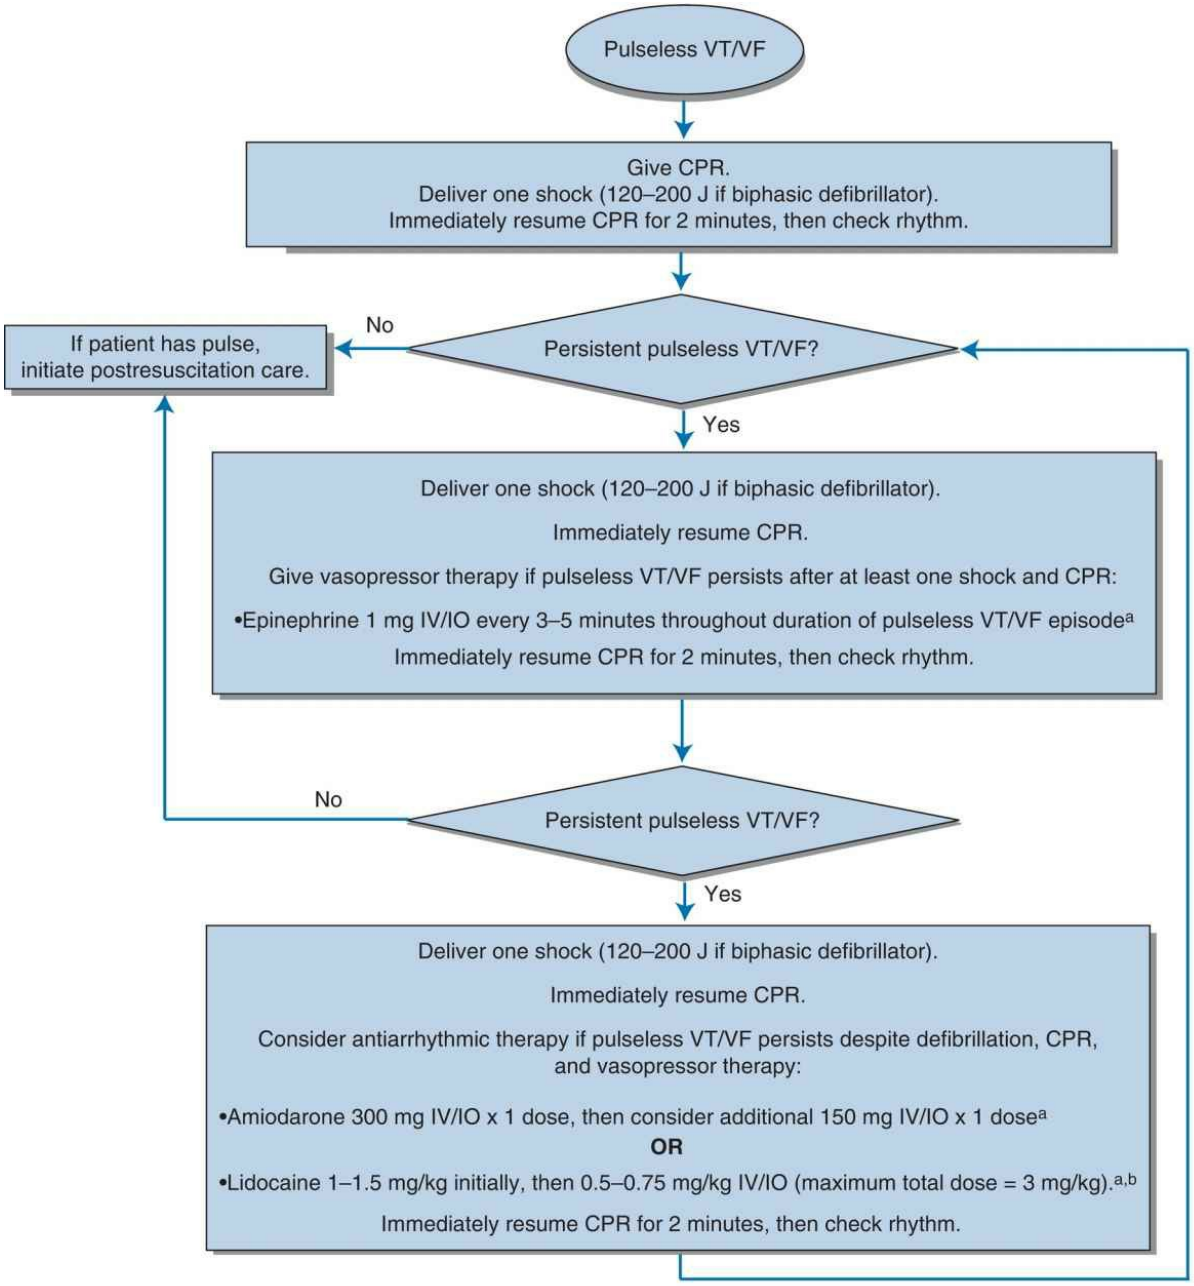
Second-Line Therapy

Once the acute episode is terminated, measures should be taken to prevent recurrent episodes of VT. Based on the results of several trials, ICDs are clearly indicated as first-line therapy in patients with a history of sustained VT or VF (Epstein et al., 2013). If the patient with an ICD experiences frequent discharges because of recurrent ventricular arrhythmias or new-onset supraventricular arrhythmias (e.g., AF), either amiodarone and a β-blocker or sotalol monotherapy can be used. For the patient who refuses or is not a candidate for an ICD, oral amiodarone should be used as an alternative therapy.

Pulseless VT/VF

The majority of cases of sudden cardiac death can be attributed to VF. Sustained VT usually precedes VF and most commonly occurs in patients with CAD. VF is usually not preceded by any symptoms and always results in a loss of consciousness and eventually death if not treated. Immediate treatment is essential in patients who develop VF or pulseless VT, since survival is reduced by 10% for every minute that the patient remains in the arrhythmia. It is imperative to identify and correct any potential reversible causes for the arrhythmia.

For administration of drug therapy during an episode of pulseless VT/VF, while IV access is preferred, the guidelines recommend the intraosseous (IO) route as an alternative if IV access cannot be established (Neumar et al., 2010). IO access can be used not only for administration of drugs and fluids but also for obtaining blood for laboratory monitoring. If neither IV nor IO access can be established, the endotracheal route can then be used for the administration of only certain agents (i.e., atropine, lidocaine, epinephrine, and vasopressin). Figure 23.4 illustrates an algorithm for the management of pulseless VT/VF.



[a] If IV or IO access cannot be established, epinephrine, and lidocaine may be administered by the endotracheal route. Because of the potential risk of pulmonary toxicity, IV amiodarone should not be administered down an endotracheal tube.

[b] Lidocaine can be used as alternative to IV amiodarone.

CPR = cardiopulmonary resuscitation; IO = intraosseous; IV = intravenous; J = joules; VF = ventricular fibrillation; VT = ventricular tachycardia;

FIGURE 23.4 Treatment algorithm for pulseless VT/VF. (Adapted from Link, M. S., Berkow, L. C., & Kudenchuk, P. J., et al. (2010). Part 7: Adult advanced cardiovascular life support: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*, 132 (Suppl. 2), S444–S464.)

First-Line Therapy

In patients with pulseless VT/VF, high-quality cardiopulmonary resuscitation (CPR) should be immediately initiated until a defibrillator or automated external defibrillator (AED) arrives (Kleinman et al., 2015). High-quality CPR is composed of the following components: minimizing interruptions in chest compressions (i.e., providing chest compressions for at least 80% of the time that the patient is in cardiac arrest), delivering 100 to 120 chest compressions per minute, delivering chest compressions at a depth of at least 2 inches (but avoiding a depth of greater than 2.4 inches), minimizing leaning over the patient's chest (leaning can result in a reduction in venous return and cardiac output), and providing a ventilation rate of 10 breaths per minute. Each cycle of CPR involves delivering 30 chest compressions followed by two breaths. If a defibrillator or AED is not readily available, hands-only CPR (compressions only; no ventilations) should be provided if the bystander possesses no CPR training or is trained but lacks confidence in providing effective CPR with rescue breaths. If the bystander possesses CPR training and is confident in their ability to provide effective CPR with rescue breaths, conventional cycles of CPR (30 chest compressions followed by two breaths) should be delivered until a defibrillator or AED becomes available. Once an advanced airway (e.g., endotracheal tube) is placed, chest compressions should be delivered continuously at a rate of 100 to 120 compressions per minute without pausing for ventilation (should be provided by a separate individual at a rate of one breath every 6 seconds). Once a defibrillator or AED arrives, defibrillation should be administered immediately.

With regard to defibrillation, delivery of only one shock at a time is recommended in patients with pulseless VT/VF to minimize interruptions in chest compressions (Link et al., 2015). For biphasic defibrillators, the dose of the shock is device specific (usually 120 to 200 J); the maximum dose available can be used for the initial shock if the effective dose range of the defibrillator is unknown. This dose or a higher dose can then be used for any subsequent shocks that may be needed. After delivery of the initial shock in patients with pulseless VT/VF, CPR should be immediately resumed and continued for 2 minutes, after which the patient's pulse and rhythm should be checked. Delaying pulse and rhythm checks until after this period of CPR is administered is intended to minimize interruptions in chest compressions and increase the potential for success with defibrillation. If pulseless VT/VF persists, another shock should be delivered at the appropriate dose, followed by 2 minutes of CPR. This general sequence of resuscitation and defibrillation should be followed for as long as the patient remains in pulseless VT/VF.

Second-Line Therapy

If pulseless VT/VF persists after delivery of at least one shock and CPR, vasopressor therapy with epinephrine should be initiated (Link et al., 2015). Although vasopressin had previously been recommended in the 2010 guidelines as an alternative vasopressor to epinephrine, this drug is no longer recommended in the pulseless VT/VF treatment

algorithm in the recently updated guidelines. The recommended dosage of epinephrine for pulseless VT/VF is 1 mg given IV push/IO every 3 to 5 minutes throughout the duration of the pulseless VT/VF episode.

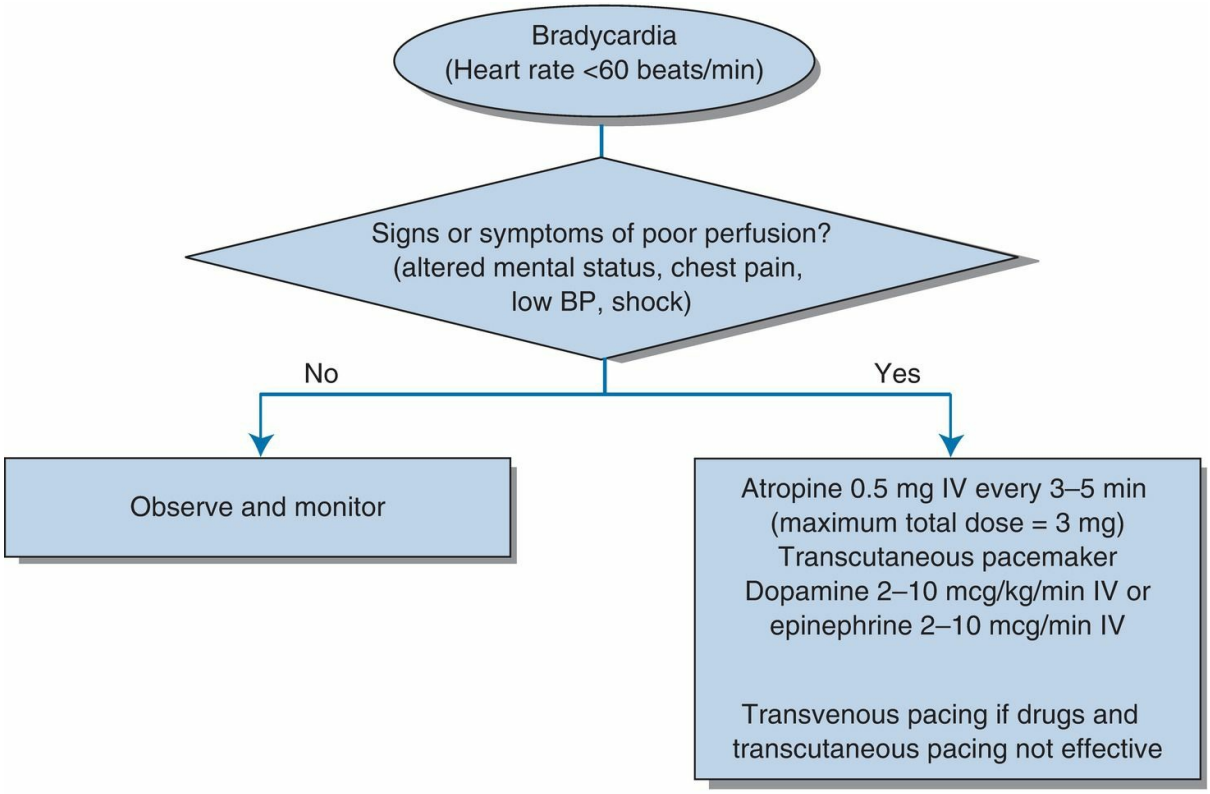
Third-Line Therapy

If pulseless VT/VF persists despite the use of defibrillation, CPR, and vasopressor therapy, AAD therapy can be considered. IV amiodarone is recommended as first-line AAD therapy for the treatment of pulseless VT/VF (Link et al., 2015). This agent has been shown to be safe and effective in the management of both in-hospital and out-of-hospital pulseless VT/VF (Dorian et al., 2002; Kudenchuck et al., 1999). Compared to lidocaine, IV amiodarone has been associated with a significantly higher rate of survival to hospital admission in patients with out-of-hospital cardiac arrest due to VF (Dorian et al., 2002). Lidocaine may be considered as an alternative to IV amiodarone for pulseless VT/VF that persists despite the use of defibrillation, CPR, and vasopressor therapy (Link et al., 2015). IV procainamide is no longer recommended for pulseless VT/VF. The routine use of IV magnesium sulfate in patients with pulseless VT/VF is not recommended.

If the patient is resuscitated from the pulseless VT/VF episode, measures should be taken to prevent recurrent episodes of cardiac arrest. Based on the results of several trials, ICDs are clearly indicated as first-line therapy in patients with a history of sustained VT or VF (Epstein et al., 2013). If patients with an ICD experience frequent discharges because of recurrent ventricular arrhythmias or new-onset supraventricular arrhythmias (e.g., AF), either amiodarone and a β-blocker or sotalol monotherapy can be used. For patients who refuse or are not candidates for an ICD, oral amiodarone should be used as an alternative therapy.

Bradycardia

If patients with bradycardia present with signs and symptoms of adequate perfusion, only close observation is required. If patients with bradycardia develop signs or symptoms of poor perfusion (e.g., altered mental status, chest pain, hypotension, shock), IV atropine (0.5 mg every 3 to 5 minutes, up to 3 mg total dose) should be immediately administered (Neumar et al., 2010). If atropine is not effective, either transcutaneous pacing or a continuous infusion of a sympathomimetic agent, such as dopamine (2 to 10 mcg/kg/min) or epinephrine (2 to 10 mcg/min) (i.e., dopamine or epinephrine), should be initiated. If symptomatic bradycardia persists despite any of these measures, transvenous pacing should be utilized. Figure 23.5 illustrates an algorithm for the management of bradycardia.



BP, blood pressure; IV, intravenous

FIGURE 23.5 Treatment algorithm for bradycardia. (Adapted from Neumar, R. W., Otto, C. W., Link, M. S., et al. (2010). Part 8: Adult advanced cardiovascular support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*, 122 (Suppl. 3), S729–S767.

Special Population Considerations

Pediatric

The epidemiology of arrhythmias is different between adults and children. Adults have arrhythmias primarily of a cardiac origin, whereas children have arrhythmias primarily of a respiratory origin.

Tachyarrhythmias occasionally compromise infants and young children. PSVT is the most common arrhythmia in young children. It typically occurs during infancy or in children with congenital heart disease. PSVT with ventricular rates exceeding 180 to 220 beats/min can produce signs of shock. If signs of shock appear, synchronized cardioversion or administration of adenosine can be done in an emergency. Common causes of PSVT in young children and infants are congenital heart disease (preoperative) such as Ebstein's anomaly, transposition of the great arteries, or a single ventricle. Postoperative PSVT also can occur after atrial surgery for correction of congenital defects of the heart. Other common causes of PSVT in children are drugs such as sympathomimetics (cold medications, theophylline, β-agonists). WPW syndrome and hyperthyroidism also can cause PSVT. Common causes of AF and AFl in children are intra-atrial surgery, Ebstein's anomaly, heart disease with dilated atria (aortic valve regurgitation), cardiomyopathy, WPW syndrome, sick sinus syndrome, and myocarditis.

Bradycardia is a common arrhythmia in seriously ill infants or children. It is usually associated with a reduction in cardiac output and is an ominous sign, suggesting that cardiac arrest is imminent. The first-line therapy for this arrhythmia in infants and young children is administration of oxygen, support respiration, epinephrine, and, possibly, atropine.

Pulseless VT and VF are treated much the same way as in adults (de Caen et al., 2015). The recommended dose of epinephrine for a child with pulseless VT/VF is 0.01 mg/kg IV/IO, administered as 0.1 mL/kg of a 1:10,000 concentration every 3 to 5 minutes throughout the duration of the pulseless VT/VF episode. If IV/IO access cannot be established, epinephrine can be administered endotracheally (0.1 mg/kg administered as 0.1 mL/kg of a 1:1,000 concentration).

Geriatric

With aging, body fat increases, lean body tissue decreases, and hepatic and renal system changes set the stage for potential overdosage and toxicity, particularly in the case of AADs. Similarly, declining organ function affects the amount and dosage of the drug prescribed as well as the occurrence of adverse effects. Cardiac disease and chronic conditions such as HF exacerbate the decline in organ function. Together, these factors can increase the risk of an adverse effect from the AADs the practitioner prescribes.

For example, digoxin toxicity is relatively common in older adult patients who are not

receiving a reduced dosage to accommodate for the reduced renal function. It is imperative for the practitioner to assess the patient's baseline renal and hepatic function to determine whether certain AADs are safe to use and the most appropriate dosage to use in this patient.

Signs and symptoms of adverse effects of many drugs are confusion, weakness, and lethargy. These signs and symptoms are often attributed to senility or disease. Therefore, it is important for the practitioner to take a thorough drug history and to document accurately the dosages and frequencies prescribed in the patient record. If the practitioner merely attributes confusion to old age, the patient may continue to receive the drug while actually experiencing drug toxicity. Furthermore, the practitioner may add another drug to treat the complications caused by the original AAD, compounding the issue of polypharmacy and excessive medication.

AADs sometimes require accurate and timely dosing. If an older adult patient forgets to take a dose or cannot remember when he or she took the last dose, undermedication or overmedication may occur. This can be dangerous when AADs are prescribed. Many older adults have multiple prescriptions, even for the same medication, and therefore take an overdose of the drug. Consequently, it is essential to review medications with older adult patients and make sure they understand and can follow a safe drug therapy regimen.

Monitoring Patient Response

The goals of AAD therapy are to restore SR and prevent recurrences of the original arrhythmia or development of new arrhythmias. Evaluating the outcomes of AAD therapy requires the practitioner to schedule regular follow-up visits after initial treatment of the arrhythmia. The outcomes to be closely monitored include impulse generation and conduction from the SA node to the AV node, time interval for conduction, heart rate within a normal range that is age specific, and patterns of AV and ventricular conduction.

Data to be monitored to evaluate therapeutic outcomes vary from the simple to complex. The patient may monitor some of them and needs to be taught the signs and symptoms to look for and the expectations from the therapeutic regimen. Patients with arrhythmias may be monitored on a regular or periodic basis with 12-lead ECGs, 24-hour Holter monitors, blood pressure, heart rate, echocardiograms, electrolytes, and serum drug levels (when applicable).

In addition, the patient needs to self-monitor for symptoms such as lightheadedness, dizziness, syncopal episodes, palpitations, chest pain, shortness of breath, or weight gain. Other clinical outcomes to be monitored are those that affect quality of life, such as activity tolerance, organ perfusion, cognitive function, fear, anxiety, and depression.

Patient Education

Drug Information

Included in the therapeutic plan for arrhythmias is patient education. Learning outcomes can be evaluated by monitoring compliance with the medication regimen, recurrences of arrhythmia, adverse effects, weight gain, blood pressure, heart rate, and emergency department visits or hospitalizations.

AADs have narrow therapeutic windows. Toxicity is common at normal dosages. Consequently, patient education is essential for providing maximal benefits and avoiding adverse effects and accidental overdosing or underdosing.

The patient, family, and significant others should be taught the basics, such as the name of the drug (both the generic and trade name), the dose, the frequency and timing of the dose, and the reason the drug is needed. This may avoid duplicate prescribing and administration of AADs. The patient should communicate, either verbally or in writing, the names and dosages of these drugs to all other health care providers and should wear a medical identification device listing all medications. In addition, the patient should inform his or her health care provider when any new prescription, over-the-counter, or complementary or alternative medications are started so that potential drug interactions can be minimized or avoided.

The practitioner should provide written instructions for the medication regimen. Providing instructions in large print and simple language may be helpful to patients who have difficulty with memory, hearing, or vision. Instructions should include what to do when the patient misses a dose of medication, has an adverse response to the medication, or wants to stop taking the drug. If β-blockers are prescribed, the patient should be warned that abrupt discontinuation may result in rebound angina, an increased heart rate, and hypertension. The symptoms associated with these adverse effects also should be identified.

The practitioner can also teach the patient or caregiver how to take blood pressure and pulse readings, how to interpret the readings, and how to recognize and respond to signs and symptoms of hypotension, dizziness, chest pain, shortness of breath, peripheral edema, or palpitations. The patient should take his or her weight each day and call the practitioner if weight gain of over 2 lb occurs. If the patient has difficulty learning these monitoring techniques or cannot perform them, he or she may need to schedule regular follow-up appointments for monitoring. Patients with AF or AFl should know the signs and symptoms of a stroke.

In today's health care environment, the insurance plan's pharmacy provider sometimes makes substitutions with generics or less expensive brands of medications. To prevent harmful drug effects, the patient needs to be aware of this practice and should be cautioned not to change brands of the prescribed AAD or anticoagulant without the approval of the

practitioner.

An important teaching point from an ethical and legal perspective is to warn the patient to avoid hazardous activities such as driving, using electrical tools, climbing ladders, or any activity that would put the patient or others in harm's way until the effects of the drug are demonstrated. Patients with an ICD should refrain from driving for at least 6 months after the last arrhythmic event (for devices implanted for secondary prevention) or for at least 7 days following implantation of the ICD (for devices implanted for primary prevention). Documentation of patient teaching on risks, benefits, lifestyle modification, and safety issues with AAD treatment should always be entered in the patient's medical record.

Nutrition

Clear instructions should be given to avoid alcohol, excessive salt intake, and caffeine during treatment for arrhythmias. Many AADs may cause periods of hypotension resulting in dizziness, or the dose of the drug may need to be regulated, especially in the initial weeks.

Complementary and Alternative Medications

The practitioner must emphasize to the patient the importance of reporting the use of any of these agents so that interactions with AAD therapy can be minimized or avoided. While the information regarding potential interactions between AADs and specific complementary and alternative medications is relatively sparse, there are a few notable interactions of which practitioners should be aware. Patients taking AADs should avoid licorice root. Licorice has mineralocorticoid effects, which can promote hypokalemia. In patients taking digoxin, the presence of hypokalemia may predispose the patient to digoxin toxicity. In patients taking other AADs, the presence of hypokalemia may promote the development of atrial or ventricular arrhythmias. In addition, certain licorice preparations have been shown to cause a prolonged QT interval, which may increase the risk for TdP in patients receiving class III AADs. The use of Siberian ginseng or oleander should also be avoided in patients receiving digoxin, as digoxin toxicity may result. The use of St. John's wort may decrease digoxin concentrations; therefore, digoxin concentrations should be closely monitored when concomitant therapy is used. St. John's wort may also decrease plasma concentrations of amiodarone and dronedarone, which may predispose the patient to arrhythmia recurrence. Consequently, the use of St. John's wort in patients receiving amiodarone or dronedarone should be avoided. Patients with a history of atrial or ventricular arrhythmias should also be instructed to avoid the use of any medication containing ephedra (e.g., Ma Huang) because it can promote the development of arrhythmias.

Case Study*

H.T. is a 66-year-old man with HFrEF (NYHA class III) who presents to the emergency department with shortness of breath and palpitations. An ECG reveals AF with a heart rate of 130 beats/min. He states that these symptoms have been occurring for the past 5 days. H.T. has a past medical history of diabetes (A1C 12.2%) and chronic kidney disease requiring hemodialysis. His current medications include insulin glargine 40 units subcut every evening, insulin lispro 12 units subcut before meals, metoprolol succinate 100 mg PO daily, and lisinopril 5 mg PO daily. His vitals are BP 145/95 mm Hg and HR 130 beats/min.

Diagnosis:Atrial Fibrillation

1. Which of the following would be the most appropriate treatment to acutely manage this patient's symptoms?
   A. Metoprolol IV
   B. Diltiazem IV
   C. Digoxin IV

D. Amiodarone IV

2. What additional therapy, if any, should be recommended for this patient to prevent thromboembolic complications?
   A. No antithrombotic therapy is necessary because his CHA_2DS_2-VASc score is 0.
   B. Dabigatran because his CHA_2DS_2-VASc score is 1.
   C. Apixaban because his CHA_2DS_2-VASc score is 2.
   D. Warfarin because his CHA_2DS_2-VASc score is 3.

UNIT 5
Pharmacotherapy for Respiratory Disorders

24 Upper Respiratory Infections

Karleen Melodyn ■ Anisha B. Grover

Upper respiratory tract infections (URIs), including the common cold and rhinosinusitis, are some of the most common problems seen in primary care. URIs are usually self-limiting, minor illnesses that account for half or more of all acute illnesses. It is difficult to differentiate the common cold from rhinosinusitis or allergic rhinitis (see Chapter 48). URIs commonly involve rhinitis, which refers to irritation and inflammation of the intranasal mucous membrane and is characterized by nasal congestion, nasal discharge, sneezing, and postnasal drip. Other common URI symptoms include tenderness over the sinuses, fever, headache, malaise, sore throat, myalgias, a full feeling around the eyes and ears, and coughing. Symptoms may present individually or in combination, and it can be difficult to determine whether the cause is viral or bacterial.

URIs can progress to involve acute or chronic complications. In children especially, URIs may progress to otitis media. In a small percentage of cases, the viral or bacterial cause may travel, causing rhinosinusitis and bronchitis. Acute respiratory infections have been projected to kill approximately 3.9 million people annually and represent a leading cause of mortality in children living in developing countries who are less than 5 years of age (Liu et al., 2012). There also is an enormous economic burden associated with URIs.

Common Cold

Acute infectious rhinitis, also known as the common cold, nasopharyngitis, rhinopharyngitis, or acute coryza, is caused by one of more than 200 viral types and most commonly involves rhinovirus. It is one of the most common infections and is usually minor and self-limiting. Coryza is an acute inflammation of the mucous membranes of the respiratory passages, particularly of the nose, sinuses, and throat, and is characterized by sneezing, rhinorrhea (watery nasal discharge), and coughing.

In 2012, the U.S. Attitudes of Consumers Toward Health, Cough, and Cold (ACHOO) survey was developed to collect information regarding participant demographics, basic knowledge of cough and cold symptoms, treatment choices, and treatment preferences (Blaiss et al., 2015). Of the 2,505 survey participants, 84.6% had experienced at least one cold in the past year and lasted approximately 1 to 7 days. Cough was the most common cold symptom, affecting 73.1% of participants, and this symptom, along with nasal congestion, was reported as the most bothersome symptom. A subsequent publication examined the data from this study in order to assess the impact of cough and cold on daily activity, productivity, and absenteeism (Dicpinigaitis et al., 2015). Fifty-two percent of participants described the impact on daily life as a "fair amount" to "a lot" for the duration of the illness (Dicpinigaitis et al., 2015). During the time of a cold, participants reported a decrease in productivity by a mean of 26.4%. Almost half of respondents reported absenteeism from work or school lasting 1 to 2 days (Dicpinigaitis et al., 2015). A survey published in 2002 reported an approximate $2 billion spent in the United States annually on over-the-counter (OTC) preparations to relieve cold symptoms, predominantly in children (West, 2002). Another survey published in 2003 estimated that noninfluenza viral respiratory infections result in an annual $40 billion in costs. This includes costs related to cold-related absenteeism, including 70 million missed workdays, 186 million missed school days, and 126 million missed workdays among caregivers of children suffering from colds (Fendrick et al., 2003).

Causes

The pathogen most frequently associated with common colds is human rhinovirus (HRV), a single-stranded ribonucleic acid accounting for one half to two thirds of common colds (Jacobs et al., 2013). The coronavirus, respiratory syncytial virus, influenza virus, human parainfluenza virus, human metapneumovirus, and adenovirus can also contribute to cold-like symptoms, but HRVs are the single most pervasive cause of colds and in some cases can increase the susceptibility to bacterial infection within the upper and lower airway epithelial cells (Jacobs et al., 2013).

Predisposition to viral infections can be attributed to many factors, including frequent exposure to viral infectious agents; in children, the age of the child; and the inability to resist invading organisms because of allergies, malnutrition, immune deficiencies, physical abnormalities, or other comorbid conditions. Some experts propose a relationship between the host response to the virus and the production of cold symptoms. Studies show that common colds are more frequent or more severe in those under increased stress, probably as a result of stress weakening the immune system.

Pathophysiology

If there is a breakdown or failure in the protective barriers of the URI (i.e., cough, gag, and sneeze reflexes, lymph nodes, immunoglobulin [Ig] A antibodies, and rich vasculature), viral pathogens trigger an acute inflammatory reaction with release of vasoactive mediators and increased parasympathetic stimuli. This produces congestion and rhinorrhea. Viral URI also produces inflammatory mediators that increase the sensitivity of afferent sensory nerves in the airway, which may contribute to the cough typically associated with the common cold.

Bradykinin and lysyl-bradykinin contribute to the pathogenesis of HRV infections. An increase in kinin levels is associated with increased permeability of the vasculature. However, histamine levels remain unchanged, indicating the lack of involvement of mast cells and basophils (Jacobs et al., 2013). The involvement of prostaglandins can be elucidated by the demonstrated effectiveness of cyclooxygenase inhibitors in reducing headache, malaise, myalgias, and cough during HRV infection.

Transmission of HRV occurs predominantly by intranasal or conjunctival inoculation and has been attributed to three methods: airborne transmission by small particles (droplets), airborne transmission by large particles, and direct contact. Large particle transmission is not efficient and requires prolonged exposure. Direct contact involves donor nose-to-hand contact, which is then transmitted to the hand of a recipient. From there, transmission occurs primarily when the infected hand makes contact with the eyes or nose. Although conjunctival cells are not thought to harbor HRV, it probably can be passed through the tear duct into the nose. HRVs can survive indoors for a range of hours to days at room temperature (Jacobs et al., 2013). Rhinoviruses grow in the upper airway and attach and gain entry to host cells by binding to an intracellular adhesion molecule. Infection begins in the adenoidal area and spreads to the ciliated epithelium in the nose. HRVs remain infectious for at least 3 hours after drying on hard surfaces such as telephones or countertops, but they do not last as long on porous surfaces, such as tissues.

Diagnostic Criteria

The expansion in the availability of laboratory diagnostics includes the collection and processing of specimens, detection and serology of antigens, conventional and rapid virus culture, and many other technologies; however, diagnostic tests are not recommended (Jacobs et al., 2013). In order to evaluate specimens, collection would have to occur as soon as possible after symptom onset, since HRV titers are most elevated during the first 2 days of clinical presentation. The short duration of most colds results in an impractical window of appropriate timing, and there are inaccuracies involved in the diagnostic process, making the testing process unreasonable.

The most commonly used method of diagnosis involves symptom evaluation. Onset of common cold signs and symptoms occurs 1 to 2 days after viral infection and peaks in approximately 2 to 4 days. A cough may persist following the resolution of other symptoms. Symptoms consist primarily of clear nasal discharge, sneezing, nasal congestion, cough, low-grade fever (below 102°F [38.9°C]), scratchy or sore throat, mild aches, chills, headache, watery eyes, tenderness around the eyes, full feeling in the ears, and fatigue. In children, the presentation could also include fever with seizures, anorexia, vomiting, diarrhea, and abdominal pain. Symptoms usually resolve in approximately 1 week, but they may linger for up to 2 weeks.

Initiating Drug Therapy

Improper treatment of the common cold by clinicians is common for several reasons. It is often difficult to determine whether the cause is viral or bacterial. There is no cure for the common cold; therefore, treatment strategies are supportive in nature and consist primarily of symptom relief.

Nonpharmacologic alternatives to treating the common cold are the first line of treatment. Rest allows the body to gain strength. An alternative to decongestants and expectorants involves increasing water or juice intake, which assists in liquefying tenacious secretions, making expectoration easier, soothing scratchy, sore throats, and relieving dry skin and lips. Saline gargles also are effective for soothing sore throats. Saline nasal flushes and irrigation may have slight benefit in clearing nasal passages without the risk for rebound congestion; however, evidence remains limited (Fokkens et al., 2012).

Coughing caused by chest congestion can cause a muscular chest pain. Menthol rubs can soothe this ache and open airways for some congestion relief. Menthol lozenges also have been effective in soothing scratchy throats and clearing nasal passages. Petrolatum-based ointments for raw and macerated skin around the nose and upper lip ease the drying effects of dehydration and the use of multiple tissues. Inhalation of steam has not demonstrated benefit in the drainage of mucus or the destruction of the cold virus and is therefore not recommended (Fokkens et al., 2012).

Goals of Drug Therapy

The main goals of treatment for the common cold are relief of symptoms, reduction of the risk for complications, and prevention of spread to others.

Decongestants

Decongestants come in topical or oral preparations and can be somewhat effective for the short-term relief of cold symptoms (Fashner et al., 2012). Topical decongestants, such as oxymetazoline hydrochloride (Afrin) and phenylephrine hydrochloride (Afrin Childrens, Little Remedies, Neo-synephrine), are available in nasal spray and pump mist preparations. Oral decongestants, such as pseudoephedrine (Sudafed) and phenylephrine (Sudafed PE), are also available. Decongestants are typically available OTC. Preparations containing pseudoephedrine can be obtained without a prescription but are available behind the counter and must be purchased from a pharmacy.

Mechanism of Action

Decongestants are sympathomimetic agents that stimulate alpha- and beta-adrenergic receptors, causing vasoconstriction in the respiratory tract mucosa and thereby improving ventilation. Topical decongestants have little systemic absorption but work locally by slowing ciliary motility and mucociliary clearance. Oral agents have the same mechanism of action and assist in the clearance of nasal mucus and obstruction. Their use may help to prevent rhinosinusitis and eustachian tube blockage in patients susceptible to these conditions.

Dosage

Oxymetazoline hydrochloride 0.05% nasal spray and pump mists can be used in patients who are at least 6 years old at a dosage of 2 to 3 sprays in each nostril not more often than every 10 to 12 hours. Patients should not exceed 2 doses of oxymetazoline in a 24-hour time period. Phenylephrine nasal sprays are available as 0.125%, 0.25%, 0.5%, and 1% preparations. For specific dosing recommendations, please see Table 24.1. Despite the ability to use the spray every 4 hours, it should generally not be used more than two to three times daily. Topical decongestants should not be used for more than 3 days because prolonged use can cause rhinitis medicamentosa (rebound congestion), which is characterized by severe nasal edema, rebound congestion, and increased discharge due to decreased receptor sensitivity. Rebound congestion interferes with ciliary action and dries the nasal mucosa.

TABLE 24.1 Overview of Agents for Upper Respiratory Infections

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Decongestants			
oxymetazoline hydrochloride (Afrin, Mucinex Sinus, Neo-Synephrine, Vicks Sinex) Nasal spray and pump mists (0.05%) ≥6 y: 2–3 sprays per nostril q10–12h	Palpitations, headaches	Hypersensitivity	These drugs may cause rebound congestion. Use only 2–3 d, then switch to oral decongestants.
phenylephrine hydrochloride (Neo-Synephrine, Sudafed PE, Afrin Childrens) Nasal spray (0.125%) 2–5 y: 2–3 sprays per nostril q4h Mild nasal spray (0.25%) 6–12 y: 2–3 sprays per nostril q4h Regular nasal spray (0.5%) ≥12 y: 2–3 sprays per nostril q4h Extra strength nasal spray (1%) ≥12 y: 2–3 sprays per nostril q4h Tablet, oral (10 mg) ≥12 y: 10 mg q4h	Palpitations, headaches	Hypersensitivity, urinary retention, severe uncontrolled hypertension, coronary artery disease, MAO inhibitor use within 14 d	These drugs may cause rebound congestion. Use only 2–3 d, then switch to oral decongestants.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
pseudoephedrine (Sudafed) IR tablet, oral (30 mg) ≥12 y: 60 mg q4–6h 6–11 y: 30 mg q4–6h 12-hour tablet, oral (120 mg) ≥12 y: 120 mg q12h ER tablet, oral (240 mg) ≥12 y: 240 mg q24h	Palpitations, headaches, increased blood pressure, dizziness, GI upset, tremor, insomnia	Hypersensitivity, narrow-angle glaucoma, severe uncontrolled hypertension, coronary artery disease, MAO inhibitor use within 14 d	Give at least 2 h before bedtime. Do not crush, break, or chew tablets.
Expectorants			
guaifenesin (Antitussin, Mucinex, Robitussin, Uni-Tussin) Liquid, oral (100–200 mg/5 mL) Solution, oral (100 mg/5 mL) Syrup, oral (100 mg/ 5 mL) Packet, oral (50 mg, 100 mg) 6 mo–12 y: 25–50 mg q4h 2–5 y: 50–100 mg q4h 6–12 y: 100–200 mg q4h ≥12 y: 200–400 mg q4h IR tablet, oral (200 or 400 mg) ≥12 y: 200–400 mg q4h ER tablet, oral (600 mg) ≥12 y: 600–1,200 mg q12h	Drowsiness, headache, dizziness, GI upset	Hypersensitivity	Not given for prolonged time if cough persists or accompanied by high fever Oral packet may be swallowed whole or opened and sprinkled on soft food.
Antitussives			
dextromethorphan (Delsym) Lozenge, oral (5 mg) Capsule, oral, 15 mg Sublingual strip, oral (7.5 mg) Gel, oral (7.5 mg/5 mL) Syrup, oral (varying strengths) IR liquid, oral (varying strengths) 4–6 y: 2.5–7.5 mg q4–8h 6–12 y: 5–10 mg q4h ≥12 y: 10–20 mg q4h or 30 mg q6–8h ER liquid, oral (30 mg/5 mL) 4–6 y: 15 mg q12h 6–12 y: 15 mg q6–8h ≥12 y: 60 mg q12h	Dizziness, nausea, drowsiness	Hypersensitivity, MAO inhibitor use within 14 d	None
benzonatate (Tessalon Perles) Capsule, oral (100 or 200 mg) ≥10 y: 100–200 mg q8h	Constipation, drowsiness, headache, GI upset, confusion	Hypersensitivity	
Anti-inflammatories			
naproxen sodium (Naprosyn, Aleve) Tablet, oral (220 mg) ≥12 y: 220 mg q8–12h	Dizziness, drowsiness, headache, edema, abdominal pain, constipation, nausea, heartburn	Hypersensitivity	Take on full stomach to reduce GI upset.
Anticholinergics			
ipratropium bromide (Atrovent) Nasal spray (0.06%) ≥12 y: 2 sprays per nostril bid–qid 5–11 y: 2 sprays per nostril tid	Headache, epistaxis, pharyngitis, nasal dryness	Hypersensitivity to atropine Use caution in patients with narrow-angle glaucoma, BPH, bladder neck obstruction, pregnancy, and lactation	Safety and efficacy not established beyond 4 d

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Antihistamines			
diphenhydramine (Benadryl) Tablet, oral (25 mg) ≥12 y: 25–50 mg q4–6h	Confusion, dizziness, drowsiness, fatigue, paradoxical excitability, nervousness, headache, sedation, blurred vision, dry mouth, hallucinations, tachycardia, urinary retention	Hypersensitivity, patients who are breast-feeding, neonates, premature infants	Caution in elderly, as it may increase fall risk.
chlorpheniramine (Chlor-Trimeton) IR tablet, oral (4 mg) ≥12 y: 4 mg q4–6h ER tablet, oral (12 mg) ≥12 y: 12 mg q12h	Headache, fatigue, nervousness, dizziness, nausea, dry mouth, GI upset, urinary retention, blurred vision	Hypersensitivity, narrow-angle glaucoma, bladder neck obstruction, symptomatic prostate hypertrophy, during acute asthma attacks, stenosing peptic ulcer, pyloroduodenal obstruction	Caution in elderly, as it may increase fall risk.
amoxicillin with clavulanic acid (Augmentin) Adults or children >40 kg: 500 mg q8h Children 3 mo to adolescence who are ≤40 kg: 20 mg/kg/d q8h or 25 mg/kg/d q12h Children <3 mo: 30 mg/kg/d every 12 h Children with severe ABRS: 40 mg/kg/d q8h or 45 mg/kg/d q12h CrCl 10–30 mL/min: 250–500 mg q12h CrCl < 10 mL/min: 250–500 mg q24h	Common: GI upset, rash, vaginal infections, photosensitivity Rare: Stevens-Johnson syndrome, seizures	Hypersensitivity or allergy to penicillin or cephalosporins Do not use ER formulation in patients with CrCl < 30 mL/min	"High dose" (2 g q12h) is reserved for patients with risk for antibiotic resistance.*
Doxycycline (Oracea) Adults and children >8 y of age weighing >45 kg: 200 mg daily in 1–2 divided doses	Common: GI upset, rash, vaginal infections, headache Rare: Stevens-Johnson syndrome, hepatotoxicity	Hypersensitivity or allergy to tetracyclines	Not recommended for children ≤8 y of age Take on an empty stomach if tolerated.
levofloxacin (Levaquin) Adults: 500–750 mg q24h Children: 10–20 mg/kg/d q12–24h CrCl 20–49 mL/min: 500 mg × 1 followed by 250 mg q24h or 500 mg × 1 followed by 750 mg q48h	Common: GI upset, rash, dyspepsia, headache, chest pain, decreased blood glucose, edema, photosensitivity, vaginal infections Black box warning for tendon inflammation and rupture	Hypersensitivity or allergy to fluoroquinolones	Avoid in patients with myasthenia gravis. Can prolong QTc interval. Avoid concurrent use with other medications that prolong the QTc interval. Avoid taking with corticosteroids due to increased risk of ruptured Achilles tendon.
moxifloxacin (Avelox) Adults: 400 mg q24h	Same as above	Same as above	Same as above
clindamycin (Cleocin) Children: 30–40 mg/kg/d divided q8h	Common: GI upset	Hypersensitivity or allergy to lincosamides	Must be taken with third-generation cephalosporins.
cefpodoxime (Vantin) Children >2 mo and <12 y: 5 mg/kg q12h Children ≥12 y: 200 mg q12h	Common: GI upset headache	Caution with penicillin allergy	Interacts with antacids, H2 antagonists.
cefixime (Suprax) Children >6 mo and <12 y: 4 mg/kg q12h Children ≥12 y: 400 mg divided every 12–24 h	Same as above	Same as above	Same as above.

*Patients with ABRS from regions with high endemic rates of resistant *S. pneumoniae*, those with severe infection, children in daycare, ages <2 or >65, immunosuppressed or those with a recent hospitalization or antibiotic use within the past month.

Oral pseudoephedrine is available in 30-mg tablets in preparations that vary with regard to duration of action. Adults greater than 12 years of age can take a short-acting preparation at a dose of 60 mg every 4 to 6 hours or a long-acting preparation at a dose of 120 mg every 12 hours. All-day preparations are also available at a dosage of 240 mg and should not be taken more than once in a 24-hour time period. Children who are 4 to 5 years of age can take a 15-mg dose every 4 to 6 hours to a maximum daily dose of 60 mg. Children aged 6 to 12 should take 30 mg every 4 to 6 hours and should not exceed 120 mg within 24 hours. Oral preparations should be given at least 2 hours before bedtime, and extended-release (ER) formulations should not be crushed, broken, or chewed. Oral phenylephrine has not demonstrated consistent benefit and should not be recommended.

Time Frame for Response

Topical decongestants have a rapid onset of action and can begin to work within several minutes. Oral decongestants have a slower onset of action of approximately 30 minutes.

Contraindications

Decongestants are contraindicated in patients with hypersensitivity to any component of the formulation, narrow-angle glaucoma, severe uncontrolled hypertension, and coronary artery disease and in patients who have been treated with a monoamine oxidase (MAO) inhibitor within 14 days. Caution is recommended in patients with hypertension, cardiovascular disease, renal impairment, hyperthyroidism, diabetes, prostatic hypertrophy, and urinary incontinence.

Adverse Events

Adverse drug events (ADEs) include increased blood pressure and heart rate, palpitations, headache, dizziness, gastrointestinal (GI) distress, insomnia, and tremor. These reactions are especially seen at doses above 210 mg. In patients with controlled hypertension, products can be taken for a short course and with frequent monitoring.

Interactions

Decongestants interact with appetite suppressants, MAO inhibitors (hypertensive crisis), and beta-adrenergic agents (bradycardia and hypertension). Decongestants are less effective when taken with drugs that acidify the urine and more effective when taken with drugs that alkalize the urine.

Expectorants

One of the most important nondrug considerations in treating coughs involves an exploration of the etiology, because the prolonged use of OTC expectorants or other cough products may mask symptoms of a serious underlying disorder. This drug should not be used for more than 1 week. If the cough persists, additional measures should be investigated. The most commonly available expectorant is guaifenesin (Antitussin, Mucinex, Robitussin). Some studies have shown this product to have limited advantage over increased fluid intake, and evidence regarding benefit is generally controversial (Fashner et al., 2012).

Mechanism of Action

Expectorants, including water, increase the output of respiratory tract fluid by decreasing the adhesiveness and surface tension of the respiratory tract and by facilitating the removal of viscous mucous.

Dosage

Guaifenesin is available in both liquid and tablet oral preparations. Some preparations are available in the form of oral sprinkles, which may be swallowed whole or sprinkled on soft food, such as applesauce. The recommended dose for adults over the age of 12 is 200 to 400 mg every 4 hours to a maximum daily dose of 2.4 grams (g). ER tablets can be taken at a dosage of 600 to 1,200 mg every 12 hours, with the same maximum daily dose as the immediate-release (IR) preparations. For children less than 4 years of age, a physician or pharmacist should be consulted prior to treatment with expectorants. If recommended by a health care professional, children aged 6 months to 2 years can be given a dose of 25 to 50 mg every 4 hours to a maximum of 300 mg/d. Children aged 2 to 5 can take a dose of 50 to 100 mg every 4 hours, not to exceed 500 mg/d. Children who are 6 to 12 years of age can be given a dose of 100 to 200 mg every 4 hours to a maximum of 1.2 mg/d.

Time Frame for Response

Expectorants have an onset of action of approximately 1 to 2 hours.

Contraindications

Expectorants are contraindicated in patients with hypersensitivity to any component of the formulation.

Adverse Events

ADEs include drowsiness, headache, dizziness, and GI upset.

Interactions

There are no known drug interactions.

Antitussives

Cough suppressants, such as dextromethorphan (Delsym) and benzonatate (Tessalon Perles), are available in oral preparations, including liquids, gels, capsules, lozenges, and sublingual strips, but studies have shown minimal benefit with the common cold (Fashner et al., 2012). For some patients, these agents may reduce cough frequency and help achieve sleep; however, consistent benefit has not been demonstrated. There is little evidence to support the use of narcotic antitussives, such as codeine and hydrocodone, to relieve cough. Many practitioners believe that cough suppressants are ineffective in children.

Mechanism of Action

Antitussives may diminish the cough reflex by direct inhibition of the cough center in the medulla.

Dosage

Patients over the age of 12 years can take IR preparations of dextromethorphan at a dose of 10 to 20 mg every 4 hours or 30 mg every 6 to 8 hours. ER products can be taken at a dose of 60 mg twice daily. Adult patients should not exceed a dose of 120 mg within a 24-hour time period. Dextromethorphan is not recommended for children less than 4 years of age. Children who are 4 to 6 years of age may take an IR preparation at a dose of 2.5 to 7.5 mg every 4 to 8 hours or an ER preparation at a dose of 15 mg twice daily to a maximum of 30 mg/d. Children aged 6 to 12 years may take IR preparations at a dose of 5 to 10 mg every 4 hours or 15 mg every 6 to 8 hours. ER preparations can be taken at a dose of 30 mg twice daily. The maximum dose of dextromethorphan for this age range is 60 mg per 24-hour time period.

Benzonatate can be taken by patients greater than 10 years of age at a dose of 100 to 200 mg three times daily, as needed with total daily doses not to exceed 600 mg.

Time Frame for Response

Onset of action is noted within 15 to 30 minutes.

Contraindications

Antitussives are contraindicated in a patient who has a hypersensitivity to these agents or in a patient who has taken an MAO inhibitor within 2 weeks.

Adverse Events

Adverse events include dizziness, nausea, and drowsiness.

Interactions

Drug–drug interactions occur with concomitant use of amiodarone (Cordarone), MAO inhibitors, quinidine, and proserotonergic drugs, such as selective serotonin reuptake inhibitors, serotonin norepinephrine reuptake inhibitors, or triptans. Caution should also be used with other antidepressants.

Anti-inflammatories and Analgesics

Mechanism of Action

Cyclooxygenase inhibitors, such as nonsteroidal anti-inflammatory drugs (NSAIDs), inhibit prostaglandin secretions, which can reduce headache, malaise, myalgias, cough, and even sneezing. Naproxen (Naprosyn, Aleve) is available as an oral tablet or suspension and is the NSAID of choice in the American College of Clinical Pharmacy (ACCP) guidelines because it does not impact viral shedding (Jacobs et al., 2013).

Dosage

Naproxen available in an OTC preparation can be taken by patients who are 12 years of age or older at a dose of 220 mg every 8 to 12 hours. Total daily dosage should not exceed 600 mg. NSAIDs should be taken with food to avoid GI upset.

Time Frame for Response

Effects are noted within 1 to 2 hours.

Contraindications

Contraindications include hypersensitivity to any component of the formulation. Caution should be used for patients with active peptic ulcers or GI bleeds, bleeding disorders, asthma, severe hepatic impairment, severe renal impairment involving a creatinine clearance (CrCl) of less than 30 milliliters per minute (mL/min), severe uncontrolled heart failure, and hyperkalemia, or who are in their third trimester or are breastfeeding. Aspirin, a common NSAID, should not be used in children because of the secondary risk of Reye syndrome. Patients should also refrain from taking acetaminophen (Tylenol) and ibuprofen (Motrin, Advil) because these drugs are believed to shed the virus. NSAIDs are discussed in greater detail in Chapter 7.

Adverse Events

Adverse events include dizziness, drowsiness, headache, edema, abdominal pain, constipation, nausea, and heartburn.

Interactions

Naproxen may increase the action of antiplatelet agents, anticoagulants, lithium, methotrexate, haloperidol, potassium-sparing diuretics, quinolone antibiotics, salicylates, tacrolimus, tenofovir, vitamin K antagonists, and several other drugs. The levels of naproxen may be increased by angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), tricyclic antidepressants, cyclosporine, ketorolac,

omega-3 fatty acids, proserotonergic agents, and several other drugs.

Anticholinergic Agents

Ipratropium bromide (Atrovent) nasal spray is available at concentrations of 0.03% and 0.06% and has been recommended for rhinorrhea associated with the common cold. This agent has not shown consistent benefit for the alleviation of nasal congestion or sneezing (Fokkens et al., 2012).

Mechanism of Action

Local application of anticholinergic agents to the nasal mucosa inhibits vagally mediated reflexes by antagonizing the action of acetylcholine at the cholinergic receptor, thereby inhibiting secretions from the serous and seromucous glands lining the nasal mucosa. The result is a decrease in nasal discharge and rhinorrhea.

Dosage

Adults greater than 12 years of age should use the ipratropium bromide 0.06% nasal spray at a dose of 2 sprays per nostril three to four times daily. Children who are 5 to 11 years of age can use the 0.06% solution at a dose of 2 sprays in each nostril three times daily. The safety and efficacy of use beyond 4 days for patients with the common cold has not been established.

Time Frame for Response

The onset of action for these products is 30 to 60 minutes.

Contraindications

Ipratropium bromide is contraindicated in patients with hypersensitivity to any component of the formulation, including atropine or its derivatives. Caution should be used in patients with narrow-angle glaucoma, prostatic hyperplasia, or bladder neck obstruction.

Adverse Events

Adverse effects include headache, epistaxis, pharyngitis, and nasal dryness.

Interactions

There are no known drug interactions.

Antihistamines

Antihistamines should not be recommended as monotherapy for the treatment of cough and other cold symptoms, as they are ineffective. Antihistamine-induced dryness may even exacerbate symptoms of congestion and cause upper airway obstruction by impairing the flow of mucus. For symptoms of rhinorrhea and a feeling of fullness in the ears, first-generation antihistamines, such as diphenhydramine and chlorpheniramine, may be effective when combined with decongestants. See commentary below on combination treatments. Treatment of cough with second-generation, nonsedating antihistamines, such as loratadine (Claritin) and cetirizine (Zyrtec), is ineffective and should not be recommended (Pratter, 2006). Antihistamines are discussed further in Chapter 48.

Mechanism of Action

Antihistamines are theorized to block the release of histamine from mast cells and basophils in the nasal passageways that is activated by cold virus inoculation. This release of histamine may result in the sneezing symptom that affects patients during the course of a common cold. Antihistamines competitively antagonize histamine at the H1 receptor, and first-generation antihistamines also competitively antagonize acetylcholine activity at the neuronal muscarinic receptors.

Dosage

Antihistamines are not recommended for symptoms of the common cold in children less than 12 years of age. Diphenhydramine can be given at a dose of 25 to 50 mg every 4 to 6 hours, to a maximum of 300 mg daily. IR preparations of chlorpheniramine can be given at a dose of 4 mg every 4 to 6 hours, and ER preparations can be given at a dose of 12 mg every 12 hours. The total daily dose of chlorpheniramine should not exceed 24 mg.

Time Frame for Response

The onset of action for first-generation antihistamines is typically 30 to 60 minutes.

Contraindications

Diphenhydramine should not be used in patients with hypersensitivity, in patients who are breast-feeding, and in neonates or premature infants. Caution should be used in patients with asthma, cardiovascular disease, increased intraocular pressure, prostatic hyperplasia, bladder neck obstruction, and thyroid dysfunction.

Chlorpheniramine is contraindicated in patients with hypersensitivity, narrow-angle glaucoma, bladder neck obstruction, symptomatic prostate hypertrophy, during acute asthma attacks, stenosing peptic ulcer, and pyloroduodenal obstruction. Use should also be avoided in newborns due to possible association with sudden infant death syndrome.

Neither first-generation antihistamine listed in this section should be used as a sedative to help a child sleep. Additionally, these agents should be used with caution in elderly patients, due to the increased risk for confusion, constipation, and dizziness.

Adverse Events

The ability of first-generation antihistamines to pass the blood–brain barrier and the impact on acetylcholine contributes to a higher incidence of anticholinergic and central nervous system ADEs, as compared to the second-generation products. These can include confusion, dizziness, drowsiness, fatigue, paradoxical excitability, nervousness, headache, sedation, blurred vision, dry mouth, hallucinations, tachycardia, and urinary retention.

Interactions

First-generation antihistamines may potentiate the effects of other sedative drugs or alcohol.

Combination Treatments

A limitless selection of combination products is available for the alleviation of cough and cold symptoms. These products can often be difficult to recommend, as they contain multiple active ingredients, each associated with unique ADEs. If recommending one of these products, it is important to ensure that there is an indication for each active ingredient, to avoid overmedicating the patient. Additionally, individual symptoms may last for varying durations; therefore, even if the patient initially presented with symptoms matching each ingredient, they may be overmedicating at some point during the course of their illness if some symptoms persist longer than others. For example, congestion may predominate in the first few days, but a cough may last for up to 2 weeks. If a patient purchases products that each contain only one active ingredient, they have increased flexibility in medicating specific symptoms for the appropriate amount of time.

For sneezing, rhinorrhea, acute cough, and postnasal drip, a combination of decongestant and first-generation antihistamine may be effective in adult or adolescent patients. Evidence for this combination treatment is generally limited and of poor quality; therefore, clinically significant benefits are difficult to conclude. The benefit of symptomatic relief should be weighed against the risk for adverse effects. This combination has not proven effective in children under the age of 12 (Fokkens et al., 2012).

Several products also combine expectorants and antitussives. This combination is not recommended, as the ingredients are associated with opposing mechanisms. As stated previously, expectorants increase respiratory tract fluid output, while antitussives diminish the cough reflex.

Selecting the Most Appropriate Agent

Because symptoms of a cold are manifested individually or in combination, not everyone will present with the same signs and symptoms. Therefore, the therapeutic approach involves treatment of symptoms as specifically as possible (Figure 24.1).

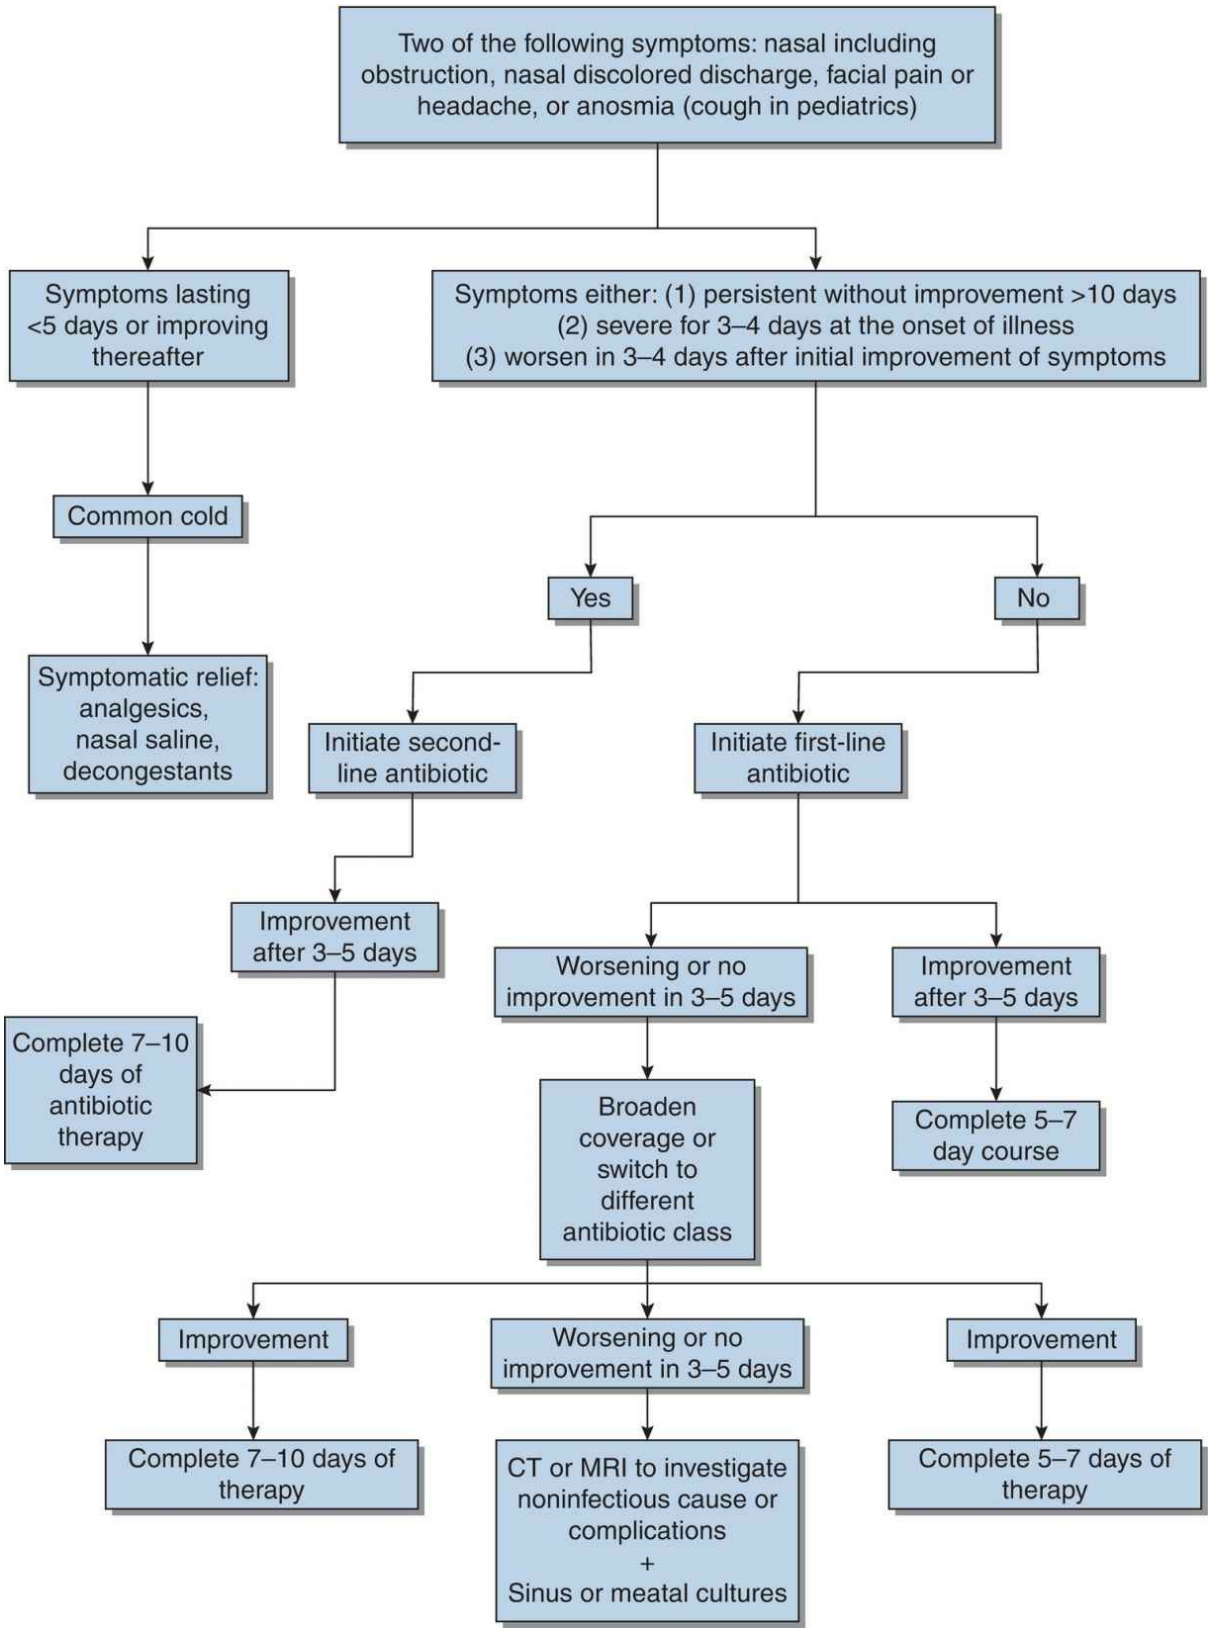

FIGURE 24.1 Treatment algorithm for the URIs: cold and sinusitis.

First-Line Therapy

Initial therapy consists of symptom relief. For nasal obstruction and rhinorrhea, which are caused by secretions and increased vascular permeability with leakage of serum into the nasal mucosa, topical decongestants, such as oxymetazoline hydrochloride (Afrin) or phenylephrine hydrochloride (Neo-Synephrine), are often used for the first 3 days, when the patient feels the worst. If other symptoms are diminished but nasal obstruction remains a problem, the use of an oral decongestant, such as pseudoephedrine, or a combination decongestant and antihistamine, or an antihistamine alone may relieve symptoms and help prevent complications such as sinusitis and eustachian tube blockage. Anti-inflammatories, such as naproxen, may be recommended to relieve aches and discomfort.

Second-Line Therapy

Second-line therapy may be instituted if first-line therapy fails to relieve symptoms or if complications, such as secondary infection (ear infections, sinusitis, bronchitis, or pneumonia), develop. The therapy should be specific to the disorder.

Monitoring Patient Response

Patient response is monitored by the decrease of symptoms. If symptoms decrease without onset of complications, then therapy was successful. If the common cold does not improve in 8 to 10 days, a bacterial cause is suspected and antibiotic therapy should be considered.

Rhinosinusitis

Rhinosinusitis is an URI characterized by inflammation of the mucous membranes that line the sinuses and nasal cavity causing nasal blockage, purulent discharge, and facial pain or pressure. Sinusitis and rhinitis are unlikely to occur without inflammation of the nasal cavity membranes, so the term rhinosinusitis provides a better description of the inflammatory disease involving the URI (Rosenfield et al., 2015).

Rhinosinusitis is classified by duration of symptoms as either acute rhinosinusitis (ARS), lasting for less than 4 weeks, or chronic rhinosinusitis (CRS), persisting for more than 12 weeks. Rhinosinusitis with symptoms lasting more than 4 weeks and less than 12 weeks is defined as subacute rhinosinusitis (Rosenfield et al., 2015). ARS is typically infectious, whereas CRS is less infectious and more inflammatory mediated (Dykewicz & Hamilas, 2010).

ARS can further be stratified by etiology into viral rhinosinusitis (AVRS) or acute bacterial rhinosinusitis (ABRS). ARS is more frequently caused by a viral infection with only 0.5% to 2% of AVRS transitioning to ABRS. However, antibiotics are prescribed in 85% to 98% of ARS cases (Dykewicz & Hamilas, 2010).

ARS has a global prevalence of 6% to 15% and is one of the most common reasons for primary care visits, affecting over 30 million Americans every year (Fokkens et al., 2014; Rosenfield et al., 2015). ARS is also the fifth most common diagnosis for which an antibiotic is prescribed, even though there is consistent evidence of spontaneous resolutions and recent guidelines recommend restricting antibiotic use (Fokkens et al., 2014; Rosenfield et al., 2015). It is estimated that rhinosinusitis costs the U.S. health care system more than $11 billion on medications, laboratory tests, workplace absenteeism, and outpatient and emergency room visits each year (Rosenfield et al., 2015).

Causes

Most cases of AVRS can be attributed to respiratory viruses including rhinovirus, influenza, and parainfluenza virus. The most common pathogens involved in ABRS include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*, with the latter being the most common pathogen in pediatric cases (Dykewicz & Hamilas, 2010). Most healthy persons harbor bacteria in their URIs with no problems until the bodily defenses are weakened or drainage from the sinuses is blocked by a cold or other viral infection. Then, bacteria that may have been living harmlessly in the nose can multiply and invade the sinuses, causing a secondary infection. Risk factors for ARS are outlined in Box 24.1 (Anselmo-Lima & Sakana, 2015).

BOX 24.1 Selected Risk Factors for ARS

- Winter season
- Air pollution
- Septal deviation
- Nasal polyps
- Allergic rhinitis
- Tobacco smoke
- Gastroesophageal reflux
- Asthma
- Prior upper respiratory tract infection
- Cystic fibrosis
- Dental infections
- Immunodeficiency
- Intranasal medications or illicit drugs
- Mechanical ventilation
- Nasogastric tubes

CRS is believed to be due to a dysfunctional interaction between environmental factors, including allergens, toxins, and microbial agents, and host factors, such as a deficiency of the immune system and anatomical defects. Fungi and bacteria are the most common environmental causes of CRS (Lam et al., 2015). Patients with CRS tend to have a higher immunological response to the *Alternaria* species, which is a fungi commonly found in the sinus mucus. *Staphylococcus aureus* is usually the bacterial pathogen causing CRS (Dykewicz & Hamilas, 2010). Frequently, patients with CRS will present with other comorbidities including gastroesophageal reflux disease, defects in mucociliary clearance (as in cystic fibrosis), or anatomical abnormalities including nasal septal deviation. Additionally, allergic

rhinitis and asthma occur in 60% and 20% of patients with CRS, respectively (Dykewicz & Hamilas, 2010).

Pathophysiology

There are four paired, air-filled cavities that make up the sinuses. Small tubular openings called the sinus ostia connect the sinus cavities and facilitate drainage of the sinuses into the nasal cavity using ciliated cells. Proper sinus functioning requires motile cilia, unobstructed ostia, and mucus of a low viscosity that allows transport (Dykewicz & Hamilas, 2010). The nose reacts to the viral invasion by increasing production of mucus and sending white blood cells to the lining of the nasal passage, which causes inflammation. This inflammation results in dysfunctional cilia, obstruction of the ostia, or both. Blocked sinuses provide an ideal environment for bacterial growth, which can lead to a secondary bacterial infection. Air trapped within a blocked sinus, along with pus or other secretions, can increase pressure on the sinus wall. The result is sinus pain, which can sometimes be intense. Similarly, when a swollen membrane prevents air from entering a paranasal sinus cavity, a vacuum can form, causing additional pain.

Diagnostic Criteria

The diagnosis of ARS in adults at primary health care levels is based on the presence of two or more of the following hallmark symptoms: nasal congestion, nasal discharge, facial pain or headache, and anosmia (loss of smell). For pediatric patients, cough replaces decreased sense of smell as one of the four hallmark symptoms. Additionally, a patient may present with painful swallowing, cough, ear pressure, fever, and fatigue (Anselmo-Lima & Sakana, 2015). The clinical presentation of AVRS and ABRS is very similar and therefore difficult to differentiate based on symptoms alone. Therefore, practitioners need to rely on symptom severity, duration, and nature to differentiate between AVRS and ABRS (Fokkens et al., 2014). The European Respiratory Society/European Academy of Allergy and Clinical Immunology rhinosinusitis guidelines characterize ABRS if three of the hallmark symptoms previously mentioned are present (Fokkens et al., 2012). The Infectious Disease Society of America (IDSA) has identified three clinical features to distinguish patients who have ABRS versus AVRS: (1) symptoms persistent greater than 10 days from onset without any clinical improvement, (2) severe symptoms or an elevated temperature (≥102°F) and either facial pain or purulent nasal discharge lasting for 3 to 4 consecutive days at the onset of illness, and (3) symptoms worsen (fever, headache, or increased nasal discharge) following a typical viral URI that lasted 5 to 6 days after an initial improvement of symptoms (Chow, 2012). Radiographic imaging in ARS is not recommended (Rosenfield et al., 2015).

Diagnostic tests such as nasal endoscopy or computerized tomography (CT) scan should be used to diagnose CRS. However, diagnosis in most patients is based on the presence of two or more hallmark symptoms lasting longer than 12 weeks.

Initiating Drug Therapy

Primarily specialists manage CRS; therefore, ARS will be the focus of this section. Before initiating drug therapy, it is critical to determine the etiology of ARS because antibiotic therapy is inappropriate to prescribe for patients with AVRS. For both AVRS and ABRS, it is recommended to provide the patient with symptomatic relief including analgesics, topical intranasal steroids, and/or nasal saline irrigation. For patients meeting diagnosis criteria for ABRS as previously described, practitioners should either offer watchful waiting or treat with antibiotics.

While weighing these choices, the practitioner should consider a few points. The first is the ability for the patient to follow up when choosing the watchful waiting option (Rosenfield et al., 2015). Another consideration when deciding whether or not to initiate antibiotics is that systematic reviews have demonstrated that antibiotics did not provide benefits in uncomplicated ARS and only reduced length of disease by less than half a day (Fokkens et al., 2014). This evidence should be weighed against the risk of adverse effects with antibiotics and antibiotic resistance before prescribing antibiotics for ABRS. The need for a specialist referral should also be contemplated when considering drug therapy. Reasons to refer may include mental status changes, visual disturbances, immunosuppressive illness, anatomic defects, unilateral findings, recurrent URI, or a history of antibiotic resistance (Chow et al., 2012).

The recommended length of therapy for uncomplicated ABRS in adults is 5 to 7 days, whereas treatment duration in children should be 10 to 14 days (Chow et al., 2012).

Goals of Drug Therapy

The primary treatment goal is to restore sinuses to health. Other goals include decreasing the duration and severity of symptoms, promoting appropriate use of antibiotic treatment, preventing complications and the progression from acute illness to chronic disease, and preventing the transmission of illness to other people.

Antibiotics

Obtaining cultures is only recommended for patients who do not respond to first- or second-line treatment; therefore, management strategies will focus on the empiric treatment of ABRS. Guidelines no longer recommend the regular use of macrolides, third-generation cephalosporins, or trimethoprim–sulfamethoxazole (Bactrim) for empiric treatment due to their high resistance rates with *S. pneumoniae*.

Amoxicillin and Amoxicillin–Clavulanate

Mechanism of Action

Amoxicillin, a beta-lactam antibiotic, inhibits synthesis of the bacterial cell wall by binding to one or more of the penicillin-binding proteins causing the bacteria to lyse. Adding clavulanate to amoxicillin expands its spectrum of activity by inhibiting beta-lactamases that inactivate amoxicillin.

Dosage

Amoxicillin–clavulanate (Augmentin) is dosed based on the amoxicillin component and is available in 250-, 500-, or 875-mg IR oral tablets and 1,000-mg ER tablets. Amoxicillin–clavulanate is also available in a 125, 250, 200 or 400 mg/5 mL suspension and 200- or 400-mg chewable tablets. For adults or adolescents weighing greater than 40 kg, a dose of 500 mg every 8 hours or 875 mg every 12 hours should be given. Infants less than 3 months old should be given 30 mg/kg/d every 12 hours. Children aged 3 months to adolescents weighing less than 40 kg should be given 20 mg/kg/d every 8 hours or 25 mg/kg/d every 12 hours for mild infections. For severe infections in this pediatric population, a dose of 40 mg/kg/d every 8 hours or 45 mg/kg/d every 12 hours should be prescribed. "High-dose" amoxicillin consists of 2,000 mg every 12 hours and should be reserved for children and adults with ABRS from regions with high endemic rates of resistant *S. pneumoniae*, those with severe infection, children in daycare, patients of ages less than 2 or greater than 65, immunosuppressed individuals, and those with a recent hospitalization or antibiotic use within the past month. For patients with a CrCl of 10 to 30 mL/min or less than 10 mL/min, the recommended dose is 250 to 500 mg every 12 hours and 250 to 500 mg every 24 hours, respectively. No dose adjustments are required in hepatic impairment.

Contraindications

Amoxicillin is contraindicated in patients who have a history of an allergic reaction to beta-lactam antibiotics or any component of the formulation (e.g., penicillins, cephalosporins), cholestatic jaundice, or hepatic dysfunction. The ER formulation of amoxicillin–clavulanate has an additional contraindication for use in patients with a CrCl of less than 30 mL/min or those on hemodialysis.

Adverse Events

Diarrhea is the most frequent ADE that patients experience while taking amoxicillin. Other common ADEs include rash or hives, nausea, vomiting, photosensitivity, and vaginal infections.

Interactions

Amoxicillin may increase levels of methotrexate and warfarin and can decrease the effects of mycophenolate and the typhoid vaccine, and therefore, patients should be monitored accordingly. Concurrent use of probenecid and amoxicillin should be avoided as probenecid may increase the levels of amoxicillin. Tetracyclines may reduce the effect of amoxicillin and should also be avoided. Additionally, caution is warranted in patients taking allopurinol because they may have an increased risk of allergic reaction to amoxicillin.

Doxycycline

Mechanism of Action

Doxycycline (Oracea, Vibramycin), a tetracycline antibiotic, binds with the 30S and possibly the 50S ribosomal subunit(s) of the bacteria, which inhibits protein synthesis resulting in bacteriostatic effects.

Dosage

Doxycycline has an off-label use to treat ABRS at a dose of 200 mg daily in one to two divided doses for adults and children older than 8 years of age and weighing greater than 45 kg. It is available in 50-, 75-, 100-, or 150-mg capsules or tablets; 40-mg delayed-release capsules; and 25 or 50 mg/5 mL suspensions. In children older than 8 years of age weighing less than or equal to 45 kg, the dose is 2 to 5 mg/kg/d in one to two divided doses. Doxycycline is not recommended for children 8 years and younger. No dose adjustments are necessary in hepatic or renal impairment.

Contraindications

The only contraindication is a hypersensitivity to tetracyclines or any component of the formulation.

Adverse Events

Although GI ADEs such as nausea, vomiting, diarrhea, and abdominal pain are common ADEs of doxycycline, diarrhea occurs less frequently than with amoxicillin. Other common ADEs include vaginal infections, headache, and rash. Stevens-Johnson syndrome and hepatotoxicity are rare but serious ADEs associated with doxycycline.

Interactions

Antacids, lanthanum, bismuth subsalicylate, sucralfate, bile acid sequestrants, calcium, multivitamins, and quinapril can lower the absorption or concentration of tetracyclines and should be given 2 hours prior or 6 hours after doxycycline. Iron salts may decrease the levels of doxycycline and vice versa, so therapy can be modified to ferrous gluconate, which does not have this interaction. The following medications should be used with caution because of their effect on reducing doxycycline levels: barbiturates, carbamazepine, fosphenytoin, phenytoin, and rifampin. Doxycycline should be avoided in patients on retinoic acid derivatives due to increased risk of ADEs and toxicity as well as neuromuscular blocking agents due to enhanced neuromuscular blocking effects. Furthermore, chronic alcohol consumption and food or milk reduce the serum levels of doxycycline. Patients on warfarin should be monitored closely while on tetracyclines as they may increase the risk of bleeding.

Levofloxacin and Moxifloxacin

Mechanism of Action

Fluoroquinolone antibiotics such as levofloxacin (Levaquin) and moxifloxacin (Avelox) inhibit topoisomerase IV and DNA gyrase, which are essential enzymes that maintain the superhelical structure of DNA and are required for DNA replication and transcription, repair, recombination, and transposition.

Dosage

Levofloxacin is available in the following oral preparations: 25 mg/mL suspension and 250-, 500-, or 750-mg tablets. Recommended dosing of levofloxacin in adults is 500 to 750 mg every 24 hours for 5 to 7 days. Levofloxacin can be used off-label for pediatrics and should be dosed 10 to 20 mg/kg/d every 12 to 24 hours. Patients with a CrCl of 20 to 49 mL/min should be prescribed a 500-mg loading dose followed by 250 mg every 24 hours or 750 mg every 48 hours. Patients with a CrCl of 10 to 19 mL/min or on hemodialysis should be prescribed a 500-mg loading dose followed by 250 mg every 48 hours or a loading dose of 750 mg followed by 500 mg every 48 hours. Hepatic dosing adjustments are not required. Moxifloxacin is recommended for adults at a dose of 400 mg every 24 hours and should not be used in children. It is available in the following oral formulations: 400 mg/250 mL solution or 400-mg tablet.

Contraindications

The only contraindication is a hypersensitivity to quinolones or any component of the formulation.

Adverse Events

The most common ADEs with fluoroquinolones are GI disturbances such as nausea, diarrhea, constipation, abdominal pain, vomiting, and dyspepsia. Less common ADEs such as rash, headache, chest pain, decreased blood glucose, edema, photosensitivity, and vaginal infections can occur. A rare but serious ADE of fluoroquinolones involves exacerbations of myasthenia gravis; therefore, this medication should be avoided in patients with this disease. Fluoroquinolones also have a black box warning for tendon inflammation and rupture, so they should be avoided in patients older than 60 years of age, who are taking concurrent corticosteroids, or have had a solid organ transplant.

Interactions

Antacids, lanthanum, sucralfate, calcium, sevelamer, didanosine, multivitamins, quinapril, and magnesium, iron, and zinc salts can lower the absorption or concentration of fluoroquinolones and should be given 2 hours prior or 6 hours after doxycycline.

Fluoroquinolones may also prolong the QTc interval; therefore, caution should be used with other medications that can prolong the QTc interval. Fluoroquinolones can also interact with antidiabetic agents resulting in poor blood glucose control. The use of corticosteroids and fluoroquinolones is not recommended due to the increased risk of ruptured Achilles tendon. Patients on warfarin should be monitored closely while on fluoroquinolones as they may increase the risk of bleeding.

Clindamycin

Mechanism of Action

Clindamycin (Cleocin), a lincosamide antibiotic, reversibly binds to 50S ribosomal subunits preventing the formation of a peptide bond, which in turn inhibits bacterial protein synthesis. Depending upon drug concentration, infection site, and organism, this action results in bacteriostatic or bactericidal effects.

Dosage

Since the use of clindamycin is only recommended in pediatric patients after failing initial therapy or in those with an increased risk of antibiotic resistance, only pediatric dosing will be discussed. Clindamycin is available in 75- or 150-mg oral capsules and 75 mg/5 mL solution and should be dosed at 30 to 40 mg/kg/d divided every 8 hours. Clindamycin is only recommended with concomitant use of cefpodoxime or cefixime for 10 to 14 days (Chow et al., 2012).

Contraindications

The only contraindication is a hypersensitivity to lincosamide antibiotics or any component of the formulation.

Adverse Events

Common ADEs include diarrhea, nausea, vomiting, and abdominal pain.

Interactions

Lincosamide antibiotics may enhance the neuromuscular-blocking effects of neuromuscular-blocking agents and should be avoided.

Cefpodoxime and Cefixime

Mechanism of Action

Cefpodoxime (Vantin) and cefixime (Suprax), third-generation cephalosporin antibiotics, inhibit synthesis of the bacterial cell wall by binding to one or more of the penicillin-binding proteins, causing the bacteria to lyse.

Dosage

Since the use of third-generation cephalosporins is only recommended in pediatric patients after failing initial therapy or in those with an increased risk of antibiotic resistance, only pediatric dosing will be discussed. Recommended dosing of cefpodoxime for children older than 2 months but less than 12 years of age is 5 mg/kg/d and 200 mg every 12 hours for children 12 years and older. Cefpodoxime is available in 50 or 100 mg/5 mL suspensions or 100- or 200-mg oral tablets. Recommended dosing of cefixime for children older than 6 months but less than 12 years of age is 8 mg/kg/d divided every 12 hours and 400 mg divided every 12 to 24 hours for children 12 years and older. Cefixime is available in 400-mg oral capsules and tablets, 100- or 200-mg chewable tablets, as well as in 100, 200, and 500 mg/5 mL suspensions. Both agents must be used in combination with clindamycin for 10 to 14 days (Chow et al., 2012).

Contraindications

The only contraindication is a hypersensitivity to cephalosporins or any component of the formulation.

Adverse Events

Diaper rash and diarrhea are the most common ADEs associated with third-generation cephalosporins. Other common ADEs include nausea, vomiting, abdominal pain, and headache.

Interactions

Cephalosporins may increase the nephrotoxic effect of aminoglycosides and should be monitored with concurrent use. Antacids and histamine-2 receptor antagonists may decrease the absorption of cephalosporins and therefore their dosing should be separated by 2 hours. Additionally, effects of warfarin may be enhanced when taken concurrently with cephalosporins, so patients should be monitored more carefully.

Symptomatic Therapy

Nonpharmacologic therapies include the following: adequate rest and hydration, elevating the head of the bed while sleeping, use of a humidifier, and avoidance of environmental factors such as allergens, cigarette smoke, and pollution (Peters et al., 2014). Unlike the common cold, topical or oral decongestants or antihistamines should not be used as adjunctive treatment in ABRS (Chow et al., 2012). Intranasal corticosteroids are recommended as adjunctive treatment, particularly in patients with a history of allergic rhinitis (see Chapter 48) (Chow et al., 2012). Even though there is minimal clinical evidence supporting the benefit of nasal lavage in rhinosinusitis to improve ciliary function and reduce inflammation, it is a generally recommended treatment strategy. Surgical intervention is to be avoided in ARS and should be individualized in patients with CRS. A lack of randomized controlled trials has resulted in the absence of a gold standard technique (Anselmo-Lima & Sakana, 2015).

Selecting the Most Appropriate Agent

Due to the increasing levels of antimicrobial resistance worldwide, clinicians must re-evaluate their approaches to treating ARS by using evidence-based methods of diagnosis and treatment. As mentioned previously, it is imperative to differentiate AVRS from ABRS. When ABRS pathogen is suspected or diagnosed, antibiotics may not always be the optimal choice; therefore, patients need to be educated regarding the appropriate initial treatment regimens. When prescribing antibiotics, the provider should consider cost, formulation, whether the patient is at risk for resistant bacteria (Box 24.2), and if the patient can be compliant with the selected regimen.

BOX 24.2 Risk Factors for Antibiotic Resistance

- Age <2 or >65
- Child in daycare
- Prior antibiotics in the past month
- Comorbidities
- Immunocompromised

First-Line Therapy

Amoxicillin–clavulanate is preferred over amoxicillin for ABRS in adults and children. For penicillin-allergic adults, doxycycline, levofloxacin, or moxifloxacin should be used. Levofloxacin is the antibiotic of choice in children with a penicillin allergy.

Second-Line Therapy

Second-line agents for patients include doxycycline (not recommended for most children), levofloxacin, or moxifloxacin. Combination therapy with clindamycin and a third-generation oral cephalosporin such as cefixime or cefpodoxime is an alternative treatment for children with a penicillin allergy.

Monitoring Patient Response

Patients should notice relief within 48 to 72 hours. If there is no relief of symptoms in 3 to 5 days or symptoms worsen after 48 to 72 hours of treatment, an alternative antibiotic should be selected. It is recommended that patients who fail to respond to first- or second-line treatment should have cultures collected via direct sinus aspiration rather than nasopharyngeal swab. Alternatively, endoscopically guided cultures of the middle meatus could be taken in adults; however, the integrity of this option in pediatric patients has not been established. CT, which is preferred over magnetic resonance imaging, may also be necessary to investigate noninfectious causes (Chow et al., 2012). Once an uncomplicated episode of ARS resolves, there is no further evaluation required (Peters et al., 2014).

Patient Education

The role of the practitioner is to make the patient aware not only of appropriate symptom management but also of prevention. It is essential that patients understand that symptoms of viral and bacterial URIs are similar, that viral URIs and allergies are more prevalent than bacterial URIs, and that antibiotics are not appropriate to treat viral URIs. Education about the importance of completing the full course of antibiotics, should they be prescribed, despite symptoms subsiding in 48 to 72 hours is also imperative. The patient also needs to know how to recognize and respond to ADEs of antibiotic therapy, especially because allergic reactions are more prevalent with these drugs than other drug classes.

Education needs to begin before cold and flu season so that patients can take steps to prevent disease and to make educated decisions on whether a health care visit is needed or whether the symptoms are likely to be self-limiting. Progress toward the development of vaccines to prevent viral URIs has been difficult due to the abundance of existing viral serotypes (Jacobs et al., 2013). Approved prophylactic antiviral therapies do not currently exist; therefore, prevention consists of behavioral modifications.

Drug Information

The ACCP published an evidence-based clinical practice guideline on cough and the common cold (Irwin et al., 2006). The National Institute for Health and Clinical Excellence (NICE) published a guideline using evidence from randomized placebo-controlled trials in 2008 regarding the prescribing of antibiotics for self-limiting respiratory tract infections in adults and children in primary care (Centre for Clinical Practice, 2008). This document describes evidence from randomized placebo-controlled trials that demonstrate the limited efficacy of antibiotics in the treatment of most respiratory tract infections, including acute otitis media (AOM), acute cough/ bronchitis, acute sore throat/pharyngitis/tonsillitis, ARS, and the common cold. In 2012, the Infectious Disease Society of America published a Clinical Practice Guideline for Acute Bacterial Rhinosinusitis in Children and Adults (Chow et al., 2012). Additionally in 2012, there was a European Position Paper on Rhinosinusitis and Nasal Polyps (Fokkens et al., 2012). A common theme found in all of these guidelines was to use caution regarding the inappropriate prescribing of antibiotics, which may contribute to drug-related adverse events and an increase in antibiotic-resistant organisms.

Patient-Oriented Information Sources

The American Academy of Family Physicians, American Rhinologic Society, Cleveland Clinic, Mayo Clinic, and Centers for Disease Control and Prevention are organizations that provide patient-oriented information on their Web sites. Another helpful Web site for patient-oriented information resources is www.medicine.net.

Lifestyle Changes

The most important aspect of patient education is to prevent contraction of the virus by practicing good hygiene, such as frequent hand washing, getting adequate sleep and exercise, and avoiding contact with infected people. One study found hand sanitizers containing ethanol to be significantly more effective than hand washing with soap and water (Turner et al., 2010). It is important to consider that hand washing by any method is effective, even without antiseptic. Social distancing can involve avoidance of crowded public spaces or the temporary closing of schools or day cares. Since these strategies can be difficult to execute, utilization of surgical respiratory masks may be a more feasible approach, particularly in health care settings. Another important aspect of patient education is teaching patients to prevent spreading the virus through correct tissue disposal, hand washing, covering the mouth when coughing, and so on.

For persons prone to ARS, it may be uncomfortable to swim in pools treated with chlorine, because it irritates the lining of the nose and sinuses. Divers often get sinus congestion and infection when water is forced into the sinuses from the nasal passages. Air travel may also pose a problem for persons with ARS or CRS. As the air pressure in a plane is reduced, pressure can build up in the head, blocking sinuses or eustachian tubes. The patient may feel discomfort in the sinus or middle ear during ascent or descent of the airplane.

Alternative Therapies

There is a growing interest in alternative or complementary therapies for treating the common cold. A review of complementary and alternative medicine for the prevention and treatment of the common cold was published in *Canadian Family Physician* in 2011 (Nahas & Balla, 2011). *Echinacea angustifolia*, *Echinacea pallida*, and *Echinacea purpurea* have all been studied, but *E. purpurea* is associated with the most evidence. These products have been investigated for their effects in increasing and enhancing many immune processes, including macrophage activation, cytokine production, phagocytosis, natural killer cell activity, lymphocyte and monocyte production, and antibody response. Among conducted studies, there is a high degree of variability in the species, plant parts, and method of extraction that have been used. Therefore, despite a moderate level of evidence supporting the use of *E. purpurea* for the treatment of the common cold, it is challenging to recommend specific product formulations or doses. The use of these products for the prevention of cold symptoms has not shown benefit. *Echinacea* products are available in a variety of preparations, including a crude extract at a daily dose of 2,000 to 3,000 mg, a pressed juice at a daily dose of 6 to 9 mL, and a tincture at a daily dose of 0.75 to 1.5 mL. Use should be avoided in patients who are allergic to *Echinacea* or members of the Asteraceae or Compositae families, including chrysanthemums, daisies, marigolds, and ragweed. Caution should also be used in patients with asthma and seasonal allergies, as they may have a higher risk of experiencing allergic reactions. Adverse effects include hives, rash, itching, GI upset, and headache. There are no known drug interactions.

Panax ginseng (Asian ginseng) and *Panax quinquefolius* (North American ginseng) have been studied for the stimulation of macrophages, natural killer cells, and lymphocytes, as well as for increased production of cytokines and antibodies. Data to support the use of ginseng for the prevention or treatment of the common cold are limited and conflicting; therefore, use of these products is not recommended. Side effects include headache, GI upset, anxiety, and insomnia. Drug interactions include phenelzine, involving the induction of mania; warfarin, involving an increase in international normalized ratio (INR); and alcohol, involving increased blood clearance. These products should not be used by pregnant or breast-feeding patients, due to the risk of estrogenic effects and teratogenicity.

Vitamin C has been a focus of several studies related to the common cold, due to its antioxidant properties, its impact on glutathione regeneration, and its theoretical ability to activate neutrophils and monocytes. Studies have implemented a wide range of doses and have explored the use of this product in both the prevention and treatment of the common cold. An interesting finding involves the potential reduction of colds in study participants who were exposed to subarctic cold or intense physical activity. Patients taking doses of 200 to 2,000 mg daily of vitamin C had half as many colds as those taking placebo, according to a small group of trials studying a total of 642 patients (Nahas & Balla, 2011). Based on the review of many studies, vitamin C can be recommended at a dose of at least 1 g/d for

the prevention of colds and may also reduce the duration of symptoms by 1 to 2 days.

Allium sativum, or allicin, is found in garlic and is activated upon chopping or chewing. It is inactivated when cooked. It has been studied for its antiviral properties against HRVs. Evidence supporting the use of this product for the prevention of the common cold is limited, but it can be recommended at a dose of 180 mg of allicin. The use of fresh garlic is not reasonable, as each clove contains approximately 5 to 9 mg of allicin. Odor-free formulations are ineffective, as these do not contain allicin. The most common ADE is malodorous belching. Evidence does not support the use of this product for treatment.

Probiotics have been investigated for their role in the improvement of mucosal barrier function, GI microflora, and gut-associated lymphoid tissue. They may also interfere with toxin and cell binding sites. Current literature does not support the use of these products for the prevention or treatment of the common cold.

Several trials have studied zinc, due to a proposed mechanism involving the interference with rhinovirus protein cleavage or the disruption of capsid binding to adhesion molecules in the epithelium of the nasal passageways. Results have been variable, but several studies have demonstrated the potential for these products to shorten the duration and severity of cold symptoms. The difficulty exists in selecting the appropriate dose and proper formulation. Lozenges that contain at least 13 mg of elemental zinc can be recommended for use every 2 hours at the immediate onset of cold symptoms. ADEs include bitter taste and nausea. Intranasal zinc should not be used due to its potential association with anosmia. Use of zinc for 6 to 8 weeks may contribute to copper deficiency.

In ARS and CRS, complementary or alternative medicines have also been considerably utilized. Similarly to the common cold, evidence-based recommendations are difficult to suggest due to the scarcity of randomized controlled trials. One study that included 102 patients with ARS examined the use of *Pelargonium sidoides* (*P. sidoides*) extract, a common root plant from South Africa. This study concluded that *P. sidoides* may be effective in relieving symptoms; however, some doubt exists because of a poor quality of evidence (Fokkens et al., 2012).

Myrtol, an essential oil derived from pine, lime, and eucalyptus, showed a statistically significant difference in the improvement of sinusitis symptom scores and reduced the need for an antibiotic after treatment with myrtol (Fokkens et al., 2012).

Case Study*

J.M. is a 45-year-old female with past medical history of controlled hypertension, controlled asthma, and eczema. She has a 4-day history of nasal congestion, headache, sore throat, sneezing, and productive cough. She denies fever, nausea, vomiting, and myalgias. She has three children who recently went back to school following a summer vacation. No one else in her household is currently presenting with similar symptoms. She

has no known drug allergies but is allergic to mums and ragweed. She calls her primary care provider's office requesting a medication to treat her illness.

She takes several medications, including the following:

- Mometasone 220 mcg—1 puff daily for asthma
- Albuterol 90 mcg—1 to 2 puffs q4–6 hours as needed for shortness of breath
- Lisinopril 10 mg—one tablet by mouth daily for hypertension
- Oxymetazoline hydrochloride 0.05% nasal spray—2 sprays per nostril bid × 3 days

1. Which of the following is the MOST appropriate drug to recommend?
   a. Oxymetazoline hydrochloride 0.05% nasal spray—2 sprays per nostril bid until symptoms resolve
   b. Naproxen 220 mg—one tablet by mouth every 12 hours as needed until symptoms resolve
   c. Dextromethorphan ER oral liquid—60 mg every 12 hours until symptoms resolve
   d. Amoxicillin–clavulanic acid 500 mg every 8 hours for 7 days

2. Which of the following nonpharmacological therapies is NOT recommended?
   a. Steam inhalation
   b. Increased water intake
   c. Menthol lozenges
   d. Saline gargle

3. J.M. is insistent on taking a complementary therapy to help treat her symptoms. What is the MOST appropriate recommendation?
   a. *Echinacea purpurea* tincture—0.75 mL
   b. Fresh garlic—3 cloves
   c. Acidophilus probiotic—1 tablet daily
   d. Vitamin C—1 g

25 Asthma

Karen J. Tietze

Approximately 25.7 million people in the United States have asthma, with a prevalence of 9.5% and 7.7% in children 0 to 17 years and adults 18+ years, respectively (Moorman et al., 2012). Asthma is more common in persons below 100% of the federal poverty rate and in persons living in the northeast United States (Moorman et al., 2012). Asthma prevalence is greater in blacks than in whites (11.2% vs. 7.7%), in boys than in girls (11.1% vs. 7.8%), and in women than in men (9.7% vs. 5.7%) (Moorman et al., 2012). In 2009, asthma accounted for 10.6 million office visits, 2.1 million emergency department visits, and 479,300 hospitalizations (Moorman et al., 2012). The cost of asthma in the United States is approximately $56 billion per year (Centers for Disease Control and Prevention [CDC], 2013b). The noneconomic costs of asthma are high. Nine persons with asthma die from asthma every day and nearly one in three adults and one in two children miss 1 day or more of work or school for asthma-related reasons (CDC, 2013b).

The current National Asthma Education and Prevention Program (NAEPP) guidelines for the diagnosis and management of asthma were released in 2007 (NAEPP, 2007). The guidelines, originally developed in 1997 by an expert panel commissioned by the NAEPP Coordinating Committee of the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH), were updated in 2002 and 2007. The 1993 Global Initiative for Asthma (GINA) Global Strategy for Asthma Management and Prevention report, an international collaboration of the NHLBI and the World Health Organization, is updated annually (GINA, 2014).

Causes

Asthma is a heterogeneous chronic inflammatory medical condition of unknown etiology. The hygiene hypothesis theorizes that a lack of exposure to a variety of microbiological agents at a young age creates a predominant T helper cell type-2 (Th2) lymphocyte immune response that is associated with allergy (Brown et al., 2013). Some genetic associations have been identified. For example, although there is no single "asthma gene," more than 100 single nucleotide polymorphisms (SNPs) of the gene that encodes the ADAM metallopeptidase domain 33 gene (ADAM33) have been identified. Smooth muscle, fibroblasts, and myofibroblasts express ADAM-related proteins with a variety of signaling, adhesion, and fusion functions that influence the epithelial–mesenchymal unit (EMTU). Additionally, more than 25 polymorphic genes expressed in the EMTU have been identified.

Common asthma phenotypes include allergic asthma, nonallergic asthma, late-onset asthma, asthma with fixed airflow limitation, and asthma with obesity. Symptom triggers include upper respiratory tract viral infections, allergens, exercise, changes in the weather, laughter, exposure to inhaled irritants (e.g., smoke, vehicle exhaust fumes, strong smells), gastroesophageal reflux disease (GERD), aspirin (in individuals sensitive to aspirin), stress, and exposure to sulfites. Hormonal changes during a woman's menstrual cycle or during pregnancy may trigger or worsen asthma symptoms.

Pathophysiology

Asthma is characterized by airway narrowing and airway hyperresponsiveness. The chronic airway inflammation and structural airway changes characteristic of asthma are the result of interactions between the activated EMTU and inflammatory mediators (Holgate, 2008). Key cellular mediators include chemokines, cysteinyl leukotrienes, cytokines, histamine, nitric oxide, and prostaglandins. Sources of these mediators include airway epithelial cells, mast cells, eosinophils, and T lymphocytes. In the presence of these cellular mediators, airway smooth muscle cells proliferate, hypertrophy, and express inflammatory proteins; endothelial cells recruit circulatory inflammatory cells; and fibroblasts and myofibroblasts produce collagens and proteoglycans (components of connective tissue). Cellular mediators activate airway cholinergic nerves causing bronchoconstriction and mucous secretion and airway sensory nerves causing cough and the sensation of chest tightness.

Chronic airway structural changes, including subepithelial fibrosis, increased airway smooth muscle, increased airway wall blood vessels, increased airway epithelium goblet cells, and submucosal gland hypertrophy, are the result of airway inflammation and other mechanisms independent of airway inflammation. The airways narrow as a result of airway smooth muscle contraction, airway edema, airway wall thickening from structural changes, and mucus plugging. Airway hyperresponsiveness is caused by excessive airway smooth muscle contraction, airway wall thickening, and sensory nerve stimulation.

Diagnostic Criteria

The diagnosis of asthma is based on the presence of symptoms consistent with asthma and the presence of variable airflow limitation. Typical asthma symptoms include wheeze, shortness of breath, cough, and chest tightness. These symptoms are not exclusive to asthma; persons with a variety of upper and lower respiratory tract (e.g., inhaled foreign body, vocal cord dysfunction, bronchopulmonary dysplasia, cystic fibrosis, chronic obstructive pulmonary disease) and cardiovascular (e.g., pulmonary emboli, heart failure) medical conditions have the same symptoms. Asthma symptoms and symptom severity are variable. Persons with asthma may be symptom free for short or prolonged periods of time. Symptom intensity varies from mild to severe; symptoms typically worsen at night or early morning, often waking the patient.

The physical examination is nonspecific and may be normal. Wheezing may be absent or range from soft end-expiratory wheezing to loud inspiratory and expiratory wheezing; the chest may be silent during a severe exacerbation. Nasal polyps or signs of allergic rhinitis or other atopic medical conditions such as eczema may be present. Persons with a severe asthma exacerbation may present with hunched shoulders, a preference for sitting upright, cyanosis, use of accessory respiratory muscles (abdominal, sternocleidomastoid), elevated or decreased blood pressure, tachycardia or bradycardia, tachypnea or bradypnea, an inability to speak in full sentences, and anxiety.

Spirometry measures lung volumes during a forced maximal exhalation. Airflow limitation is assessed using the forced expiratory volume in the first second (FEV_1), the total volume of exhaled air (forced vital capacity, FVC), and the FEV_1/FVC ratio. Airflow obstruction is present when the FEV_1/FVC is less than 0.70. Bronchoprovocation testing with methacholine or histamine may be performed in patients with suspected asthma who have normal baseline airflow. The current NAEPP guidelines categorize asthma severity in children older than 4 years of age and adults according to nonspirometric and spirometric criteria (Tables 25.1 and 25.2). Children 0 to 4 years of age are classified according to nonspirometric criteria (Table 25.3). A reduced peak expiratory flow (PEF) is consistent with airway obstruction but is not diagnostic of asthma. PEF is commonly used for self-monitoring and assessment of airway obstruction reversibility following inhalation of a short-acting bronchodilator. Spirometry is performed at baseline (prior to starting treatment), after 3 to 6 months of treatment, then repeated annually or more frequently if indicated.

TABLE 25.1 Asthma Severity—Chronic Disease Classification (Age 12 Years and Older)

	Intermittent	Mild Persistent	Moderate Persistent	Severe Persistent
Severity Components	**Step 1**	**Step 2**	**Step 3 and Step 4**	**Step 5 and Step 6**
Symptoms	2 or fewer days per week	More than 2 days per week but not daily	Daily	Throughout the day
Nighttime awakenings	2 or fewer nights per month	3 to 4 nights per month	More than 1 night per week but not nightly	Often 7 nights per week
Short-acting $beta_2$-adrenergic agonist use for symptom control	2 or fewer days per week	More than 2 days per week but not more than one time per day	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Exacerbations requiring systemic corticosteroids	0–1 per year	2 or more per year	2 or more per year	2 or more per year
Lung function Normal FEV_1/FVC: 8–19 y: 85% 20–39 y: 75% 40–59 y: 75% 60–80 y: 70%	Normal FEV_1 between exacerbations $FEV_1 \geq 80\%$ predicted FEV_1/FVC normal	$FEV_1 \geq 80\%$ predicted FEV_1/FVC normal	$FEV_1 > 60\%$ but $< 80\%$ predicted FEV_1/FVC reduced 5%	$FEV_1 < 60\%$ predicted FEV_1/FVC reduced > 5%

Severity is determined by the most severe category for any feature. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity. From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health. 2007 *Expert Panel Report III: Guidelines for the diagnosis and management of asthma*. TABLE 25.3 Asthma Severity—Chronic Disease Classification (Children 0 to 4 Years of Age)

Severity Components	Intermittent	Mild Persistent	Moderate Persistent	Severe Persistent
Symptoms	2 or fewer days per week	More than 2 days per week but not daily	Daily	Throughout the day
Nighttime awakenings	0	1 to 2 nights per month	3–4 nights per month	More than 1 night per week
Short-acting $beta_2$-adrenergic agonist use for symptom control	2 or fewer days per week	More than 2 days per week but not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Exacerbations requiring systemic corticosteroids	0 to 1 per year	≥2 in 6 mo or ≥4 wheezing episodes per 1 y lasting >1 day AND risk factors for persistent asthma		

Severity is determined by the most severe category for any feature. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity. From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health. 2007 *Expert Panel Report III: Guidelines for the diagnosis and management of asthma*. Bethesda, MD: U.S. Department of Health and Human Services. Originally published July 2007. Revised 2002, August 2007. NIH Publication No. 07-4051. Retrieved from http://www.nhlbi.nih.gov/files/docs/guidelines/asthgdln.pdf

Airflow obstruction reversibility, an important parameter for the diagnosis of asthma, is documented by comparing baseline FEV_1 to postbronchodilator FEV_1 10 to 15 minutes following the administration of 2 to 4 puffs of a short-acting beta-adrenergic drug. The NAEPP guidelines define airflow obstruction reversibility as an increase in FEV_1 of at least 12% and an absolute increase in FEV_1 of at least 200 mL (NAEPP, 2007).

Initiating Drug Therapy

Drug therapy is initiated according to the age-specific NAEPP chronic disease recommendations (Tables 25.4 to 25.6). All persons with asthma, regardless of the severity of asthma, require a short-acting beta$_2$-adrenergic agonist (SABA) bronchodilator for quick relief of acute symptoms. Long-term control medication is added according to the severity of disease. The GINA guidelines recommend reassessing 1 to 3 months after starting treatment and then every 3 to 12 months (GINA, 2015).

TABLE 25.4 Asthma Control Assessment

	Well Controlled	Not Well Controlled	Very Poorly Controlled
Symptoms	2 or fewer days per week	More than 2 days per week	Throughout the day
Nighttime awakenings	2 or fewer nights per month	1 to 3 nights per week	4 or more nights per week
Interference with normal activities	None	Some limitations	Extremely limited
Short-acting beta$_2$-adrenergic agonist use for symptom control	2 or fewer days per week	More than 2 days per week	Several times per day
FEV$_1$ or PEF	>80% predicted or personal best	60%–80% predicted or personal best	<60% predicted or personal best
Validated questionnaire	ATAQ™ 0 ACT™ ≥ 20	ATAQ™ 1–2 ACT™ 16–19	ATAQ™ 3–4 ACT™ ≤ 15
Exacerbations	0 to 1 per year	≥2 per year	≥2 per year
Recommended action*	• Maintain current step • Regular follow-up every 1–6 mo • Consider stepping down if well controlled for at least 3 mo	• Step up one step • Reevaluate in 2–6 weeks	• Consider short-course oral CS • Step up 1–2 steps • Reevaluate in 2 weeks

*If medication-related side effects, consider alternate treatment options. From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health. 2007 *Expert Panel Report III: Guidelines for the diagnosis and management of asthma*. SABA, inhaled short-acting beta$_2$ agonist; ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$ agonist; CS, corticosteroid. From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health. 2007 *Expert Panel Report III: Guidelines for the diagnosis and management of asthma*. Bethesda, MD: U.S. Department of Health and Human Services. Originally published July 2007. Revised 2002, August 2007. NIH Publication No. 07-4051. Retrieved from http://www.nhlbi.nih.gov/files/docs/guidelines/asthgdln.pdf

Treatment can be stepped down to a less intensive regimen if asthma symptoms have been well controlled for 3 months. Stepping down treatment is done systematically with close monitoring of asthma control. Oral corticosteroids are reduced and then discontinued first. The dose of inhaled corticosteroid (ICS) may then be reduced by 50%. Further reductions in therapy can be made by reducing the dose of the ICS/long-acting bronchodilator regimen to once daily. The long-term control regimen may be stopped if the person with asthma has been free of symptoms for 6 to 12 months and has no risk factors for exacerbations (GINA, 2015).

Treatment is stepped up if persons with asthma are not well controlled despite 2 to 3 months of treatment with long-term control medication. Medication adherence, inhaler drug delivery technique, environmental exposures, and concurrent medications must be assessed and any issues addressed before stepping up to a more intensive medication regimen. Alternate treatment should be stopped and the preferred treatment regimen tried before stepping up therapy.

Goals of Drug Therapy

The NAEPP goals of asthma therapy are to reduce impairment and reduce risk (NAEPP, 2007). Impairment may be reduced by preventing chronic and/or problematic symptoms and maintaining near "normal" pulmonary function. The patient and family should be satisfied and their expectations met. Indicators of reduced impairment include the ability to maintain normal activities (e.g., work, school) and the infrequent use (2 days or fewer per week) of short-acting "rescue" bronchodilators.

Asthma control and the presence of risk factors for exacerbations should be assessed and documented during each patient encounter (NAEPP, 2007). The NAEPP levels of asthma control include well controlled, not well controlled, and very poorly controlled (Table 25.7). Assessment of the level of control over the previous 2 to 4 weeks is based on information from the patient, including self-assessment using validated questionnaires, pulmonary function (FEV_1 or PEF), and the number of asthma exacerbations in the preceding year. The two self-assessment questionnaires incorporated in the NAEPP asthma control assessment include the Asthma Therapy Assessment Questionnaire™ (ATAQ) and the Asthma Control Test™ (ACT); age-appropriate versions are available. The ATAQ™ consists of four questions with a maximum score of 4 points; a score of 3 to 4 points indicates very poorly controlled asthma. The ACT™ consists of five questions with a maximum score of 25 points; a score of 19 points or less indicates asthma is not as controlled as it could be.

SABA, inhaled short-acting beta$_2$ agonist; ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$ agonist; CS, corticosteroid. From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health. 2007 *Expert Panel Report III: Guidelines for the diagnosis and management of asthma*. Bethesda, MD: U.S. Department of Health and Human Services. Originally published July 2007. Revised 2002, August 2007. NIH Publication No. 07-4051. Retrieved from http://www.nhlbi.nih.gov/files/docs/guidelines/asthgdln.pdf

Risk may be reduced by preventing exacerbations and optimizing drug therapy. The presence of one or more of the following factors increases the risk for an asthma exacerbation (GINA, 2015):

- Uncontrolled asthma symptoms
- Use of more than one 200-dose short-acting bronchodilator canisters per month
- Inadequate ICS
- Low FEV_1, especially if less than 60% of predicted
- Important psychological or socioeconomic problems
- Inhaled irritant exposures (e.g., smoke, allergens)
- Comorbidities that trigger and/or worsen asthma (e.g., rhinosinusitis, allergies, obesity)
- Eosinophilia
- Pregnancy
- History of one or more asthma exacerbations in the last 12 months
- History of intubation or intensive care unit admission for asthma

Risks for developing fixed airflow obstruction include chronic exposure to inhaled irritants (e.g., tobacco smoke, chemicals), lack of treatment with ICS, a low FEV_1 at the time of diagnosis, chronic mucus hypersecretion, sputum eosinophilia, and blood eosinophilia. Risks for medication-related adverse effects include a prior history of allergy or adverse reaction to a similar medication, addition of medications that interact with asthma medications, and altered hepatic or renal function from concurrent medical conditions or advanced age.

Drugs used to treat asthma include $beta_2$-adrenergic agonists, corticosteroids, leukotriene modifiers, mast cell stabilizers, methylxanthines, and monoclonal antibodies (Table 25.8).

TABLE 25.8 Overview of Selected Agents Used to Treat Asthma

Generic (Trade) Name and Adult Dosage	Selected Adverse Events	Contraindications	Special Considerations
Short-Acting Beta$_2$-Adrenergic Agonists			
albuterol (Proventil HFA, Ventolin HFA, ProAir HFA) MDI 90 mcg/inhalation; 1–2 inhalations q4–q6 h as needed albuterol (ProAir) DPI 117 mcg/inhalation 1–2 inhalations q4–q6 h as needed albuterol (Accuneb) 0.083% (2.5 mg/3 mL), 0.5% (2.5 mg/0.5 mL) solution for nebulization; 2.5 mg three to four times a day as needed	Tachycardia, skeletal muscle tremor, nervousness, dizziness, hypokalemia, hyperglycemia	Hypersensitivity to beta$_2$-adrenergic agonists Hypersensitivity to lactose or milk proteins (dry powder formulations; product specific)	Fewer systemic effects with inhaled therapy Use with caution in patients with cardiovascular disease, diabetes mellitus, glaucoma, hyperthyroidism, or seizure disorders Beta-adrenergic blockers diminish the bronchodilator effects Concurrent sympathomimetic drugs, monoamine oxidase inhibitors, or tricyclic antidepressants enhance the risk of adverse effects
Inhaled Corticosteroids			
beclomethasone aerosol for inhalation 40 mcg/inhalation and 80 mcg/inhalation (Qvar) budesonide aerosol powder 90 mcg/actuation and 180 mcg/actuation; suspension 0.25 mg/2 mL, 0.5 mg/2 mL, 1 mg/2 mL (Pulmicort) ciclesonide aerosol solution for inhalation 80 mcg/actuation and 160 mcg/actuation (Alvesco)	Oral candidiasis, hoarseness	Hypersensitivity to corticosteroids Hypersensitivity to lactose or milk proteins (dry powder formulations; product specific)	Dosage depends on asthma severity, prior use of bronchodilators, inhaled corticosteroids, and oral corticosteroids Dosing interval depends on specific product: beclomethasone, budesonide, and ciclesonide are given twice daily; fluticasone and mometasone may be given daily or twice daily depending on the dosage formulation and prior history
Generic (Trade) Name and Adult Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
fluticasone aerosol for inhalation (as propionate) 44 mcg/actuation, 110 mcg/actuation, and 220 mcg/actuation (Flovent HFA); aerosol powder for inhalation (as furoate) 100 mcg/actuation and 200 mcg/actuation (Arnuity Ellipta); aerosol powder for inhalation (as propionate) 50 mcg/blister, 100 mcg/blister, 250 mcg/blister (Flovent Diskus) mometasone aerosol for inhalation 100 mcg/inhalation and 200 mcg/inhalation (Asmanex HFA); aerosol powder for inhalation 110 mcg/inhalation and 220 mcg/inhalation (Asmanex Twisthaler)			Titrate to lowest effective dose once asthma control has been achieved Not for relief of acute bronchospasm Rinse, gargle, and spit after each use to reduce local adverse effects and systemic absorption
Oral Corticosteroids			
	Short-term oral corticosteroids: sodium and water retention, increased appetite and weight gain, central nervous system stimulation and/or nightmares, peptic ulcer, and leukocytosis	Same as above	Adrenal suppression unlikely with short-term therapy
Combination Inhaled Corticosteroids and Long-Acting Beta$_2$-Adrenergic Agonists			
formoterol 4.5 mcg and budesonide 80 mcg per inhalation MDI (Symbicort); 2 inhalations twice daily formoterol 4.5 mcg and budesonide 160 mcg per inhalation MDI (Symbicort); 2 inhalations twice daily formoterol 5 mcg and mometasone 100 mcg MDI (Dulera); 2 inhalations twice daily formoterol 5 mcg and mometasone 200 mcg MDI (Dulera); 2 inhalations twice daily formoterol 5 mcg and mometasone 200 mcg MDI (Dulera); 2 inhalations twice daily salmeterol 21 mcg and fluticasone 45 mcg MDI (Advair HFA); 2 inhalations twice daily salmeterol 21 mcg and fluticasone 115 mcg MDI (Advair HFA); 2 inhalations twice daily salmeterol 21 mcg and fluticasone 230 mcg MDI (Advair HFA); 2 inhalations twice daily salmeterol 50 mcg and fluticasone 100 mcg per inhalation DPI (Advair Diskus); 1 inhalation q12h salmeterol 50 mcg and fluticasone 250 mcg per inhalation DPI (Advair Diskus); 1 inhalation q12h salmeterol 50 mcg and fluticasone 500 mcg per inhalation DPI (Advair Diskus); 1 inhalation q12h	Long-acting beta$_2$ agonists: same as above Inhaled corticosteroids: same as above	Long-acting beta$_2$ agonists: same as above Corticosteroids: same as above	Not for relief of acute bronchospasm Rinse, gargle, and spit after each use to reduce local adverse effects and systemic absorption Long-acting beta$_2$-adrenergic agonists: black box warning for increased risk of death in patients with asthma
Generic (Trade) Name and Adult Dosage	**Selected Adverse Events**	**Contraindications**	**Special Considerations**
vilanterol 25 mcg and fluticasone (as furoate) 100 mcg per inhalation DPI (Breo Ellipta); 1 inhalation q24h vilanterol 25 mcg and fluticasone (as furoate) 200 mcg per inhalation DPI (Breo Ellipta); 1 inhalation q24h			
Leukotriene-Modifying Drugs			
montelukast 10-mg tablets, 4-mg, and 5-mg chewable tablets, 4-mg packet (Singulair); adolescents 15 and older and adults 10 mg daily, children ≥6 y to <15 y 5 mg once daily, children ≥2 y to <6 y 4 mg once daily, children ≥1 y to <2 y 4 mg once daily zafirlukast 10- and 20-mg tablets (Accolate); children ≥12 y of age and adults 20 mg twice daily; children 5–11 y of age 10 mg twice daily zileuton 600 mg IR tablets, 600 mg CR tablets (Zyflo); children ≥12 y of age and adults 600 mg four times daily (IR tablets) or 1,200 mg twice daily (CR tablets)	montelukast, zafirlukast, zileuton: neuropsychiatric events (e.g., sleep disturbances, agitation, anxiety, depression, suicidal thinking) montelukast: headache, fatigue, dyspepsia zafirlukast: headache, hepatotoxicity (rare but serious) zileuton: sinusitis, nausea, pharyngolaryngeal pain, hepatotoxicity (rare but serious)	montelukast, zafirlukast, zileuton: hypersensitivity to the drug or any component of the formulation montelukast 4- and 5- mg chewable tablets contain phenylalanine (a component of aspartame); contraindicated in patients with phenylketonuria. zafirlukast is contraindicated in persons with hepatic impairment including cirrhosis. zileuton is contraindicated in persons with active liver disease or transaminase elevations ≥3 times the upper limit of normal.	Not for relief of acute asthma exacerbations. montelukast is taken once daily in the evening zafirlukast: consider liver function testing; early detection may increase recovery zileuton: obtain baseline liver function tests prior to starting therapy; repeat monthly for 3 mo, every 2–3 mo for 9 mo and then periodically; stop therapy if ALT > 5 times the upper limit of normal; use with caution in persons with a history of liver disease and/or in persons who consume substantial quantities of alcohol
Mast Cell Stabilizers			
cromolyn 20 mg/2 mL solution for nebulization; 20 mg four times daily	Taste disturbances, nausea Anaphylaxis (rare)	Hypersensitivity of cromolyn or any component of the formulation	Not for relief of acute bronchospasm Takes 2–6 weeks for full response to treatment
Methylxanthines			
theophylline extended-release tablets and capsules, elixir (80 mg/15 mL), oral solution (80 mg/15 mL), intravenous solution	Tachyarrhythmias, restlessness, insomnia, seizures, tremor, nausea, vomiting, gastroesophageal reflux, peptic ulcer aggravation	Hypersensitivity to theophylline. Intravenous dosage forms may contain propylene glycol. Oral dosage forms may contain dyes, alcohol, or sugar.	Use with caution in patients with tachyarrhythmias, peptic ulcer disease, seizure disorders, hyperthyroidism Dose to therapeutic theophylline plasma serum concentration (10–20 mg/L)
Monoclonal Antibodies			
omalizumab (Xolair); 150 mg lyophilized powder per vial (delivers 150 mg in 1.4 mL sterile water for injection)	Anaphylaxis, injection site reactions (pain, erythema, burning, stinging)	Hypersensitivity to omalizumab or any component of the formulation	Black box warning for risk of life-threatening anaphylaxis Dose depends on serum IgE and patient weight; dosing interval (every 2 weeks or every 4 weeks) depends on the dose

HFA, hydrofluoroalkane; MDI, metered-dose inhaler; DPI, dry powder inhaler; IR, immediate release; CR, controlled release; ALT, alanine aminotransferase.

Beta2-Adrenergic Agonists

Mechanism of Action

Beta$_2$-adrenergic agonists stimulate beta$_2$-adrenergic receptors, increasing the production of cyclic 3′5′ adenosine monophosphate (cAMP). Increased cAMP relaxes airway smooth muscle and increases bronchial ciliary activity. Adverse effects of beta$_2$-adrenergic receptor stimulation include increased skeletal muscle activity, central nervous system stimulation, hyperglycemia, and hypokalemia. All beta$_2$-adrenergic agonists have slight cardiovascular stimulatory effects including increased heart rate, increased force of cardiac contractility, and increased cardiac conductivity.

Dosage and Time Frame for Response

The SABAs (e.g., albuterol, levalbuterol) have a quick onset (peak effect 10 minutes) and a short duration of action (3 to 4 hours). Salmeterol, the first long-acting beta$_2$-adrenergic agonist (LABA), has an onset of action of about 2 hours and a 12-hour duration of action. Formoterol has an onset of action of 3 minutes and a 12-hour duration of action. Vilanterol has an onset of action of about 15 minutes and a 24-hour duration of action. Arformoterol, the R-enantiomer of formoterol, and other ultra-long-acting beta$_2$-adrenergic agonists (ULABAs) indacaterol and olodaterol are not FDA approved for the management of asthma. Oral (e.g., albuterol syrup and tablets; terbutaline tablets) and parenteral (e.g., terbutaline) dosage forms are available but have limited clinical use due to the quick onset of action, ease of administration, beta$_2$-adrenergic specificity, and minimal systemic exposure with the inhaled route of administration. SABAs are indicated for the relief of acute asthma symptoms. LABAs are indicated for chronic maintenance therapy.

Contraindications

Beta$_2$-adrenergic agonists are contraindicated in persons with a history of hypersensitivity to beta-adrenergic agonists or any component of the formulation. Beta$_2$-adrenergic agonists should be used with caution in patients with known cardiovascular disease, diabetes mellitus, glaucoma, hyperthyroidism, or seizure disorders.

Adverse Effects

LABAs are associated with an increased risk of asthma-related deaths; product package inserts contain a black box warning of this risk. In addition, manufacturers of LABAs must participate in a Risk Evaluation and Mitigation Strategy (REMS) program that requires a patient medication guide and health care professional education. In 2010, the FDA released new safety requirements for LABAs when used in the treatment of asthma (FDA, 2010). LABAs must be used in combination with an asthma controller medication such as an ICS.

LABAs must be used for the shortest duration of time and then discontinued if possible. Combination products containing the LABA plus an ICS are recommended for pediatric and adolescent persons with asthma.

Common adverse effects with SABA and LABA include tachycardia, skeletal muscle tremor commonly seen as a fine hand tremor, nervousness, dizziness, hypokalemia, and hyperglycemia. Adverse effects are more common with high doses of inhaled drug and systemic administration (oral, parenteral).

Interactions

Other sympathomimetic drugs (e.g., catecholamines, catecholamine analogs, and amphetamines) increase the risk for $beta_2$-adrenergic agonist adverse effects and toxicities. Nonselective and higher doses of $beta_1$-selective adrenergic blocking drugs diminish the bronchodilator effects of the $beta_2$-adrenergic agonists; the risk-to-benefit ratio must be considered before prescribing beta-adrenergic blocking drugs. Concurrent administration of beta-adrenergic agonists and monoamine oxidase inhibitors (MAOIs) or tricyclic antidepressants (TCAs) increases blood pressure and the risk of stroke. MAOIs and TCAs must be discontinued at least 14 days prior to initiating $beta_2$-adrenergic agonists. Thiazide (e.g., hydrochlorothiazide) and loop diuretics (e.g., furosemide) enhance the hypokalemic effect of $beta_2$-adrenergic agonists. The oxazolidinones (e.g., linezolid, tedizolid) enhance the hypertensive effect of $beta_2$-adrenergic agonists. Atomoxetine, a selective norepinephrine reuptake inhibitor indicated for the management of attention deficit hyperactivity disorder, may increase the tachycardic effect of $beta_2$-adrenergic agonists.

Corticosteroids

Mechanism of Action

Corticosteroids reduce airway inflammation by inhibiting or inducing the production of end-effector proteins. An activated intracellular drug–receptor complex binds to glucocorticoid-responsive elements in the gene promoter regions of DNA, stimulating or inhibiting protein transcription. End-effector proteins alter vascular tone, vascular permeability, and body water distribution; stimulate lipolysis, gluconeogenesis, and glycogen secretion; increase responsiveness of beta-adrenergic receptors; mobilize amino acids from muscles; impair leukocyte migration; and inhibit nuclear factor-kappa, which regulates production of proinflammatory proteins such as cytokines, interleukins, interferons, and chemokines.

Dosage and Time Frame for Response

ICS are indicated for all persons with persistent asthma. The dosage of the ICS depends on the severity of asthma. Low-dose ICS are indicated for persons with mild persistent asthma (Step 2). Medium-dose ICS are indicated for persons with moderate persistent asthma (Steps 3 and 4). High-dose ICS are indicated for persons with severe persistent asthma (Steps 5 and 6). ICS differ in terms of oral bioavailability, pulmonary deposition, on-site activation, receptor binding affinity, lipophilicity, protein binding, and pharmacokinetics.

A short course of oral corticosteroids (e.g., a 5- to 10-day course of therapy with prednisone 40 to 60 mg/day in one or two divided doses per day with rapid dose reduction) is indicated for the treatment of an acute asthma exacerbation.

The onset of action of systemic and ICS (hours to days) is delayed due to the time it takes for the drug to influence protein expression. It takes several hours for lung function to improve in response to systemic (oral or intravenous) corticosteroids. The response to ICS typically begins during the first week of therapy and continues to increase for weeks to months with continued treatment.

Contraindications

Corticosteroids are contraindicated in persons with a history of hypersensitivity to corticosteroids or any component of the formulation.

Adverse Events

Common adverse events with ICS include oral candidiasis and dysphonia. Patients should be counseled to rinse their mouth, gargle, and spit out the water after each dose. Common adverse effects with short-term oral corticosteroids include sodium and water retention (peripheral edema, increased blood pressure, exacerbation of congestive heart failure),

hyperglycemia, increased appetite and weight gain, CNS stimulation and/or nightmares, peptic ulcer, and leukocytosis.

Common adverse effects with long-term (more than 14 days) high doses (typically greater than 7.5 mg/d of prednisone or equivalent) include adrenal suppression, muscle wasting, myopathy, decreased bone mineral density, posterior subcapsular cataracts, dermal thinning, ecchymosis, and peptic ulcer. Persons taking high-dose ICS are at risk of the same adverse effects.

Interactions

Corticosteroids are metabolized by the hepatic cytochrome P-450 isoenzyme CYP3A4. Corticosteroids induce CYP2C19 and CYP3A4. The prescriber should check for potential drug interactions before prescribing corticosteroids and counsel persons with COPD to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Concurrent use of ICS and strong inhibitors of CYP3A4 (e.g., ritonavir, clarithromycin, itraconazole, ketoconazole, telithromycin) increases the risk of systemic corticosteroid adverse effects and is not recommended.

Systemic corticosteroids decrease the response to skin tests, enhance adverse effects from live vaccines, and decrease the response to oral antidiabetic drugs. Antacids decrease the oral bioavailability of oral corticosteroids; counsel the patient to wait at least 2 hours between doses of an antacid and oral corticosteroid.

Leukotriene Modifier Drugs

Mechanism of Action

There are two types of leukotriene modifiers: the 5-lipoxygenase (5-LO) inhibitors and the leukotriene receptor antagonists. Zileuton inhibits 5-lipoxygenase (5-LO), preventing the first and second steps in the conversion of arachidonic acid to the bronchoconstrictor and proinflammatory cysteinyl leukotrienes (LTC4, LTD4, and LTE4). Montelukast and zafirlukast bind to cysteinyl leukotriene receptors on eosinophils and other proinflammatory cells, preventing LTC4, LTD4, and LTE4 from binding to the receptors and the subsequent bronchoconstrictor and proinflammatory responses.

Dosage and Time Frame for Response

Leukotriene modifiers, less effective than inhaled glucocorticoids or beta$_2$-adrenergic agonists, are indicated as alternate medications for the long-term control of mild persistent asthma and for the long-term control of moderate persistent asthma when used in combination with ICS. The montelukast dose for adolescents ≥15 years of age and adults is 10 mg daily in the evening; dosages for children 1 year of age to less than 15 years of age depend on the child's age. The zafirlukast dose for adolescents ≥12 years and adults is 20 mg twice daily; the dose for children 5 to 11 years of age is 10 mg twice daily. The zileuton dose for adolescents ≥12 years of age and adults is 600 mg four times daily (immediate-release formulation) or 1,200 mg twice daily (extended-release formulation).

Response to treatment with leukotriene modifiers is gradual, with improved symptoms and lung function observed during the first week of therapy and continued improvement over the following weeks of continued treatment. Heterogeneity in response to treatment with leukotriene modifiers has been observed and may be associated with genetic variations in the leukotriene metabolic pathway and bioavailability of the drugs (Tantisira and Drazen, 2009).

Contraindications

All leukotriene modifiers are contraindicated in persons with a history of hypersensitivity to the leukotriene modifier or any component of the formulation. The montelukast chewable tablet contains phenylalanine and is contraindicated in persons with phenylketonuria. Zafirlukast and zileuton are contraindicated in persons with hepatic impairment. Zileuton is contraindicated in persons with active liver disease and in persons with transaminase elevations ≥3 times the upper limit of normal. Baseline liver function tests should be obtained prior to starting zileuton therapy, monthly for 3 months, every 2 to 3 months for 9 months, and then periodically thereafter; zileuton should be discontinued if the serum ALT is greater than five times the upper limit of normal.

Adverse Events

Headache is a common adverse event reported with leukotriene modifiers. Churg-Strauss syndrome, a systemic vasculitis, is a rare but potentially serious immune-mediated idiosyncratic reaction reported with leukotriene modifiers. Neuropsychiatric events (behavioral changes and sleep disturbances) were identified postmarketing (FDA, 2009).

Interactions

Significant drug interactions are reported for the leukotriene modifiers. Montelukast is CYP2C8, CYP2C9, and CYP4A4 substrate; medications such as carbamazepine, phenytoin, phenobarbital, and rifampin induce montelukast metabolism resulting in decreased montelukast drug concentrations and effectiveness. Zafirlukast is a CYP2C9 and CYP2C8 substrate; a weak inhibitor of CYP1A2, CYP2C19, CYP2D6, and CYP3A4; and a moderate inhibitor of CYP2C8/9; medications such as erythromycin and theophylline decrease zafirlukast drug concentrations and effectiveness. Zileuton is a minor CYP1A2, CYP2C9, and CYP3A3/4 substrate and a weak inhibitor of CYP1A2. Zileuton decreases theophylline metabolism doubling the theophylline drug concentration. Zileuton decreases warfarin metabolism, increasing warfarin activity.

Mast Cell Stabilizers

Mechanism of Action

Mast cells, present in body tissues that interact with the environment (e.g., lungs, skin, gastrointestinal tract), release preformed proinflammatory mediators and stimulate the synthesis of newly formed proinflammatory mediators when activated by antigens. Mast cell stabilizers prevent the release and synthesis of proinflammatory mediators by inhibiting the influx of calcium into activated mast cells. Preformed mediators (e.g., histamine, proteases, proteoglycans, and cytokines) are responsible for the acute allergy response. Newly synthesized mediators (e.g., prostaglandins, cysteinyl leukotrienes, platelet activating factor) are potent mediators of inflammation. Mast cell-derived cytokines and chemokines (e.g., interleukin-4, interleukin-5, tumor necrosis factor alpha) recruit and activate additional inflammatory cells, extending the inflammatory response.

Dosage and Time Frame for Response

Cromolyn is marketed as a solution for nebulization (20 mg/2 mL). The initial dose is 20 mg four times a day. Once asthma symptoms are controlled, the dose may be tapered to the lowest effective dose (e.g., 20 mg three to four times a day). It takes 2 to 4 weeks of regular treatment to achieve maximum benefit. Less than 10% of the administered dose reaches the airways. Cromolyn absorbed from the lungs is rapidly eliminated unchanged in the urine and bile.

Contraindications

Cromolyn is contraindicated in persons with a history of hypersensitivity to cromolyn or any component of the formulation.

Adverse Events

Adverse events reported with cromolyn include a bad taste in the mouth and nausea. Rare cases of IgE-mediated allergic responses including anaphylaxis and rash have been reported. Anaphylaxis usually appears within minutes of drug administration. A rash may appear hours to days following drug administration.

Interactions

Significant drug interactions have not been identified for cromolyn.

Methylxanthines

Mechanism of Action

Methylxanthine bronchodilators (theophylline, aminophylline) relax bronchial smooth muscle, enhance diaphragmatic contractility, and have a slight anti-inflammatory effect; the exact mechanisms of action are not known. Methylxanthines, nonselective phosphodiesterase inhibitors, increase cAMP by inhibiting phosphodiesterase 1, 2, 3, 4, and 7. Increased cAMP relaxes airway smooth muscle and increases bronchial ciliary activity. The enhanced diaphragmatic contractility is probably mediated by weak adenosine antagonism. The slight anti-inflammatory effect is mediated by other molecular mechanisms.

Dosage and Time Frame for Response

Theophylline and aminophylline, the ethylenediamine salt of theophylline, are dosed to a target serum drug concentration. Aminophylline is approximately 80% theophylline. Although the therapeutic theophylline serum drug concentration range is generally accepted to be 10 to 20 mg/L, persons with asthma may do well with lower serum drug concentrations or experience unacceptable adverse effects with plasma drug concentrations within the therapeutic range. The half-life of theophylline is short (approximately 8 hours in nonsmokers); sustained-release dosage formulations (q12h and q24h) are recommended to improve patient adherence. Theophylline is metabolized in the liver; many medical conditions and drugs induce or inhibit theophylline metabolism. It is therefore important to monitor the serum drug concentrations and individualize the dosage based upon patient response, concurrent medical conditions, and drug interactions.

Contraindications

Theophylline and aminophylline are contraindicated in persons with a history of hypersensitivity to theophylline or any component of the formulation. Patients with a history of allergy to aminophylline are most likely allergic to the ethylenediamine component of the medication, not theophylline. Methylxanthines should be used with caution in patients with a history of tachyarrhythmias, peptic ulcer disease, seizure disorders, or hyperthyroidism. Intravenous dosage forms may contain propylene glycol, which can accumulate in persons with renal dysfunction. Large amounts of propylene glycol may cause lactic acidosis, hyperosmolality, seizures, and respiratory depression. Oral dosage forms may contain dyes, alcohol, or sugar.

Adverse Events

Common adverse events with methylxanthines include tachyarrhythmias, restlessness, insomnia, tremor, nausea, vomiting, gastroesophageal reflux, seizures, and peptic ulcer

aggravation. Tachycardia and potentially life-threatening cardiac arrhythmias may occur at therapeutic concentrations. Seizures usually occur with serum theophylline concentrations above 35 mg/L but may occur at lower concentrations.

Interactions

Theophylline is primarily metabolized by the hepatic cytochrome P-450 isoenzymes CYP1A2, CYP2E1, and CYP3A4; theophylline is a minor substrate of CYP2C9 and CYP2D6. Hepatic metabolism can be induced or inhibited by hundreds of drugs and by medical conditions that affect hepatic function. The prescriber should check for potential drug interactions before prescribing theophylline and counsel persons with asthma to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Examples of commonly used drugs that inhibit theophylline metabolism (increase theophylline serum concentration) include ciprofloxacin, cimetidine, erythromycin, and allopurinol. Examples of commonly used drugs that induce theophylline metabolism (decrease theophylline serum concentration) include phenobarbital, diphenylhydantoin, and rifampin. The prescriber should check for potential drug interactions before prescribing theophylline and counsel persons with asthma to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Smoking induces theophylline metabolism, lowering the serum drug concentration. Caffeine and sympathomimetic drugs have similar adverse effects as the methylxanthines; concurrent use increases the risk of adverse effects. Theophylline may antagonize the sedating and anxiolytic effect of benzodiazepines.

Omalizumab

Mechanism of Action

Omalizumab, a recombinant humanized monoclonal anti-IgG antibody, selectively binds to circulating IgE forming immune complexes that prevent IgE from binding to high-affinity IgE receptors on the surface of mast cells and basophils and the subsequent release of histamine and other mediators of allergy. Omalizumab also decreases the number of high-affinity receptors on basophils.

Dosage and Time Frame for Response

Omalizumab is indicated for treatment of persons with severe persistent allergic asthma with total serum IgE levels from 30 to 700 IU/mL. The dose is based on the total serum IgE and patient weight. The dosing interval depends on the dose. Persons needing more than 300 mg every 4 weeks are dosed on an every 2-week schedule to minimize the number of injections per dose.

The peak omalizumab serum concentration is achieved in about a week. The half-life of omalizumab is long (approximately 20 days), providing a long duration of effect (4 to 6 weeks). Individual responses are highly variable. The response to treatment should be assessed after 16 weeks of therapy. The optimal duration of therapy is not known. Circulating IgE increases rapidly after therapy is stopped with a return of symptoms. However, omalizumab may induce a long-term remission.

Contraindications

Omalizumab is contraindicated in persons with a history of hypersensitivity to omalizumab or any component of the formulation.

Adverse Events

Omalizumab is associated with a high risk of anaphylaxis; product package inserts contain a black box warning of this risk. Signs and symptoms of anaphylaxis include bronchospasm, angioedema of the throat or tongue, hypotension, and syncope. Anaphylaxis may occur with the first dose or after multiple doses. Anaphylaxis may occur within the first hour after treatment or be delayed for several days. Most anaphylactic reactions have occurred in the first 2 hours after the first 3 doses. Patients should be observed closely for 2 hours after the first 3 doses and for 30 minutes after following doses and should be given an epinephrine autoinjector for home administration (Pelaia et al., 2011).

Injection site reactions are common. Nearly half (45%) of persons experience an injection site reaction, including bruising, redness, warmth, burning, stinging, itching, pain, induration, and inflammation. The injection site reactions appear within an hour of

injection and persist for about a week. Less common adverse events (less than 10%) include dizziness, fatigue, arthralgias, and dermatitis.

Interactions

Omalizumab may increase the toxicity of belimumab, a monoclonal antibody indicated for the management of systemic lupus erythematosus.

Selecting the Most Appropriate Drug

Initial drug therapy selection depends on patient age and asthma severity (Tables 25.4 to 25.6) (NAEPP, 2007).

First-Line Therapy

A short-acting rescue bronchodilator to be used as needed is required for all persons with asthma, regardless of asthma severity. Chronic maintenance therapy with an asthma controller medication is indicated for persons with persistent asthma. Mild intermittent asthma (Step 1) is managed with a short-acting rescue bronchodilator. The preferred therapy for adults with Step 2 mild persistent asthma is low-dose ICS. The preferred therapy for adults with moderate persistent asthma (Step 3 and Step 4) is low- to medium-dose ICS plus a LABA bronchodilator or medium-dose ICS. Adults with Step 5 and Step 6 severe persistent asthma are treated with high-dose ICS plus a LABA bronchodilator; omalizumab may be added for adults with confirmed allergic asthma.

Alternative Therapy

Alternative therapies to low-dose ICS for persons with Step 2 mild persistent asthma include cromolyn, a leukotriene modifier, or theophylline. Alternative therapies to the combination of a low-dose ICS and a LABA bronchodilator for persons with Step 3 moderate persistent asthma include a combination of low-dose ICS plus a leukotriene modifier or theophylline. Alternative therapies to the combination of medium-dose ICS plus a long-acting $beta_2$-adrenergic agonist for persons with Step 4 moderate persistent asthma include a combination of medium-dose ICS plus a leukotriene modifier or theophylline.

Special Considerations

All persons with asthma should receive an annual influenza vaccine. The Center for Disease Control Advisory Committee on Immunization Practices recommends that immunocompetent children with asthma aged 6 to 18 years and adults with asthma 19 years of age and older receive the 23-valent pneumococcal polysaccharide vaccine (PPSV23) (CDC, 2012; CDC, 2013a). The 13-valent pneumococcal conjugate vaccine (PCV13) is recommended for persons receiving long-term systemic corticosteroids.

Pediatric

Not all asthma medications are indicated for use in children. For example, omalizumab is FDA approved for use in adults and children 12 years of age and older. Even within the same class of medication, age-related indications may differ. Among the leukotriene modifiers, montelukast is FDA approved for children ≥1 year of age, zafirlukast is FDA approved for children ≥5 years of age, and zileuton is FDA approved for children ≥12 years of age.

Parents and adolescents may express concerns about the effect of ICS on adult height. A small (mean 1.2 cm) decrease in adult height is reported with ICS (Kelly et al., 2012). The effect appears to be the greatest with drug administration during the prepubertal years and with larger daily doses. Use of the lowest effective dose may reduce the risk.

Pulmonary function testing is indicated for children 5 years of age and older. Pulmonary function testing in younger children is unreliable.

Use of some respiratory drug delivery devices is limited to older children; younger children may not be able to reliably generate an adequate inspiratory flow rate to disperse the medication (GINA, 2015). Older children (greater than 8 years of age) can effectively use a pressurized metered-dose inhaler. The combination of a pressurized metered-dose inhaler plus a spacer device is appropriate for younger children, including infants. Drug delivery with a nebulizer is effective for all ages. The RespiClick dry powder inhaler is FDA approved for adults and children 12 years of age and older.

Geriatric

Elderly persons with asthma are diagnosed and managed the same as younger persons. However, there are several unique age-related issues that must be considered (Reed, 2010). Recognition of asthma-related symptoms is delayed due to reduced activity levels and a tendency to regard symptoms as part of normal aging. Diagnosis of asthma in elderly persons may be difficult due to the presence of medical conditions with similar signs and symptoms (e.g., other cardiopulmonary conditions such as congestive heart failure). Elderly persons with asthma are more likely to be taking multiple other medications, increasing the likelihood of drug–drug and drug–medical condition interactions. Kinesthetic motor skills, visual acuity, and inspiratory flow may decline with aging making it difficult for patients to

prepare and self-administer medication with respiratory drug delivery devices.

Women

Women with asthma may be concerned about the use of medications during and after pregnancy. There are fewer risks to the fetus from treating with standard asthma medications than from uncontrolled asthma during pregnancy (NAEPP, 2005). For most women, asthma is more difficult to control during pregnancy; the current guidelines recommend monthly assessments with baseline spirometry and then PEF monitoring with a peak flow meter.

The NAEPP guidelines provide specific recommendations for preferred and alternate medications to be used during pregnancy (NAEPP, 2007). Albuterol is the preferred short-acting bronchodilator. Low-dose ICS are the preferred therapy for Step 2 mild persistent asthma; alternatives include cromolyn, leukotriene receptor antagonists, and theophylline. A combination of low-dose ICS plus a long-acting inhaled $beta_2$-adrenergic agonist or medium-dose ICS are the preferred therapy for Step 3 moderate persistent asthma. The guidelines recommend high-dose ICS for severe persistent asthma; budesonide is preferred. Systemic corticosteroids may be indicated for management of severe uncontrolled asthma in which the risk to the life of the mother and fetus is greater than the risk of systemic corticosteroids.

Ethnic

Culturally specific beliefs regarding cause of disease, acceptance of acute or chronic medications, medication color, dosage formulation, and route of administration may influence a person's acceptance and adherence to the prescribed drug and nondrug therapy. Persons with asthma may seek care from healers and may use natural remedies. It is important to ask about, respect, and integrate these beliefs into the asthma management plan.

Genomics

There are no gene-specific therapeutic recommendations for managing asthma.

Acute Exacerbation

Persons with mild or persistent asthma may experience an acute exacerbation of any severity (NAEPP, 2007). An asthma exacerbation is characterized by an acute or subacute episode of any combination of symptoms, including chest tightness, wheezing, cough, and worsening shortness of breath. Mild exacerbations may be self-managed at home; moderate or severe exacerbations are managed in an urgent office visit or emergency department or may require hospital admission.

A mild exacerbation is characterized by dyspnea with activity and an initial PEF 70% or better than predicted or personal best. A moderate exacerbation is characterized by dyspnea that interferes with or limits usual activity and an initial PEF 40% to 69% of predicted or personal best. A severe exacerbation is characterized by dyspnea at rest that interferes with conversation and a PEF less than 25% of predicted or personal best. During a life-threatening exacerbation, the person may be too dyspneic to speak, may have a silent chest, and may have a PEF less than 25% of predicted or personal best.

Initial self-care for an asthma exacerbation consists of 2 to 6 puffs of the quick-relief SABA inhaler albuterol; the dose may be repeated in 20 minutes and then every 3 to 4 hours for the next 24 to 48 hours or until the patient's symptoms and PEF are stable (NAEPP, 2007). Depending on the response to the initial SABA doses, additional therapy, such as a short course of oral corticosteroid, may be added. Persons with marked wheezing and dyspnea and PEF less than 50% predicted or personal best that continues after the initial albuterol doses should repeat the albuterol dose and seek emergency care.

Emergency department and hospital-based management of asthma depend on exacerbation severity (NAEPP, 2007). All patients are treated with oxygen to achieve S_aO_2 of 90% or greater and repetitive (up to 3 doses in the first hour) or continuous high-dose short-acting inhaled beta$_2$-adrenergic bronchodilator; most patients need systemic corticosteroids. The NAEPP guidelines recommend adding repetitive high doses (0.5 mg nebulizer solution or 8 puffs by MDI) of the short-acting anticholinergic bronchodilator ipratropium bromide to the short-acting beta$_2$-adrenergic bronchodilator when treating patients with severe exacerbations (NAEPP, 2007). Subsequent treatment depends on the exacerbation severity and patient response.

Monitoring Patient Response

It takes approximately 3 to 4 months to achieve maximal benefit with most asthma controller medications. The GINA guidelines recommend that persons with asthma be assessed 1 to 3 months after initiation of therapy and then every 3 to 12 months thereafter depending on the clinical urgency; persons with asthma should be seen within one week of an acute asthma exacerbation (GINA, 2015). The NAEPP guidelines recommend that persons with mild or moderate persistent asthma controlled for 3 months or longer be seen every 6 months; persons with more severe asthma should be seen more frequently (NAEPP, 2007). Spirometry is performed at baseline (prior to starting treatment), after 3 to 6 months of treatment, than repeated annually or more frequently if indicated.

The control of asthma, risk factors, response to treatment (including review of the peak flow diary if part of the self-monitoring plan), adherence, drug delivery techniques, exacerbation history, and occurrence of medication-related adverse effects should be assessed and documented at every patient interaction. The NAEPP guidelines recommend that spirometry be performed at the time of initial assessment, once symptoms and PEF have stabilized in response to initial treatment, when asthma is out of control, and at least every 1 to 2 years (NAEPP, 2007).

Patient Education

Exercise-Induced Bronchospasm

Exercise-induced bronchospasm (EIB), acute airway narrowing in response to exercise, is a common asthma trigger but may occur in persons without an asthma diagnosis. Environmental exposures associated with EIB include exposure to cold air, dry air, high ozone air, high allergen environments, and airborne particulates. Symptoms are variable and nonspecific but may include chest tightness, cough, wheezing, and dyspnea; symptoms may be mild to severe. Symptoms typically appear within a few minutes after exercise begins and continue for 10 to 15 minutes after exercise stops.

Nonpharmacologic management includes warming up before exercise or breathing through a face mask or scarf to prewarm and humidify inspired air; dietary modifications (e.g., low-salt diet, dietary supplementation with fish oils) have been proposed (Parsons, 2013). A short-acting $beta_2$-adrenergic agonist is administered 15 minutes before exercise to prevent EIB. A mast cell–stabilizing drug (e.g., cromolyn) or short-acting anticholinergic drug (e.g., ipratropium bromide) may be considered if an SABA is ineffective. Controller medications (e.g., daily ICS with or without a LABA and/or a leukotriene receptor antagonist) are indicated if preventive therapy is needed daily or more frequently (Parsons, 2013).

Environmental Control

Common environmental allergens include house dust mites, cockroaches, furred animals, indoor and outdoor molds, and pollens. House dust mites live on human skin cells found in dust; the allergen is found in fecal pellets and body fragments. Environmental control consists of removal of items that collect dust (e.g., carpets, curtains, stuffed animals), encasement of mattresses and bedding in mite-impermeable covers, and keeping the environment dust-free. Maintaining household humidity at ≤50% and the household temperature at 70°F may reduce the dust mite population. Cockroaches are controlled by encasing food supplies, removing waste food from the environment, preventing access to water, repairing cracks and openings around pipes, and use of insecticide bait traps. Ideally, furred animals should be removed from the home and contact with furred animals outside the home discouraged. Minimally, furred animals should be kept out of the bedroom of the person with asthma. Persons with outdoor mold allergies should avoid decaying vegetation. Indoor mold exposure avoidance strategies include ventilating high humidity areas, lowering the household humidity to less than 50%, removing carpets on concrete slabs, and sealing structural defects to prevent water from entering the home. Pollen avoidance strategies include staying indoors as much as possible, especially in the evenings, and keeping car and house windows closed.

Self-Monitoring

The current NAEPP asthma guidelines encourage all persons with moderate or severe persistent asthma, a history of severe exacerbations, or poorly controlled asthma to have a written asthma action plan. The written asthma action plan includes a daily management plan and how to recognize and manage worsening asthma. The asthma action plan is individualized based on symptoms, PEF, or both symptoms and PEF. An asthma action plan based on PEF is recommended for patients who have poor perceptions of worsening asthma.

A written asthma action plan is organized around three zones: green zone (doing well; PEF 80% or more of personal best), yellow zone (worsening asthma; PEF 50% to 79% of personal best), and red zone (medical alert; PEF less than 50% of personal best). Template asthma action plans for children and adults are available from the National Institute of Health and several professional organizations. A green zone plan includes instructions for preventing asthma symptoms (e.g., long-term control medication regimen, medications to prevent exercise-induced bronchoconstriction, and avoidance strategies for environmental triggers). The yellow zone plan includes a list of symptoms suggestive of worsening asthma and instructions for managing the worsening lung function (e.g., add a medication, increase the dose of a current medication, whom to call for help, how to monitor the response). The red zone plan includes symptoms that indicate a medical alert and instructions for managing the worsening lung function (e.g., add a medication, whom to call, and when to seek emergency help).

Respiratory Drug Delivery Systems

Device-specific patient education regarding the correct use of the specific expiratory drug delivery system is essential. Multiple types of respiratory drug delivery devices are marketed, each with unique drug administration techniques. Respiratory drug delivery systems include metered-dose inhalers, holding chambers (valved and nonvalved), dry powder inhalers (single-dose inhalers, premetered blisters, and reservoir style), soft mist inhaler, and small volume nebulizers (jet nebulizers and ultrasonic nebulizers). Each type of device has advantages and disadvantages; device selection depends on product availability, patient age, patient ability, cost, and patient preference. General drug delivery device administration techniques are listed in Table 25.9; refer to the product package inserts for device-specific drug administration information.

TABLE 25.9 Drug Delivery Device Techniques

Device	General Technique
Pressurized metered-dose inhalers	1. Remove dust cap 2. Inspect for debris 3. Shake vigorously for 5 s 4. Hold the device upright (mouthpiece down) 5. Position mouthpiece; do not block with the tongue 6. Press down on the canister and breathe in at the same time (midinspiration actuation is more effective but is very difficult to perform) 7. Continue to inhale to the end of a quiet breath (about 4–6 s) 8. Hold breath for 10 s 9. Exhale slowly 10. Replace dust cap Wait at least 1 min between puffs for SABAs and 15–30 s for all other drugs
Spacers and valved holding chambers	1. Visually check for debris 2. Prepare metered-dose inhaler 3. Insert metered-dose inhaler in spacer 4. Hold the spacer/valved holding chamber level 5. Gently exhale to end of a quiet breath 6. Press the canister once 7. Immediately inspire slowly and deeply 8. Remove spacer from the mouth 9. Hold breath for 10 s 10. Exhale slowly
Device	**General Technique**
Dry powder inhalers	1. Remove cover 2. Prepare dose 3. Exhale softly *away* from device 4. Seal lips around mouthpiece 5. Inhale rapidly and forcefully 6. Remove device from the mouth 7. Hold breath for 10 s 8. Exhale softly *away* from device 9. Replace cover
Small volume nebulizers	1. Place the equipment on a stable surface 2. Connect the tubing to the compressor 3. Hold the medication chamber upright; add the premixed drug solution or measure and add drug and saline 4. Place the lid on the medication chamber 5. Connect the tubing to the medication chamber 6. Turn on the air compressor 7. Check for the generation of a fine mist 8. Sit up comfortably straight 9. Seal lips around the mouthpiece; do not block with the tongue 10. Holding the medication chamber upright, breathe in and out normally; take a deeper breath and hold it for a few seconds every minute or so 11. Continue until the medication chamber begins to sputter 12. Turn off the compressor 13. Disconnect the medication chamber and tubing

Drug Information

The NAEPP and GINA guidelines contain pharmacologic class and product-specific drug information. Drug information is available on professional organization (e.g., the American Academy of Allergy, Asthma, and Immunology [AAAAI]), nonprofit organization (e.g., The American Lung Association [ALA]), and government (e.g., NIH) Web sites. Pharmaceutical company websites often include links to respiratory drug delivery device videos. Pharmacy therapeutics and medical pulmonary textbooks provide more in-depth drug information.

Patient-Oriented Information Sources

Many national, state, and local government websites (e.g., National Heart, Lung, Blood Institute, Center for Disease Control; NHLBI) contain information and links to other resources for persons with asthma. Professional organizations such as the AAAAI, the American Academy of Family Physicians, (AAFP), and the American Academy of Pediatrics (AAP) provide information for persons with asthma on their websites. Other organizations such as the ALA and the Asthma and Allergy Foundation of America (AAFA) provide patient information on their websites. Websites for the NAEPP and the GINA contain patient-oriented information.

Nutrition/Lifestyle Changes

There is no “asthma diet” though good nutrition is important to maintain overall health. Physical activity is important; persons with asthma should be encouraged to remain physically active.

Complementary and Alternative Medications

More than 20 types of complementary and alternative medical treatments are used for the management of asthma, including many types of herbal remedies, homeopathic medications, acupuncture, chiropractic therapy, breathing techniques, relaxation techniques, and yoga. The current NAEPP guidelines do not recommend any complementary and alternative medical therapies (NAEPP, 2007). Clinicians should ask persons with asthma about the use of these therapies, especially herbal and other products, to identify potential disease and drug interactions.

Case Study*

S.C. is a 21-year-old college student. She presents with intermittent wheezing. She has a history of asthma as a child but had been free of symptoms until this year. She has symptoms 1 to 2 days/week but denies nocturnal wheezing. Her symptoms do not interfere with her normal activities. She has never taken systemic corticosteroids and has never been hospitalized for asthma. On physical exam, you observe soft end-expiratory wheezing at the bases bilaterally. Pulmonary function tests today show an FEV_1/FVC of 80% with an FEV_1 90% of predicted. She has no other medical conditions and is not taking any nonprescription, prescription, or complementary alternative medicines. She has no known environmental or drug allergies.

Diagnosis: Asthma

1. List specific goals for treatment for S.C.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for S.C.?
8. What lifestyle changes would you recommend for S.C.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

26 Chronic Obstructive Pulmonary Disease

Karen J. Tietze

Chronic obstructive pulmonary disease (COPD) is characterized by chronic progressive airflow limitation. COPD typically is thought of as chronic bronchitis and/or emphysema. However, chronic bronchitis, defined clinically as cough and sputum production for at least 3 months of the year in at least two consecutive years, occurs independently of COPD and may not be associated with fixed airflow limitation. Emphysema refers to alveolar destruction, one of several structural abnormalities in COPD. The current Global Obstructive Lung Disease (GOLD) guidelines do not include either term in the definition of COPD (GOLD, 2016).

In the United States, COPD affects 6.8 million noninstitutionalized adults (Schiller et al., 2012) and 10.8% of institutionalized residents (NSRCF, 2010). COPD is the third leading cause of death in the United States accounting for 138,080 deaths in 2010 (Schiller et al., 2012). In 2010, the cost of COPD in the United States was estimated to be nearly $50 billion, including nearly $30 billion in direct health care expenditures (ALA, 2015).

Historically identified with older men, COPD demographics have shifted. In 2009, COPD prevalence was highest in women of all age groups, except for the oldest age groups (75 and older) in which the prevalence among men and women was the same (Akinbami & Liu, 2011). COPD prevalence increases with age (Akinbami & Liu, 2011). For women, the highest prevalence is among women aged 65 to 74. For men, the highest prevalence is among men aged 75 to 84. In men and women aged 45 to 64 and women aged 65 and older, the prevalence of COPD is higher in whites than in blacks (NHLBI, 2012). One of the challenges identifying persons with COPD is that people are asymptomatic during the early stages of the disease; by the time symptoms appear, the disease has progressed significantly.

Causes

Tobacco smoking is the most common risk factor for COPD (U.S. DHHS, 2014). Although most persons with COPD have smoked tobacco, not all tobacco smokers develop COPD. Other risk factors for COPD include exposure to air pollutants in the home and the workplace, a history of severe respiratory infections as a child, and hereditary alpha-1 antitrypsin deficiency.

Pathophysiology

In susceptible persons, chronic exposure to inhaled noxious particles results in lung inflammation. Inflammatory cells (neutrophils, macrophages, and CD8+ T lymphocytes) produce a variety of proinflammatory mediators (interleukins, tumor necrosis factor, leukotrienes, and growth factors), proteases (oxidants), and oxidants (nitrogen species) (GOLD, 2016; MacNee, 2006). The imbalances between proteases and antiproteases and oxidants and antioxidants lead to irreversible changes in the peripheral airways (i.e., squamous metaplasia, mucous metaplasia, small airway fibrosis), lung parenchyma (i.e., parenchymal destruction), and pulmonary blood vessels (i.e., pulmonary vascular remodeling). These changes result in airflow obstruction, hyperinflation, mucous hypersecretion, ciliary dysfunction, and gas exchange abnormalities (GOLD, 2016; MacNee, 2006). Inflammation most likely is the common link between COPD and the extrapulmonary medical conditions associated with COPD including systemic venous thromboembolism, anemia, metabolic syndrome, sleep disturbances, osteoporosis, obesity, anxiety, and depression (Cavailles et al., 2013).

Diagnostic Criteria

COPD symptoms include chronic cough with or without chronic sputum production and persistent progressive dyspnea that worsens with exercise; persons with COPD may or may not complain of chest tightness or have audible wheezing. On physical exam, persons with COPD may have wheezing, cyanosis, a barrel-shaped chest, low diaphragms, and signs of cor pulmonale (e.g., peripheral edema, enlarged heart).

Spirometry is required for the diagnosis of COPD (GOLD, 2016). Airflow limitation is assessed using the forced expiratory volume in the first second (FEV_1), the total volume of exhaled air (forced vital capacity, FVC), and the FEV_1/FVC ratio. Airflow obstruction is present when the FEV_1/FVC is less than 0.70. A postbronchodilator FEV_1/FVC less than 70% identifies the fixed airway obstruction of COPD. Although peak expiratory flow (the highest flow rate during forced exhalation) is sensitive, it lacks specificity and is not used to diagnose COPD.

The GOLD guidelines categorize COPD into groups (A, B, C, and D) based on the severity of airflow limitation, patient symptoms, and exacerbation risk (Table 26.1). GOLD group A is characterized as low risk, less symptoms. GOLD group B is characterized as low risk, more symptoms. GOLD group C is characterized as high risk, less symptoms. GOLD group D is characterized as high risk, more symptoms.

TABLE 26.1 COPD Categories

Group	Symptoms	GOLD Spirometric Risk	Exacerbations in Preceding Year NOT NEEDING Hospitalization	Exacerbations in Preceding Year NEEDING Hospitalization
A Low Risk, Less Symptoms	mMRC 0–1 CAT™ < 10	Grade 1: Mild, FEV_1/FVC < 70%, and FEV_1 ≥ 80% predicted Grade 2: Moderate, FEV_1/FVC < 70%, and FEV_1 ≥ 50% to < 80% predicted	0–1	0
B Low risk, More Symptoms	mMRC ≥ 2 CAT™ ≥ 10	Grade 1: Mild, FEV_1/FVC < 70%, and FEV_1 ≥ 80% predicted Grade 2: Moderate, FEV_1/FVC < 70%, and FEV_1 ≥ 50% to < 80% predicted	0–1	0
C High Risk, Less Symptoms	mMRC 0–1 CAT™ < 10	Grade 3: Severe, FEV_1/FVC < 70%, and FEV_1 ≥ 30% to < 50% predicted Grade 4: Very severe, FEV_1/FVC < 70%, and FEV_1 < 30% predicted	≥2	≥1
D High Risk, More Symptoms	mMRC ≥ 2 CAT™ ≥ 10	Grade 3: Severe, FEV_1/FVC < 70%, and FEV_1 ≥ 30% to < 50% predicted Grade 4: Very severe, FEV_1/FVC < 70%, and FEV_1 < 30% predicted	≥2	≥1

From Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease. (2016). Global initiative for chronic obstructive lung disease. Retrieved from www.goldcopd.org

Severity of airflow limitation is based on postbronchodilator FEV_1. The four GOLD spirometric levels of severity include GOLD 1 (mild), FEV_1 ≥ 80% of predicted; GOLD 2 (moderate), 50% ≤ FEV_1 < 80% predicted; GOLD 3 (severe), 30% ≤ FEV_1 < 50%

predicted; and GOLD 4 (very severe), FEV_1 <30% predicted. Patient symptoms and breathlessness are assessed using the COPD Assessment Test (CAT™) (Jones et al., 2009) or the Modified British Medical Research Council (mMRC) dyspnea (Bestall et al., 1999) questionnaires. Persons with CAT™ scores of less than 10 or mMRC scores of 0 to 1 are considered to have less symptoms and breathlessness, respectively. Persons with CAT™ scores of 10 or more or mMRC scores of 2 or more are considered to have more symptoms and breathlessness, respectively. Exacerbation risk is based on the number of exacerbations in the preceding year not needing hospitalization and needing hospitalization. Persons with 0 to 1 exacerbations in the preceding year not needing hospitalization or no exacerbations in the preceding year needing hospitalization are at low risk of exacerbations. Persons with two or more exacerbations in the preceding year not needing hospitalization or one or more exacerbations in the preceding year needing hospitalization are at high risk of exacerbations.

Initiating Drug Therapy

The current GOLD guidelines recommend drug therapy based on the COPD group (Table 26.2). Nondrug therapy includes tobacco cessation, avoidance of environmental and occupational irritants, and energy conservation. A variety of drug and nondrug therapies are available for tobacco cessation. All health care professionals should ask every patient at every encounter about tobacco smoking and then advise, assess, assist, and arrange for smoking cessation interventions as appropriate. Outdoor exercise and exertion should be avoided when pollution levels are high or temperatures are extreme. Maintaining physical activity is recommended for all persons with COPD. Persons with group B or D COPD may benefit from pulmonary rehabilitation and energy conservation techniques.

TABLE 26.2 Initial Treatment of COPD

Group	As Needed Medication	First Choice Maintenance Medication	Second Choice Maintenance Medication	Comments
A	SABA or SAMA	Not indicated	LAMA or LABA or SABA + SAMA	One short-acting bronchodilator; SABA if on LAMA
B	SABA, SAMA, or SABA plus SAMA	LAMA or LABA	LAMA + LABA	One or two short-acting bronchodilators; SABA if on LAMA
C	SABA, SAMA, or SABA plus SAMA	ICS + LAMA or ICS + LABA	LAMA + LABA or LAMA + PDE4I or LABA + PDE4I	One or two short-acting bronchodilators; SABA if on LAMA
D	SABA, SAMA, or SABA plus SAMA	ICS + LAMA or ICS + LABA	ICS + LAMA + LABA or ICS + LABA + PDE4I or LABA + LAMA or LAMA + PDE4I	One or two short-acting bronchodilators; SABA if on LAMA

(2016). Global initiative for chronic obstructive lung disease. Retrieved from www.goldcopd.org

Goals of Drug Therapy

COPD is an irreversible but treatable medical condition; the goals of therapy are to reduce symptoms and reduce risk (GOLD, 2016). Medications, improving exercise tolerance, and improving overall health status may reduce symptoms and improve quality of life. Risk may be reduced by delaying disease progression and preventing and treating exacerbations. Drugs used to treat COPD include beta$_2$-adrenergic agonists, anticholinergics, corticosteroids, methylxanthines, and phosphodiesterase 4 inhibitors (Table 26.3).

TABLE 26.3 Overview of Selected Agents Used to Treat COPD

Generic (Trade) Name and Adult Dosage	Selected Adverse Events	Contraindications	Special Considerations
Short-Acting Beta$_2$-Agonists			
albuterol (Proventil HFA, Ventolin HFA, ProAir HFA) MDI 90 mcg/inhalation 1–2 inhalations q4–q6 hours as needed albuterol (ProAir) DPI 117 mcg/inhalation 1–2 inhalations q4–q6 hours as needed albuterol (AccuNeb) 0.083% (2.5 mg/3 mL), 0.5% (2.5 mg/0.5 mL) solution for nebulization 2.5 mg three to four times a day as needed	Tachycardia, skeletal muscle tremor, nervousness, dizziness, hypokalemia, hyperglycemia	Hypersensitivity to beta$_2$-adrenergic agonists Hypersensitivity to lactose or milk protein (dry powder formulations, product specific)	Fewer systemic effects with inhaled therapy Use with caution in patients with cardiovascular disease, diabetes mellitus, glaucoma, hyperthyroidism, or seizure disorders Beta-adrenergic blockers diminish the bronchodilator effects Concurrent sympathomimetic drugs, monoamine oxidase inhibitors, or tricyclic antidepressants enhance the risk of adverse effects
Short-Acting Anticholinergics			
ipratropium bromide (Atrovent) MDI 17 mcg/inhalation; 34 mcg four times daily ipratropium bromide (Atrovent) solution for nebulization 0.02%; 500 mcg (2.5 mL) three to four times per day	Cough, dry mouth, dry throat, throat irritation, blurred vision, mydriasis, dyspepsia	None	Use with caution in patients with narrow-angle glaucoma, myasthenia gravis, prostatic hyperplasia, or bladder neck obstruction
Combination Short-Acting Anticholinergic and Short-Acting Beta$_2$-adrenergic Agonist			
ipratropium bromide plus albuterol (DuoNeb) solution for nebulization 500 mcg ipratropium bromide plus 2.5 mg albuterol per 3 mL/3 mL every 4–6 h ipratropium bromide plus albuterol (Combivent Respimat) SMI 20 mcg ipratropium bromide plus 100 mcg albuterol per inhalation; 1 inhalation four times daily	Same as above	Same as above	Same as above
Long-Acting Beta$_2$-agonists			
arformoterol (Brovana) 15 mcg/2 mL solution for nebulization; 15 mcg twice daily formoterol (Perforomist) 20 mcg/2 mL solution for nebulization; 20 mcg q12h formoterol (Foradil Aerolizer) DPI 12 mcg/inhalation; 12 mcg q12h indacaterol (Arcapta Breezhaler) DPI 75 mcg/inhalation; 75 mcg once daily olodaterol (Striverdi Respimat) SMI 2.5 mcg/actuation; 5 mcg once daily salmeterol (Serevent Diskus) DPI 50 mcg/inhalation; 50 mcg q12h	Same as above	Same as above	Same as above Not for relief of acute bronchospasm
Long-Acting Anticholinergics			
tiotropium bromide (Spiriva HandiHaler) DPI 18 mcg; 18 mcg once daily tiotropium bromide (Spiriva Respimat) SMI 2.5 mcg/inhalation; 5 mcg once daily aclidinium bromide (Tudorza Pressair) DPI 400 mcg/actuation; 400 mcg twice daily umeclidinium bromide (Incruse Ellipta) DPI 62.5 mcg/inhalation; 62.5 mcg once daily	Same as above	Same as above	Same as above Not for relief of acute bronchospasm

Generic (Trade) Name and Adult Dosage	Selected Adverse Events	Contraindications	Special Considerations
Combination Long-Acting Anticholinergic and Long-Acting Beta$_2$-agonists			
tiotropium 2.5 mcg and olodaterol 2.5 mcg per inhalation SMI (Stiolto Respimat); two inhalations once daily	Long-acting anticholinergics: same as above Long-acting beta$_2$-agonists: same as above	Long-acting anticholinergics: same as above Long-acting beta$_2$-agonists: same as above	Not for relief of acute bronchospasm
Combination Long-Acting Beta$_2$-agonists and Corticosteroids			
formoterol 4.5 mcg and budesonide 160 mcg per inhalation MDI (Symbicort); 2 inhalations twice daily salmeterol 50 mcg and fluticasone 250 mcg per inhalation DPI (Advair Diskus); 1 inhalation q12h vilanterol 25 mcg and fluticasone 100 mcg per inhalation DPI (Breo Ellipta); 1 inhalation daily	Long-acting beta$_2$-agonists: same as above Inhaled corticosteroids: oral candidiasis, hoarseness	Long-acting beta$_2$-agonists: same as above Corticosteroids: hypersensitivity to corticosteroids	Not for relief of acute bronchospasm Rinse, gargle, and spit after each use to reduce local adverse effects and systemic absorption Inhaled corticosteroids increase the risk of pneumonia; indicated for patients with grades C and D COPD
Oral Corticosteroids			
	Short-term oral corticosteroids: sodium and water retention, increased appetite and weight gain, CNS stimulation and/or nightmares, peptic ulcer, and leukocytosis	Same as above	Adrenal suppression unlikely with short-term therapy
Methylxanthines			
theophylline extended-release tablets and capsules, elixir (80 mg/15 mL), oral solution (80 mg/15 mL), intravenous solution	Tachyarrhythmias, restlessness, insomnia, seizures, tremor, nausea, vomiting, gastroesophageal reflux, peptic ulcer aggravation	Hypersensitivity to theophylline Intravenous dosage forms may contain propylene glycol Oral dosage forms may contain dyes, alcohol, or sugar	Use with caution in patients with tachyarrhythmias, peptic ulcer disease, seizure disorders, hyperthyroidism Dose to therapeutic theophylline serum concentration (10–20 mg/L)
Phosphodiesterase 4 Inhibitors			
roflumilast (Daliresp) 500 mcg tablet 500 mcg once daily	Supraventricular tachyarrhythmias, weight loss, diarrhea, anxiety, depression including suicidal behavior/ideation and completed suicide	Hypersensitivity to roflumilast Contraindicated in patients with moderate to severe hepatic impairment (Child-Pugh class B or C)	Adjunctive therapy with bronchodilators Not for relief of acute bronchospasm

MDI, metered-dose inhaler; DPI, dry powder inhaler; SMI, soft mist inhaler; CNS, central nervous system.

Beta2-Adrenergic Agonists

Mechanism of Action

Beta$_2$-adrenergic agonists stimulate beta$_2$-adrenergic receptors, increasing the production of cyclic 3′5′ adenosine monophosphate (cAMP). Increased cAMP relaxes airway smooth muscle and increases bronchial ciliary activity. Adverse effects of beta$_2$-adrenergic receptor stimulation include increased skeletal muscle activity, central nervous system stimulation, hyperglycemia, and hypokalemia. All beta$_2$-adrenergic agonists have slight cardiovascular stimulatory effects including increased heart rate, increased force of cardiac contractility, and increased cardiac conductivity.

Dosage and Time Frame for Response

The short-acting inhaled beta$_2$-adrenergic agonists (SABAs) (e.g., albuterol, levalbuterol) have a quick onset (peak effect 10 minutes) and a short duration of action (3 to 4 hours). Salmeterol, the first long-acting beta$_2$-adrenergic agonist (LABA), has an onset of action of about 2 hours and a 12-hour duration of action. Formoterol and arformoterol have an onset of action of 3 minutes and 7 to 20 minutes, respectively, and a 12-hour duration of action. The newer LABAs indacaterol, vilanterol, and olodaterol, sometimes called ultra-long–acting beta$_2$-adrenergic agonists (ULABAs), have an onset of action of several minutes and a 24-hour duration of action. Oral (e.g., albuterol syrup and tablets, terbutaline tablets) and parenteral (e.g., terbutaline) dosage forms are available but have limited clinical use due to the quick onset of action, ease of administration, beta$_2$-adrenergic agonist specificity, and minimal systemic exposure with inhaled beta$_2$-adrenergic agonists. SABAs are indicated for the relief of acute COPD symptoms. LABAs are indicated for chronic maintenance therapy.

Contraindications

Beta-adrenergic agonists are contraindicated in persons with a history of hypersensitivity to beta-adrenergic agonists or any component of the formulation. Beta$_2$-adrenergic agonists should be used with caution in patients with known cardiovascular disease, diabetes mellitus, glaucoma, hyperthyroidism, or seizure disorders.

Adverse Effects

Common adverse effects with beta$_2$-adrenergic agonists include tachycardia, skeletal muscle tremor commonly seen as a fine hand tremor, nervousness, dizziness, hypokalemia, and hyperglycemia. Adverse effects are more common with high doses of inhaled drug and systemic administration (oral, parenteral).

Interactions

Other sympathomimetic drugs (e.g., catecholamines, catecholamine analogs, and amphetamines) increase the risk for beta$_2$-adrenergic agonist adverse effects and toxicities. Nonselective and higher doses of beta$_1$-selective adrenergic blocking drugs diminish the bronchodilator effects of the beta$_2$-adrenergic agonists; the risk to benefit ratio must be considered before prescribing beta-adrenergic blocking drugs. Concurrent administration of beta-adrenergic agonists and monoamine oxidase inhibitors (MAOIs) or tricyclic antidepressants (TCAs) increases blood pressure and the risk of stroke. MAOIs and TCAs must be discontinued at least 14 days prior to initiating beta$_2$-adrenergic agonists. Thiazide (e.g., hydrochlorothiazide) and loop diuretics (e.g., furosemide) enhance the hypokalemic effect of beta$_2$-adrenergic agonists. The oxazolidinones (e.g., linezolid, tedizolid) enhance the hypertensive effect of beta$_2$-adrenergic agonists. Atomoxetine, a selective norepinephrine reuptake inhibitor indicated for the management of attention deficit hyperactivity disorder, may increase the tachycardic effect of beta$_2$-adrenergic agonists.

Anticholinergics

Mechanism of Action

Anticholinergic drugs competitively block acetylcholine at muscarinic receptors, decreasing cGMP. The decreased cGMP results in a relatively higher proportion of cAMP. Increased cAMP relaxes airway smooth muscle and increases bronchial ciliary activity. Anticholinergic drugs also decrease mucus secretion, dilate the pupil, and prevent acetylcholine-induced release of allergenic mediators from mast cells. Although atropine, the classic anticholinergic, crosses the blood–brain barrier and stimulates the central nervous system, the drugs used to manage COPD are quaternary amines. Quaternary amines are poorly absorbed after oral administration and unable to cross the blood–brain barrier.

Dosage and Time Frame for Response

The short-acting anticholinergic (SAMA) ipratropium bromide has an onset of action within 15 minutes, a peak effect within 1 to 2 hours, and a duration of action of 2 to 5 hours. The long-acting anticholinergics (LAMAs) tiotropium bromide, aclidinium bromide, and umeclidinium bromide have a duration of action of 24 hours or more.

Contraindications

Anticholinergics are contraindicated in persons with a history of hypersensitivity to anticholinergics or any component of the formulation. Anticholinergics should be used with caution in patients with narrow-angle glaucoma, myasthenia gravis, prostatic hyperplasia, or bladder neck obstruction.

Adverse Effects

The most common adverse effects with inhaled anticholinergics are dry mouth, cough, and, if the medication gets in the eyes, blurred vision. Due to poor absorption after oral administration, systemic side effects are uncommon but may include restlessness, dizziness, gastrointestinal distress, and urinary obstruction. Paradoxical bronchospasm may occur after administration of inhaled anticholinergics.

Interactions

Concurrent administration of drugs with anticholinergic properties (e.g., first-generation antihistamines) increases the risk of anticholinergic adverse effects.

Corticosteroids

Mechanism of Action

Corticosteroids reduce airway inflammation by inhibiting or inducing the production of end-effector proteins. An activated intracellular drug–receptor complex binds to glucocorticoid responsive elements in the gene promoter regions of DNA, stimulating or inhibiting protein transcription. End-effector proteins alter vascular tone, vascular permeability, and body water distribution; stimulate lipolysis, gluconeogenesis, and glycogen secretion; increase responsiveness of beta-adrenergic receptors; mobilize amino acids from muscles; impair leukocyte migration; and inhibit nuclear factor-kappa, which regulates production of proinflammatory proteins such as cytokines, interleukins, interferons, and chemokines.

Dosage and Time Frame for Response

Moderate to high doses of inhaled corticosteroids are indicated as a component of the chronic maintenance regimen for patients with GOLD groups C and D. Inhaled corticosteroids are used in combination with long-acting bronchodilators to reduce the risk of exacerbations in persons with COPD at high risk of exacerbations. There is no evidence for lower doses or for benefit in persons at lower exacerbation risk.

A short-course of oral corticosteroids (e.g., prednisone 40 mg daily for 5 days) is indicated for the treatment of an acute COPD exacerbation. The dose is lower and the duration of therapy is shorter than for patients with asthma exacerbations.

The onset of action of systemic and inhaled corticosteroids (hours to days) is delayed due to the time it takes for the drug to influence protein expression. It takes several hours for lung function to improve in response to systemic (oral or intravenous) corticosteroids. The response to inhaled corticosteroid typically begins during the first week of therapy and continues to increase for weeks to months with continued treatment.

Contraindications

Corticosteroids are contraindicated in persons with a history of hypersensitivity to corticosteroids or any component of the formulation.

Adverse Events

Common adverse events with inhaled corticosteroids include oral candidiasis and dysphonia. Patients should be counseled to rinse their mouth, gargle, and spit out the water after each dose. Common adverse effects with short-term oral corticosteroids include sodium and water retention (peripheral edema, increased blood pressure, exacerbation of congestive heart failure), hyperglycemia, increased appetite and weight gain, CNS

stimulation and/or nightmares, peptic ulcer, and leukocytosis.

Common adverse effects with long-term (more than 14 days) high doses (typically greater than 7.5 mg/d of prednisone or equivalent) include adrenal suppression, muscle wasting, myopathy, decreased bone mineral density, posterior subcapsular cataracts, dermal thinning, ecchymosis, and peptic ulcer. Persons taking high-dose inhaled corticosteroids are at risk of the same adverse effects.

Interactions

Corticosteroids are metabolized by the hepatic cytochrome P-450 isoenzyme CYP3A4. Corticosteroids induce CYP2C19 and CYP3A4. The prescriber should check for potential drug interactions before prescribing corticosteroids and counsel persons with COPD to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Concurrent use of inhaled corticosteroids and strong inhibitors of CYP3A4 (e.g., ritonavir, clarithromycin, itraconazole, ketoconazole, telithromycin) increases the risk of systemic corticosteroid adverse effects and is not recommended.

Systemic corticosteroids decrease the response to skin tests, enhance adverse effects from live vaccines, and decrease the response to oral antidiabetic drugs. Antacids decrease the oral bioavailability of oral corticosteroids; counsel the patient to wait at least 2 hours between doses of an antacid and oral corticosteroid.

Methylxanthines

Mechanism of Action

Methylxanthine bronchodilators (theophylline, aminophylline) relax bronchial smooth muscle, enhance diaphragmatic contractility, and have a slight anti-inflammatory effect; the exact mechanisms of action are not known. Methylxanthines, nonselective phosphodiesterase inhibitors, increase cAMP by inhibiting phosphodiesterase 1, 2, 3, 4, and 7. Increased cAMP relaxes airway smooth muscle and increases bronchial ciliary activity. The enhanced diaphragmatic contractility is probably mediated by weak adenosine antagonism. The slight anti-inflammatory effect is mediated by other molecular mechanisms.

Dosage and Time Frame for Response

Theophylline and aminophylline, the ethylenediamine salt of theophylline, are dosed to a target serum drug concentration. Aminophylline is about 80% theophylline. Although the therapeutic serum drug concentration range is generally accepted to be 10 mg to 20 mg/L, persons with COPD may do well with lower serum drug concentrations or experience unacceptable adverse effects with serum drug concentrations within the therapeutic range. The half-life of theophylline is short (approximately 8 hours in nonsmokers); sustained-release dosage formulations (q12h and q24h) are recommended to improve patient adherence. Theophylline is metabolized in the liver; many medical conditions and drugs induce or inhibit theophylline metabolism. It is therefore important to monitor the serum drug concentrations and individualize the dosage based upon patient response, concurrent medical conditions, and drug interactions.

Contraindications

Theophylline and aminophylline are contraindicated in persons with a history of hypersensitivity to theophylline or any component of the formulation. Patients with a history of allergy to aminophylline are most likely allergic to the ethylenediamine component of the medication, not theophylline. Methylxanthines should be used with caution in patients with a history of tachyarrhythmia, peptic ulcer disease, seizure disorders, or hyperthyroidism. Intravenous dosage forms may contain propylene glycol, which can accumulate in persons with renal dysfunction. Large amounts of propylene glycol may cause lactic acidosis, hyperosmolality, seizures, and respiratory depression. Oral dosage forms may contain dyes, alcohol, or sugar.

Adverse Events

Common adverse events with methylxanthines include tachyarrhythmias, restlessness, insomnia, tremor, nausea, vomiting, gastroesophageal reflux, seizures, and peptic ulcer

aggravation. Tachycardia and potentially life-threatening cardiac arrhythmias may occur at therapeutic concentrations. Seizures usually occur with serum theophylline concentrations above 35 mg/L but may occur at lower concentrations.

Interactions

Theophylline is primarily metabolized by the hepatic cytochrome P-450 isoenzymes CYP1A2, CYP2E1, and CYP3A4; theophylline is a minor substrate of CYP2C9 and CYP2D6. Hepatic metabolism can be induced or inhibited by hundreds of drugs and by medical conditions that affect hepatic function. The prescriber should check for potential drug interactions before prescribing theophylline and counsel persons with COPD to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Examples of commonly used drugs that inhibit theophylline metabolism (increase theophylline serum concentration) include ciprofloxacin, cimetidine, erythromycin, and allopurinol. Examples of commonly used drugs that induce theophylline metabolism (decrease theophylline serum concentration) include phenobarbital, diphenylhydantoin, and rifampin. The prescriber should check for potential drug interactions before prescribing theophylline and counsel persons with COPD to check with the prescriber before starting or stopping any nonprescription, prescription, or complementary medication.

Smoking induces theophylline metabolism, lowering the serum drug concentration. Caffeine and sympathomimetic drugs have similar adverse effects as the methylxanthines; concurrent use increases the risk of adverse effects. Theophylline may antagonize the sedating and anxiolytic effect of benzodiazepines.

Phosphodiesterase 4 Inhibitors

Mechanism of Action

Roflumilast inhibits phosphodiesterase 4, an enzyme commonly found in respiratory inflammatory cells (e.g., neutrophils, monocytes, macrophages, CD4+ and CD8+ T lymphocytes) and structural cells (e.g., endothelial cells, epithelial cells, smooth muscle cells, and fibroblasts). Phosphodiesterase 4 inhibition increases intracellular cAMP, modifying the inflammatory response in these respiratory cells and structures.

Dosage and Time Frame for Response

Roflumilast is an alternative maintenance medication for patients with GOLD groups C and D COPD. The dose is 500 mcg daily. Although roflumilast increases FEV_1 slightly, the increase may not be clinically significant. Roflumilast is used to reduce the risk of exacerbations in persons at high risk for exacerbations.

Contraindications

Roflumilast is contraindicated in persons with a history of hypersensitivity to roflumilast or any component of the formulation. Roflumilast undergoes hepatic metabolism. Given the risk for serious and potentially life-threatening adverse events, roflumilast is contraindicated in persons with Child-Pugh B or C moderate to severe liver impairment.

Adverse Events

Roflumilast increases the risk of suicide even in persons with no history of suicidal ideation; several completed suicides were reported during preapproval trials. Patients and their families must be counseled to report new or worsening insomnia, anxiety, depression, suicidal thoughts, or changes in mood. Weight loss has been reported with roflumilast. Patient weight must be monitored regularly. Roflumilast should be discontinued if persons with COPD experience significant weight loss while taking the drug.

Interactions

Roflumilast is metabolized by the hepatic cytochrome P-450 isoenzymes CYP3A4 and CYP1A2. CYP3A4 inhibitors and dual CYP3A4 and CYP1A2 inhibitors impair roflumilast hepatic metabolism, increasing the serum concentration of roflumilast and increasing the risk for clinically significant adverse events, and should only be used with caution. The concurrent administration of strong CYP3A4 inducers such as rifampicin, phenobarbital, carbamazepine, and phenytoin is not recommended.

Immunizations

All persons with COPD should receive an annual influenza vaccine. The Center for Disease Control Advisory Committee on Immunization Practices recommends that immunocompetent and adults with COPD receive the 23-valent pneumococcal polysaccharide vaccine (PPSV23) (CDC, 2012, 2013). The 13-valent pneumococcal conjugate vaccine (PCV13) is recommended for persons receiving long-term systemic corticosteroids.

Oxygen

Chronic oxygen therapy (greater than 15 hours/d) is indicated for persons with COPD if twice over a 3-week period of disease stability the resting P_aO_2 is ≤55 mm Hg or the S_aO_2 is 88% or less with or without hypercapnia (Stoller et al., 2010). For persons with COPD and pulmonary hypertension, congestive heart failure, or polycythemia (hematocrit greater than 55%), chronic oxygen therapy is indicated if the P_aO_2 is 55 to 60 mm Hg or the S_aO_2 is 88% or less.

Antibiotics

Respiratory infections (viral or bacterial) are common causes of COPD exacerbations. A 5- to 10-day course of antibiotics is indicated if all three cardinal symptoms of an acute exacerbation (i.e., increased dyspnea, increased sputum volume, purulent sputum) are present or purulent sputum and one other cardinal symptom are present or if the person requires mechanical ventilation (GOLD, 2016). The most common bacterial pathogens associated with COPD exacerbations are *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*; persons with a history of frequent exacerbations are at risk for infections with *Pseudomonas aeruginosa* (Sethi & Murphy, 2008). Local antibiotic sensitivity and resistance patterns must be considered when selecting the antibiotic.

Selecting the Most Appropriate Drug

Initial drug therapy selection depends on COPD severity, symptoms, and exacerbation risk (Table 26.2).

First-Line Therapy

All persons with COPD need at least one short-acting bronchodilator for self-management of acute symptoms. Either the short-acting beta$_2$-adrenergic agonist albuterol or the SAMA ipratropium bromide is indicated; a SABA is preferred for persons taking a LAMA for maintenance therapy. The combination SABA plus SAMA is an option for persons with GOLD group B, C, or D COPD.

Maintenance therapy is not indicated as first-line therapy for persons with GOLD group A COPD. The first-line maintenance therapy for persons with GOLD group B COPD is a LAMA or a LABA. The first-line maintenance therapy for persons with GOLD groups C and D is an inhaled corticosteroid plus a LAMA or LABA.

Second-Line Therapy

The second-line maintenance therapy for persons with GOLD group A is a LAMA, LABA, or the combination of a SABA plus a SAMA. The combination of a LAMA plus a LABA is second-line therapy for persons with GOLD groups B, C, and D. The combination of the phosphodiesterase 4 inhibitor roflumilast plus a LAMA or LABA is another second-line option for persons with GOLD groups C and D COPD. Other second-line therapy options for persons with GOLD group D include triple therapy (inhaled corticosteroid plus a LAMA plus a LABA) or quadruple therapy (inhaled corticosteroid plus LAMA plus LABA plus roflumilast).

Other Options

Theophylline, alone or in combination with first-line or second-line regimens for GOLD groups A, B, C, and D, is an option. A SABA, SAMA, or the combination of a SABA plus a SAMA may be used alone or in combination with first-line or second-line regimens for GOLD groups B, C, and D.

Special Considerations

Geriatric

Older persons with COPD at risk of cardiovascular disease or with known cardiovascular disease may be at risk from the cardiovascular stimulatory effects of $beta_2$-adrenergic agonists, especially with higher doses; inhaled anticholinergics may be better tolerated. Theophylline clearance may be decreased in older persons with COPD increasing the risk of theophylline cardiovascular stimulatory adverse effects. Theophylline dosing must be individualized and serum drug concentrations monitored closely. Elderly persons are more likely to be taking multiple other medications, increasing the likelihood of drug–drug and drug–medical condition interactions. Kinesthetic motor skills, visual acuity, and inspiratory flow may decline with aging making it difficult for patients to prepare and self-administer medications using respiratory drug delivery devices. Higher doses of inhaled corticosteroids and repeated doses of oral corticosteroids may increase the risk of osteoporosis. Women and men with known osteopenia or osteoporosis should be advised to take supplemental calcium (1,000 to 1,500 mg calcium) and vitamin D (400 units) per day.

Women

There are no gender-specific recommendations for managing COPD.

Ethnic

Culturally specific beliefs regarding cause of disease, acceptance of acute or chronic medications, medication color, dosage formulation, and route of administration may influence a person's acceptance and adherence to the prescribed drug and nondrug therapy. Persons with COPD may seek care from healers and may be using natural remedies. It is important to ask about, respect, and integrate these beliefs into the COPD management plan.

Genomics

There are no gene-specific therapeutic recommendations for managing COPD.

Acute Exacerbations

COPD exacerbations are common; a frequent exacerbator experiences two or more exacerbations per year. Viral or bacterial respiratory infections are common causes of acute exacerbations though the cause may not be identifiable. The GOLD guidelines define a COPD exacerbation as "An acute event characterized by a worsening of the patient's respiratory symptoms that is beyond normal day-to-day variation and leads to a change in medication" (GOLD, 2016). Exacerbations are characterized by an acute change in one or more of the following symptoms: cough (increased frequency and severity), sputum (increased volume or change in appearance), and dyspnea (increased). The decision to hospitalize a person for management of an acute COPD exacerbation often is difficult. Indicators for hospitalization include severe baseline COPD, presence of significant comorbidities, older age, inadequate home support, new cardiopulmonary signs on physical exam (e.g., cyanosis), and failure of drug therapy to resolve the exacerbation (GOLD, 2016). Discharge may be considered when the person has been clinically stable for 12 to 24 hours and needs the short-acting bronchodilator no more frequently than every 4 hours.

Management of an acute COPD exacerbation includes increasing the dose and/or frequency of the short-acting bronchodilator (SABA or SAMA); adding a 5-day course of oral corticosteroids (e.g., prednisone 40 mg daily) if the FEV_1 is less than 50% of predicted; adding a 5- to 10-day course of antibiotics if all three cardinal COPD exacerbation symptoms, are present (increased dyspnea, increased sputum volume, and purulent sputum), the person has purulent sputum plus one other cardinal or the person required endotracheal intubation and mechanical ventilation; and supplemental oxygen to maintain the P_aO_2 55 mm Hg or more (GOLD, 2015).

Monitoring Patient Response

Routine follow-up appointments should be scheduled every 2 to 3 months. Self-assessment questionnaires should be completed at each visit. Assess trends in patient symptoms, including cough, sputum, breathlessness, and fatigue, and determine if the person smokes tobacco or is exposed to environmental inhaled toxins. Encourage and support smoking cessation. Identify exacerbations and discuss modifiable factors. Assess medication adherence and identify any medication-related adverse effects. Evaluate respiratory drug administration techniques to ensure adequate drug delivery. Assess serum theophylline concentrations before adjusting the dose and no sooner than 48 hours after a change in dose. For persons on a stable theophylline regimen, assess the serum theophylline concentration at least annually. Perform the physical exam, monitoring lung function and any comorbidities. The GOLD 2016 guidelines recommend that spirometry be performed at least annually (GOLD, 2016).

Patient Education

Patient education includes counseling about medications, including indications, dosing, mechanisms of action, potential side effects, and drug delivery techniques. Advise persons with COPD to avoid medications that suppress the respiratory system, including first-generation antihistamines, cough suppressants, narcotics, and tranquilizers. Encourage all persons with COPD to check with a health care professional before starting any nonprescription, prescription, or complementary alternative medication.

Drug Information

The GOLD guidelines contain pharmacologic class and product-specific drug information. Drug information is available on professional organization (e.g., the American College of Chest Physicians), nonprofit organization (e.g., the American Lung Association), and government (e.g., National Institutes of Health) Web sites. Pharmaceutical company Web sites often include links to respiratory drug delivery device videos. Pharmacy therapeutics and medical pulmonary textbooks provide more in-depth drug information.

Patient-Oriented Information Sources

Patient-oriented information about COPD is available from many resources. Local support groups, often affiliated with local hospitals, provide ongoing multidisciplinary support for patients and their families. Many Web sites provide patient-oriented information. Sources of noncommercial information include the National Heart, Lung, and Blood Institute Web site (www.nhlbi.nih.gov), the American Lung Association Web site (www.lungusa.org), and the American College of Chest Physicians Web site (www.chest.net.orgeducaton/patient/guide/copd).

Nutrition/Lifestyle Changes

Weight loss frequently occurs in persons with COPD; as many as one third to one half of persons with COPD are undernourished. Low body weight in persons with COPD is associated with impaired pulmonary status, reduced diaphragmatic mass, lower exercise capacity, and a higher mortality rate. Weight loss occurs because of increased energy requirements; metabolic and mechanical inefficiency contribute to the increased energy expenditure. An imbalance between protein synthesis and protein breakdown may cause a disproportionate depletion of fat-free mass. Persons with COPD need to be on an appropriate diet; supplemental nutrition may be necessary.

Complementary and Alternative Medications

The current GOLD guidelines do not recommend any complementary and alternative medical therapies (GOLD, 2016). Clinicians should ask persons with COPD about the use of these therapies, especially herbal and other products, to identify potential disease and drug interactions.

Respiratory Devices

Patient education regarding inhaled drug administration is essential (Table 26.4). Respiratory drug delivery systems include metered-dose inhalers, dry powder inhalers, soft mist inhalers, and nebulizers. Each device has unique characteristics, requiring different dose preparation and inhalation steps. This can be very confusing, especially for older persons with COPD using multiple different respiratory drug delivery systems.

TABLE 26.4 Drug Delivery Device Techniques

Device	General Technique
Pressurized metered-dose inhalers	1. Remove dust cap. 2. Inspect for debris. 3. Shake vigorously for 5 s. 4. Hold the device upright (mouthpiece down). 5. Position mouthpiece; do not block with tongue. 6. Press down on the canister and breathe in at the same 7. time (midinspiration actuation is more effective but is very difficult to perform). 8. Continue to inhale to the end of a quiet breath (about 4–6 s). 9. Hold breath for 10 s. 10. Exhale slowly. 11. Replace dust cap. 12. Wait at least 1 min between puffs for short-acting beta$_2$-adrenergic agonists and 15–30 s for all other drugs.
Device	**General Technique**
Spacers and valved holding chambers	1. Visually check for debris. 2. Prepare metered-dose inhaler. 3. Insert metered-dose inhaler in spacer. 4. Hold the spacer/valved holding chamber level. 5. Gently exhale to end of a quiet breath. 6. Press the canister once. 7. Immediately inspire slowly and deeply. 8. Remove spacer from mouth. 9. Hold breath for 10 s. 10. Exhale slowly.
Dry powder inhalers	1. Remove cover. 2. Prepare dose. 3. Exhale softly *away* from device. 4. Seal lips around mouthpiece. 5. Inhale rapidly and forcefully. 6. Remove device from mouth. 7. Hold breath for 10 s. 8. Exhale softly *away* from device. 9. Replace cover.
Soft mist inhaler	Priming: Prime for first use (different priming instructions if not used for more than 3 d and if not used for more than 21 d). 1. Hold upright with cap closed. 2. Turn clear base in the direction of the white arrows until it clicks (half a turn). 3. Flip open cap. 4. Breathe out slowly and fully. 5. Close lips around the end of the mouthpiece. 6. Point the inhaler to the back of throat. 7. While taking a slow deep breath, press the dose-release button. 8. Continue to breathe in slowly for as long as possible. 9. Remove inhaler from mouth. 10. Hold breath for 10 s. 11. Exhale slowly.
Small-volume nebulizers	1. Place the equipment on a stable surface. 2. Connect the tubing to the compressor. 3. Hold the medication chamber upright; add the premixed drug solution or measure and add drug and saline. 4. Place the lid on the medication chamber. 5. Connect the tubing to the medication chamber. 6. Turn on the air compressor. 7. Check for the generation of a fine mist. 8. Sit up comfortably straight. 9. Seal lips around the mouthpiece; do not block with tongue. 10. Holding the medication chamber upright, breathe in and out normally; take a deeper breath and hold it for a few seconds every minute or so. 11. Continue until the medication chamber begins to sputter. 12. Turn off the compressor. 13. Disconnect the medication chamber and tubing.

Case Study*

M.V. is a 53-year-old accountant who smoked a pack of cigarettes a day for 30 years. He quit smoking 6 months ago. He presents with shortness of breath while hurrying on level ground or walking up a slight hill but is not limited doing any activities at home. He complains of a chronic productive morning cough. He was treated at home for one respiratory infection last year. On physical exam, you observe wheezing throughout all lung fields, hyperresonance on percussion of the lungs, and low flat diaphragms. He has no cyanosis, clubbing, or edema. His mMRC dyspnea score is 1. His CAT™ score is 6. Pulmonary function studies show an FEV_1/FVC less than 70% with an FEV_1 72% of predicted. He has no other medical conditions and is not taking any nonprescription, prescription, or complementary alternative medicine. He has no known drug allergies.

Diagnosis: Chronic Obstructive Pulmonary Disease

1. List specific goals for treatment for M.V.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for M.V.?
8. What lifestyle changes would you recommend to M.V.?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

27 Bronchitis and Pneumonia

Andrew J. Grimone ■ Virginia P. Arcangelo ■ Eric T. Wittbrodt

Acute Bronchitis

In the United States, acute bronchitis is diagnosed in 5% of adults and accounts for over 10 million outpatient office visits annually (Liapikou & Torres, 2014). The disease is a reversible inflammatory condition of the tracheobronchial tree that occurs in all age groups and is usually self-limiting. Typically, acute bronchitis occurs during the winter months. Predisposing factors for acute bronchitis include cold air, damp climates, fatigue, malnutrition, and inhalation of irritating substances, such as polluted air and cigarette smoke.

Causes

Viral infections cause over 90% of acute bronchitis episodes; the most common respiratory viruses associated with acute bronchitis are rhinovirus, coronavirus, influenza virus A and B, parainfluenza virus, adenovirus, and respiratory syncytial virus (RSV). Bacterial infections cause less than 10% of acute bronchitis (Liapikou & Torres, 2014). The only bacterial microorganisms implicated in the pathogenesis of uncomplicated acute bronchitis are *Bordetella pertussis*, *Chlamydophila pneumoniae*, and *Mycoplasma pneumoniae*. Limited evidence indicates that other common respiratory tract pathogens such as *Streptococcus pneumoniae* can contribute to acute bronchitis.

Pathophysiology

Acute bronchitis is characterized by infection of the tracheobronchial tree. This infection results in hyperemic and edematous mucous membranes, yielding an increase in bronchial secretions. Destruction of the respiratory epithelial lining and reduced mucociliary function result from these changes. This process is usually transient and resolves after the infection clears.

Diagnostic Criteria

Signs and symptoms of acute bronchitis are preceded by manifestations of an upper respiratory tract infection such as coryza, malaise, chills, back and muscle pain, headache, and sore throat. If fever is present, it rarely exceeds 102.2°F (39°C) and lasts for 3 to 5 days. Fever is more commonly seen with adenovirus, influenza virus, and *M. pneumoniae* infection. The hallmark of acute bronchitis is a cough that is initially dry and nonproductive; however, as the production of bronchial secretions increases, the cough becomes more abundant and mucoid. The cough usually lasts for 7 to 10 days, although in some patients, it can persist for weeks to months. Patients also present with phlegm, hoarseness, and wheezing.

Pulmonary examination may reveal signs of coarse, moist bilateral crackles, rhonchi, and wheezing. The chest x-ray typically reveals no active disease; thus, a chest x-ray is not indicated unless pneumonia is suspected. The usefulness of cultures to identify the causative microorganisms is limited because most cases of acute bronchitis are viral in origin, and cultures usually are negative or grow normal nasopharyngeal flora. Laboratory tests may reveal a normal or slightly elevated white blood cell (WBC) count.

The high reported incidence of acute bronchitis can be correlated with the absence of definitive diagnostic signs or laboratory tests. Thus, the diagnosis is based purely on the patient's risk factors and signs and symptoms. In many patients, an upper respiratory tract infection (sinusitis or allergic rhinitis) may be misdiagnosed as acute bronchitis.

Initiating Drug Therapy

The general treatment for acute bronchitis is symptomatic and supportive care (Figure 27.1). Patients should be encouraged to drink plenty of fluids to prevent dehydration and decrease the viscosity of bronchial secretions. Bed rest is indicated until fever subsides. Mild analgesic/antipyretic therapy is effective for relief of fever and musculoskeletal pains. Aspirin or acetaminophen (Tylenol; 650 mg in adults or 10 to 15 mg/kg per dose in children) or ibuprofen (Advil, others; 200 to 400 mg in adults or 5 to 10 mg/kg per dose in children) administered every 4 to 6 hours can be used as analgesic/antipyretic therapy. Acetaminophen is the agent of choice because aspirin should be avoided in children, given the correlation of aspirin and the development of Reye syndrome in this age group. Aspirin and ibuprofen should also be used cautiously in the elderly, patients with a history of peptic ulcer disease or recent gastrointestinal (GI) bleeding, and patients with renal insufficiency.

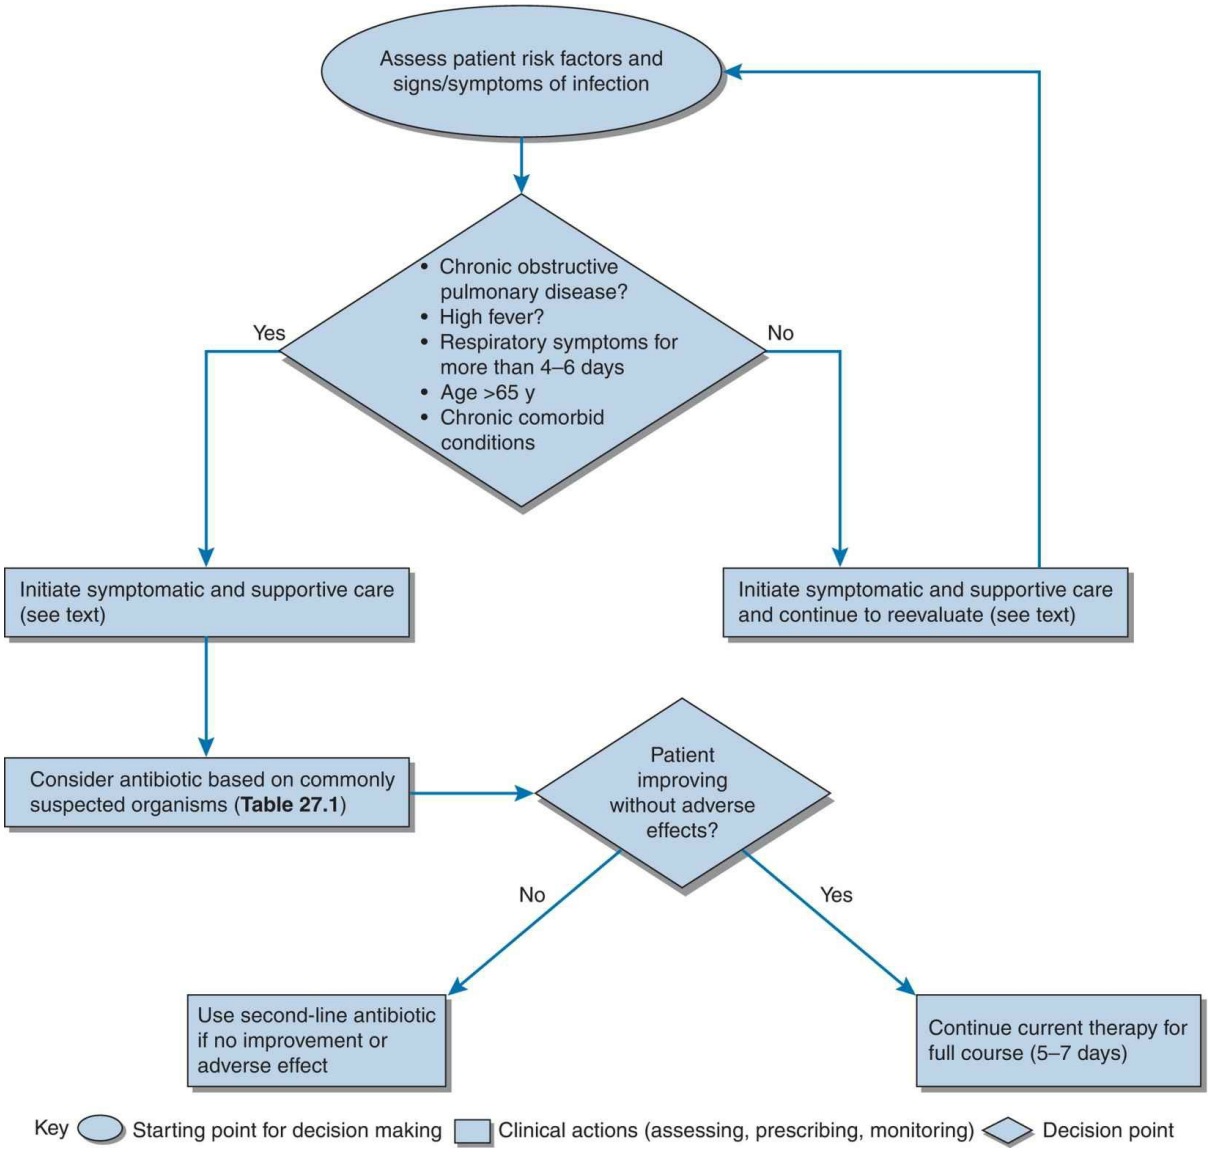

FIGURE 27.1 Treatment algorithm for acute bronchitis.

Nonprescription cough and cold medications (see Chapter 24) often are used to help reduce the signs and symptoms of acute bronchitis. The use of nonprescription medications that contain various combinations of antihistamines, sympathomimetic agents, and antitussives can result in dehydration of bronchial secretions. This could lead to further aggravation of symptoms, which prolongs the recovery process. Cough that is associated with acute bronchitis can become bothersome. Dextromethorphan, an antitussive agent, is recommended to help treat mild, persistent cough. Severe cough may require a more potent cough medication that contains codeine or hydrocodone.

In patients with fever and a productive cough persisting beyond 4 to 6 days, treatment with antibiotics may be indicated to treat bacterial coinfection, especially in patients with underlying pulmonary disease.

Goals of Drug Therapy

The goals of pharmacotherapy include providing the patient with comfort and, in severe cases, treating associated dehydration and respiratory compromise. If antibiotics are administered, minimizing side effects is also a goal.

Antibiotics

Antibiotics are often prescribed for patients with acute bronchitis; however, in otherwise healthy patients, they offer little relief from the respiratory symptoms of the disease and do not shorten the course of the illness. Therefore, routine use of antibiotics for acute bronchitis is discouraged. Despite this, studies have shown that approximately two thirds of patients diagnosed with acute bronchitis in the United States are prescribed antibiotic therapy. Part of the reason for antibiotic overprescribing is lack of patient and caregiver education on the causes of acute bronchitis. Surveys suggest that over 50% of patients believe that antibiotics are effective in treating viral upper respiratory tract infections. Patient education on appropriate treatment is crucial to prevent inappropriate antibiotic use. One educational method useful in teaching patients and caregivers about this illness is selection of descriptive words such as “chest cold” or “viral upper respiratory tract infection” instead of using the term “acute bronchitis.”

Antibiotics are indicated if the patient has concomitant chronic obstructive pulmonary disease (COPD), high fevers, purulent sputum, or respiratory symptoms for more than 4 to 6 days. Additionally, antibiotics may be considered in patients over 65 years of age or those with chronic diseases such as heart failure, diabetes mellitus, or serious neurological disorders. Empiric antibiotic therapy should be directed against the microorganisms commonly suspected to cause acute bronchitis.

Selecting the Most Appropriate Agent

Table 27.1 lists the antibiotics that are commonly used to treat acute bronchitis caused by bacteria. Aminopenicillins such as amoxicillin (Amoxil) are effective against infections caused by *S. pneumoniae* and *Haemophilus influenzae*.

TABLE 27.1 Acute Bronchitis: Drug Therapy for Selected Microorganisms

Microorganism	Treatment
H. influenzae	aminopenicillin (amoxicillin)
M. catarrhalis, H. influenzae (beta-lactamase producing)	amoxicillin + clavulanate (Augmentin)
M. pneumoniae, Chlamydophila pneumoniae	macrolide (erythromycin, clarithromycin, or azithromycin) or doxycycline
B. pertussis	macrolide (erythromycin, clarithromycin, or azithromycin)
Influenza A	oseltamivir or zanamivir
Influenza B	oseltamivir or zanamivir

For microorganisms that produce beta-lactamase, such as *Moraxella catarrhalis* and *H. influenzae*, aminopenicillins given in combination with a beta-lactamase inhibitor, such as amoxicillin–clavulanate (Augmentin), or a second- or third-generation cephalosporin should be administered.

For acute bronchitis due to atypical bacteria such as *M. pneumoniae* and *Chlamydophila* species, macrolides (e.g., erythromycin [Eryc], clarithromycin [Biaxin], or azithromycin [Zithromax]) or doxycycline (Vibramycin) are effective. Doxycycline should not be used in children younger than age 8. In this population, the agent of choice is a macrolide. If *B. pertussis* is the likely microorganism, erythromycin or another macrolide is the drug of choice.

During epidemics caused by influenza A or B virus, oseltamivir (Tamiflu) and zanamivir (Relenza Diskhaler) may be administered early in the course of the illness to minimize symptoms of influenza in adults and pediatrics who have been symptomatic for no longer than 2 days. For more information about antibiotic/antimicrobial therapy, refer to Chapter 8.

Chronic Bronchitis

Chronic bronchitis is a component of COPD, which is one of the five leading causes of death in the United States. (see Chapter 26 for a discussion of COPD.) The standard description/definition of chronic bronchitis is productive cough and sputum production for 3 months per year for at least two consecutive years. An acute exacerbation of chronic bronchitis is defined as worsening of respiratory symptoms such as increased cough, sputum, and dyspnea that warrants a change in medications. Chronic bronchitis primarily affects adults and occurs more commonly in men than in women. Over 10% of the adult population in the United States aged 40 or older is afflicted with chronic bronchitis, which accounts for a large amount of health care expenditures and lost wages (Kim & Criner, 2013). Patients with chronic bronchitis are more likely to have frequent and severe episodes of acute bacterial bronchitis. Exacerbations of COPD account for more than 50% of the overall cost related to the treatment of COPD (Qureshi et al., 2014). Because many infections are untreated, the exact morbidity of acute exacerbations of chronic bronchitis is unknown.

Causes

Several factors are implicated in the pathogenesis of chronic bronchitis, leading to chronic inflammation and sputum production. The predominant factor in chronic bronchitis is cigarette smoke, a well-known respiratory irritant, and most patients with chronic bronchitis have a history of cigarette smoking. However, chronic bronchitis has been noted in 4% to 22% of patients who never smoked (Kim & Criner, 2013), suggesting other causative factors. Occupational dust, fumes, and environmental pollution are some additional risk factors that contribute to the etiology of the disease. The presence of gastroesophageal reflux and hypersecretion of mucus in patients with asthma has also been shown to yield symptoms of chronic bronchitis. Evidence suggests that recurrent respiratory infections may predispose a person to development of chronic bronchitis, although the exact reason for this is unclear.

Colonization of the lower airways with bacteria such as *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae* has been frequently detected in patients with chronic bronchitis. Up to 25% of patients with stable COPD have been found to be colonized with these bacteria. These and other microorganisms harbored in the bronchial epithelium act as reservoirs for infection when patient host defenses become compromised. In patients with acute exacerbations of COPD, 70% to 80% of cases are triggered by bacterial or viral infections (Liapikou & Torres, 2014). Viral infections account for nearly one third of acute exacerbations. Other bacteria such as *Pseudomonas aeruginosa* and Enterobacteriaceae are more likely to be associated with acute exacerbations in patients with frequent exacerbations and advanced stages of COPD. Exposures to environmental pollution or unknown factors contribute to the remainder of acute exacerbations. The frequency and severity of exacerbations of chronic bronchitis are more frequent and severe with increasing stages of COPD.

Pathophysiology

Several physiologic abnormalities of the bronchial mucosa may lead to chronic bronchitis. It has been suggested that patients with chronic bronchitis are predisposed to respiratory infections because of overproduction and hypersecretion of mucus from goblet cells and impaired mucociliary clearance due to chronic inhalation of irritating substances. A factor leading to impaired mucociliary clearance is the replacement of ciliated epithelium with nonciliated metaplastic cells. This leads to the inability of the bronchi to clear the profuse, thick, sticky secretions present in patients with chronic bronchitis. In addition, inhalation of toxic irritants results in bronchial obstruction because of stimulation of cholinergic activity and increased bronchomotor tone.

Diagnostic Criteria

As with acute bronchitis, cough is the hallmark of chronic bronchitis. Cough, with sputum production, can be mild or severe and may be stimulated by simple conversation. Many patients with chronic bronchitis expectorate a large quantity of white to yellow tenacious sputum in the morning. Because of the characteristics of sputum, many patients complain of a foul taste in the mouth.

Clinical assessment and the patient's medical history contribute to the diagnosis of chronic bronchitis. Other diseases such as bronchiectasis, cardiac failure, cystic fibrosis, tuberculosis, pulmonary emboli, and lung carcinoma must be excluded before diagnosing a patient with chronic bronchitis or an acute exacerbation of chronic bronchitis. Patients with chronic bronchitis must have a cough with sputum production for at least 3 consecutive months for 2 consecutive years.

Physical examination of patients with chronic bronchitis is usually unremarkable except that chest auscultation reveals inspiratory and expiratory rales, rhonchi, and mild wheezing; normal breath sounds are diminished. As the severity of the disease progresses, an increase in the anteroposterior diameter of the thoracic cage (barrel chest appearance), hyperresonance on percussion, and limited mobility of the diaphragm are observed. Pulmonary function tests demonstrate a decrease in vital capacity and prolongation of expiratory flow. Other features of disease progression include clubbing of the fingers, cor pulmonale, hepatomegaly, and edema of the lower extremities.

The diagnosis of an acute exacerbation of chronic bronchitis relies on the clinical presentation of an acute change in symptoms. Since an acute exacerbation of chronic bronchitis is defined as worsening of respiratory symptoms that warrants a change in medications, diagnosis focuses on early changes in symptoms such as an increase in frequency and severity of cough. Other symptoms include increased sputum production, purulent sputum, hemoptysis, chest congestion and discomfort, increased dyspnea, and wheezing. Malaise, loss of appetite, and fever may also be present. True chills (rigors) and high-grade fever suggest pneumonia rather than an acute exacerbation of chronic bronchitis. This finding requires a chest x-ray for diagnosis. The duration of worsening or new symptoms, number and frequency of previous exacerbations, severity of underlying disease, comorbidities, and current treatment regimen for COPD are helpful in assessing a patient who presents with an acute exacerbation of chronic bronchitis. In these patients, pulse oximetry is useful for tracking and/or adjusting supplemental oxygen therapy. An electrocardiogram (ECG) may help in the diagnosis of or to rule out cardiac problems. A complete blood count (CBC) will help to identify leukocytosis.

To determine the need for hospitalization during an acute exacerbation of chronic bronchitis, the presence of severe symptoms including use of accessory muscles, worsening or new cyanosis, development of peripheral edema, hemodynamic instability, or

deterioration in mental status needs to be assessed. A sputum gram stain can assist in empiric antibiotic prescribing. Sputum culture and susceptibility testing may guide the clinician in choosing appropriate antibiotic therapy. In outpatients, sputum cultures are not often feasible or practical, as they take too long to return and frequently do not provide reliable results (i.e., more than 4 hours often elapses between expectoration of sputum and analysis in the laboratory). However, a sputum culture should be considered, especially in patients with frequent exacerbations requiring antibiotic use, failing current antibiotic therapy, known or suspected resistant pathogens, severe airflow limitation, and/or exacerbations requiring mechanical ventilation. Additionally, procalcitonin, a biomarker specific for bacterial infections, can be obtained to help in determining the presence of active infection. However, this test is currently reserved for patients in acute care settings, given the cost, lack of widespread availability, and delayed turnaround time for results.

A classification system for patients with chronic bronchitis is frequently used to identify high-risk patients and select the appropriate antimicrobial therapy for acute exacerbations according to the suspected microorganism. Table 27.2 outlines the classification system and treatment options, taking into consideration the baseline clinical status, risk factors, and common pathogens.

TABLE 27.2 Classification of Chronic Bronchitis and Treatment Options for Acute Exacerbations

Clinical Status	Risk Factors	Microorganisms	Treatment
Simple chronic bronchitis	Increased sputum production and purulence, no major risk factors, less than 3 exacerbations/year	*S. pneumoniae, H. influenzae,* and *M. catarrhalis* (low risk for antibiotic resistance)	First-line: amoxicillin, doxycycline, macrolide, or sulfamethoxazole/trimethoprim Second-line: amoxicillin–clavulanate (Augmentin); second- or third-generation cephalosporin
Complicated chronic bronchitis	FEV_1 < 50% of predicted value, advanced age (over 65 y of age), significant comorbidity (e.g., cardiac disease, diabetes, renal or hepatic insufficiency), home oxygen use, antibiotic use in the past 3 mo, and/or 3 or more exacerbations/year	*S. pneumoniae, H. influenzae, M. catarrhalis,* (resistance to beta-lactam antibiotics common)	First-line: amoxicillin–clavulanate (Augmentin XR); second- or third-generation oral cephalosporin; doxycycline Second-line: macrolide; fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin)
Severe complicated chronic bronchitis	FEV_1 < 35% of predicted value with risk factors for *P. aeruginosa* (frequent or recent antibiotic use, chronic corticosteroid use, advanced disease, and/or history of bronchiectasis)	The above microorganisms and Enterobacteriaceae, *P. aeruginosa* (more likely to have antibiotic-resistant bacteria)	levofloxacin or ciprofloxacin

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2015). Retrieved from www.goldcopd on July 10, 2015.

Patients with uncomplicated chronic bronchitis have little or no lung impairment and no major risk factors for antibiotic resistance. The most common pathogens include *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*. Viral infections should be considered before bacterial infections in this patient category. Although antibiotic resistance is less common in this group, over 50% of *H. influenza* and *M. catarrhalis* produce beta-lactamase, making

amoxicillin ineffective. This should be considered especially in patients who fail amoxicillin therapy.

Patients with complicated chronic bronchitis include those with moderate to severe (FEV_1 50% less than predicted) lung impairment, those who are elderly (over 65 years of age), those who have frequent exacerbations, and those who have comorbid illnesses such as congestive heart failure, diabetes mellitus, chronic renal failure, or chronic liver disease. The most common pathogens isolated in severe chronic bronchitis are *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. Frequent exacerbations in this population increase the likelihood of antibiotic use and the risk for antibiotic resistance, including penicillin-resistant *S. pneumoniae*.

Patients with severe complicated chronic bronchitis have characteristics similar to those in the previous group, but they have severe airflow obstruction and often have constant purulent sputum production. The same microorganisms found in the other groups should be considered in these patients; however, gram-negative microorganisms such as *P. aeruginosa* and Enterobacteriaceae should also be suspected.

Initiating Drug Therapy

A complete assessment of the patient's occupational and environmental history should be performed to treat chronic bronchitis properly. Patients should reduce or eliminate cigarette smoking and their exposure to second-hand smoke. This can be accomplished by counseling sessions and the use of nicotine replacement therapy. Also, exposure to inhaled irritants at work or home should be reduced or eliminated. Pharmacologic treatment should be optimized to prevent or control symptoms, reduce the frequency of exacerbations, and improve quality of life. (see Chapter 26 for a discussion of COPD.)

The approach to treatment of acute exacerbations of chronic bronchitis is multifactorial (Figure 27.2). The therapies listed in Box 27.1 should be initiated. Antibiotics should be initiated in patients with the three "cardinal symptoms" (Box 27.2) (or at least two cardinal symptoms if increased purulence of sputum is one of the two symptoms) or in hospitalized patients who require mechanical ventilation. Fever alone is not an indication for antibiotic therapy.

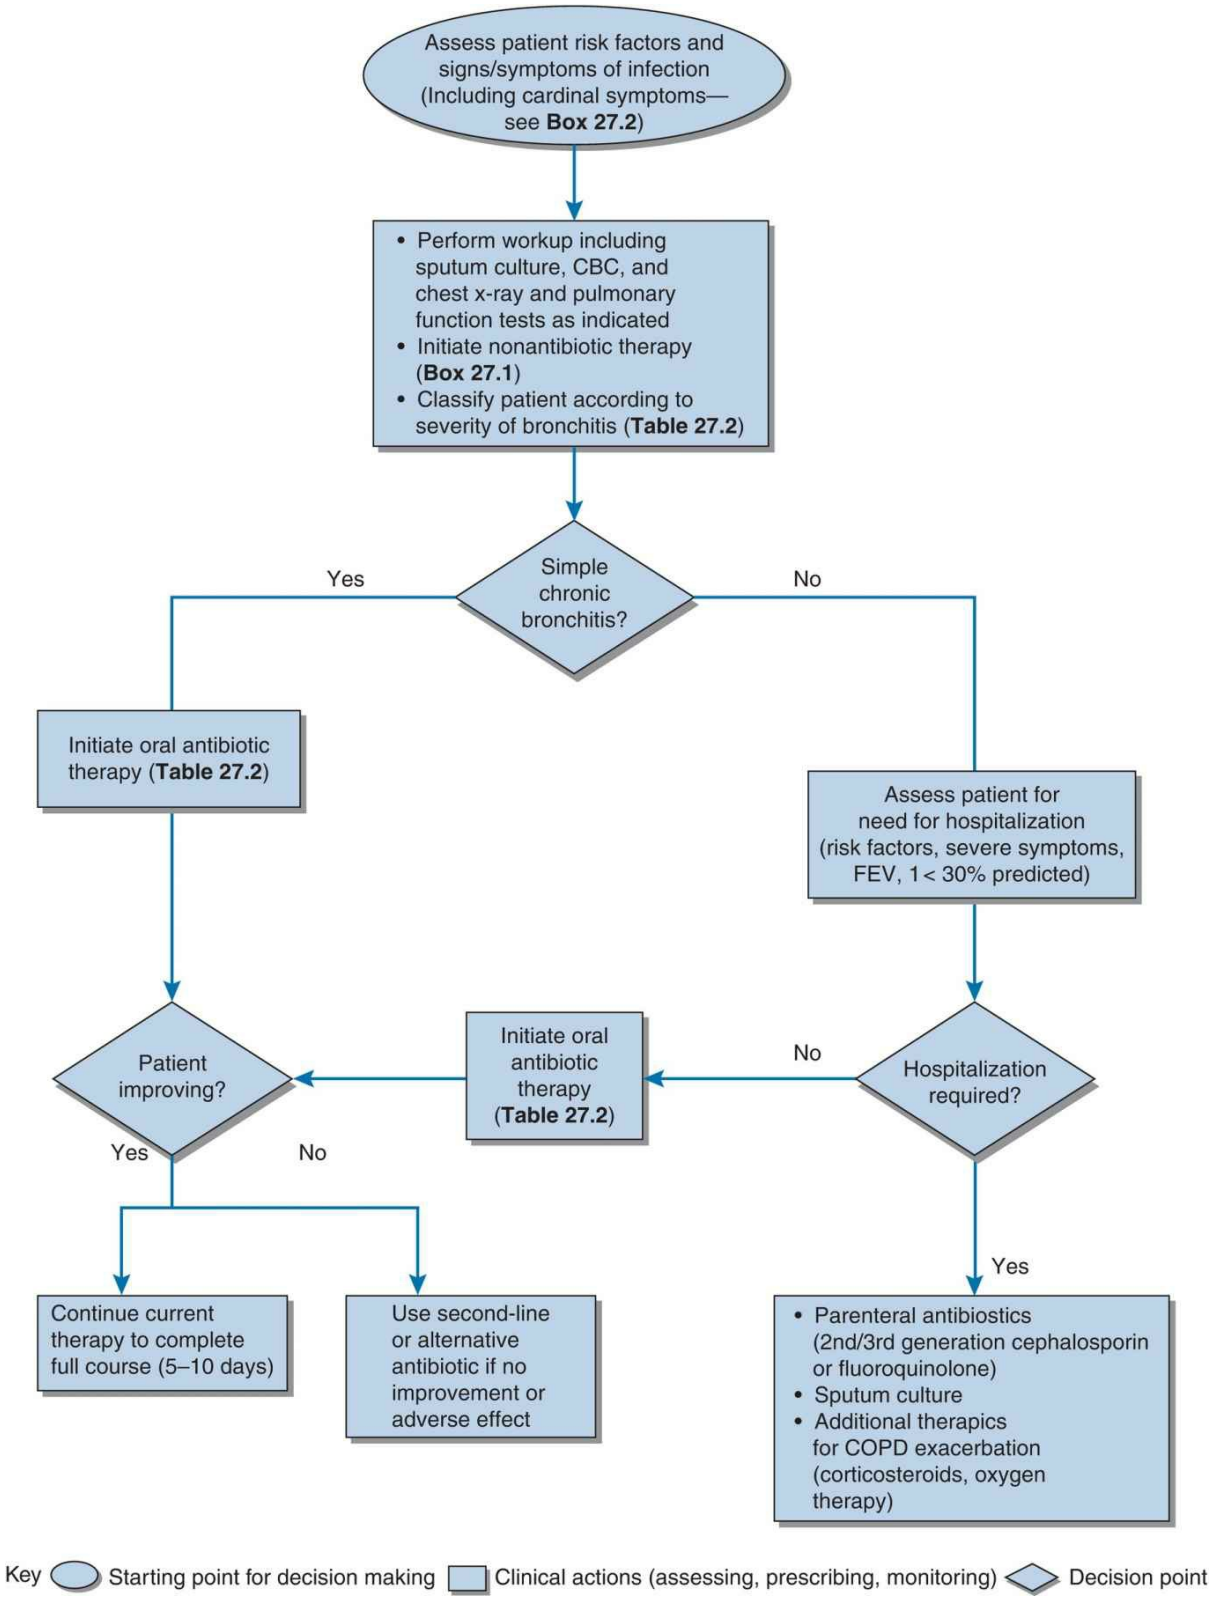

FIGURE 27.2 Treatment algorithm for chronic bronchitis.

BOX 27.1 Nonantibiotic Therapy for Acute

Exacerbations of Chronic Bronchitis

- Stop smoking
- Avoid inhalation of polluted air
- Increase ingestion of fluids (nonalcoholic)
- Humidify atmosphere
- Use short-acting bronchodilators
- Treat any associated asthma

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2015). Retrieved from www.goldcopd on July 10, 2015.

BOX 27.2 Cardinal Symptoms Associated with Exacerbations of COPD

- Increase in dyspnea (shortness of breath)
- Increase in sputum volume
- Increase in or presence of sputum purulence

Goals of Drug Therapy

There are two goals for the treatment of exacerbations of chronic bronchitis: to minimize the impact of the current exacerbation and to prevent the development of subsequent exacerbations with prolonged infection-free intervals. Depending on the severity of the exacerbation and the underlying disease, exacerbations can be managed in the outpatient or inpatient setting. More than 80% of exacerbations can be managed on an outpatient basis (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2015).

Antimicrobial Therapy

Among the antimicrobial agents used to treat acute exacerbations of chronic bronchitis are the aminopenicillins (amoxicillin) with or without clavulanic acid, cephalosporins, tetracyclines, macrolides, and fluoroquinolones. Table 27.3 reviews antibiotic agents used for patients with chronic bronchitis and pneumonia.

TABLE 27.3 Overview of Selected Antibiotics for Bronchitis and Pneumonia

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Aminopenicillins			
amoxicillin (Amoxil, Trimox) Adults: 500 mg q8h or 875–1,000 mg q12h Children: 40 mg/kg/d in divided doses q8h–12 h (high-dose regimen 80–90 mg/kg/d in divided doses q12h)	Nausea, vomiting, diarrhea, gastritis, rash, hypersensitivity reactions	Hypersensitivity reactions to penicillin derivatives Pregnancy category B	High incidence of development of rash in patients with infectious mononucleosis. Amoxicillin should be used with extreme caution in this patient population. Take with or without food. Food may decrease GI symptoms. Interacts with warfarin and oral contraceptives; probenecid decreases renal excretion, and allopurinol increases the risk of rash. Safe for young children
amoxicillin–clavulanate Adults: Augmentin 500 mg/125 mg q8h or 875/125 mg q12h Augmentin XR 2000 mg/125 mg q12h Children: Same as for amoxicillin Augmentin ES 90 mg/kg/d in divided doses q12h	Nausea, vomiting, diarrhea, gastritis, hypersensitivity reactions, Stevens-Johnson syndrome, seizures (high doses)	Hypersensitivity reactions to penicillin, clavulanic acid Pregnancy category B	High incidence of development of rash in patients with infectious mononucleosis. Amoxicillin clavulanate should be used with extreme caution in this patient population. Take with or without food. Food may decrease GI symptoms. Interacts with warfarin and oral contraceptives; probenecid decreases renal excretion, and allopurinol increases the risk of rash. Safe for young children
Cephalosporins			
cephalexin (Keflex) Adults: 500 mg q6h Children: 25–100 mg/kg/d in divided doses q6h to q8h; not to exceed 4,000 mg/d	Nausea, vomiting, diarrhea, rash, hypersensitivity reactions, fungal infections Serious: pseudomembranous colitis, seizures (high doses)	Hypersensitivity or allergy to cephalosporin antibiotics Not recommended in children <1 mo Pregnancy category B	Avoid cephalosporins for patients who have had an anaphylactic hypersensitivity reaction to other beta-lactam antibiotics. Use with caution in patients with a delayed type of reaction to other beta-lactam antibiotics. Take with or without food. Food may decrease GI symptoms. Probenecid decreases renal excretion.
cefaclor (Ceclor) Adults: 250–500 mg q8h Children: 20–40 mg/kg/d in divided doses q8–12 h	Nausea, vomiting, diarrhea, rash, hypersensitivity reactions, fungal infections Serious: Pseudomembranous colitis	Hypersensitivity to cephalosporin Not recommended in children <1 mo Pregnancy category B	Avoid cephalosporins for patients who have had an anaphylactic hypersensitivity reaction to other beta-lactam antibiotics. Use with caution in patients with a delayed type of reaction to other beta-lactam antibiotics. Take with or without food. Food may decrease GI symptoms. Probenecid decreases renal excretion.
cefuroxime axetil (Ceftin) Adults: 250–500 mg q12h Children: 20–30 mg/kg/d in divided doses q12h	Same as above	Same as above	Same as above
cefpodoxime (Vantin) Adults: 200 mg q12h Children: 10 mg/kg/d in divided doses q12h; not to exceed 400 mg/d	Same as above	Same as above	Same as above

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
cefdinir (Omnicef) Adults: 300 mg q12h Children: 14 mg/kg/d once daily or in divided doses q12h; not to exceed 600 mg/d	Same as above	Same as above	Same as above
Tetracyclines			
doxycycline (Vibramycin, Doryx, Vibra-Tab, Monodox) Adults: 100 mg q12h or 200 mg q24h Children: Not recommended for use in children less than 8 y of age	GI upset (nausea, vomiting, diarrhea, bulky, loose stools, anorexia), hypersensitivity reactions, photosensitivity reactions, superinfection, enterocolitis, rash, blood dyscrasias, hepatotoxicity	Hypersensitivity reactions to any tetracycline Pregnancy category D, breast-feeding Not recommended in children. Use of drug during tooth development may cause dental discoloration.	Capsules or tablets should be administered with adequate amounts of fluid. Capsules or tablets should not be given to patients with esophageal obstruction. Antacids containing aluminum, calcium, or magnesium should be given 1–2 h before. Avoid sunlight or ultraviolet light.
Sulfonamides			
trimethoprim–sulfamethoxazole (Bactrim) Adults: 800 mg sulfamethoxazole/160 mg trimethoprim (TMP) q12h (for PCP: 15–20 mg TMP/kg/d in divided doses q6–8 h) Children >2 mo: 8 mg TMP/kg/d in divided doses q12h (for PCP: 15–20 mg TMP/kg/d in divided doses q6–8 h)	Nausea, vomiting, rash, pruritus, urticaria, photosensitivity, Stevens-Johnson syndrome, toxic epidermal necrolysis	Allergy to sulfa Pregnancy category C (D at term)	Preferred agent in the treatment of pneumonia secondary to Pneumocystis jirovecii pneumonia (PCP) in patients with HIV/AIDS or other immunosuppression
Macrolides			
erythromycin (Eryc, PCE) Adults: 250–500 mg q6h Children: 30–50 mg/kg/d in divided doses q6h (not to exceed 4,000 mg/d)	Abdominal pain and cramping, nausea, vomiting, diarrhea, hepatic dysfunction, QTc prolongation, urticaria, fungal infection, skin eruptions, rash, ototoxicity	Allergy to erythromycin, hypersensitivity to macrolides, hepatic dysfunction, or preexisting liver disease Pregnancy category B	Erythromycin is a potent inhibitor of CYP450 3A4 isoenzymes. Screen medication list for potential drug–drug interactions prior to initiating erythromycin. Avoid in patients with known prolongation of QTc intervals and in patients receiving class IA (quinidine, procainamide) or class III (dofetilide, amiodarone, sotalol) antiarrhythmic agents. Take on empty stomach for better absorption 1 h before or 2 h after a meal.
clarithromycin (Biaxin) Adults: 500 mg q12h or 1,000 mg q24h Children >6 mo: 15 mg/kg/d in divided doses q12h	Diarrhea, nausea, abnormal taste, dyspepsia, abdominal discomfort, fungal infection, pseudomembranous colitis, hepatic dysfunction, QTc prolongation, headache, mild urticaria, mild skin eruptions	Hypersensitivity to macrolides, hepatic dysfunction or preexisting liver or renal disease, pregnancy, or breast-feeding Pregnancy category C	Clarithromycin is a potent inhibitor of CYP450 3A4 isoenzymes. Screen medication list for potential drug–drug interactions prior to initiating clarithromycin. Avoid in patients with known prolongation of QTc intervals and in patients receiving class IA (quinidine, procainamide) or class III (dofetilide, amiodarone, sotalol) antiarrhythmic agents. Tablets and oral suspension can be taken with or without food. Extended-release tablets should be taken with food.

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
azithromycin (Zithromax) Bronchitis: Adults: 500 mg once daily for 3 d or 500 mg for 1 d and then 250 once daily for 4 additional days CAP: 500 mg once daily for 5–7 d Children >6 mo: 10 mg/kg for 1 d and then 5 mg/kg once daily for 4 additional days	Diarrhea, loose stools, nausea, abdominal pain, dizziness, headache, rash photosensitivity, fungal infection, dizziness, fatigue, palpitations, QTc prolongation	Hypersensitivity to macrolides Use with caution in hepatic disease. Pregnancy category B	Prolongation of QTc intervals has been reported in patients receiving azithromycin. Use with caution in patients with a history of QTc prolongation or in patients receiving class IA (quinidine, procainamide) or class III (dofetilide, amiodarone, sotalol) antiarrhythmic agents. Administer the suspension 1 h before or 2 h after a meal. Use of antacids with aluminum or magnesium decreases peak serum levels.
Fluoroquinolones			
levofloxacin (Levaquin) 500–750 mg once daily Not recommended for use in children less than 18 y of age	Nausea, diarrhea, vomiting, abdominal pain or discomfort, hypersensitivity reactions, photosensitivity, confusion, dizziness, hallucinations, pseudomembranous colitis	Hypersensitivity to quinolone antibiotics Pregnancy category C	All fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture. The risk is higher in older patients over 60 y of age, in patients taking corticosteroids, and in patients with kidney, heart, or lung transplants. Antacids, sucralfate, iron, or multivitamins with zinc should be administered 2 h before or 2 h after taking levofloxacin as these agents may interfere with the GI absorption of levofloxacin.
moxifloxacin (Avelox) 400 mg once daily Not recommended for use in children less than 18 y of age	Same as above	Same as above	Same as above. Moxifloxacin should be administered 4 h before or 8 h after taking antacids, sucralfate, iron, or multivitamins with zinc as these agents may interfere with the GI absorption of moxifloxacin.
gemifloxacin (Factive) 320 mg once a day Not recommended for use in children less than 18 y of age	Same as above	Same as above	Same as above. Antacids, sucralfate, iron, or multivitamins with zinc should be administered 2 h before or 3 h after taking gemifloxacin as these agents may interfere with the GI absorption of gemifloxacin

Aminopenicillins

Aminopenicillins, such as amoxicillin, inhibit the final step of bacterial cell wall synthesis by binding to one or more of the penicillin-binding proteins. They are safe for use in children, adults, and pregnant women. Table 27.3 reviews the dose of amoxicillin for acute exacerbations of chronic bronchitis.

Contraindications

Aminopenicillins should not be administered to patients with severe hypersensitivity reactions to these agents.

Adverse Events

Hypersensitivity reactions to aminopenicillins manifest as eosinophilia or rash (urticarial, erythematous, morbilliform). Angioedema, exfoliative dermatitis, and erythema multiforme have also been reported as hypersensitivity reactions to aminopenicillins. These reactions occur less frequently than does eosinophilia or rash. Rarely, Stevens-Johnson syndrome has been reported as a hypersensitivity reaction to aminopenicillins.

Nausea, vomiting, and diarrhea, however, are the most common adverse effects that occur with aminopenicillins. Diarrhea is more common with amoxicillin–clavulanate. Pseudomembranous colitis may occur during or after the antibiotic treatment.

Interactions

Aminopenicillins may interrupt the enterohepatic circulation of estrogen by reducing the bacterial hydrolysis of conjugated estrogen in the GI tract. Therefore, the efficacy of oral contraceptives is decreased. Probenecid may increase the effects of aminopenicillins by competing with renal tubular secretion. An increased risk for rash occurs with the coadministration of allopurinol (Zyloprim) and aminopenicillins; the exact mechanism of this interaction has not been established.

Cephalosporins

Cephalosporins consist of several agents, including cephalexin (Keflex), cefaclor (Ceclor), cefuroxime axetil (Ceftin), cefpodoxime (Vantin), cefdinir (Omnicef), and others that are frequently used for the treatment of acute exacerbations of chronic bronchitis. Like penicillins, cephalosporins inhibit bacterial cell wall synthesis by binding to one or more of the penicillin-binding proteins. These drugs are safe for use by children and adults. The dosages of cephalosporins are listed in Table 27.3.

Contraindications

Cephalosporins are contraindicated in patients who have had hypersensitivity reactions to

any member of the cephalosporin class of antimicrobial agents. There is a 5% to 7% cross-sensitivity reaction between cephalosporins and penicillins, and therefore, cephalosporins should be avoided in patients who have had an anaphylactic reaction to penicillins.

Adverse Events

Nausea, diarrhea, and vomiting are common adverse effects with cephalosporins. Fungal infections and pseudomembranous colitis can also occur with the administration of cephalosporins.

Interactions

Probenecid increases the serum concentrations of cephalosporins by reducing their renal clearance.

Doxycycline

Doxycycline inhibits protein synthesis by binding with the 30S ribosomal subunit of susceptible microorganisms. The dosage of doxycycline is listed in Table 27.3.

Contraindications

Doxycycline is contraindicated in patients with severe hypersensitivity reactions to doxycycline or tetracycline. The drug should not be administered to children younger than 8 years of age; its use in infants has resulted in retardation of bone growth. Doxycycline can localize in the enamel of developing teeth, resulting in enamel hypoplasia and permanent yellow-gray to brown tooth discoloration. Doxycycline is a pregnancy category D drug and should not be administered to pregnant or lactating women.

Adverse Events

GI adverse effects such as nausea, vomiting, diarrhea, and bulky, loose stools commonly occur with the administration of doxycycline. Superinfection, enterocolitis, blood dyscrasias, and hepatotoxicity have also been reported to occur with the administration of doxycycline.

Interactions

The administration of antacids, iron, and bismuth subsalicylate (Pepto-Bismol), which contain divalent or trivalent cations, reduces the efficacy of doxycycline by impairing its absorption because of chelation of the cation by doxycycline. Barbiturates, phenytoin (Dilantin), and carbamazepine (Tegretol) can reduce the serum concentration of doxycycline by induction of hepatic metabolism. The effects of warfarin (Coumadin) can be potentiated when administered with doxycycline.

Doxycycline can decrease vitamin K production by GI bacteria. The significance of this

interaction is unknown, but patients should be monitored for signs of bleeding when anticoagulant drugs are used concomitantly with doxycycline.

Macrolides

The three macrolides—erythromycin, clarithromycin, and azithromycin—work by inhibiting ribonucleic acid–dependent protein synthesis by binding to the 50S ribosomal subunit. The dosage regimens of the macrolides are listed in Table 27.3.

Contraindications

Macrolides are contraindicated in patients with known hypersensitivity reactions to erythromycin, clarithromycin, or azithromycin, and these products should not be administered to patients with hepatic impairment or preexisting liver disease. Clarithromycin and some formulations of erythromycin should not be administered to pregnant and lactating women because the safety of these agents has not been fully established.

Adverse Events

Abdominal pain, cramping, nausea, vomiting, diarrhea, and hepatic dysfunction commonly occur with the administration of macrolides. Skin rashes and pseudomembranous colitis have also been reported.

Interactions

Erythromycin and clarithromycin are inhibitors of the hepatic cytochrome P-450 microsomal enzyme system (CYP3A4) and P-glycoproteins (Pgp). Elevations of carbamazepine (Tegretol), cyclosporine (Sandimmune), theophylline (Slo-Phyllin), zidovudine (Retrovir), ritonavir (Norvir), midazolam (Versed), sildenafil (Viagra), digoxin, and warfarin can occur when these agents are administered concomitantly with erythromycin or clarithromycin. There are many interactions with erythromycin and clarithromycin, so a complete drug interaction assessment should be done prior to initiating either of these antibiotics. Antacids should not be administered simultaneously with azithromycin as they may inhibit azithromycin absorption.

Fluoroquinolones

Levofloxacin (Levaquin), moxifloxacin (Avelox), and gemifloxacin (Factive) (the so-called antipneumococcal or respiratory fluoroquinolones) inhibit deoxyribonucleic acid gyrase and topoisomerase IV in susceptible microorganisms, thereby interfering with bacterial replication. The dosing regimens of the fluoroquinolones are listed in Table 27.3.

Contraindications

Fluoroquinolones are contraindicated in patients with known hypersensitivity reactions to any member of the fluoroquinolone class. Fluoroquinolones generally should not be administered to patients younger than age 18. Limited data are available for use in pregnant or lactating women; thus, these medications should only be used when the benefit outweighs the risk. Gemifloxacin, levofloxacin, and moxifloxacin should be used cautiously in patients with known prolongation of the QT interval, in patients with uncorrected hypokalemia, and in those receiving class IA (e.g., quinidine, procainamide) or class III (e.g., amiodarone, sotalol) antiarrhythmic agents. These agents should also be used cautiously in patients who are receiving other agents known to prolong the QT interval, such as erythromycin, antipsychotics, and tricyclic antidepressants.

Gemifloxacin and levofloxacin are eliminated through the kidneys; therefore, dosage adjustments are necessary in patients with renal impairment. Moxifloxacin is metabolized primarily through sulfate and glucuronide conjugation. Moxifloxacin should be administered with caution to patients with hepatic insufficiency due to the risk for QT prolongation.

Adverse Events

GI adverse effects (e.g., nausea, diarrhea, vomiting, and abdominal pain) have commonly been reported with the administration of fluoroquinolones. Central nervous system adverse effects such as headache, agitation, confusion, and restlessness have occurred after the administration of fluoroquinolones. Photosensitivity has been reported with the administration of some fluoroquinolones.

Interactions

Fluoroquinolones should not be administered concomitantly with antacids, calcium products, sucralfate (Carafate), iron, and multivitamins. These products should be spaced at least 2 to 4 hours apart from the fluoroquinolone. The manufacturers of moxifloxacin recommend spacing at least 4 hours before or 8 hours after the administration of iron- or zinc-containing multivitamins, magnesium, calcium, or aluminum products or sucralfate.

Selecting the Most Appropriate Agent

For simple chronic bronchitis, treatment with an aminopenicillin (amoxicillin) or doxycycline is sufficient. In patients with complicated chronic bronchitis, therapy with amoxicillin–clavulanate, a second- or third-generation cephalosporin, a macrolide, or fluoroquinolone is effective. Fluoroquinolones should be reserved for patients who fail alternative antibiotics, those with allergies or contraindications to alternative antibiotics, or patients with resistant pathogens. Overuse of this class of medications has led to increased resistance among certain bacteria. For severe complicated chronic bronchitis, a fluoroquinolone (such as levofloxacin) is the agent of choice because gram-negative microorganisms, such as *Pseudomonas* species, need to be considered as potential pathogens. (Table 27.2 and Figure 27.2 provide more information about treatment choices.) In addition to antibiotic therapy, use of short-acting bronchodilators, short courses of corticosteroids (e.g., prednisone for 5 to 10 days), and oxygen supplementation are used in the treatment of acute exacerbations of chronic bronchitis.

Special Population Considerations

Pediatric

Antimicrobials related to the tetracyclines (e.g., doxycycline) may discolor dental enamel in fetuses and children while teeth are developing and should be avoided in children less than 8 years of age.

Women

Women who take antibiotics, especially the aminopenicillins, may experience secondary symptoms, such as vaginitis, that require treatment.

Monitoring Patient Response

Signs and symptoms of infection should improve within days of drug administration. If patients fail to improve, sputum culture and susceptibility should be performed to evaluate the possibility of resistance. Additionally, if fever with chills develops, additional workup (e.g., chest x-ray) should be considered to rule out pneumonia.

The recommended duration of antimicrobial therapy for acute exacerbation of chronic bronchitis is 5 to 10 days. This decreases morbidity and increases the posttherapy infection-free period in patients. Some patients may require a longer duration of therapy or hospitalization for parenteral antibiotic therapy. Because patients with chronic bronchitis are predisposed to recurrent infections, antimicrobial agents that were previously successful in eradicating the infection should be readministered. However, frequent use of antibiotics increases the risk of resistance; thus, patients should be monitored for response. In patients who fail to respond, bacterial resistance should be considered.

Measures to prevent exacerbations of chronic bronchitis should be initiated, as recurrent exacerbations are associated with accelerated decline in lung function. Frequent exacerbations are associated with reduced physical activity, poor quality of life, and increased risk of death. One method to prevent exacerbations is annual administration of an influenza vaccine. This reduces the rate and severity of infections with the influenza virus in some patients with chronic bronchitis. Patients should also receive the pneumococcal vaccine. Sufficient data do not exist to support the theory that the pneumococcal vaccine may reduce the frequency or severity of exacerbations in patients with chronic bronchitis. However, this vaccine may potentially reduce the frequency of pneumococcal pneumonia. The use of long-term antibiotics to prevent acute exacerbations is generally discouraged. However, azithromycin 250 mg orally once daily for a year has been shown to reduce the frequency of exacerbations and improve quality of life in patients with COPD (Albert et al., 2011). The mechanism is thought to be related to anti-inflammatory properties of azithromycin and not antibacterial activity. The use of azithromycin for this purpose is generally limited to select patients with moderate to severe underlying COPD.

Patient Education

Drug Information

The patient needs to understand that the entire course of antimicrobial therapy should be finished to ensure eradication of the causative microorganisms. Moreover, the patient should be cautioned to report adverse effects, such as diarrhea, immediately to the health care provider for further evaluation. Other adverse effects may include photosensitivity, and the patient needs to be advised to protect the skin from excessive exposure to sunlight or ultraviolet light, particularly when taking doxycycline. If sunburn-like reactions or skin eruptions occur, the patient should contact the prescriber immediately.

Additional patient counseling includes whether to take the drug with food or on an empty stomach. Storage instructions include whether the drug needs refrigeration, as does the oral suspension of amoxicillin, which is stable for only 7 days at room temperature but for 14 days under refrigeration. The reconstituted oral suspension of amoxicillin–clavulanate should be kept in the refrigerator, as should most oral cephalosporin suspensions.

Patients should be encouraged to take the macrolides with food to lessen the GI adverse effects, except for the oral suspension of azithromycin, which must be taken on an empty stomach. Most oral suspensions of erythromycin should be refrigerated, but the oral suspension of clarithromycin should not be refrigerated because it is more palatable when taken at room temperature. The oral suspension of azithromycin can be refrigerated if the patient so desires.

Because fluoroquinolones may cause dizziness and light-headedness, patients need to be aware of this when operating an automobile or other potentially dangerous machinery or engaging in activities requiring mental alertness or coordination.

Community-Acquired Pneumonia

Pneumonia is an infection of the lungs that leads to consolidation of the usually air-filled alveoli. It occurs in all age groups and can be caused by various pathogens, including viruses, bacteria, mycobacteria, mycoplasma, and fungi. Systemic viral infections such as influenza A or B in adults and measles or varicella in children can also lead to pneumonia.

Pneumonia occurs in about 3 to 4 million people each year in the United States, with over one million patients requiring hospitalization (Remington & Sligl, 2014). The symptoms of pneumonia include cough, chills, shortness of breath, sputum production, and chest pain. Physical examination includes fever in most, tachycardia, and tachypnea, with decreased breath sounds and crackles on auscultation in about 80% of cases. Pneumonia is classified by where it was acquired: community-acquired pneumonia (CAP), health care–associated pneumonia (HCAP), and hospital-acquired pneumonia (HAP). The latter two types of pneumonia occur in patients with exposure to the hospital and/or health care settings that predispose them to different pathogens than seen in CAP. This chapter focuses on the diagnosis and treatment of CAP.

Pneumonia carries an age-adjusted mortality rate of up to 22%. CAP is an acute infection of the lower respiratory tract that is usually associated with:

- symptoms of acute infection and acute infiltrates detected by chest x-ray OR
- auscultatory findings consistent with pneumonia on physical examination

Elderly individuals and those with other coexistent illnesses such as COPD, diabetes mellitus, renal insufficiency, congestive heart failure, and chronic liver disease are at a high risk for acquiring pneumonia compared with other patient populations. Additionally, individuals with immunosuppression related to malignancy, chronic corticosteroid use or other myelosuppressive medications, or history of HIV infection have an increased risk for developing pneumonia. New microorganisms as a cause of CAP and the emergence of antimicrobial-resistant organisms require broader antimicrobial coverage in treating CAP, as compared to bronchitis.

Causes

Although several pathogens are identified in CAP, the etiology is only established in about 40% of cases. *S. pneumoniae* is the most commonly isolated pathogen. Up to 65% of all diagnosed CAP cases can be attributed to *S. pneumoniae* (Remington & Sligl, 2014). However, widespread use of the pneumococcal vaccine has reduced the incidence of *S. pneumoniae* as a causative pathogen. Other pathogens that have been commonly isolated in patients with CAP are *H. influenzae* (12%), *S. aureus* (2%), and gram-negative bacilli (1%). Less common pathogens that have been implicated in CAP are *M. catarrhalis*, *Streptococcus pyogenes*, *Chlamydia psittaci*, and *Neisseria meningitidis*. Atypical microorganisms, such as *Legionella* species, *M. pneumoniae*, and *C. pneumoniae*, account for 10% to 20% of cases. Between 2% and 15% of CAP cases are due to viral infections (Remington & Sligl, 2014). The most common virus known to be associated with CAP is the influenza virus; however, parainfluenza virus, RSV, and adenovirus also have been isolated as CAP pathogens. Methicillin-resistant *S. aureus* (MRSA) has emerged as the most common pathogen isolated in community-acquired skin and soft tissue infections and is increasingly recognized as a cause of CAP.

Pathophysiology

Microorganisms gain access to the lower respiratory tract by inhalation as airborne particles, by way of the bloodstream to the lung from an extrapulmonary site of infection or, most commonly, through aspiration of oropharyngeal contents. This is a common method of transmission of microorganisms into the lower respiratory tract for both healthy and ill people.

Diagnostic Criteria

Patients with pneumonia typically present with cough, fever, dyspnea, malaise, pleuritic chest pain, and/or sputum production. It is difficult to distinguish other respiratory tract infections such as bronchitis from pneumonia based on signs and symptoms alone (Figure 27.3). A chest x-ray plays a critical role in differentiating pneumonia from other infections and can also indicate whether coexisting conditions, such as COPD, heart failure, and/or pleural effusions, are present.

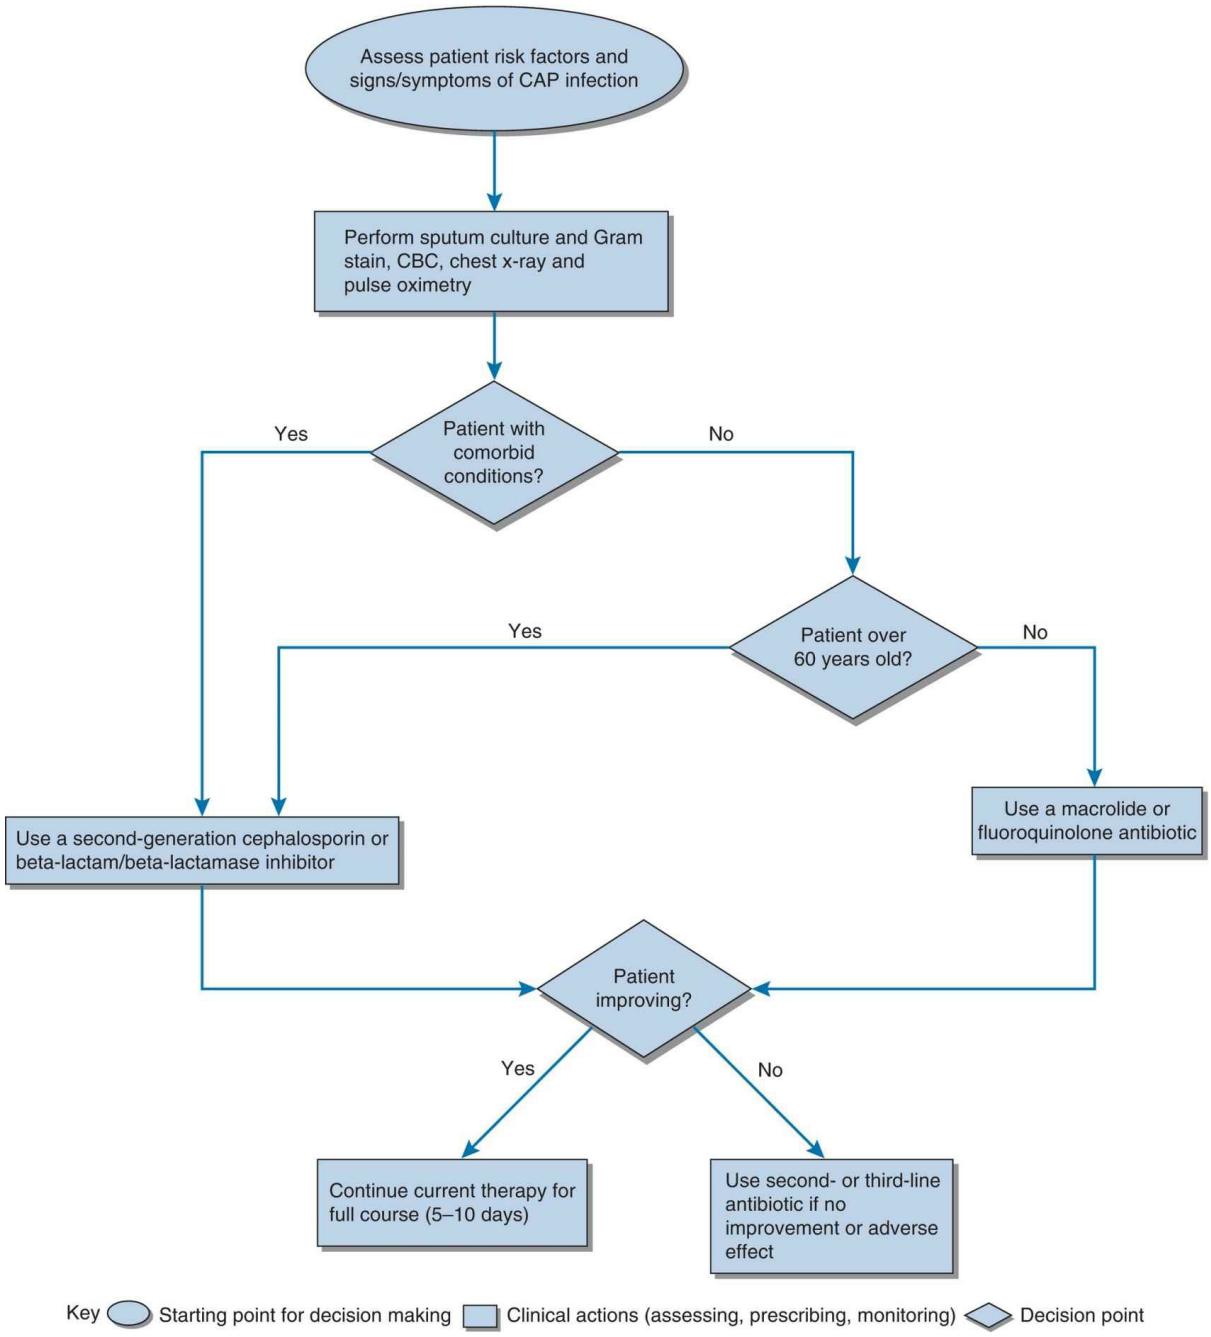

FIGURE 27.3 Treatment algorithm for CAP.

The presence of infiltrates on chest x-ray usually indicates pneumonia, which necessitates antibiotic treatment. In general, chest x-rays cannot distinguish between bacterial and nonbacterial microorganisms. The patterns found on chest x-ray in patients with pneumonia are not helpful in making a specific etiologic diagnosis; however, certain findings on the chest x-ray can guide the practitioner to a diagnosis. The severity of illness can also be detected by an x-ray; multilobar involvement typically indicates severe illness. A Gram stain of the sputum specimen is useful in the initial evaluation of patients with pneumonia, as it can assist with empiric antibiotic prescribing. However, 40% to 60% of

patients do not produce sputum, and in those who do, poor sampling reveals oropharyngeal colonization in nearly half of all culture results. Therefore, obtaining a sputum culture in outpatients is not necessary (Mandell et al., 2007). However, sputum cultures should be obtained in patients requiring hospitalization and when resistant microorganisms are suspected. Blood cultures should be obtained in patients with severe CAP requiring hospitalization. Urinary antigen tests are used to detect *S. Pneumoniae* or *Legionella pneumophila* as a cause of pneumonia. The urinary antigen tests may reveal positive results even after initiation of antibiotic therapy. Limitations of urinary antigen tests include the potential for false-negative results due to poor sensitivity and false-positive *S. pneumoniae* urinary antigen results in children colonized with *S. pneumoniae*. Additionally, the urinary Legionella antigen test only detects one serogroup of *L. pneumophila*, although it is the most common type that causes Legionella pneumonia. Due to the need to obtain a urine specimen and added cost of testing, urinary antigen tests may not be practical for use in the outpatient setting. Invasive diagnostic techniques such as transtracheal aspiration, bronchoscopy, bronchoalveolar lavage, and direct needle aspiration may be useful in patients with severe CAP.

It can be difficult to determine when an outpatient needs hospitalization for closer observation. There are severity scoring tools [Pneumonia Scoring Index (PSI), CURB-65, and SMART-COP] available online to assess adult patients and assist in determining the risk of morbidity and mortality associated with pneumonia and the need for hospitalization. Box 27.3 lists some objective findings of severe CAP that suggest the need for hospitalization. Once patients are hospitalized, several routine tests must be performed to determine the severity of illness, possible complications, the status of underlying conditions, and the most appropriate treatment choices. A WBC count is not useful for distinguishing between the various causative microorganisms; however, a WBC count greater than 12,000 cells/mm^3 typically suggests bacterial infection. Pulse oximetry can help reflect the severity of the disease. An arterial oxygen saturation of less than 90% on room air is a standard criterion for hospital admission.

BOX 27.3 Indications for Hospitalization Secondary to Pneumonia

- Severe vital sign abnormality: pulse >140/min, systolic blood pressure <90 mm Hg, and respiratory rate >30/min
- Altered mental status (newly diagnosed): disorientation to person, place, or time and stupor or coma
- Arterial hypoxemia: Arterial oxygen saturation <90% or a P_aO_2 <60 mm Hg
- Suppurative pneumonia-related infection: empyema, septic arthritis, meningitis, and endocarditis
- Inability to tolerate oral medications

- Severe electrolyte, hematologic, and metabolic laboratory value not known to be chronic
- Lack of adequate outpatient support services for follow-up treatment

Data from Mandell, L. A., Wunderink, R. G., Anzueto, A., et al. (2007). Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community acquired pneumonia in adults. *Clinical Infectious Diseases*, 44, S27–S72.

Initiating Drug Therapy

General treatment approaches for pneumonia consist of providing adequate hydration (replacement of loss of water that may occur because of fever, poor intake, or vomiting), providing bronchodilators for dyspnea, and controlling fever with acetaminophen, ibuprofen, or aspirin. Additionally, in severe cases of CAP with hypoxia, supplemental oxygen may be needed until symptoms improve. Early identification of the causative microorganism is optimal for proper management of CAP. However, diagnostic tests cannot always identify all potential pathogens and no single antimicrobial regimen covers all possible causes; therefore, empiric therapy is common.

Goals of Drug Therapy

The goals of pharmacotherapy for pneumonia include eradicating the offending microorganism through the selection of appropriate antibiotic therapy, complete clinical cure, preventing complications from pneumonia (e.g., respiratory failure, sepsis, empyema), and minimizing adverse effects of medications.

Unless diagnostic tests can determine a specific etiology upon diagnosis, which is not commonly the case, empiric antibiotics should be initiated for CAP. Empiric antibiotic treatment for pneumonia should always be active against *S. pneumoniae* because this pathogen is the most common pathogen identified as a cause of bacterial pneumonia. For adults treated as outpatients without recent antibiotic use or existing comorbidities (e.g., COPD, diabetes, renal insufficiency), treatment with a macrolide (clarithromycin or azithromycin) or doxycycline is recommended (Table 27.4). In adult outpatients with an increased risk for poor outcomes (comordibities and/or recent antibiotic use), a beta-lactam (high-dose amoxicillin, amoxicillin– clavulanate, or a second- or third-generation cephalosporin) plus a macrolide or an antipneumococcal fluoroquinolone (e.g., levofloxacin, moxifloxacin, gemifloxacin) alone is recommended (Table 27.4). Doxycycline may be used as an alternative in patients intolerant or allergic to azithromycin. Ciprofloxacin should not be used for treating CAP because of the high level of resistance that *S. pneumoniae* exhibits to this drug.

TABLE 27.4 Recommended Outpatient Antimicrobial Treatment for CAP in Adults

Category	Preferred Agents
Previously healthy; no recent antibiotic use; no risk factors for DRSP infection*	A macrolide (azithromycin or clarithromycin) or doxycycline
Presence of comorbidities (chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancy; asplenia; immunosuppressing conditions or use of immunosuppressing drugs), use of antimicrobials within the previous 3 mo (in which case an alternative from a different class should be selected), or other risk factors for DRSP*	B-lactam [high-dose amoxicillin (e.g., 1 g three times daily) or amoxicillin–clavulanate (2 g twice a day)] is preferred; alternatives include cefpodoxime, cefdinir, and cefuroxime + a macrolide (azithromycin, clarithromycin, or erythromycin)†. Fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin) alone
Geographic region with a high rate (>25%) of macrolide-resistant *S. pneumoniae* (for any patient, including those without comorbidities)	Consider the use of alternative agents such as high-dose amoxicillin, amoxicillin–clavulanate + a macrolide (if atypical organisms suspected) Fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin [750 mg]) alone
Suspected aspiration	Amoxicillin–clavulanate or clindamycin
Influenza pneumonia	Oseltamivir 75 mg PO twice daily for 5 d or zanamivir 10 mg (two inhalations) twice daily for 5 d. Begin within 2 d of signs or symptoms.

*Risks for drug-resistant *S. pneumoniae* (DRSP) include age >65 y, beta-lactam therapy within the previous 3 mo, alcoholism, immunosuppressive therapy, and exposure to a child in day care.

†Doxycycline may be used as an alternative in patients with an intolerance or allergy to macrolides.

Data from Mandell, L. A., Wunderink, R. G., Anzueto, A., et al. (2007). Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community acquired pneumonia in adults. *Clinical Infectious Diseases*, 44, S27–S72.

Community-acquired MRSA (CA-MRSA) is a common pathogen isolated in community-acquired skin and soft tissue infections and is increasingly recognized as a cause of CAP. CA-MRSA pneumonia typically presents as a severe, rapidly progressing pneumonia with sepsis, often in children or healthy young adults. Antimicrobial agents with consistent in vitro activity against CA-MRSA isolates include vancomycin, clindamycin, sulfamethoxazole/trimethoprim, linezolid, and ceftaroline. Although it is not necessary to provide empiric coverage of MRSA for all pneumonia cases, it should be strongly considered for patients with severe pneumonia associated with sepsis, especially persons with concurrent influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia. Patients infected with CA-MRSA pneumonia frequently require hospitalization due to the severity of symptoms.

Differences among antibiotic agents were discussed previously in the chronic bronchitis section and must be considered when choosing antimicrobial therapy for CAP. Resistance patterns also should be considered when choosing an antibiotic. Because 15% to 30% of *S. pneumoniae* isolates in the United States are resistant to doxycycline and macrolides, caution should be used in prescribing these medications as first-line agents in areas where resistance is more prevalent. Aminopenicillins, such as amoxicillin, have excellent activity against *S. pneumoniae* and remain the drug of choice to treat *S. pneumoniae*; however, amoxicillin does not have activity against beta-lactamase producing strains of *H. influenzae* and *M. catarrhalis*. Adding a beta-lactamase inhibitor to amoxicillin (e.g., amoxicillin–clavulanate) provides activity against these beta-lactamase–producing organisms and may be an option in place of macrolides or doxycycline. If beta-lactam antibiotics are used and a patient fails therapy, atypical pathogens (*L. pneumophila*, *C. pneumoniae*, and *M. pneumoniae*) should be considered, as beta-lactam antibiotics do not cover these pathogens. Macrolides, fluoroquinolones, and doxycycline have activity against the atypical pathogens that can cause pneumonia. If Legionella pneumonia is suspected, a macrolide or fluoroquinolone is preferred. If aspiration pneumonia is suspected, the antibiotic of choice is amoxicillin–clavulanate. Clindamycin is an alternative for aspiration pneumonia in patients with an allergy to penicillins.

Adult hospitalized patients should receive a beta-lactam, such as cefotaxime (Claforan) or ceftriaxone (Rocephin) in combination with a macrolide (azithromycin or clarithromycin) or a fluoroquinolone with activity against *S. pneumoniae* (Table 27.5). Patients hospitalized in the intensive care unit for pneumonia should receive the same therapy as do other hospitalized patients, unless *P. aeruginosa* is a concern. In these cases, antibiotics with broader gram-negative coverage (e.g., piperacillin–tazobactam, cefepime, or a carbapenem) should be added.

TABLE 27.5 Recommended Antimicrobial Treatment for CAP in Adults Requiring Hospitalization

Category	Preferred Agents
General inpatient medical ward	Parenteral beta-lactam antibiotic (ceftriaxone, cefotaxime, ampicillin/sulbactam, ertapenem) + a macrolide (azithromycin or clarithromycin)* Fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin) alone
Intensive care/critically ill	Same as above
Intensive care with risk for pseudomonas	Antipseudomonal beta-lactam (piperacillin/tazobactam, cefepime, imipenem, or meropenem) + either ciprofloxacin or levofloxacin Antipseudomonal beta-lactam (piperacillin/tazobactam, cefepime, imipenem, or meropenem) + an aminoglycoside + azithromycin Antipseudomonal beta-lactam (piperacillin/tazobactam, cefepime, imipenem or meropenem) and an antipneumococcal fluoroquinolone (moxifloxacin or levofloxacin) If CA-MRSA suspected, add vancomycin or linezolid†
Influenza pneumonia‡	Oseltamivir 75 mg PO twice daily for 5 d (longer courses may be required in severely ill patients). Treatment of any person with confirmed or suspected influenza who requires hospitalization is recommended, even if the patient presents more than 48 h after illness onset.
Influenza with bacterial superinfection‡	Ceftriaxone, cefotaxime, or fluoroquinolone (levofloxacin or moxifloxacin) + vancomycin or linezolid
Suspected aspiration	Ampicillin/sulbactam, piperacillin/tazobactam, or clindamycin

*Doxycycline may be considered as an alternative in patients with an intolerance or allergy to macrolides.

†Risk factors for CA-MRSA infection include preceding influenza, previous infection/colonization with MRSA, cavitary infiltrates, and/or suspected necrotizing pneumonia.

‡Refer to Chapters 8 and 24 for additional information on antimicrobial therapy and treatment guidelines.

Data from Mandell, L. A., Wunderink, R. G., Anzueto, A., et al. (2007). Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community acquired pneumonia in adults. *Clinical Infectious Diseases*, 44, S27–S72.

Selecting the Most Appropriate Agent

Identification of the likely microorganism simplifies treatment for pneumonia. The reader is referred to the comprehensive references for appropriate antimicrobial agents that are commonly used once pathogens have been identified (see Figure 27.3).

Special Population Considerations

Pediatric

Antimicrobial therapy is not routinely required for preschool-aged children with CAP, because viral pathogens are responsible for the majority of clinical disease. For mild to moderate CAP of bacterial origin treated in the outpatient setting, amoxicillin should be used as first-line therapy for previously healthy, appropriately immunized infants and preschool children through adolescent age (Table 27.6). Amoxicillin provides appropriate coverage for *S. pneumoniae*, the most prominent pathogen in children. If atypical organisms, such as *M. pneumoniae* or *C. pneumoniae*, are suspected, a macrolide antibiotic should be prescribed. Antiviral therapy for influenza (oseltamivir or zanamivir) should be administered as soon as possible to children with moderate to severe CAP consistent with influenza virus. Treatment after 48 hours of symptomatic infection may still provide clinical benefit to those with more severe disease.

TABLE 27.6 Recommended Antimicrobial Treatment of CAP in Children

	First-Line Therapy	Alternative Therapy
Treatment for Outpatient Therapy in Children		
Suspected bacterial infection in preschool age children (<5 y of age) (preschool)	amoxicillin 90 mg/kg/d in two divided doses	amoxicillin–clavulanate 90 mg/kg/d based on amoxicillin component in two divided doses If atypical organisms suspected: azithromycin 10 mg/kg on day 1, followed by 5 mg/kg/d once daily on days 2–5 or clarithromycin 15 mg/kg/d in two divided doses
Suspected bacterial infection in children ≥5 y of age	amoxicillin 90 mg/kg/d in two divided doses; amoxicillin–clavulanate 90 mg/kg/d (based on amoxicillin component) in two divided doses	Same as above. In children >7 y of age, doxycycline may be used.
Influenza suspected or influenza widespread in the community	oseltamivir (refer to product information for weight-based dosing) for 5 d; zanamivir (children ≥7 y of age) 2 inhalations (10 mg total per dose) in two divided doses for 5 d	
Treatment for Hospitalized Children		
All ages (fully immunized)*; local penicillin resistance rates against *S. pneumoniae* is low.	ampicillin or penicillin G plus azithromycin (if atypical pathogens considered) Add clindamycin or vancomycin if CA-MRSA suspected.	Alternatives to ampicillin and penicillin G include ceftriaxone or cefotaxime. Alternatives to azithromycin include clarithromycin or erythromycin. In children >7 y of age, doxycycline may be used
All ages (not fully immunized or unknown)*; local penicillin resistance rates against *S. pneumoniae* is high or unknown.	ceftriaxone or cefotaxime + azithromycin if atypical pathogens considered Add clindamycin or vancomycin if CA-MRSA suspected	Alternatives to azithromycin include clarithromycin or erythromycin. In children >7 y of age, doxycycline may be used.

*Childhood immunizations include conjugate vaccines for *H. influenzae* type b and *S. pneumoniae*.

Data from Bradley, J. S. Byington, C. L., Shah, S. S., et al. (2011). The management of community-acquired pneumonia in infants and children older than 3 months of age: Clinical practice guidelines by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America. *Clinical Infectious Diseases*, 53(7), e25–e76.

For children requiring hospitalization, ampicillin or penicillin G should be administered to

fully immunized infants or school-aged children in areas without local high-level penicillin resistance against *S. pneumoniae*. Empiric therapy with a third-generation parenteral cephalosporin (ceftriaxone or cefotaxime) should be prescribed for hospitalized infants and children who are not fully immunized, in regions where local epidemiology of documented high-level penicillin resistance against *S. pneumoniae*, or for infants and children with life-threatening infection. Empiric combination therapy with a macrolide, in addition to a beta-lactam antibiotic, should be prescribed for hospitalized children when *M. pneumonia* and *C. pneumoniae* are significant considerations. Vancomycin or clindamycin should be provided in addition to beta-lactam therapy if *S. aureus* (particularly CA-MRSA) is suspected.

Monitoring Patient Response

The patient's response to therapy must be evaluated carefully. Response to treatment should be based on clinical illness, pathogen isolated, severity of illness, host factors, and chest x-ray findings. Subjective symptoms usually respond within 3 to 5 days of initiating therapy. Objective findings such as fever, leukocytosis, and chest x-ray abnormalities resolve at different times. Fever lasts for 2 to 4 days in most cases of CAP; however, defervescence occurs more quickly with *S. pneumoniae* infection. Leukocytosis usually resolves by the 4th day of initiation of antimicrobial therapy. Chest x-rays indicate that signs of pneumonia last longer than symptoms. Of course, this depends on many factors, such as the causative microorganism and underlying illness. The overall suggested chest x-ray follow-up is 7 to 12 weeks after initiation of therapy. In clinical practice, patients who develop clinical cure may not require a follow-up chest x-ray.

Duration of therapy for treating CAP depends on the severity of the illness, response to therapy, and the antimicrobial agent used to treat the infection. The standard treatment duration for CAP is 7 to 10 days for most patients; however, shorter courses of therapy are effective, especially in those with mild pneumonia. Because the half-life of azithromycin is around 68 hours, it remains in the tissues longer than erythromycin or clarithromycin. Five days of azithromycin therapy is sufficient to treat mild CAP. Additionally, 5 days of levofloxacin (750 mg once daily) is recommended. Patients with a poor response to therapy or those with Legionella pneumonia who are immunocompetent typically receive 14 days of treatment. Patients with complications from pneumonia, such as empyema, may require longer courses lasting 2 to 4 weeks.

Patient Education

The patient must take the full course of medication even though he or she may feel better within days of initiation of antibiotics. Early discontinuation of therapy can result in reinfection or the development of resistant microorganisms. If the patient continues to worsen despite several days of therapy, he or she should contact the prescriber immediately. The organism causing infection in the patient could be resistant to the antibiotic originally prescribed. Refer to the chronic bronchitis section for further information on drug therapy and specific patient education.

Case Study*

G.G., a 59-year-old male, presents to the clinic with complaints of cough, shortness of breath, and increased sputum production. His past medical history is significant for COPD with chronic bronchitis, hypertension, diabetes, and hyperlipidemia. He reports that his sputum has increased in consistency and amount over the past few days. His last exacerbation was about 6 months ago, for which he received amoxicillin. This is his third exacerbation in the past year. He has a 40-pack year history of cigarette smoking and quit smoking 3 years ago. He does not take chronic steroids. Physical exam reveals rhonchi and expiratory wheezes. His vital signs are blood pressure 140/83 mm Hg, pulse rate 80 beats/min, respiration rate 20 breaths/min, and temperature 98.8°F. He has no known drug allergies. A sputum Gram stain in the office reveals purulent sputum (presence of WBCs). Chest x-ray findings are negative for pneumonia.

Diagnosis: Acute Exacerbation of Chronic Bronchitis

1. Which of the following would suggest the need for antibiotic therapy in G.G.?
   a. Cough, history of smoking, and expiratory wheezes on physical examination
   b. Elevated respiratory rate and shortness of breath
   c. Increased dyspnea, increased sputum production, and increased sputum purulence
   d. History of previous COPD exacerbations, cough, and fever

2. What is a likely pathogen associated with an acute exacerbation of chronic bronchitis in G.G.?
   a. *Mycobacterium tuberculosis*
   b. *Pseudomonas aeruginosa*
   c. *Staphylococcus aureus*
   d. *Streptococcus pneumonia*

3. What antibiotic would be most appropriate to treat an acute exacerbation of chronic bronchitis in G.G.?
   a. Amoxicillin–clavulanate
   b. Azithromycin
   c. Linezolid
   d. Sulfamethoxazole/trimethoprim

UNIT 6
Pharmacotherapy for Gastrointestinal Tract Disorders

28 Nausea and Vomiting

Virginia P. Arcangelo ■ Veronica F. Wilbur

Nausea and vomiting are common complaints in humans. The severity of the event can range from a slight discomfort or queasiness to uncontrollable, forceful vomiting. Despite this range of symptoms, all are perceived to be uncomfortable and troublesome and should be treated in a proper and timely manner. Patients may refer to this experience by many different names: *upchuck, urp, queasy, throw up,* and *puke*, to name a few. There are many different causes of nausea and vomiting, such as motion sickness, pregnancy, and medications. Likewise, many treatment options can be used to manage this complication. People of all ages experience emesis, although the etiology may be related to age-specific factors. Drugs are most frequently used for the treatment of nausea and vomiting, but alterations of nondrug factors may decrease the severity of emesis. This chapter reviews the pathophysiology and pharmacotherapy of specific types of nausea and vomiting.

Causes

There are multiple causes for nausea and vomiting; however, some of the most common are from the ingestion or administration of substances or drugs, gastrointestinal (GI) disorders, neurologic processes, and metabolic disorders. The presence of noxious stimuli is frequently a cause of nausea and vomiting. Supratherapeutic digoxin (Lanoxin) and theophylline (Theo-Dur or Slo-Phyllin) are known to produce emesis. Nausea and vomiting occur more frequently with high-dose chemotherapy than with moderate doses of the same drugs. Erythromycin and some penicillin derivatives are acknowledged for inducing uncomfortable GI complications. Emesis can also result from excessive ethanol intake. It is well known that other sensory experiences, such as pungent odors or gruesome sights, can induce nausea and vomiting. Box 28.1 presents specific etiologies for nausea and vomiting.

BOX 28.1 Etiologies of Nausea and Vomiting

- Therapy-induced causes
  - Chemotherapy
  - Radiation therapy
  - Opiates
  - Anticonvulsants
  - Ipecac
  - Antibiotics
  - Digitalis or digoxin toxicity
  - Theophylline
  - Nonsteroidal anti-inflammatory drugs
  - Hormonal therapies
- Drug withdrawal
  - Opiates
  - Benzodiazepines
- Metabolic disorders
  - Addison disease
  - Water intoxication
  - Volume depletion
  - Diabetic ketoacidosis
  - Hypercalcemia
  - Renal dysfunction–uremia
  - Gastrointestinal mechanisms
  - Mechanical gastric outlet obstruction
  - Peptic ulcer disease
  - Gastric carcinoma

- Pancreatic disease
- Motility disorders
- Gastroparesis
- Drug-induced gastric stasis
- Irritable bowel syndrome
- Postgastric surgery
- Idiopathic gastric stasis

Intra-abdominal emergencies
- Acute pancreatitis
- Acute pyelonephritis
- Acute cholecystitis
- Acute cholangitis
- Acute viral hepatitis
- Intestinal obstruction

Acute gastroenteritis
- Viral gastroenteritis
- Salmonellosis
- Shigellosis
- Staphylococcal gastroenteritis (enterotoxins)

Cardiovascular disease
- Acute myocardial infarction
- Congestive heart failure
- Shock and circulatory collapse

Neurologic processes
- Cerebellar hemorrhage
- Increased intracranial pressure
- Hematoma
- Subdural effusion
- Tumor (benign or malignant)
- Hydrocephalus
- Reye syndrome

Headache
- Migraine
- Severe hypertension

Head trauma
- Vestibular disorders

Psychogenic causes
- Anorexia nervosa
- Anticipatory

Miscellaneous causes
- Pregnancy
- Noxious odors

Ingestion of an irritant
Operative procedures
Septicemia
Nicotine

Patient-specific factors that increase susceptibility to nausea and vomiting include age, previous nausea and vomiting experiences, and sex. Most of the research identifying these characteristics was done in patients receiving chemotherapy. Poor control of nausea and vomiting with previous surgeries or chemotherapy predisposes a patient to subsequent episodes of emesis, also referred to as *anticipatory nausea and vomiting*. This form of emesis is often difficult to treat with standard antiemetics drug therapy.

Patients who receive previously received chemotherapy have been noted to experience emesis compared to those who are chemotherapy naive. Additionally, younger female patients are noted to have a greater risk of emesis (Hesketh, 2008). Surprisingly, patients who have higher chronic ethanol intake exceeding 100 g/d (roughly 5 beers or mixed drinks per day) are associated with better emesis control and decreased incidence of vomiting. A history of motion sickness may increase the risks of nausea and vomiting in another situation, such as with chemotherapy or surgery. Children in general experience nausea and vomiting more frequently than do adults. Obesity and anxiety have also been associated with heightened emesis incidence (Hesketh, 2008).

The prevalence of nausea and vomiting may complicate 20% to 70% of surgical procedures (Gan, 2008). Prevalence is also increased by the use of certain inhalation agents (nitrous oxide, in particular) and by concomitant use of opiate medications; the use of propofol as an intravenous anesthetic agent lowers the risk of postoperative nausea and vomiting (PONV). PONV is more likely to occur after general than regional anesthesia, and its prevalence increases in parallel with the duration of surgery and anesthesia. PONV is especially common after gynecologic and middle ear surgery and also occurs more commonly with abdominal and orthopedic surgery than with laparoscopic or other extra-abdominal operations. PONV is also more likely in those with a history of PONV or motion sickness.

Pathophysiology

The pathophysiology of nausea and vomiting is complex (Figure 28.1) and involves the modulation of medullary sites and neurotransmitters. Many sensory centers accept noxious stimuli from the body, including the chemoreceptor trigger zone (CTZ), visceral afferent nerves, cerebral cortex, limbic system, vestibular system, and midbrain intracranial pressure receptors.

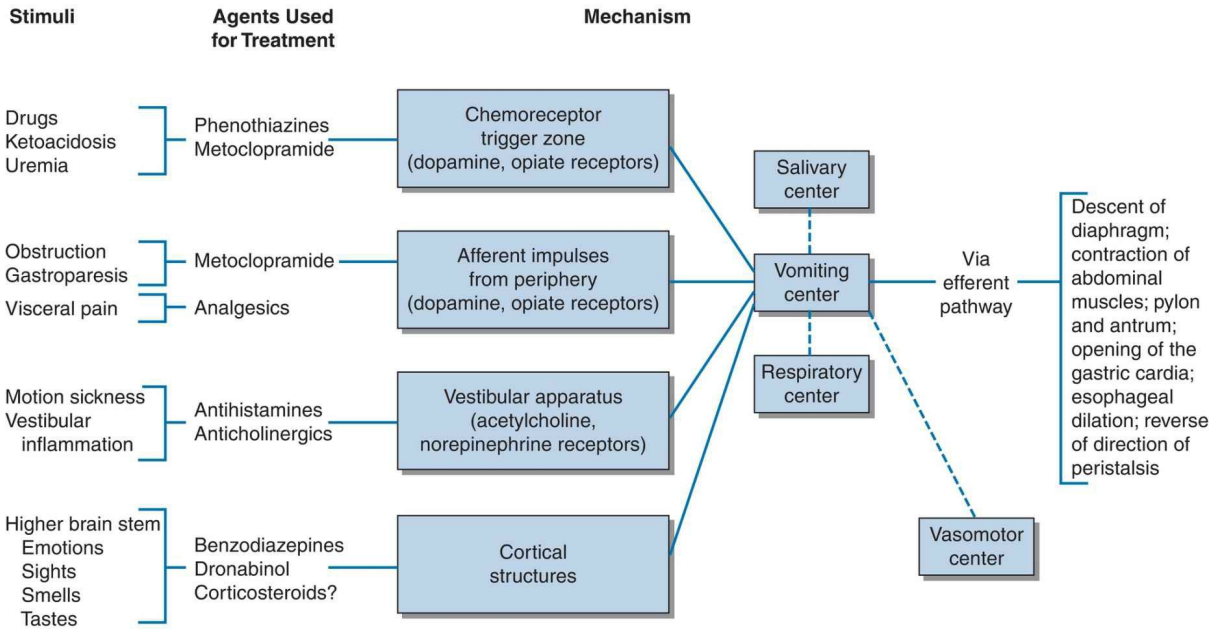

FIGURE 28.1 Pathophysiology of nausea and vomiting. (Reprinted from Koda-Kimble, M. A., & Young, L. Y. (2012). Nausea and vomiting. In M. A. Koda-Kimble, L. Y. Young, & B. J. Guglielmo (Eds.), *Applied therapeutics: The clinical use of drugs* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins, with permission.)

Modulation of Nausea and Vomiting

These stimuli are transmitted to the *emetic complex* (EC), a loose group of organized neurons throughout the medulla, which coordinates the sensory inputs and the act of vomiting. The EC is the key component in the modulation of nausea and vomiting. Located in the lateral reticular formation of the medulla, it receives afferent impulses from the aforementioned sensory centers. On activation of the EC, efferent impulses are sent to the nucleus tractus solitarius, an intertwined neural network that innervates the salivary, vasomotor, and respiratory centers and cranial nerves VIII and X. Efferent impulses are also sent to the stomach, abdominal muscles, diaphragm, and associated sphincters to execute the involuntary act of vomiting. Much like the sensory centers that stimulate it, the vomiting center is rich in dopamine, histamine, serotonin, and acetylcholine receptors and can also be affected by binding to opiate and benzodiazepine receptors. An intact EC is essential for coordination of the vomiting act or the emetic reflex.

Stimulatory Centers

The CTZ is one of the most important chemosensory organs responsible for the detection of noxious stimuli. It is uniquely located in the area postrema in the floor of the fourth ventricle of the (medulla) brain and is exposed to both blood and cerebrospinal fluid (CSF). Thus, toxins in both the blood and CSF can stimulate a response by the CTZ. These toxins may be drugs (chemotherapy, opiates, and digoxin), poisons, or substances found naturally in the body (excess calcium, hormones). The CTZ is rich in neurotransmitter receptors for dopamine, serotonin, histamine, and acetylcholine. Neurokinin 1 (NK) receptors found in the cerebral cortex/thalamus/limbic system also feed in the EC. An antiemetic effect is elicited when these receptors are blocked.

Gastrointestinal Tract

The GI tract and pharynx are sites of origin for the stimulation of nausea and vomiting. Visceral afferent nerves, also referred to as *splanchnic nerves*, from the pharynx and GI tract transmit impulses from local neuroreceptors along the vagus nerve to the vomiting center. The GI tract is rich in local dopamine, histamine, and serotonin receptors. The visceral afferent nerves are also responsible for transmitting stimuli from other peripheral sites such as the heart, lungs, and testes; hence, the vomiting response may occur when a person has been punched in the abdomen or kicked in the groin. Abdominal surgery is another example in which visceral afferent nerves are involved in nausea and vomiting.

Central Nervous System

Motion sickness is primarily a central nervous system (CNS) response mediated by the vestibular system. Acetylcholine and histamine receptors have been found in the vestibular center. Blockade of these receptors provides some degree of protection from emesis. The cerebral cortex, the largest portion of the brain, is responsible for the motor coordination of the body, sensory perception, learning, memory, and many other functions. Afferent impulses from specific sites of the cerebral cortex can result in emesis. The cerebellum is responsible for the regulation of balance, equilibrium, and coordination. Disruption of this portion of the brain can lead to temporary or chronic nausea and vomiting. These structures may also play a role in anticipatory emesis.

Limbic System

The limbic system and the midbrain intracranial pressure receptors can stimulate nausea and vomiting, although their mechanisms are not fully understood. In humans, the primary function of the limbic system is associated with the expression of mood, emotions, and feelings, as well as memory recall. Anxiety, fear, and other emotions may play a role at this site in the perception of nausea and vomiting. Head trauma, intracranial bleeding, and mass effect from a benign or malignant tumor can produce increased pressure in the brain.

This increased intracranial pressure can cause nausea and vomiting. The optimal treatment in these situations is a reduction in intracranial pressure through surgery or corticosteroids.

Diagnostic Criteria

The three identified phases of emesis are nausea, retching, and vomiting. Nausea is the unpleasant physical sensation of impending retching or vomiting. Nausea often occurs without the other two steps of emesis, although they are all treated with the same pharmacologic agents. Common symptoms accompanying nausea are flushing, pallor, tachycardia, and hypersalivation. Gastric stasis, decreased pyloric tone, mucosal blood flow, and contractions of the duodenum with reflux into the stomach are physiologic responses to nausea. Retching, the second phase of emesis, is the involuntary synchronized labored movement of abdominal and thoracic muscles before vomiting. Vomiting is the coordinated contractions of the abdominal and thoracic muscles to expel the gastric contents. The lower esophageal sphincter contracts, allowing GI retroperistalsis. The actual expulsion of gastric contents differentiates vomiting from retching.

The acuteness of the symptomatology is based on history and physical examination. Several issues need to be addressed such as whether this is an acute emergency, such as mechanical obstruction, perforation, or peritonitis, clinical clues that the problem is likely to be self-limited, such as would be expected with viral gastroenteritis or a potentially offending medication. The goal is to determine whether empiric treatment with an antiemetic, a gastric acid-suppressing, or a prokinetic agent would be beneficial or whether the patient should be admitted to the hospital to correct fluid and electrolyte imbalance.

Acute nausea and vomiting differs considerably from that of chronic nausea and vomiting differing in symptom duration. Acute onset of nausea and vomiting suggests gastroenteritis, pancreatitis, cholecystitis, or a drug-related side effect. When nausea and vomiting are associated with diarrhea, headache, and myalgias, the cause is viral gastroenteritis; in this instance, symptoms should resolve spontaneously within 5 days. A more insidious onset of nausea without vomiting is suspicious of gastroparesis, a medication-related side effect, metabolic disorders, pregnancy, or even gastroesophageal reflux disease. Nausea and vomiting are considered chronic when their duration is longer than 1 month.

Timing and description of the vomiting are important. Vomiting that occurs in the morning before breakfast is typical of that related to pregnancy, uremia, alcohol ingestion, and increased intracranial pressure. Projectile vomiting suggests intracranial disorders, especially those that result in increased intracranial pressure. In this case, vomiting may not be preceded by nausea.

The onset of vomiting caused by gastroparesis or gastric outlet obstruction tends to be delayed, usually by more than 1 hour, after meal ingestion. Vomiting may be suggestive of psychiatric disorders.

Associated symptoms such as abdominal pain, fever, diarrhea, vertigo, or a history of a similar contemporaneous illness among family, friends, or associates are important data to

gather.

The physical examination looks at vital signs for signs of dehydration. Jaundice, lymphadenopathy, abdominal masses, and occult blood in the stool may reveal features suggestive of thyrotoxicosis or Addison disease. The abdominal examination should look for distention, visible peristalsis, and abdominal or inguinal hernias. Areas of tenderness are important: tenderness in the midepigastrium suggests an ulcer, and in the right upper quadrant, cholecystitis or biliary tract disease. Auscultation may demonstrate increased bowel sounds in obstruction or absent bowel sounds in ileus.

Initiating Therapy

The treatment of nausea, retching, or vomiting in any patient begins with an evaluation and correction of possible causes. Most sources of nausea and vomiting may be reversed or palliated by surgery or medical interventions. Infectious causes should be promptly treated with antibiotics, and metabolic disorders require medical management. Some drug toxicities may be treated with antidotes, such as digoxin toxicity reversed with digoxin immune Fab (Digibind). The following section discusses medications used to treat nausea and vomiting. They should be used with definitive treatments when possible.

Alterations in a patient's daily activities may aid in managing nausea and vomiting and decrease the resources used to control the problem. Nonpharmacologic management of nausea and vomiting should be tailored to the presumed etiology.

Changes in a patient's diet may affect the frequency or severity of nausea and vomiting, such as avoidance of spicy foods and excessive grease or oil, and decreased caffeine intake. Professional counseling or group therapy may prove favorable for patients with psychogenic nausea and vomiting.

Hypnosis, behavior modification, and imagery are beneficial tools in controlling nausea and vomiting that has an anxiety component, such as chemotherapy-related anticipatory emesis. However, prevention of anticipatory nausea and vomiting is the optimal form of management.

Goals of Drug Therapy

The goals of drug therapy are simple: to alleviate the subjective feeling of nausea and the objective act of vomiting and their associated complications (Box 28.2). It is important to rely on the patient's subjective response when evaluating the efficacy of a specific therapy for nausea. Secondary goals are to minimize drug toxicity/adverse events and contain costs. The prevention of nausea and vomiting is the goal in the setting of chemotherapy and certain surgical procedures. Control or improvement in nausea and vomiting should occur within 5 to 60 minutes of a pharmacologic intervention. If this does not ensue, another method should be used promptly. Table 28.1 reviews available antiemetic agents, dosages, comparable efficacy, and adverse effects. Pregnancy risk factors are included in the discussion of each drug class and in the pregnancy-related nausea and vomiting section.

TABLE 28.1 Overview of Selected Antiemetic Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Phenothiazines			
chlorpromazine (Thorazine) 10–25 mg q4–6 h prn PO, 25–50 mg q4–6h prn IV, IM, 50–100 mg q6–8h prn rectal	Sedation or drowsiness EPSs: agitation, insomnia, motor restlessness, spasms of facial muscles, protrusion of tongue, and mandibular tics Anticholinergic effects: dry mouth, urinary retention, and blurred vision	Hypersensitivity Cautious use with other CNS depressants, Parkinson syndrome, poorly controlled seizure disorder, and severe hepatic dysfunction	Increased incidence of autonomic response with IV administration Higher incidence of EPSs
fluphenazine (Prolixin) 0.5–5 mg q6–8h prn PO, IM	Same as above	Same as above	
perphenazine (Trilafon) 2–6 mg q4–6h prn PO, 5–10 mg q6h prn IM	Same as above	Same as above	Higher incidence of EPSs compared with other phenothiazines
prochlorperazine (Compazine) 5–10 mg q4–6h prn PO, rectal, IM, IV 10–30 mg bid PO sustained-release capsule	Same as above	Same as above	Sustained-release capsule more expensive Higher incidence of EPSs compared with other phenothiazines
promethazine (Phenergan) 12.5–25 mg q4–6h prn PO, rectal, IM, IV	Same as above	Same as above	
Antihistamines and Anticholinergics			
benzquinamide (Emete-con) 50 mg q3–4h prn IM 25 mg q3–4h prn IV	Sedation or drowsiness, confusion Anticholinergic effects: dry mouth, tachycardia, blurred vision, urinary retention, constipation	Hypersensitivity Caution in narrow-angle glaucoma, asthma, prostatic hypertrophy	IV preparation not recommended
dimenhydrinate (Dramamine) 50–100 mg q4–6h prn PO, IM, IV	Same as above	Same as above	Do not exceed 200 mg/d
diphenhydramine (Benadryl) 25–50 mg q6–8h prn PO, 10–50 mg q2–4h prn IM, IV	Same as above	Same as above	Do not exceed 200 mg/d
hydroxyzine (Atarax, Vistaril) 25–100 mg q4–6h prn PO, IM	Same as above	Same as above	
meclizine (Antivert, Bonine) 25–50 mg q24h prn PO	Same as above	Same as above	
scopolamine (Transderm Scop) 1.5 mg q3d transdermal patch	Same as above	Same as above	
trimethobenzamide (Tigan) 250 mg q6–8h prn PO 200 mg q6–8h prn IM, rectal	Same as above	Same as above	
Benzodiazepines			
lorazepam (Ativan) 0.5–2 mg q4–8h prn PO, IM, IV	Drowsiness or fatigue, confusion, constipation	Same as above	Dose should be low in frail, elderly, or critically ill patients
diazepam (Valium) 2–5 mg bid–qid prn PO, IM, IV	Same as above	Same as above	Same as above

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Serotonin Antagonists			
dolasetron (Anzemet) 100 mg PO 1 h before chemotherapy 100 mg IV 30 min before chemotherapy 12.5 mg IV 15 min before cessation of anesthesia 100 mg PO 2 h before surgery	Headache, diarrhea, ECG changes	Hypersensitivity Use with caution in patients with severe cardiac dysfunction	Very expensive (IV > PO) Use only when indicated
granisetron (Kytril) 10 µg/kg IV 30 min before chemotherapy 1 mg PO bid (q12h)—start before chemotherapy (Sancuso) patch—3.1 mg/24 h (1 patch)	Same as above	Same as above	Very expensive (IV > PO) Use only when indicated IV dose often rounded to 1- or 2-mg doses
ondansetron (Zofran) 0.15 mg/kg IV 30 min before chemotherapy and at 4 and 8 h Oral—tablet and melt 4 mg, 8 mg	Same as above	Same as above	Generic, less expensive than other in the class
NK1 Antagonist			
aprepitant (Emend) Oral—40, 80, 125 mg 3 h prior to induction of anesthesia, 1 h prior to chemotherapy	Heartburn, confusion, decreased urination, dizziness Dyspepsia, fatigue, constipation, erythema, skin allergic reactions	Hypersensitivity to product, contraindication with some chemotherapy agents Possible hypersensitivity to 5-HT3 component, serotonin syndrome	Interacts with contraceptives Extremely expensive Interactions with dexamethasone, midazolam, oral contraceptives
NK1/Serotonin Antagonist Combo			
netupitant/palonosetron (Akynzeo) 300 mg/0.5 mg			
Other Antiemetics			
dexamethasone (Decadron) 8–20 mg IV/PO before chemotherapy; 4–8 mg IV bid (delayed nausea and vomiting)	Hyperactivity, GI irritation, mood swings, depression, hyperglycemia, anxiety	Hypersensitivity Use with caution in diabetic patients, history of ulcers, young male patients	Give IV over 5–15 min Administer orally with food Avoid chronic administration
methylprednisolone (Solu-Medrol) 125–500 mg IV q6h	Same as above	Same as above	Same as above
dronabinol (Marinol) 5–15 mg/m² PO 1–3 h before chemotherapy and q4h × 6 2.5–10 mg PO bid	Sedation, confusion, dysphoria, increased appetite	Use with caution if patient is receiving other CNS depressants	Controlled substance
antacids 15–30 mL q2–4h prn	Diarrhea, constipation	Renal dysfunction	May decrease absorption of other drugs
metoclopramide (Reglan)	EPSs		Side effects are dose dependent
20–30 mg PO qid prn, 1–2 mg/kg IV before chemotherapy and q2–4h (high dose)	Diarrhea Drowsiness		EPS reversible with diphenhydramine
doxylamine/pyridoxine (Diclegis) 10 mg each drug	Drowsiness, dizziness, impaired coordination, headache, urinary retention	Caution with CV disease, hyperthyroid, HTN, COPD, lower resp. tract sx	Only drug approved for nausea and vomiting of pregnancy by FDA Doxylamine—first-generation antihistamine

BOX 28.2 Complications of Nausea and Vomiting

Metabolic abnormalities

- Dehydration
- Alkalosis
- Hypokalemia
- Hypomagnesemia
- Hyponatremia
- Hypochloremia
- Malnutrition

Structural damage

- Wound dehiscence
- Esophagogastric tears/Mallory-Weiss tears
- Increased bleeding under skin flaps
- Tension on suture lines

Patient dissatisfaction

- Noncompliance
- Poor oral intake; anticipatory nausea and vomiting
- Delayed ambulation after surgery/procedures
- Fatigue
- Depression

Increased use of resources

- Prolongation of hospital stay
- Unexpected hospital admission
- Alteration or additional therapy

Aspiration pneumonia

Venous hypertension

Phenothiazines

Phenothiazines are a commonly used class of drugs to treat nausea and vomiting. Prochlorperazine (Compazine) and promethazine (Phenergan) are the most frequently used drugs in this class.

Mechanism of Action

Their mechanism of action presumably involves dopamine receptor blockade in the CTZ. Anticholinergic activity in the vomiting and vestibular centers of the brain may also contribute to the mechanism of action.

The phenothiazines may be used as monotherapy for mild to moderate nausea and vomiting or in combination with other antiemetics for more severe nausea and vomiting. A dose–response quality has been noted for this drug class; however, the incidence of adverse effects such as extrapyramidal effects and sedation can also be associated with higher doses. Promethazine has activities of an antihistamine antiemetic and could also be classified with the antihistamine–anticholinergic class of drugs. The phenothiazines are a viable and practical option for long-term treatment of nausea and vomiting. Products are available in oral, rectal, and injectable formulations. To improve tailoring of the drug regimen to the patient, oral preparations are available as tablets, sustained-release capsules, and liquids. Rectal suppositories are useful in patients who cannot retain oral medications and when intravenous (IV) access is not an option. Suppositories should be avoided in patients who are thrombocytopenic because of the increased risk of bleeding or hemorrhage.

Contraindications

Caution should be used in patients taking concomitant drugs that cause CNS depression, such as sedatives, hypnotics, and opiates, because further sedation may result. Phenothiazines may exacerbate the symptoms of Parkinson disease. The safety of phenothiazines during pregnancy is controversial; most studies find phenothiazines to be safe for the mother and fetus if used occasionally in low doses. Most phenothiazines are in pregnancy risk category C. Phenothiazines may decrease the seizure threshold and should be used cautiously in patients with seizure disorders.

The phenothiazines are relatively inexpensive in relation to most of the other drug classes, with the exception of the sustained-release phenothiazine preparations, which tend to be costly.

Adverse Events

The most common adverse event of phenothiazine use is drowsiness or sedation. Phenothiazines also have the ability to evoke extrapyramidal symptoms (EPSs) by blocking the central dopaminergic receptors involved in motor function, particularly at higher doses.

EPSs may present as dystonic reactions, feelings of motor restlessness, and parkinsonian signs and symptoms. Masklike face, drooling, tremor, cogwheel rigidity, pill-rolling motion, lack of ability to initiate voluntary movement, and gait abnormalities are all severe examples of parkinsonian presentations. Dystonic reactions may include spasm of the neck muscles or torticollis, extensor rigidity of back muscles, mandibular tics, difficulty swallowing or talking, and perioral spasms, often with protrusion of the tongue. Motor restlessness may consist of agitation, jitteriness, tapping of feet, and insomnia. Extrapyramidal reactions can be easily treated with the use of diphenhydramine (Benadryl) 25 mg orally or parenterally three to four times a day or benztropine (Cogentin) 1 to 4 mg orally or parenterally twice a day. Autonomic responses, such as hypotension and tachycardia, have been observed with IV phenothiazine use, particularly chlorpromazine. Hypotension and sedation are less likely to occur with prochlorperazine, thiethylperazine, and perphenazine, but these three agents are associated with a higher frequency of EPSs. Dry mouth, urinary retention, blurred vision, and other anticholinergic effects may occur with phenothiazine use. Reversible agranulocytosis is rarely associated (less than 1%) with phenothiazine therapy. This effect occurs more frequently in women and with chronic phenothiazine use. Cholestatic jaundice and photosensitivity are reactions that can occur rarely within the first few months of chronic phenothiazine use. These are more frequently observed in phenothiazine use for psychiatric conditions rather than emesis control.

Monitoring parameters include EPSs and parkinsonian symptoms. Doses may need to be decreased in severe hepatic dysfunction. Complete blood counts should be regularly monitored in chronic phenothiazine use (see Table 28.1).

Interactions

These drugs potentiate CNS depression with alcohol and other CNS depressants. They potentiate the action of α blockers and levels of the drug can be increased with propranolol. Anticonvulsant drug doses may have to be adjusted. They may antagonize oral anticoagulants.

Antihistamines–Anticholinergics

A plethora of agents are available in the antihistamine–anticholinergic drug class. These agents are most useful for mild nausea, such as motion sickness. Hydroxyzine (Vistaril, Atarax), meclizine (Bonine, Antivert), dimenhydrinate (Dramamine), and scopolamine (Transderm Scop) are some of the more common agents of this class. Unlike most of the other classes of agents discussed in this chapter, some of the antihistamine–anticholinergic agents are available without a prescription.

Mechanism of Action

The mechanism of action appears to be interruption of visceral afferent pathways that are responsible for stimulating nausea and vomiting. These drugs are most frequently administered orally, but some can be given IV, intramuscularly, transdermally, or rectally.

The antihistamines are particularly useful for the treatment and prevention of motion sickness. For this indication, it is recommended that a dose be taken at least 30 to 60 minutes before the event (e.g., boating, air flight, car ride) and then repeated at regular intervals several times a day. The scopolamine patch is a highly useful agent for the prevention of motion sickness. A patch should be applied to clean, dry skin 1 to 2 hours before the potentially emetogenic event, and a new patch may be reapplied every 3 days.

Many of the antihistamines and anticholinergics have been used for the treatment of nausea in pregnancy.

Contraindications

Precautions are recommended with asthma, glaucoma, and GI or urinary obstruction. Antihistamines–anticholinergics are not recommended for nursing mothers.

Adverse Events

Adverse effects limit the use of anticholinergics–antihistamines. Patients frequently experience sedation, drowsiness, or confusion. The anticholinergic effects are troublesome, including blurred vision, dry mouth, urinary retention, and tachycardia. These anticholinergic effects are also dose related and occur more frequently as the dose increases or the drug is given more often. Caution is warranted in patients with narrow-angle glaucoma, prostatic hypertrophy, and asthma because these patients are more prone to the anticholinergic effects of these drugs.

Anticholinergic effects may be managed by nondrug therapies. Chewing gum or sucking on ice chips or hard candy may refresh a dry mouth. The intake of a high-fiber diet and adequate daily fluid consumption may curb constipation.

Monitoring for anticholinergic effects is of paramount importance. Severe effects may warrant discontinuation of the drug. Symptoms of overdose may include dilated pupils,

tachycardia, hypertension, CNS depression, flushed skin, or, more seriously, respiratory failure and circulatory collapse. Adverse effects occur more commonly in patients with renal or hepatic dysfunction.

Interactions

These drugs can potentiate CNS depression with alcohol, tranquilizers, and sedative–hypnotics.

Benzodiazepines

Often used for other indications, benzodiazepines offer useful qualities to the antiemetic armamentarium. Not only do these agents treat and prevent emesis, they can cause anxiolysis and amnesia. These latter effects are particularly beneficial in anticipatory nausea and vomiting associated with chemotherapy.

Lorazepam (Ativan) is the most frequently used benzodiazepine for nausea and vomiting. Its mechanism of action is not fully elucidated; however, it probably acts centrally to inhibit the vomiting center. Lorazepam has only moderate antiemetic properties and is usually used in combination with other agents to control chemotherapy-associated anticipatory nausea and vomiting and delayed chemotherapy-associated nausea and vomiting.

Dosage

Both oral and parenteral forms of lorazepam are available. Patient-specific variables should be considered when identifying an appropriate dose. Usual oral or IV doses range from 0.5 to 2 mg at least 30 minutes before start of chemotherapy. As-needed (prn) antiemetic doses range from 0.5 to 3 mg IV or orally every 4 to 6 hours. To prevent oversedation, patients with poor performance status, the elderly, or frail individuals require low initial doses of lorazepam. Patients with compromised pulmonary or poor cardiac function should receive IV lorazepam with caution and have close monitoring of respiratory and cardiac status.

Contraindications

Lorazepam is not recommended for use in patients with hepatic or renal failure. Several studies have indicated that diazepam (Valium) may also cause fetal toxicity when administered to pregnant women and thus should be avoided in this patient population. The benzodiazepines are in pregnancy risk category D.

Adverse Events

For benzodiazepines, CNS depression occurs most often, with drowsiness, fatigue, memory impairment, impaired coordination, and confusion occurring frequently. Lorazepam has an amnesic effect that for some patients is a benefit, whereas others may find it unacceptable. Paradoxical CNS stimulation resulting in restlessness, anxiety, nightmares, and increased muscle spasticity may occur. The drug should be discontinued if paradoxical stimulation occurs. Other adverse effects include constipation, headache, and increased or decreased appetite. Parenteral administration may cause hypotension, bradycardia, or apnea, particularly in the elderly and critically ill (see Table 28.1).

Monitoring parameters include cardiovascular and respiratory status for initial doses. Because the liver metabolizes the benzodiazepines, liver function tests should be assessed

before dosing. The presence of adverse CNS effects should be evaluated with each clinic or hospital visit.

Interactions

These drugs potentiate CNS depression when used with other drugs that depress the CNS and alcohol.

Serotonin Antagonists

The serotonin antagonists are another class of antiemetics. Ondansetron (Zofran), granisetron (Kytril, Sancuso), palonosetron (Aloxi), and dolasetron (Anzemet) are available in the United States.

Mechanism of Action

These agents work by antagonizing the type 3 serotonin ($5HT_3$) receptors centrally in the CTZ and also peripherally at the vagal and splanchnic afferent fibers from the enterochromaffin cells in the upper GI tract. The serotonin antagonists were initially indicated for the treatment and prevention of chemotherapy-induced nausea and vomiting. They have changed the way nausea and vomiting are treated and have greatly improved the quality of life for patients receiving highly emetogenic chemotherapy regimens. Radiation-induced nausea and vomiting and PONV are two other areas where the serotonin antagonists have been studied. The unequivocal efficacy and lack of significant adverse effects make these agents ideal for select indications.

The serotonin antagonists are available orally as tablets and liquids and parenterally for IV use. Because these agents are used to prevent nausea and vomiting, oral administration in this situation is encouraged, even with highly emetogenic chemotherapy. There have been few data to support superior efficacy of one agent over another when used at recommended dosages (Barrett et al., 2011). While the cost of the serotonin antagonist preparations can be higher than other antiemetics, the recent advent of generic ondansetron (Zofran) has made this class more available for treatment of nausea and vomiting. However, this class of medication still needs to be used conservatively and appropriately. Many institutions have created antiemetic guidelines to identify the approved indications of serotonin antagonists to optimize care and resources. The appropriateness of these agents in specific circumstances is discussed later.

Contraindications

There are inadequate human data for use in pregnancy; however, animal studies do not reveal evidence of harm to the fetus. Two case reports cite the efficacy of ondansetron in the treatment of hyperemesis gravidarum, without adverse sequelae to the fetus. The serotonin antagonists are in pregnancy risk category B. The serotonin antagonists should be used with caution in breast-feeding mothers; once again, human data are lacking, but ondansetron is distributed into the milk of lactating rats.

Adverse Events

Mild to moderate headache can occur in patients receiving oral or parenteral serotonin antagonists, followed in frequency by diarrhea. A few patients experience severe headaches requiring discontinuation of the drug. Other adverse effects that occur in less than 10% of

patients are abdominal or epigastric pain, increased serum hepatic enzyme levels on liver function tests, hypertension, malaise or fatigue, constipation, pruritus, and fever. Rare cardiovascular effects have been reported, although a definite causal relationship has not been established. All three of the agents can cause electrocardiographic (ECG) alterations (prolonged PR interval and QT interval and widened QRS complex). This is best documented in the studies of dolasetron, but these ECG changes were deemed to be clinically nonsignificant by the authors (Audhuy et al., 1996). Conservatively, in patients with severe cardiac dysfunctions such as arrhythmia and heart block, the serotonin antagonists should be used cautiously.

Important monitoring parameters for serotonin antagonists include baseline and follow-up liver function tests. Dosage reductions may be made for severe hepatic dysfunction. To avoid ECG-related complications, electrolyte assessment and correction of hypokalemia and hypomagnesemia are indicated (see Table 28.1).

Interactions

Caution is used when given with drugs that prolong cardiac conduction interval, diuretics, and cumulative high-dose anthracycline.

Metoclopramide and Other Antiemetics

Metoclopramide (Reglan) has been used to treat nausea and vomiting caused by several different stimuli. It is a highly useful agent in the treatment of diabetic gastric stasis, postsurgical gastric stasis, and gastroesophageal reflux, which may be associated with some degree of nausea.

Mechanism of Action

For these indications, metoclopramide enhances motility and gastric emptying by increasing the duration and extent of esophageal contractions, the resting tone of the lower esophageal sphincter, gastric contractions, and peristalsis of the duodenum and jejunum. Metoclopramide is also used in the prevention and treatment of chemotherapy-induced nausea and vomiting. Its mechanism of action is dopamine receptor inhibition in the CTZ. The central and peripheral actions of this agent make it efficacious in multiple clinical situations. Metoclopramide can be administered orally, IV, and intramuscularly. A sugar-free syrup exists for diabetic patients who cannot take the pills. Because metoclopramide is eliminated primarily by the kidneys, the dose of this drug should be decreased by 50% if the patient's creatinine clearance is less than 40 mL/min. Subsequent doses are based on the patient's clinical response. Periodic assessment of renal function is prudent. Patients should be informed of the sedative qualities of this agent and that use of other CNS depressants could potentiate this effect.

Adverse Events

The most clinically concerning adverse effects of metoclopramide are EPSs. Much like the effects seen with high doses of phenothiazines, facial spasms, rhythmic protrusions of the tongue, involuntary movements of limbs, motor restlessness, agitation, and other dystonic reactions can occur. These effects occur most commonly in children and young adults, in men more than women, and at high doses of metoclopramide. Twenty-five percent of adults ages 18 to 30 experience dystonic reactions after receiving high-dose metoclopramide for treatment of chemotherapy-induced emesis. EPSs occur within 24 to 48 hours of the initial dose and subside within 24 hours of drug discontinuation. High-dose metoclopramide is usually defined as 2 mg/kg per dose. EPSs can be prevented or treated with the addition of diphenhydramine 25 to 50 mg IV or orally. IV administration of diphenhydramine is preferred for serious presentations. Other reversal agents are benztropine and diazepam. Secondary to its actions in the intestinal tract, metoclopramide can cause diarrhea. Management of diarrhea includes discontinuation or dosage reduction of metoclopramide, increased fluid resuscitation, and electrolyte replacement. The use of metoclopramide may not be a prudent choice in a patient who already has diarrhea. Drowsiness and fatigue are noted in approximately 10% of patients. There are inadequate data for the use of metoclopramide in pregnancy; however, supratherapeutic doses in rats did not produce evidence of fetal harm. Metoclopramide is in pregnancy risk category B.

Metoclopramide is known to be distributed into breast milk but does not appear to present a risk to the infant if the mother is taking 45 mg/d or less.

Interactions

A hypertensive crisis can occur when metoclopramide is used with monoamine oxidase inhibitors. Additive sedation can be seen when used with alcohol or other CNS depressants. These drugs are antagonized by anticholinergics and narcotics. They may diminish gastric and accelerate intestinal absorption of drugs and food.

Corticosteroids

Corticosteroids are usually reserved for chemotherapy-induced nausea and vomiting. Appreciation of the antiemetic properties of this class of agents occurred when clinicians observed decreased episodes of nausea and vomiting with Hodgkin disease protocols that included prednisone compared with protocols that did not include prednisone.

Mechanism of Action

The true mechanism of action in the relief of nausea and vomiting is unknown, but one postulated theory is the inhibition of prostaglandins. In nausea and vomiting secondary to increased intracranial pressure, corticosteroids provide relief by decreasing inflammation. Dexamethasone (Decadron) and methylprednisolone (Solu-Medrol) are the two most common corticosteroids used; however, the addition of prednisone (Deltasone) to lymphoma and leukemia chemotherapy regimens can provide heightened control of emesis. These corticosteroids are almost always used in combination with other agents in the control or prevention of emesis from highly emetogenic regimens.

Corticosteroids are available orally and parenterally. The oral form is beneficial for low doses or prolonged administration, but may cause significant GI toxicity. Patients should be encouraged to take oral corticosteroids with food to minimize GI irritation and complications. IV administration is ordinarily used in the prevention of nausea and vomiting, primarily to avoid GI complications. IV preparations should be infused over 5 to 15 minutes to prevent burning, flushing, and itching sensations associated with the phosphate salt dissociation. Of the corticosteroids studied, the utility of dexamethasone has been best defined. In clinical trials, single-agent dexamethasone was superior to prochlorperazine and comparable with high-dose metoclopramide when used for mildly to moderately emetogenic chemotherapy regimens. The combination of dexamethasone and high-dose metoclopramide was the standard of care for prevention of cisplatin-induced emesis until the introduction of the serotonin antagonists. IV doses of dexamethasone as a premedication range from 8 to 20 mg.

Corticosteroids should be used with caution in uncontrolled diabetic patients. Sliding-scale insulin or careful alterations of oral hypoglycemic agent regimens may be used for unacceptably high blood glucose levels.

Adverse Events

Although very useful, the corticosteroids are associated with many toxicities and adverse effects. Mental disturbances range from mood swings, depression, anxiety, and aggression to frank psychosis and personality changes. Men are particularly susceptible to this aggressive behavior. Headache, restlessness, and insomnia are not infrequent, particularly with higher doses of corticosteroids. Patients and family members and loved ones will benefit from knowing that these effects may occur with therapy. Sleep aids may be

necessary for secondary insomnia. Temazepam (Restoril) or diphenhydramine are viable options. Variable increases in blood glucose and decreased glucose tolerance result from glucocorticoid use. Regular evaluation of blood glucose in diabetic patients is warranted. Glucocorticoids, especially in large or chronic doses, can increase the susceptibility to and mask the symptoms of infection, such as fever. Many consequences of long-term corticosteroid use can be detrimental. Muscle wasting, adrenocortical insufficiency, fluid and electrolyte disturbances, cataract formation, and atrophy of the protein matrix of bone resulting in osteoporosis, vertebral compression fractures, aseptic necrosis of femoral or humeral heads, and pathologic fractures are some of the most serious complications of chronic corticosteroid use. Whenever possible, chronic corticosteroid use should be curtailed.

Interactions

Glucocorticoids may decrease effects of barbiturates, hydantoins, rifampin, and ephedrine. Potassium levels should be monitored when glucocorticoids are used with potassium-depleting diuretics.

Cannabinoids

Cannabinoids are indicated only for nausea and vomiting associated with chemotherapy. In the 1970s, it was observed that patients on chemotherapy who smoked marijuana experienced a lower incidence of nausea and vomiting. Investigators then determined that tetrahydrocannabinol (THC) has antiemetic properties.

Mechanism of Action

The true mechanism of action of THC is unknown, but it is most likely related to effects on the vomiting center and the opiate receptors in the CNS and cerebral cortex but probably does not involve the CTZ. The agent available in the United States is dronabinol (Marinol).

The cannabinoids can be used to treat and prevent chemotherapy-induced nausea and vomiting. Because it is necessary to reach therapeutic blood levels of THC before chemotherapy administration to prevent emesis, administration of the cannabinoids should occur at least 6 to 12 hours before chemotherapy. Emesis can be controlled from mildly to moderately emetogenic chemotherapy regimens, and cannabinoids may provide some relief to patients where other agents have failed. When used with mildly to moderately emetogenic regimens, THC has been found to be superior to placebo, prochlorperazine, low-dose metoclopramide, and haloperidol. These agents are seldom front-line therapy because of their incidence and severity of adverse effects.

Patients should be cautioned about the deleterious CNS effects and told not to drive or operate machinery. Dosages can be reduced if the patient is experiencing CNS toxicities. Patients should avoid alcohol and other CNS depressants.

Adverse Events

Most of the adverse effects of the cannabinoids are CNS related and include sedation, ataxia, and dysphoria. Dysphoria may be expressed as confusion, hallucinations, anxiety, fear, memory loss, time distortion, and other undesired occurrences. Orthostatic hypotension, blurred vision, and tachycardia have been observed with the use of these drugs. With repeated doses, the patients usually become tolerant to most of the CNS adverse effects, but not to the antiemetic activity. There is a correlation between antiemetic response and a psychological “high.” Younger patients and patients who have had previous experiences with recreational cannabinoids appreciate greater antiemetic efficacy from this drug class. The side effects of the cannabinoids occur more frequently than with many of the other agents and are particularly distressing to older adults. One potentially beneficial adverse effect is appetite stimulation, which may prove useful in hematology and oncology patients. The cannabinoids are in pregnancy risk category D and should be avoided in pregnancy or lactation.

Antacids

Over-the-counter (OTC) antacid preparations may provide relief to patients experiencing mild nausea and vomiting. The general mechanism by which these agents exhibit their effects is by coating the stomach and neutralizing gastric acid. Most preparations contain one or several of the following: calcium carbonate, magnesium hydroxide, aluminum hydroxide, or aluminum carbonate. Between 15 and 30 mL orally of an antacid preparation may provide relief. Patients should be encouraged to seek medical attention if they experience continued nausea and vomiting, and the patient may need medical workup for more serious GI diseases.

Toxicities from OTC antacids are infrequent, but they do exist. The agents containing magnesium may cause diarrhea; conversely, the agents containing aluminum or calcium may cause constipation. These adverse effects are dose dependent. Calcium-containing antacids can cause phosphate depletion. Caution should be used in patients with renal dysfunction because aluminum and magnesium may accumulate. Antacids, by coating the GI tract, can decrease the absorption of many oral medications such as digoxin, some antibiotics, corticosteroids, and allopurinol (Zyloprim), which may lead to decreased efficacy of therapy. (For additional information on antacids, see Chapter 29.)

Selecting the Most Appropriate Agent

Nausea and Vomiting Not Chemotherapy Induced

It is necessary for the practitioner to assess the etiology of the nausea and vomiting. If an organic cause can be determined, the cause should be corrected to alleviate the symptoms. For example, if the nausea and vomiting is a side effect of a medication, the medication is to be discontinued. If the cause is diabetic ketoacidosis, insulin is given. Figure 28.2 shows the treatment algorithm.

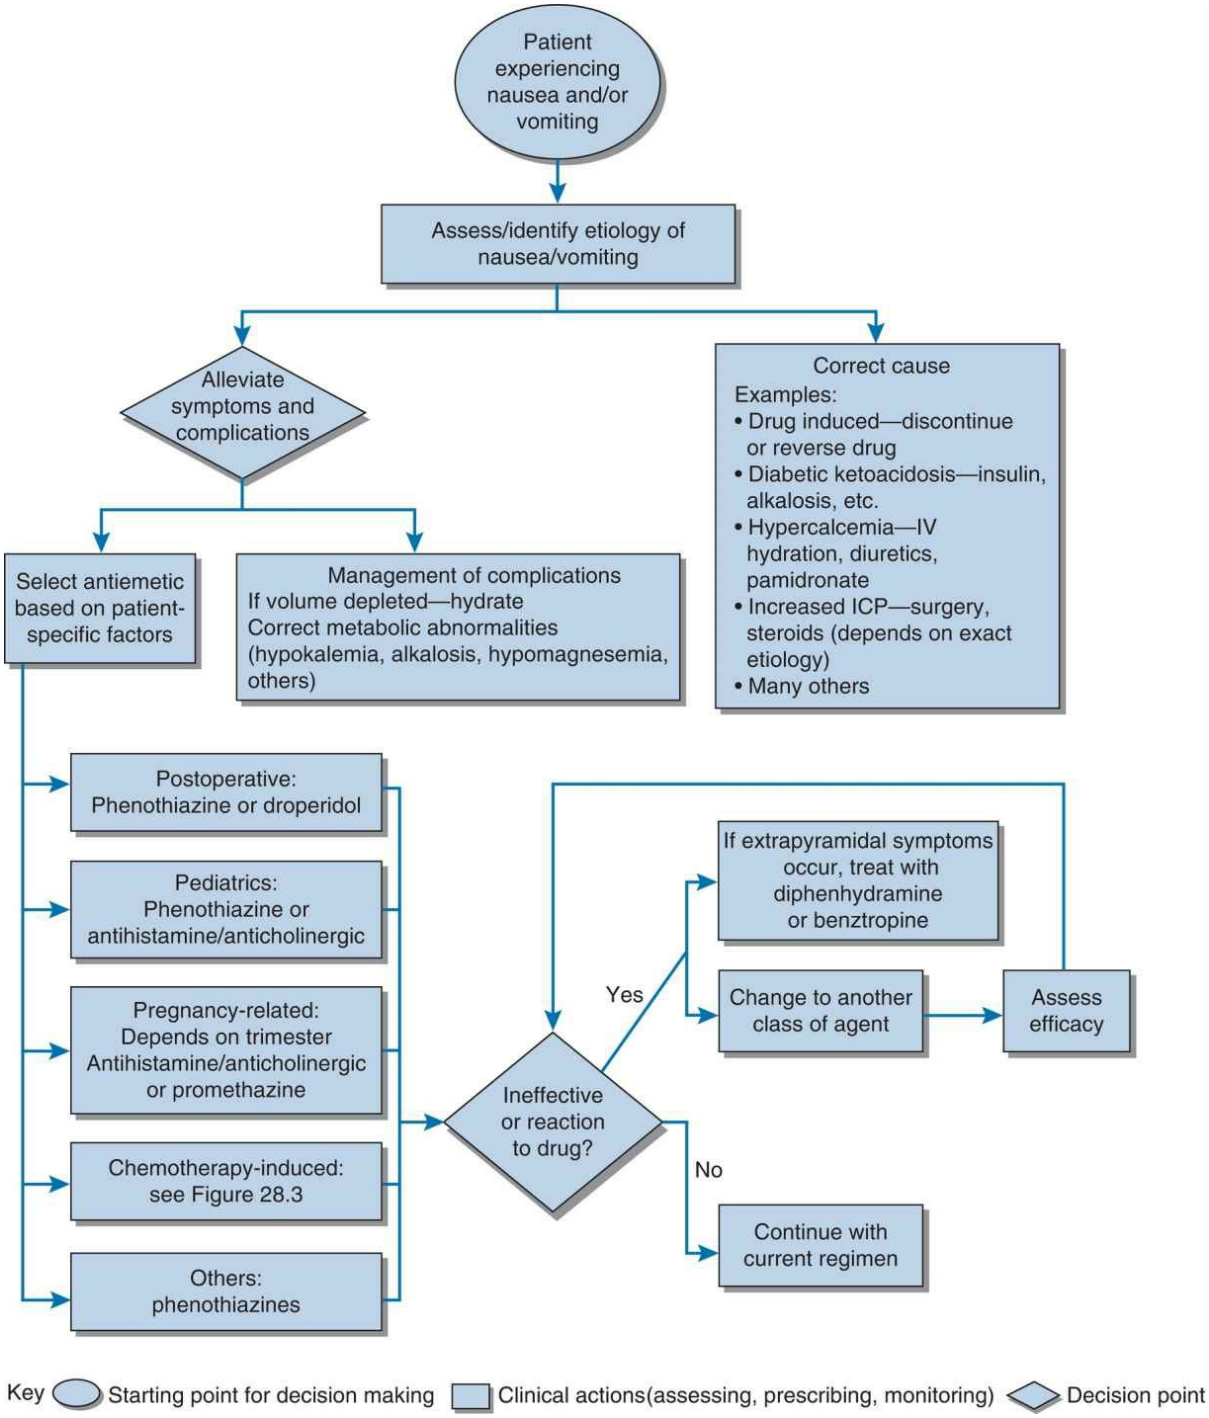

FIGURE 28.2 Treatment algorithm for nausea and vomiting.

First-Line Therapy

An antiemetic is selected based on patient-specific factors. Initially, a phenothiazine is used for mild to moderate nausea and vomiting. Promethazine and prochlorperazine are usually effective.

Second-Line Therapy

If the above treatment is not effective, an antihistamine or anticholinergic preparation can be used. These are usually not as effective as phenothiazines but may be useful in mild nausea.

Third-Line Therapy

If the first two therapies are not successful, the patient should be re-evaluated for a physiological cause that has not been treated and therapy based on patient data.

Table 28.2 lists the recommended order of treatment for nausea and vomiting.

TABLE 28.2 Recommended Order of Treatment for Nausea and Vomiting*

Order	Agents	Comments
First line	Phenothiazines	Most frequently used for mild to moderate nausea and vomiting Promethazine, prochlorperazine usually effective
Second line	Antihistamine Anticholinergic preparation	Usually not as efficacious as phenothiazines, but may be useful in mild nausea
Third line	Depends on response to other antiemetics	Tailor to patient-specific factors

*Consider patient-specific factors when choosing an antiemetic agent.

Chemotherapy-Induced Nausea and Vomiting

Nausea and vomiting are two of the toxicities of chemotherapy that patients fear most. Although not usually a life-threatening complication, uncontrolled nausea or vomiting can greatly affect a patient's quality of life and attitude. Fortunately, new agents and combinations of agents make it possible to control emesis.

The severity of chemotherapy-induced emesis depends on numerous factors. Most significant is the intrinsic ability of the chemotherapy regimen to cause nausea and vomiting. Before the U.S. Food and Drug Administration approves a drug for use, phase 1

and 2 studies must be performed to prove efficacy and safety and identify adverse effects. The incidence and severity of nausea and vomiting are initially reported at this time, when the drug is given as a single agent. Each chemotherapy agent can be identified as having highly, moderately high, moderate, moderately low, and low emetogenic potential. Based on this information, antiemetic regimens can be tailored to the chemotherapy regimen to prevent emesis. Mechanisms to identify the emetogenicity of combination chemotherapy regimens are presented in this section. Other factors that may increase the incidence of chemotherapy-induced nausea and vomiting are previous exposure to chemotherapy, psychosocial factors such as anxiety and depression, poor performance status, and younger age (less than 30 years). A history of alcohol abuse and male sex may correlate with a decreased incidence or severity of nausea and vomiting. The classifications of chemotherapy-induced nausea and vomiting include acute, delayed, and anticipatory.

Acute Emesis

Acute emesis is vomiting occurring within 24 hours of treatment. The onset of acute emesis is usually within 1 to 2 hours after the start of chemotherapy. It peaks within 4 to 10 hours and resolves within 24 hours, but these factors vary from agent to agent. This most common type of chemotherapy-induced nausea and vomiting is associated with a higher frequency and severity than the other two classifications. Acute emesis is strongly related to the agent or agents administered and the doses given. (Box 28.3 identifies the emetogenic potential of specific agents.)

BOX 28.3 Emetogenic Potential of Chemotherapy Agents

Highly emetogenic (>90%)
- Carmustine >250 mg/m^2
- Cisplatin >50 mg/m^2
- Cyclophosphamide >1,500 mg/m^2
- Dacarbazine
- Lomustine
- Mechlorethamine
- Streptozocin

Moderately high (60%–90%)
- Carboplatin
- Carmustine ≤250 mg/m^2
- Cisplatin ≤50 mg/m^2
- Cyclophosphamide ≤1,500 mg/m^2 or >750 mg/m^2
- Cytarabine >1,000 mg/m^2
- Doxorubicin >60 mg/m^2

Methotrexate >1,000 mg/m^2
Procarbazine oral
Moderate (30%–60%)
Cyclophosphamide ≤750 mg/m^2
Cyclophosphamide oral
Doxorubicin 20–60 mg/m^2
Idarubicin
Ifosfamide
Methotrexate 250–1,000 mg/m^2
Mitoxantrone
Topotecan
Moderately low (10%–30%)
Docetaxel
Etoposide
5-fluorouracil
Gemcitabine
Methotrexate >50 mg/m^2 or <250 mg/m^2
Mitomycin
Paclitaxel
Low (<10%)
Bleomycin
Busulfan
Chlorambucil oral
Cladribine
Fludarabine
Hydroxyurea
Melphalan oral
Thioguanine oral
Vinblastine
Vincristine
Vinorelbine

By definition, highly emetogenic chemotherapy agents induce emesis in greater than 90% of patients receiving that drug without antiemetic premedication. Chemotherapy agents that have moderately high emetogenicity cause emesis in 60% to 90% of patients receiving chemotherapy. Chemotherapy that is moderately emetogenic has an incidence of 30% to 60%, moderately low has a 10% to 30% incidence of emesis, and low emetogenicity is defined as an incidence of less than 10%.

All patients receiving single agents that are moderately to highly emetogenic should be adequately pretreated to prevent the incidence of nausea and vomiting for at least 24 hours

or the expected duration of nausea or vomiting. The current standard of care of antiemetic prophylaxis is the combination of a serotonin antagonist and a corticosteroid, such as granisetron or ondansetron with dexamethasone, at least 30 minutes before chemotherapy administration. Repeated doses may need to be given to prevent and treat emesis for 24 hours, depending on the pharmacokinetics of the agents used. Some practitioners use once-daily administration of serotonin antagonists, claiming that once the receptors are blocked, duration of receptor binding is the functional component rather than the plasma half-life. Because the purpose of these agents is to prevent nausea and vomiting, and the patient is not actively experiencing these effects, it is often acceptable to administer antiemetics orally. Combination regimens containing drugs that are moderately to highly emetogenic are given prophylactically in similar fashion. Although the aforementioned antiemetic combination is not universally effective, an estimated 70% to 90% of patients experience sufficient control. Examples of difficult clinical situations that may prohibit the use of a corticosteroid include poorly controlled diabetes and uncontrolled hypertension.

Contraindications to serotonin antagonists include hypersensitivity or severe cardiac dysfunction. Alternative prophylactic antiemetics must be chosen for patients who have relative contraindications and are to receive emetogenic chemotherapy. High-dose metoclopramide with dexamethasone may be considered an option to a serotonin antagonist with dexamethasone because this was the gold standard for highly emetogenic regimens before the appearance of ondansetron. Once again, the antiemetic regimen should be tailored to the patient and the chemotherapy regimen.

Single-agent or combination chemotherapy regimens that are expected to be moderately low or low in emetogenic potential can be managed less aggressively. These drugs do not warrant the use of a serotonin antagonist. For some chemotherapy regimens and agents, such as the taxanes and fluorouracil, premedication frequently is not necessary; however, patients should be encouraged to use antiemetic medications as needed to control any nausea and vomiting after chemotherapy. Premedication with dexamethasone with or without a phenothiazine or metoclopramide may be used if a patient experiences nausea and vomiting from previous chemotherapy. All of these antiemetic drugs may be scheduled for a 24- to 36-hour period to prevent any nausea and vomiting. Patient-specific factors must be considered to identify an appropriate antiemetic regimen.

Regardless of the emetogenicity of a chemotherapy regimen or the use of premedications, antiemetics should be prescribed for prn or breakthrough use. Preferred prn antiemetics, such as prochlorperazine or metoclopramide, are effective, inexpensive, and easily administered. These agents provide reliable, safe control of mild nausea. These agents may be used before meals to alleviate anorexia secondary to nausea. Patients should be counseled about the common adverse effects of these agents, and each patient should be encouraged to report ineffective control of nausea and vomiting. When adhered to, the basic principles of chemotherapy antiemetic therapy (Box 28.4) are tremendously effective.

BOX 28.4 Basic Principles of Chemotherapy Antiemetic Therapy

- Consider emetogenic potential of chemotherapy regimen.
- Give appropriate antiemetics to prevent nausea and vomiting at least 30 minutes before emetogenic chemotherapy.
- Schedule antiemetics throughout anticipated period of nausea and vomiting risk.
- Always prescribe prn antiemetics for breakthrough nausea and vomiting between scheduled doses.
- Use antiemetic combinations with nonoverlapping mechanisms of action and adverse effects, when possible.
- Consider patient-specific variables when choosing a regimen (e.g., anxiety, performance status).
- Re-evaluate patients frequently during and between chemotherapy courses for efficacy and toxicity of antiemetic regimen.
- Consider nonpharmacologic interventions, especially in patients with anticipatory nausea and vomiting.

Delayed Emesis

Delayed nausea and vomiting is defined as emesis that begins or persists more than 24 hours after completion of chemotherapy. Some investigators suggest that because there is a "peak" in incidence at 18 hours after cisplatin-based chemotherapy, a revised definition of delayed emesis should include this timetable. The new-found, reliable control of acute emesis from highly to moderately emetogenic chemotherapy regimens has unveiled delayed nausea and vomiting as a more vexing problem. Many chemotherapy agents produce mild delayed nausea and vomiting, but cyclophosphamide, cisplatin, and the anthracyclines are particularly noted for their delayed emesis.

Delayed emesis usually is not as frequent or severe as acute emesis. The mechanism of delayed emesis is believed to be different from that of acute emesis. It is believed that delayed emesis is mediated by neurotransmitters, although serotonin does not play a major role. Combination antiemetic regimens have proven to be more effective than single-agent therapies. Single-agent serotonin antagonists were found to be equally as effective as metoclopramide or placebo and less effective than dexamethasone, unlike their efficacy in preventing acute emesis. Regimens identified as most effective for delayed emesis include metoclopramide 0.5 mg/kg orally four times a day for 4 days with dexamethasone 8 mg orally twice a day for 2 days, followed by dexamethasone 4 mg orally twice a day for 2 days.

The use of scheduled phenothiazines (including long-acting phenothiazines) with dexamethasone is another effective option for the prevention of delayed nausea and

vomiting. Addition of a benzodiazepine to the antiemetic regimen may prove useful for the control of emesis in anxious patients or patients with difficulty resting.

Anticipatory Emesis

Anticipatory nausea and vomiting occurs in up to 25% of patients receiving chemotherapy. It is usually associated with a history of uncontrolled nausea and vomiting with prior chemotherapy and is a conditioned response. Multiple factors can stimulate anticipatory nausea and vomiting, but most factors remind the patient of the previous unfavorable experience. For example, patients tell stories of becoming nauseated by the sight of their oncologist's office or by a smell that reminds them of receiving chemotherapy. Other triggers may be tastes, sounds, or thoughts of chemotherapy. Anticipatory nausea and vomiting most frequently occurs before the administration of chemotherapy, and it can lead to poorer control of nausea and vomiting with subsequent courses. The most effective treatment for delayed nausea and vomiting is prevention. It is crucial to premedicate adequately for highly to moderately emetogenic chemotherapy and to reassess control on a frequent and regular basis. This form of emesis is frequently refractory to standard antiemetic treatment; however, the benzodiazepines and butyrophenones may provide anxiolysis as well as antiemetogenicity. The addition of one of these agents is strongly encouraged for patients who have had previous unsatisfactory control of nausea and vomiting.

Many practice guidelines are available for the use of antiemetics in chemotherapy-induced nausea and vomiting. These guidelines are created by experts and are based on current literature (Table 28.3 and Figure 28.3). To review treatment choices for other types of nausea and vomiting, see Table 28.2 and Figure 28.2.

TABLE 28.3 Order of Treatment for Chemotherapy-Induced Nausea and Vomiting

Order	Agents	Comments
Acute Prophylaxis for High, Moderately High, and Moderately Emetogenic Regimens		
First line	Serotonin antagonist + dexamethasone	May add other agents as needed
Second line	High-dose metoclopramide + dexamethasone	Prophylaxis for EPSs with metoclopramide
Third line	Depends on response to other antiemetics	Tailor to patient-specific factors
Acute Prophylaxis for Moderately Low and Low Emetogenic Regimens		
First line	No premedication or phenothiazine ± dexamethasone	Depends on chemotherapy regimen
Second line	Metoclopramide ± dexamethasone	Use low-dose metoclopramide
Third line	Depends on response to other antiemetics	Tailor to patient-specific factors
Delayed Nausea and Vomiting		
First line	Metoclopramide + dexamethasone	Continue 3–4 d after chemotherapy
Second line	Long-acting phenothiazine + dexamethasone	Monitor for EPSs
Third line	Depends on response to other antiemetics	Tailor to patient-specific factors

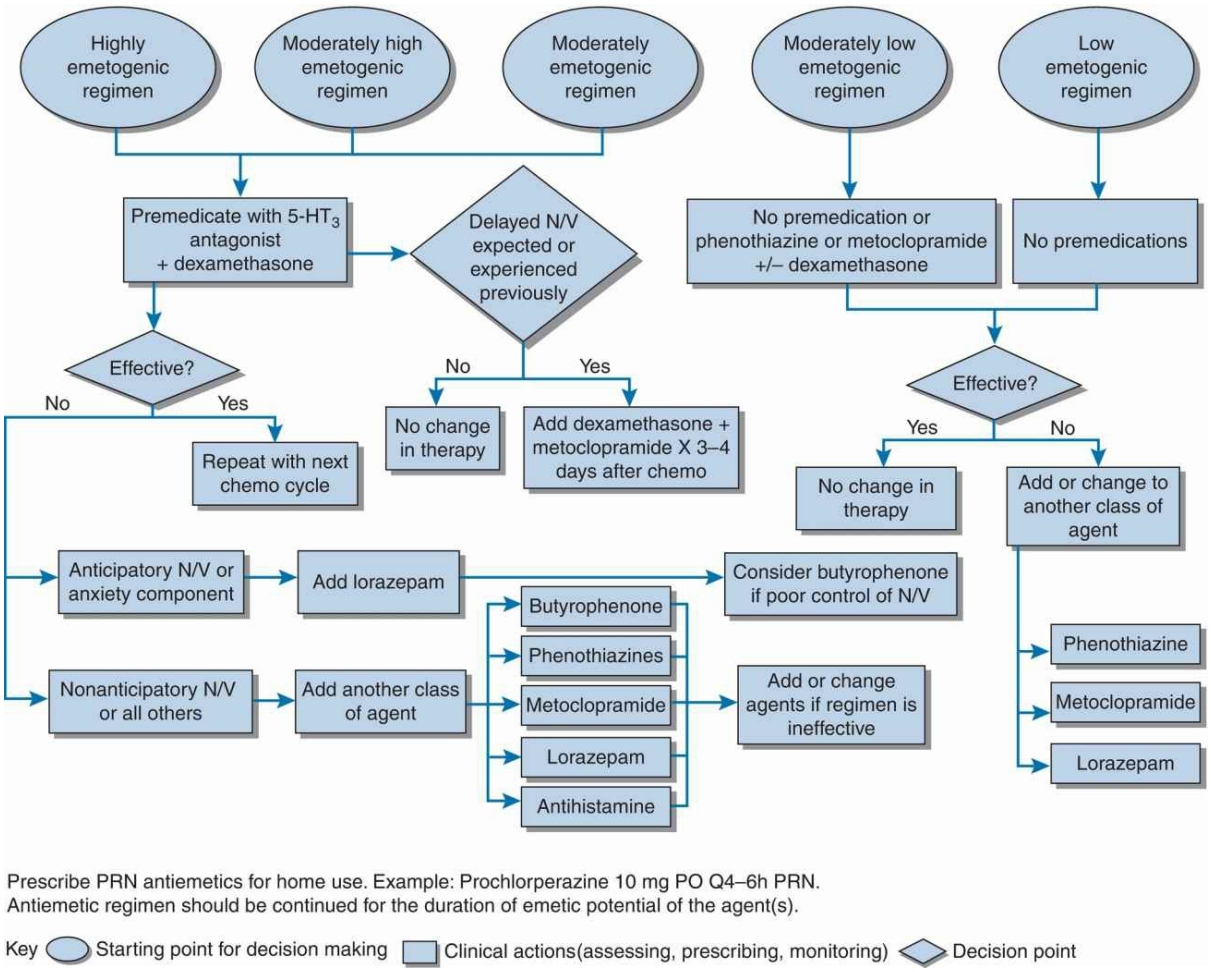

FIGURE 28.3 Treatment algorithm for chemotherapy-induced nausea and vomiting.

Special Population Considerations

Pediatric

The treatment of nausea and vomiting in children differs from that in adults. It is particularly important in the pediatric population to focus on treating the cause of the problem. The etiology of emesis can vary with age (Box 28.5). Because they are smaller, children are predisposed to dehydration and electrolyte abnormalities caused by emesis.

BOX 28.5 Differential Diagnosis of Vomiting by Age

Newborn

- Congenital obstructive GI malformations
  - ™Atresias or webs of esophagus or intestine
  - ™Meconium ileus or plug; Hirschsprung disease
- Inborn errors in metabolism

Infant

- Acquired or milder obstructive lesions
  - ™Pyloric stenosis
  - ™Malrotation and volvulus
  - ™Intussusception
- Metabolic diseases, milder inborn errors of metabolism
- Nutrient intolerances
- Functional disorders: gastroesophageal reflux
- Psychosocial disorders: rumination, injury due to child abuse

Child or Adolescent

- Please refer to adult etiologies (Box 28.1).

Pediatric patients experience more extrapyramidal or neuromuscular reactions to phenothiazines, particularly when the drugs are administered during an acute viral illness such as chickenpox, measles, or gastroenteritis. Because of its antihistamine quality, promethazine may be a viable phenothiazine option. Also, on a milligram-per-kilogram

basis, children experience more extrapyramidal reactions from metoclopramide, even at IV doses as low as 0.5 mg/kg four times a day.

Most antiemetic agents are dosed according to milligram per kilogram of body weight or the age of the child, and many of the available agents are not recommended for use in patients younger than age 2 or 3. Some agents that are considered safe and effective in most situations are dimenhydrinate or oral or rectal trimethobenzamide (Tigan; IV not recommended). The phenothiazines are beneficial but should be used cautiously. For pediatric patients receiving chemotherapy, the prevention and treatment of emesis is similar to that in their adult counterparts, although specific pediatric dosing of the agents applies.

Women

Nausea and vomiting is experienced by more than 50% of pregnant women. A few women experience hyperemesis gravidarum, which can present as uncontrollable vomiting with inability to tolerate oral intake. These symptoms are most common in the first trimester of gestation but can occur at any time during pregnancy. Pregnancy-related emesis is believed to be modulated by CTZ stimulation.

Teratogenicity is the paramount concern when evaluating the safety of an agent in pregnant women. The first trimester of the pregnancy is when drugs or other exogenous substances can most affect embryonal development. Many of the studies performed to study the teratogenic effects of drugs encounter several difficulties. Most fetal malformations occur rarely, and frequently, only a small sample size is obtained and reported. Mothers with underlying diseases, such as seizure disorder, hypertension, diabetes, and cancer, are known to have a higher incidence of infants with malformation. In these patient populations, the role of drugs versus the role of the disease in fetal abnormalities is unclear. Recall bias may play a factor in teratogenicity studies as well. Ultimately, current evidence-based information on the safety and risk of drugs during pregnancy should be used to make clinical decisions.

Most recently doxylamine–pyridoxine (Diclegis) combination pill was reintroduced as the only drug approved by the FDA for treatment of nausea and vomiting from pregnancy and is considered first line for treatment (American College of Obstetricians and Gynecologists, 2015; Nuangchamnong & Niebyl, 2014). Other agents that are used for mild to moderate nausea and vomiting in pregnancy include the phenothiazines, antihistamine–anticholinergic agents, and metoclopramide. Antihistamine drugs are generally believed to be safe for the pregnant women and her fetus, although there are incidental findings of malformations in fetuses exposed to antihistamines. Anticholinergic drugs have been proven to cause neonatal meconium ileus. Conversely, some anticholinergic agents such as scopolamine have not been associated with consistent teratogenesis.

Phenothiazines readily cross the placenta, but the bulk of evidence indicates their use is safe in this population. Antacids, such as calcium carbonate, may provide safe and reliable

relief from mild nausea. Antihistamines, phenothiazines, metoclopramide, haloperidol, droperidol, and ondansetron have all been used in hyperemesis gravidarum without adverse fetal sequelae. Drug classes that should be avoided in pregnant women are the benzodiazepines and cannabinoids. Increased rates of malformations and fetal complications have been associated with the use of these classes of agents; however, the use of other prescribed and illicit drugs by many of these mothers could cloud the picture. Corticosteroids are rarely used for the control of nausea and vomiting in pregnant women. The risks versus benefits of each drug and situation must be weighed carefully. Further studies to assess safety in this patient population are greatly needed.

Monitoring Patient Response

The best measure of nausea control is how the patient feels. To make evaluation of nausea more objective, nausea can be rated as none, mild, moderate, or severe. Another method is to ask the patient to rate the nausea on a scale from 0 to 10, with 0 equal to no nausea and 10 equal to severe nausea. These methods may help to compare nausea from day to day or week to week in the same patient. Vomiting is easily quantified by episodes per day and volume. If the volume of vomit exceeds 200 to 500 mL/d, the patient should be evaluated for electrolyte abnormalities.

Patient Education

It is pivotal to identify the cause of the nausea and vomiting and to educate the patient about actions that need to be taken. Many cases of mild nausea and vomiting can be alleviated without additional medications.

Drug Information

Some drugs may be taken with food to avoid GI discomfort, and dietary adjustments may prove to be helpful for some cases of nausea. This knowledge gives patients more control over their own well-being. Anxiety and mental illness are components of some occurrences of nausea and vomiting; therefore, counseling and education are the key components in the treatment of nausea and vomiting of this type. Patients can also be educated about the nonprescription drugs available. Realistic goals of nausea control should be set and discussed with the patient. For example, many women have morning sickness with pregnancy; however, medications should be used as infrequently as possible at the lowest dose possible.

With antiemetics, as with any other drug therapy, usual or serious toxicities should be reviewed with the patient. EPSs are frightening and uncomfortable; consequently, patients need to be aware of this potential effect and how to reverse it if necessary (diphenhydramine). Sedation and anticholinergic effects are common with many antiemetics. For most antiemetics, encourage caution when using machinery or driving. Proper administration of the medication should be reviewed. Will the patient take this on a schedule or only as needed? All of this information ensures that the patient has optimal benefit from the prescribed medication.

Nutritional and Lifestyle Changes

Maintenance of proper hydration during all forms of vomiting is important and should be emphasized to patients predisposed to nausea and vomiting (e.g., children, patients following surgery and chemotherapy, patients with GI disorders and infections). Rehydration with clear liquids is preferred over colas, milk, or caffeinated beverages. Patients should be educated on when to seek medical attention because of excessive vomiting or dehydration.

Complementary and Alternative Therapies

Patients suffering from nausea and vomiting of pregnancy (NVP) frequently do not receive therapy, in part because of fears of adverse effects of medications on the fetus. Several vitamin-based and herbal therapies have been shown to be effective and safe. Two randomized trials of vitamin B_6 have shown a benefit in reducing NVP. The recommended daily allowance is 1.3 to 2 mg/d. Women taking prenatal multivitamins are less likely to have severe NVP.

Ginger has been shown to reduce NVP. Ginger appears to work by inhibiting serotonin receptors in the GI tract and CNS. The dose of ginger for the powdered root form in motion sickness is 1 g up to 4 hours before an inciting event; in NVP, 250 mg four times a day; for chemotherapy-induced nausea and vomiting, 2 to 4 g daily; and for PONV, 1 g 1 hour before anesthesia induction.

Vitamin B_1 (thiamine) deficiency can lead to Wernicke encephalopathy in women with severe NVP. Replacement is needed for all women with vomiting of more than 3 weeks' duration. Prophylaxis with multivitamins and therapy with B_6, with or without doxylamine, are safe and effective therapies for NVP.

Case Study*

S.B. is a 57-year-old African American man with newly diagnosed late-stage small cell lung cancer. He has undergone radiation therapy to the brain for his metastases and is to start chemotherapy next week. His past medical history includes hypertension. He has no known drug allergies. A combination chemotherapy regimen has been chosen: cisplatin 100 mg/m^2 for one dose on the first day and etoposide 100 mg/m^2 IV every day for 3 days. He has experienced nausea and vomiting.

Diagnosis: Chemotherapy-Induced Nausea and Vomiting

1. List specific goals for treatment for S.B.
2. What drug therapy would you prescribe? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for the second-line therapy?
7. What OTC and/or alternative medications would be appropriate for this patient?
8. What dietary and lifestyle changes should be recommended for this patient?
9. Describe one or two drug–drug or drug–food interactions for the selected agent.

29 Gastroesophageal Reflux Disease and Peptic Ulcer Disease

Alice Lim

Gastroesophageal reflux disease (GERD) and peptic ulcer disease (PUD) are two disorders of the gastrointestinal (GI) tract that can cause tissue damage and unpleasant symptoms. They are both commonly encountered in the primary care and gastroenterology settings and can also significantly decrease a patient's health-related quality of life if left unmanaged.

Gastroesophageal Reflux Disease

GERD is defined as "troublesome symptoms and/or complications" resulting from the abnormal reflux of gastric contents into the esophagus or beyond, including the oral cavity or lungs. Troublesome symptoms are those that have a negative impact on the patient's well-being and quality of life.

Depending on how the patient presents, GERD syndromes may be classified into two categories: (1) symptoms present but without erosions seen on endoscopic exam or (2) those with esophageal tissue injury. Esophageal erosions occur as a result of repeated exposure to refluxed material for prolonged periods of time.

GERD may occur in all ages, but most commonly occurs in those older than 40 years of age. Patients with mild symptoms do not always seek medical treatment and instead self-treat with lifestyle changes or over-the-counter remedies. As a result, the true prevalence of the disease is difficult to assess. It is estimated that 18% to 28% of adults in the United States suffer GERD symptoms weekly. Prevalence seems to be increasing worldwide, with highest rates in Western countries and lowest rates found in East Asia.

Causes

Symptoms and/or tissue damage associated with GERD is caused by exposure of the esophagus to gastric contents. This happens as a result of relaxation of the lower esophageal sphincter (LES) due to increase in intra-abdominal pressure (e.g., obesity, pregnancy), delayed gastric emptying, hiatal hernia, or certain medications or foods as listed in Table 29.1. Additional risk factors include family history, smoking, alcohol consumption, respiratory diseases, obesity, and reclining or lying down after eating.

TABLE 29.1 Risk Factors for GERD

Causes of LES Relaxation

Foods	Drugs
Fatty foods	Anticholinergic agents
Chocolate	Benzodiazepines
Peppermint/Spearmint	Caffeine
Garlic	Calcium channel blockers (dihydropyridines)
Onions	Dopamine
Chili peppers	Estrogen/progesterone
Alcohol	Nicotine
Coffee/caffeinated drinks	Nitrates
	Theophylline
	Tricyclic antidepressants

Causes Direct Irritation of Esophageal Mucosa

Foods	Drugs
Spicy foods	Aspirin
Citrus juices	Bisphosphonates (e.g., alendronate)
Tomato products	Iron
Coffee	Nonsteroidal anti-inflammatory drugs (NSAIDs)
Tobacco chew	Potassium chloride

Pathophysiology

Under normal circumstances, the LES serves as a barrier between the esophagus and stomach and, coupled with peristalsis, promotes the forward movement of food. Bicarbonate found in saliva and secreted by the esophageal mucosa buffers acid present in the esophagus. Problems with these normal defense mechanisms contribute to the development of GERD.

Lower Esophageal Sphincter

The LES is a 3- to 4-cm-long smooth muscle located at the distal end of the esophagus. It serves as a high-pressure barrier between the esophagus and stomach and acts to prevent retrograde passage of gastric contents into the esophagus. The LES relaxes on swallowing, allowing food to enter the stomach. A number of mechanisms can cause disruption of this barrier, such as transient LES relaxation (TLESR), increase in intra-abdominal pressure (e.g., pregnancy, obesity, bending over), delayed gastric emptying, and hiatal hernia. Several foods and medications can also decrease LES tone as listed in Table 29.1.

TLESR is a normal physiological process that allows gas to escape the stomach and facilitate belching. This is typically accomplished without allowing liquids from escaping the stomach. In GERD, however, TLESR occurs more frequently and prolonged. TLESR is associated with more than half of the reflux episodes in patients with GERD.

Esophageal Clearance and Protection

The amount of time of exposure of gastric acid to the esophageal mucosa is an important determinant of GERD risk. Salivation and peristalsis contribute to the esophagus' ability to clear this content and minimize the duration of contact between the gastric contents and esophagus. Forty to fifty percent of patients with GERD have abnormal peristalsis. Swallowing saliva, which contains bicarbonate, helps to clear esophageal contents and neutralize acid present. However, certain patients have reduced salivary production, especially the elderly or those with Sjögren syndrome or xerostomia (dry mouth). Additionally, swallowing is hindered during sleep, leading to nocturnal GERD.

The esophageal mucosa contains mucus-secreting glands that act to protect the esophageal wall by secreting bicarbonate. However, repeated exposure to acid can compromise this defense system. Cellular damage results, leading to erosive esophagitis.

Gastric Emptying

Slow emptying of stomach contents can increase intragastric pressure, which consequently contributes to GERD. Factors that are associated with delayed emptying include smoking and high-fat meals. Medications that increase gastric emptying and motility can help.

Refluxate

The refluxate properties, acidity, and volume are important determinants of GERD risk. While the stomach can withstand very low pH levels and enzymatic activity of gastric secretions, the squamous cells lining the esophageal mucosa are more sensitive and readily damaged if exposed to this chemical environment. Gastric acid causes direct damage to the esophageal mucosa. Additionally, pepsin, which is a gastric enzyme responsible for the breakdown of food proteins, becomes activated in acidic environments, causing further injury to the esophageal lining.

Complications

Complications of GERD occur from repeated exposure to refluxed gastric contents for prolonged periods of time. These complications are outlined and defined in Table 29.2. Esophageal adenocarcinoma appears to occur more commonly in older white males with elevated body mass index (BMI). Since Barrett's esophagus is a risk factor for esophageal adenocarcinoma, screening for Barrett's esophagus is recommended in this particular group.

TABLE 29.2 Complications of GERD

Complication	Definition
Esophagitis	Inflammation of the lining of the esophagus
Erosive esophagitis	Erosion of the squamous epithelium of the esophagus
Peptic stricture development	Narrowing or tightening of the esophagus
Barrett's esophagus	Squamous epithelium of the esophagus is replaced by specialized columnar-type epithelium
Esophageal adenocarcinoma	Cancer of the esophagus

Diagnostic Criteria

Diagnosis is mainly dependent on patient report of symptoms and review of risk factors present. Symptoms are commonly classified as typical, atypical, and extraesophageal and are listed in Table 29.3. They tend to occur after meals and may be aggravated by reclining or lying down. Typical symptoms occur more commonly and include acid regurgitation and heartburn. Generally, a diagnosis of GERD is assumed if patients respond to an empiric trial of acid suppression therapy. Diagnosis of patients who present with atypical symptoms is challenging, since their symptoms may be caused by other conditions, such as PUD and gastroparesis. For these patients, further diagnostic evaluation may be considered prior to empiric therapy. Similarly, those presenting with chest pain must be evaluated to rule out cardiac causes.

TABLE 29.3 Symptoms of GERD

Typical Symptoms	Atypical Symptoms	Extraesophageal Symptoms
Acid regurgitation	Epigastric fullness	Chronic cough/ throat clearing
Heartburn	Epigastric pressure	Asthma/ bronchospasm
	Epigastric pain	Wheezing
	Dyspepsia	Hoarseness
	Nausea	Sore throat
	Bloating	Chronic laryngitis
	Belching	Dental erosions

Extraesophageal reflux syndromes are associated with symptoms that occur in organs other than the esophagus. These symptoms should only be associated with GERD if they occur with other GERD symptoms or with evidence of tissue injury since these symptoms are nonspecific and have many other causes.

Diagnostic tests may be helpful in patients who do not respond to therapy or those presenting with extraesophageal syndrome to confirm GERD as a cause, or to detect complications of GERD. Endoscopy (with or without biopsy) may be used to assess mucosal injury or other complications like strictures. Biopsy is necessary to detect esophageal adenocarcinoma or Barrett's esophagus. Of note, normal endoscopy does not

rule out GERD. On the other hand, tissue damage may not be specifically related to GERD. Other tests, such as ambulatory pH monitoring, can help to clarify diagnosis.

Initiating Drug Therapy

Lifestyle modifications can alleviate GERD symptoms and should be encouraged in every patient. However, in many cases, patients will need to supplement lifestyle changes with medication therapy to control their symptoms.

Drug classes used to treat GERD and its symptoms include (1) antacids, (2) histamine-2 receptor antagonists (H_2RAs), and (3) proton pump inhibitors (PPIs). Generally, a trial of an H_2RA or PPI is given for 2 weeks to confirm the diagnosis of GERD. The dose is increased as needed until symptoms resolve. If the patient responds to therapy, it is continued for 4 to 16 weeks. Afterward, the drug is tapered over 1 month to the minimal dose that provides symptom relief if maintenance therapy is warranted. Repeating the initial effective medication is recommended if symptoms recur. Diagnostic testing is recommended if the patient does not respond to treatment.

Goals of Drug Therapy

The goals of pharmacologic therapy are to:

- relieve symptoms
- decrease the frequency and duration of reflux
- heal the esophageal mucosa
- prevent complications

Peptic Ulcer Disease

Similar to GERD, PUD remains one of the most commonly encountered conditions and has high recurrence rates. As a result, PUD can result in significant impairment in quality of life.

Causes

There exist three common forms of PUD: *Helicobacter pylori*–positive ulcers, nonsteroidal anti-inflammatory drug (NSAID)-induced ulcers, and stress ulcers. *H. pylori* and NSAID-induced ulcers are chronic conditions that often recur in patients. Stress ulcers usually occur in critically ill patients or just following major trauma or serious illness. Management of stress ulcers is largely focused on prevention with PPIs or H_2RAs. Less commonly, peptic ulcers are also associated with Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, vascular insufficiency, and other chronic diseases. These ulcers develop mostly in the stomach and duodenum, but may occasionally develop in the esophagus, jejunum, ileum, or colon.

An estimated 30% to 40% of the U.S. population is infected with *H. pylori*; however, this prevalence has been decreasing, possibly due to improved therapies and sanitation. *H. pylori* infection typically occurs in the first few years of life and is contracted through the fecal–oral route. Though *H. pylori* infection is common, only 15% of these cases eventually progress to ulcer formation. PUD occurs in 30% of patients chronically using NSAIDs and aspirin, and 1.5% of these patients experience GI bleeding or perforation. Risk factors for ulcers related to NSAID use are listed in Table 29.4.

TABLE 29.4 Risk Factors for NSAID-Related PUD (American College of Gastroenterology)

Level of Risk	Risk Factors
Low	No risk factors present
Moderate	Presence of 1–2 of the following: • Age > 65 y • High-dose NSAID use • History of uncomplicated ulcer • Multiple NSAID use • Concurrent use of aspirin, corticosteroids, or anticoagulants
High	More than 2 of the above risk factors History of complicated ulcer

Pathophysiology

Under normal circumstances, the gastric and duodenal environments are able to maintain a state of homeostasis where food digestion can occur without compromising gastric tissue integrity. A number of defense mechanisms exist to prevent tissue injury from acid and digestive functions of the GI tract. *H. pylori* and NSAIDs can disrupt these processes, leading to the formation of ulcers.

Gastric Acid

Hydrochloric acid (HCl) and pepsin are responsible for gastric mucosal damage found in PUD. Baseline acid production occurs during fasting states, whereas maximal acid production occurs following meals. Parietal cells are stimulated to release acid by histamine, acetylcholine, and gastrin. All of these stimuli are released by the sensation of food, including the sight, smell, and taste. After stimulation, acid is released through the proton pumps located on the parietal cells. In *H. pylori* infection, acid secretion is elevated above normal, while NSAIDs do not affect acid secretion.

Pepsin

In an acidic environment, pepsinogen is converted to active pepsin in the stomach. Pepsin is responsible for protein digestion, but also can contribute to gastric mucosal damage leading to PUD.

Mucosal Protection

The gastric lining contains a mucus layer that works to protect the underlying cells of the gastric wall against gastric acid. Bicarbonate secretion acts as a buffering agent and allows the epithelial lining to maintain a neutral pH despite the acidic levels found in the gastric lumen. Prostaglandins also provide mucosal protection by decreasing gastric acid production and increasing mucus production. Both *H. pylori* and NSAID use can impede these defenses.

Helicobacter pylori

A gram-negative spiral-shaped rod bacterium with flagella, *H. pylori* is found on the surface of gastric epithelium. Infection occurs when *H. pylori* penetrates the epithelial cells. The bacterium is able to survive in the acidic environment mainly due to its ability to hydrolyze urea into carbon dioxide and ammonia through the production of urease. *H. pylori* causes ulcer formation by increasing acid production, increasing gastrin secretion, and releasing its own noxious enzymes and toxins. It is also a known carcinogen and if left untreated can lead to gastric mucosa–associated lymphoid tissue (MALT) lymphoma.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs cause PUD through direct and indirect mechanisms. As weak acids, they are direct irritants against the mucosal wall. NSAIDs also have antiplatelet properties, further compounding the bleeding complications that can occur as a result of PUD.

NSAIDs that inhibit both cyclooxygenase (COX)-1 and COX-2, inhibit endogenous prostaglandin production. Inhibition of COX-1 in the stomach reduces the production of prostaglandin, whereas COX-2 is more associated with the processes that lead to fever and pain. Therefore, selective COX-2 inhibitors carry less risk for PUD compared to nonselective NSAIDs.

Complications

Complications of PUD include GI bleed (melena or hematemesis), perforation, penetration, or gastric outlet obstruction. Symptoms of PUD-related complications include changes in nature of the pain. Patients with perforation may complain of sharp sudden pains. Patients with gastric outlet obstruction may experience bloating, anorexia, nausea, vomiting, and weight loss.

Diagnostic Criteria

Though not all patients with PUD present with symptoms, the most common complaints include epigastric pain described as burning, fullness, discomfort, gnawing, cramping, or aching. The severity and frequency of the pain can fluctuate, with some patients reporting nocturnal pain. Often, heartburn, belching, and bloating accompany the pain. Symptom presentation is dependent on location of the ulcer. *H. pylori*–associated ulcers are more commonly found in the duodenum, while NSAID-associated ulcers are more commonly found in the stomach. Symptoms of duodenal ulcer typically occur about 1 to 3 hours following meals and are usually relieved by food intake. In gastric ulcer, nausea, vomiting, and anorexia are common symptoms, and food can precipitate ulcer pain.

More severe signs and symptoms are described as alarming features. These include prior history or family history of upper GI malignancy, unintentional weight loss, GI bleeding, iron deficiency anemia, dysphagia or odynophagia, early satiety, persistent vomiting, palpable mass, or lymphadenopathy.

Endoscopy with biopsy allows access to tissue for rapid urease tests and cultures to detect *H. pylori*. Endoscopy is considered the gold standard test and is appropriate for initial evaluation of patients older than 50 years of age who have new-onset dyspepsia or patients of any age who present with alarming features. It should also be considered in those who fail a trial of acid suppression therapy, though sensitivity of the rapid urease test may be diminished with use of medications that reduce urease activity, such as antibiotics or PPIs. Obtaining a culture can provide further guidance, especially if antibiotic-resistant strains are suspected. However, this method is time consuming and costly.

Less invasive tests are also available, and include serologic testing, urea breath test, and fecal antigen assays. These tests are more appropriate for patients younger than 50 who complain of dyspepsia but without alarming features. Serologic testing can be performed in the office with results returning in 15 minutes. However, it is less sensitive and specific compared to other tests. Moreover, it is not useful in confirming eradication of the bacteria, since patients can remain seropositive for a long period of time following treatment. Given its high specificity and short turnaround time, the urea breath test is the most common noninvasive diagnostic tool for PUD. Since medications can interfere with urease activity, bismuth-containing medications and antibiotics should be held for at least 28 days and PPIS for 7 to 14 days before testing. Therefore, it is most reliable for confirming eradication 6 to 8 weeks after therapy. Fecal antigen testing is also useful in both diagnosing infection before treatment and confirming eradication after treatment. Testing is less sensitive to the effects of medications. Still, the test should be withheld within 4 weeks of antibiotic use, 2 weeks of PPI use, and 24 hours of H_2RA use.

Initiating Drug Therapy

Several pharmacologic agents are available for the treatment of PUD, and many overlap with the drugs used in the treatment of GERD. The choice in treatment depends on the etiology, presentation, and presence of complications.

For *H. pylori*–associated ulcers, a combination of antibiotics and acid suppression therapy can be prescribed. Relapses are common and can be prevented only by eradicating *H. pylori*; therefore, antibiotic therapy is indicated for all patients with *H. pylori*–induced ulcers. The empiric use of antisecretory agents for suspected PUD should be used with caution, since these can mask the symptoms of severe disease that warrants important diagnostic testing and long-term treatment. Thus, it is important to confirm *H. pylori* infection with serologic or urea breath testing prior to treatment.

Goals of Drug Therapy

The goals of pharmacologic therapy are to:

- relieve symptoms
- reduce acid secretion
- promote epithelial healing
- prevent recurrence
- prevent complications

For NSAID-induced PUD, an additional goal is to either identify an alternative for pain management or provide prophylaxis strategies to prevent ulcers if continued treatment with NSAIDs is necessary. Strategies include taking enteric-coated NSAIDs, taking with meals, adding misoprostol, or switching to a selective COX-2 inhibitor.

Drug Classes for the Treatment of GERD and PUD

The drugs used to treat GERD and PUD often overlap. Drug classes and their properties are described below and in Table 29.5.

TABLE 29.5 Drugs Used in the Management of GERD and PUD

Generic (Trade) Names	Selected Adverse Effects	Contraindications	Therapeutic Considerations
Antacids			
Calcium-, magnesium-, and aluminum-containing formulations	Rebound hyperacidity, diarrhea with magnesium-containing antacids, constipation with aluminum-containing antacids	None significant	Monitor for drug interactions Use magnesium–aluminum combination to avoid diarrhea or constipation
Histamine-2 Receptor Antagonists (H_2RAs)			
cimetidine (Tagamet) famotidine (Pepcid) nizatidine (Axid) ranitidine (Zantac)	Generally well tolerated, may experience headache, dizziness, confusion	Hypersensitivity to H_2RAs	Take without regard to meals Monitor for drug interactions Consider dose reduction in elderly and renal impairment May be scheduled or used on an as-needed basis
Generic (Trade) Names	**Selected Adverse Effects**	**Contraindications**	**Therapeutic Considerations**
Proton Pump Inhibitors (PPIs)			
omeprazole (Prilosec, Zegerid) lansoprazole (Prevacid) pantoprazole (Protonix) esomeprazole (Nexium) dexlansoprazole (Dexilant) rabeprazole (AcipHex)	Diarrhea, constipation, abdominal pain, headache	Hypersensitivity to PPIs	Take 30–60 min before meals Do not crush, chew, or split delayed-release tablets
Antibiotics			
amoxicillin (Amoxil) clarithromycin (Biaxin) metronidazole (Flagyl) tetracycline	amoxicillin: diarrhea, nausea, vomiting clarithromycin: diarrhea, abnormal taste, nausea, vomiting metronidazole: headache, metallic taste, nausea, peripheral neuropathy tetracycline: GI upset, diarrhea, photosensitivity	amoxicillin: allergy to penicillin or other beta-lactams clarithromycin: allergy to macrolides, QT prolongation, use with astemizole, cisapride, pimozide, simvastatin, or lovastatin metoclopramide: allergy to metoclopramide tetracycline: allergy to tetracycline	Take without regard to meals, except tetracycline should be taken on empty stomach Avoid clarithromycin in retreatment for those who fail initial clarithromycin-containing regimen Avoid alcohol with metronidazole Avoid dairy, antacids, and iron products within 2 h of tetracycline administration
Misoprostol			
misoprostol (Cytotec)	Diarrhea, abdominal pain, cramping, nausea	Hypersensitivity to misoprostol, pregnancy	Take with food Reduce dose if diarrhea is intolerable Avoid in pregnancy
Sucralfate			
sucralfate (Carafate)	Constipation	Hypersensitivity to sucralfate	Take on empty stomach. Monitor for drug interactions.
Bismuth Subsalicylate			
bismuth subsalicylate (Pepto Bismol)	Black stools, darkened tongue, constipation, tinnitus	Hypersensitivity to salicylates	Avoid in pregnancy and lactation

Antacids

There are numerous antacids available over the counter. Common examples include calcium carbonate (e.g., Tums), magnesium salts, and aluminum salts. They may be used for mild, intermittent symptoms (less than two times per week) or as breakthrough for patients taking other acid suppression therapies.

Mechanism of Action

Antacids partially neutralize the HCl in the stomach. By increasing the pH level, the activation of pepsin is also inhibited. Another antacid product combined with alginic acid forms a viscous solution on the surface of gastric contents to serve as a barrier against reflux.

Dosage

Antacid dosage recommendations vary and can be administered on an as-needed basis.

Time Frame for Response

Antacids provide immediate symptom relief in mild GERD and thus are commonly used as self-treatment by patients. However, they have a short duration of action, warranting frequent administration in some patients. When used to treat chronic symptoms or PUD, the sole use of antacids should be avoided since they must be administered many times daily in large doses to achieve symptom relief. Additionally, antacids do not heal ulcers and instead may mask the symptoms of serious disease and prolong the initiation of other necessary interventions.

Contraindications

No significant contraindications exist for antacids.

Adverse Events

As antacids are minimally absorbed and work locally in the GI tract, the most frequent side effects are chalky taste, cramps, constipation (aluminum-containing products), or diarrhea (magnesium-containing products). Less commonly, calcium carbonate may cause hypercalcemia. Aluminum antacids should be used with caution in those with renal failure who are more susceptible to hyperaluminemia. Similarly, hypermagnesemia may result in hypotension, nausea, vomiting, and electrocardiographic changes and thus magnesium-containing antacids should also be avoided in those with renal impairment.

Drug Interactions

Antacids also have clinically significant drug interactions by altering the rate and extent of absorption of concomitantly administered drugs, such as iron, sulfonylureas, and

tetracycline and quinolone antibiotics. It is recommended to take antacids 1 to 4 hours after other medications to avoid these interactions.

Histamine-2 Receptor Antagonists

H_2RAs are effective in mild GERD, ulcer healing, and *H. pylori* eradication when combined with other agents and may be used in the prevention of NSAID-related duodenal PUD. Like antacids, these products are available over the counter. Because all H_2RAs are equipotent, the choice in therapy depends on adverse effect profile and drug interactions.

Mechanism of Action

H_2RAs reversibly inhibit the histamine-2 receptors on gastric parietal cells and thus decrease acid secretion and pepsin activation.

Dosage

Dosing recommendations vary by product and severity of symptoms (see Table 29.6). When used in anti-*H. pylori* regimens, they are used once or twice daily. Higher doses are required for prevention of NSAID-related ulcers.

TABLE 29.6 Dosing and Administration for GERD Medications

Pharmacologic Agents	Dose	Administration Comments
Mild Symptomatic GERD		
Antacids	Varies depending on product	Use as needed, after meals, or at bedtime
Magnesium-, aluminum-, calcium-containing antacids	Dosing ranges from hourly to as needed	to control nocturnal symptoms
Histamine-2 Receptor Antagonists (Over the Counter)		
cimetidine (Tagamet HB)	200 mg once or twice daily	May be scheduled or used on an
famotidine (Pepcid AC)	10–20 mg once or twice daily	as-needed basis
nizatidine (Axid AR)	75 mg once or twice daily	
ranitidine (Zantac 75)	75 mg once or twice daily	
Proton Pump Inhibitors (Over the Counter)		
esomeprazole (Nexium 24H)	20 mg once daily	Take 30–60 min before breakfast or first
lansoprazole (Prevacid 24HR)	15 mg once daily	meal
omeprazole (Prilosec OTC)	20 mg once daily	
omeprazole/bicarbonate (Zegerid OTC)	20 mg/1,100 mg once daily	
Persistent Mild Symptomatic GERD, Moderate to Severe Symptomatic GERD		
Histamine-2 Receptor Antagonists (Prescription Strength)		
cimetidine (Tagamet)	400 mg twice daily	Duration of therapy: 6–12 wk
famotidine (Pepcid)	20 mg twice daily	Consider maintenance therapy if symp-
nizatidine (Axid)	150 mg twice daily	toms recur
ranitidine (Zantac)	150 mg twice daily	
Proton Pump Inhibitors (Prescription Strength)		
dexlansoprazole (Dexilant)	30 mg once daily	Take 30–60 min before breakfast or first
esomeprazole (Nexium)	20 mg once daily	meal (except dexlansoprazole)
lansoprazole (Prevacid)	15 mg once daily	Duration of therapy: 4–8 wk
omeprazole (Prilosec)	20 mg once daily	Consider maintenance therapy if symp-
omeprazole/bicarbonate (Zegerid)	20 mg once daily	toms recur
pantoprazole (Protonix)	20–40 mg once daily	
rabeprazole (AcipHex)	20 mg once daily	

Pharmacologic Agents	Dose	Administration Comments
Persistent Moderate to Severe Symptomatic GERD, Healing of Erosive GERD, or Complications of GERD		
Histamine-2 Receptor Antagonists		
cimetidine (Tagamet)	400 mg four times daily or 800 mg twice daily	Duration of therapy: 8–12 wk Maintenance therapy recommended
famotidine (Pepcid)	20–40 mg twice daily	
nizatidine (Axid)	150 mg four times daily	
ranitidine (Zantac)	150 mg four times daily	
Proton Pump Inhibitors		
dexlansoprazole (Dexilant)	60 mg once daily	Take 30–60 min before breakfast or first
esomeprazole (Nexium)	20–40 mg once daily	meal (except dexlansoprazole)
lansoprazole (Prevacid)	30 mg twice daily	Duration of therapy: 4–16 wk
omeprazole (Prilosec)	20 mg twice daily	Maintenance therapy recommended
omeprazole/bicarbonate (Zegerid)	20 mg/1,100 mg twice daily	
pantoprazole (Protonix)	40 mg twice daily	
rabeprazole (AcipHex)	20 mg twice daily	

Time Frame for Response

Onset of action is about 1 to 2 hours after administration. Therefore, H_2RAs may be used as needed or on an intermittent basis for mild heartburn. However, if there is lack of response within 2 weeks, standard twice-daily dosing is reasonable. In standard dosing, symptomatic relief is achieved in 60% of patients after 12 weeks, and endoscopic esophageal healing occurs in 50% of patients after 12 weeks. Importantly, prolonged use may lead to reduced efficacy and tolerance.

Contraindications

These agents are contraindicated in hypersensitivity to H_2RAs.

Adverse Effects

H_2RAs are generally well tolerated. Patients may experience headache, fatigue, dizziness, and confusion. The risk of side effects increases in renal impairment, so dosages should be reduced in the elderly and in those with creatinine clearance less than 50 mL/min. Rarely, gynecomastia and impotence may occur with cimetidine use.

Drug Interactions

Many drug interactions exist, and a thorough review of concomitant medications must be made prior to initiation of H_2RAs. Drugs that are dependent on acid gastric environments for absorption may have decreased effects, such as ketoconazole and protease inhibitors. Cimetidine is a potent inhibitor of cytochrome P-450 (CYP-450) enzymes and may inhibit the metabolism of warfarin, phenytoin, theophylline, and other strong substrates of the CYP-450 system. Additionally, antacids may decrease the effect of H_2RAs and must be taken 1 to 2 hours after the H_2RA.

Proton Pump Inhibitors

As the most potent acid-suppressing agents available, PPIs are superior to H_2RAs in moderate to severe GERD, prevention of NSAID-induced PUD, and ulcer healing. They are given empirically in the management and diagnosis of GERD. For PUD, they are used in combination with anti–*H. pylori* regimens. Several are available in many dosage forms, including intravenous, powder, and orally disintegrating tablets. Currently, only omeprazole, omeprazole–bicarbonate, lansoprazole, and esomeprazole are available over the counter.

Mechanism of Action

PPIs inhibit gastric proton pumps located on the parietal cells, producing long-lasting suppression of acid secretion.

Dosage

When used empirically to treat GERD, once-daily dosing is recommended. If this is ineffective, the dose may be increased to twice-daily dosing. With the exception of omeprazole–bicarbonate and dexlansoprazole, they are most effective when taken in the morning, 30 to 60 minutes before the first meal. Omeprazole–bicarbonate is most effective in controlling nocturnal acid secretion when taken in the evening. The dual delayed-release action of dexlansoprazole allows for its efficacy when taken at any time during the day regardless of food intake. For those with nocturnal symptoms or those taking twice-daily doses, PPIs may be taken in the evening before dinner. As-needed dosing is not effective or recommended with PPIs.

Time Frame for Response

Sixty-six percent of reduction in acid secretion is seen by day 5 of PPI therapy. After 8 weeks of therapy, 83% of patients experience symptom relief, and endoscopic healing of esophageal tissue is seen in 78% of patients.

Contraindications

These agents are contraindicated in hypersensitivity to PPIs.

Adverse Effects

Side effects may include headache, diarrhea, constipation, and abdominal pain. Recently, PPIs have been evaluated for long-term adverse effects, including hypergastrinemia, fractures, infections (*Clostridium difficile* colitis and bacterial gastroenteritis), vitamin B_{12} deficiency, and hypomagnesemia. Data on the true risk of these outcomes with chronic PPI use are conflicting; however, the FDA advisory warns of the risk of osteoporosis and

fractures in patients taking high-dose PPI therapy or if PPIs are used for more than 1 year, especially in those with other risk factors present. Generally, it is recommended to continue PPI therapy in patients with osteoporosis if indicated, but consideration of risk versus benefit must be given if the patient has additional risk factors for hip fracture. In the short term, PPIs may increase the risk of community-acquired pneumonia; however, this risk appears to disappear after long-term use.

Drug Interactions

Similar to H_2RAs, PPIs may decrease the efficacy of drugs that depend on an acidic gastric environment for adequate absorption. PPIs are also implicated in drug interactions involving the cytochrome (CYP) P-450 system. Omeprazole and lansoprazole are metabolized by CYP2C19, which is an enzyme necessary for the conversion of the antiplatelet drug clopidogrel to its active form. It has been suggested that inhibition of CYP2C19 by PPIs inhibits the efficacy of clopidogrel and may result in cardiovascular harm. The clinical significance of this interaction is not well understood, and reports demonstrate a lack of evidence of increased cardiac events when PPIs are used alongside clopidogrel. Decisions regarding concomitant use of these medications should consider both the benefits of acid-suppression therapy and the potential risk of cardiovascular complications. Omeprazole likely carries the highest risk for interaction, while pantoprazole has the least risk.

Antibiotics

Antibiotics are used in combination with acid-suppressing medications to eradicate *H. pylori*–induced PUD. They are ineffective when used as monotherapy due to high risk of resistance and should therefore be given with other antibiotics and acid suppression therapies. They do not have a role in GERD management.

Amoxicillin

Mechanism of Action

Amoxicillin is an aminopenicillin that kills bacteria by interfering with cell wall synthesis. It is most effective at neutral pH levels and therefore must be administered with an acid suppression agent such as a PPI or H_2RA.

Dosage

It is dosed at 1 g by mouth twice daily.

Time Frame for Response

A 10- to 14-day treatment duration is needed for maximal efficacy.

Contraindications

Amoxicillin must be avoided in those with allergy to penicillins or other beta-lactams.

Adverse Effects

The most common side effects associated with amoxicillin are diarrhea, nausea, and vomiting, which may be relieved by taking the medication with food. Patients should be monitored for hypersensitivity reactions.

Drug Interactions

Amoxicillin is not commonly implicated in drug interactions, though it may increase the anticoagulant effects of warfarin therapy.

Clarithromycin

Mechanism of Action

Clarithromycin is a macrolide antibiotic that inhibits bacterial protein synthesis. While highly effective against *H. pylori*, it is susceptible to resistance, so it should be avoided as retreatment if a clarithromycin-containing regimen fails.

Dosage

Clarithromycin is dosed 500 mg by mouth twice daily.

Time Frame for Response

A 10- to 14-day treatment course is needed for maximal efficacy.

Contraindications

Clarithromycin is contraindicated in known allergy to macrolide antibiotics, history of QT prolongation, and concomitant use with astemizole, cisapride, pimozide, simvastatin, or lovastatin.

Adverse Effects

The most common side effects associated with clarithromycin are diarrhea, abnormal taste, nausea, and vomiting, which may be relieved by taking the medication with food.

Drug Interactions

Clarithromycin is a strong CYP3A4 substrate and therefore should be used with caution when used concomitantly with strong CYP3A4 substrates, inducers, and inhibitors.

Metronidazole

Mechanism of Action

Metronidazole kills anaerobic bacteria and protozoa by interfering with DNA structure, causing inhibition of protein synthesis and subsequent cell death.

Dosage

Depending on the regimen, dosing ranges from 125 to 500 mg taken two to four times daily.

Time Frame for Response

A 10- to 14-day treatment course is needed for maximal efficacy.

Contraindications

Metronidazole is contraindicated in known allergy to metronidazole.

Adverse Effects

Metronidazole may cause headache, metallic taste, nausea, and peripheral neuropathy.

Drug Interactions

Alcohol consumption with metronidazole should be avoided to prevent disulfiram-like reactions. It may also increase the anticoagulant effect of warfarin.

Tetracycline

Mechanism of Action

Tetracycline inhibits bacterial protein synthesis and is effective against gram-positive and gram-negative bacteria.

Dosage

Tetracycline is dosed at 500 mg, two to four times daily depending on the regimen. It must be given either 2 hours before or 2 hours after food intake to optimize absorption.

Time Frame for Response

A 10- to 14-day treatment course is needed for maximal efficacy.

Contraindications

It is contraindicated in known allergy to tetracycline.

Adverse Effects

Side effects of tetracycline include GI upset, diarrhea, and photosensitivity.

Drug Interactions

Tetracycline is a major substrate and moderate inhibitor of CYP3A4. Antacids, dairy products, and iron may decrease the absorption of tetracycline.

Misoprostol

Misoprostol is used as prophylaxis against NSAID-induced ulcers in patients at high risk for gastric ulcers and its complications.

Mechanism of Action

Misoprostol is a synthetic prostaglandin E_1 analog that inhibits acid secretion and increases mucosal defenses.

Dosage

It is dosed at 200 mcg four times daily taken with food.

Time Frame for Response

Time to peak effect is between 6 and 22 minutes.

Contraindications

Misoprostol is contraindicated in hypersensitivity to prostaglandins and in pregnancy.

Adverse Effects

GI effects are common and include diarrhea, abdominal pain, flatulence, and nausea. A dose reduction to 100 mcg is warranted if diarrhea persists or is intolerable.

Drug Interactions

Antacids may increase the risk of adverse effects of misoprostol, especially those containing magnesium.

Sucralfate

Sucralfate is approved for the treatment and maintenance of duodenal ulcers. It is also used in stress ulcer prophylaxis. It is not effective in *H. pylori* eradication.

Mechanism of Action

Sucralfate forms a viscous, adhesive substance that attaches to and protects ulcers against noxious gastric content.

Dosage

Sucralfate is given 1 g by mouth four times daily.

Time Frame for Response

Paste formation and symptom improvement occurs in 1 to 2 hours after administration. Its short half-life necessitates frequent administration.

Contraindications

Sucralfate should not be used in known hypersensitivity to the drug.

Adverse Effects

The most common side effect is constipation. Systemic effects are not common since sucralfate is minimally absorbed from the GI tract. Because it contains aluminum, there is a possibility for aluminum toxicity, particularly in patients with impaired renal function.

Drug Interactions

Because sucralfate coats the GI mucosa, sucralfate may decrease the absorption and effect of many medications. Separating sucralfate by 2 hours before or 6 hours after administration of other drugs is prudent to avoid interactions.

Bismuth Subsalicylate

Bismuth subsalicylate is highly effective against *H. pylori* when used in combination with antibiotics. It is available both in chewable tablet and liquid form. It is also available as a combination with ranitidine for use with clarithromycin in the eradication of *H. pylori*.

Mechanism of Action

Bismuth subsalicylate has acid secretion suppressing effects. The bismuth component exhibits antimicrobial effects, preventing *H. pylori* adhesion to epithelial cells. The salicylate component may provide anti-inflammatory action as well.

Dosage

It is dosed at 525 mg by mouth four times daily.

Time Frame for Response

In *H. pylori* eradication regimens, it must be taken for 10 to 14 days to achieve maximal effects.

Contraindications

Bismuth subsalicylate should be avoided in sensitivity to salicylates.

Adverse Effects

Common side effects include black stools, darkened tongue, and constipation. At higher doses, tinnitus may be seen.

Drug Interactions

Due to the salicylate component, which acts similarly to aspirin, bismuth subsalicylate may increase bleeding risk when used with anticoagulants or antiplatelets.

Selecting the Most Appropriate Agent for GERD

Initial treatment choice depends on the symptoms severity, symptom frequency, and whether complications are present or not (Figure 29.1).

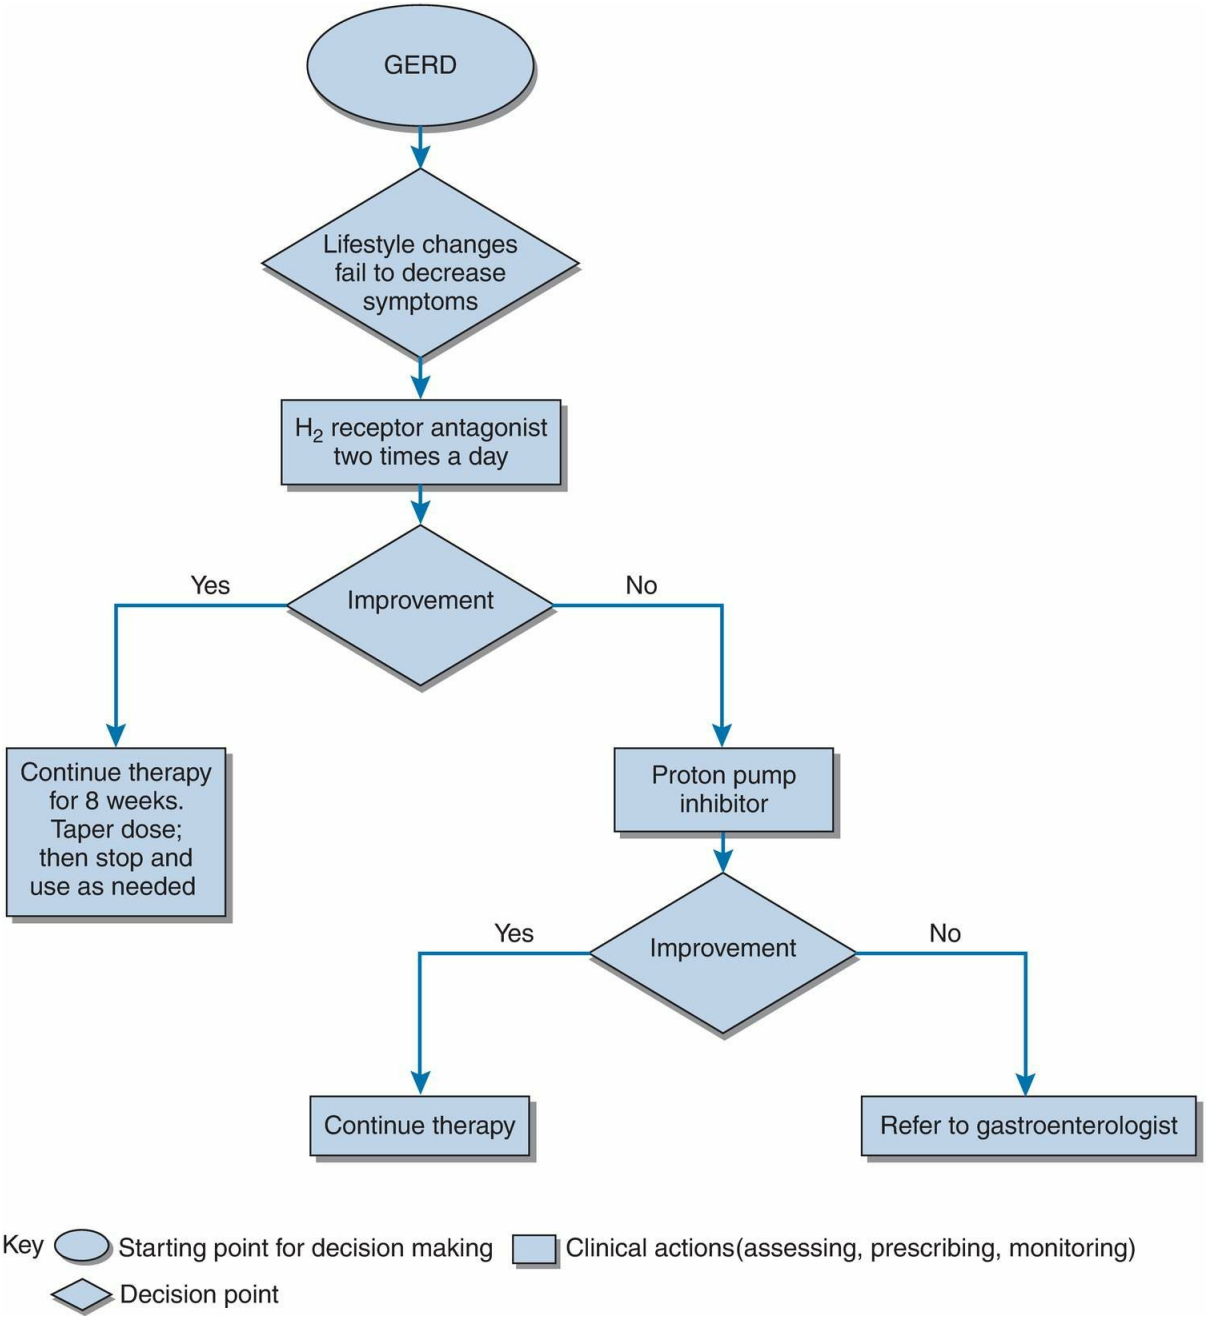

FIGURE 29.1 Treatment algorithm for GERD.

First-Line Therapy

For patients with mild symptoms (typical symptoms fewer than three times a week), lifestyle changes should be initiated. Over-the-counter acid suppression therapies with antacids, H_2RAs, or PPIs can be added if lifestyle changes alone do not resolve symptoms. If symptoms are unrelieved after 2 weeks of lifestyle changes alongside acid suppression therapies, the patient should seek medical attention for advancement of pharmacologic therapy to an empiric acid suppression therapy or diagnostic testing as necessary.

For patients with moderate to severe symptomatic GERD or persistent mild GERD

symptoms that are troublesome, empiric prescription dosing of acid suppression therapy is first-line. There are two general approaches to therapy: step-up versus step-down. The step-up approach begins with lifestyle modifications and the gradual increase of pharmacologic intervention with an H_2RA, progressing to PPI therapy or surgery until symptom improvement. The step-down approach begins with PPI therapy, then stepping down to the lowest dose of either a PPI or H_2RA that is needed to control symptoms. PPIs are favored in moderate to severe GERD since they provide the most rapid relief of symptoms as well as the most optimal chance of tissue healing. Dosing of these agents is presented in Table 29.6. Combination therapy with H_2RAs plus PPIs has not been shown to be more effective and is generally not recommended.

Patients with evidence of erosive esophagitis will require high-dose acid suppression therapy for longer durations. Again, PPIs are preferred over H_2RAs due to its superiority in tissue healing.

After treatment with H_2RAs or PPIs, maintenance therapy should be considered to continue symptom control and to prevent complications. Patients with moderate-to-severe symptoms or erosive esophagitis are especially susceptible to rebound effects after treatment discontinuation, and often, PPI maintenance therapy is necessary for these patients. The treatment dose should be titrated down to the lowest most effective strength. Longstanding use of PPIs is limited by the potential for long-term adverse effects as discussed earlier.

Second-Line Therapy

For patients with incomplete response to acid suppression therapy, adding an H_2RA at bedtime may be beneficial in controlling overnight symptoms. H_2RAs are generally considered second-line after PPI therapy for erosive esophagitis and other complications of GERD due to weaker and slower tissue healing. For symptomatic GERD, if maximal doses have been reached with PPI therapy with partial or no response, once-daily PPI dosing may be increased to twice-daily dosing. Switching the PPI to another in the same class may be considered, but limited data support this practice.

Patients who do not respond to twice-daily PPI therapy, who present with atypical symptoms, or who present with alarming symptoms like dysphagia may need endoscopic testing to detect tissue injury and GERD complications.

Third-Line Therapy

Antireflux surgery is available as an alternative for patients who have atypical symptoms, refractory symptoms, or complications or cannot tolerate long-term acid suppression therapy. Fundoplication, the common procedure, attempts to reposition the LES to optimize intra-abdominal pressure. Ninety percent of patients report resolution of symptoms following surgery. A meta-analysis comparing the efficacy of antireflux surgery versus medical management showed more favorable effects with surgery in improving

quality of life and patient satisfaction. Though fewer patients required maintenance medical management, a high proportion of patients still needed maintenance acid suppression following surgery. Possible adverse effects of the procedure include dysphagia, inability to belch or vomit, flatulence, bloating, and increased abdominal girth. Data on the long-term safety and efficacy of antireflux surgery are lacking.

Promotility drugs like metoclopramide have been studied for their use in treating GERD symptoms. Theoretically, they aim to target symptoms that arise as a result of slow gastric emptying. However, results of studies to date have not shown an added benefit to these agents when weighed against their many side effects. Similarly, baclofen has the potential to improve GERD symptoms, but owing to lack of long-term data and numerous adverse effects, it is not currently recommended. Sucralfate has also been shown to have limited benefit in GERD management.

Special Population Considerations

Pediatric

In infants, regurgitation known as "spitting up" is common and occurs daily in 50% of infants younger than 3 months. The cause is likely due to immaturity of the LES, which typically resolves by 12 to 14 months of age. These episodes usually do not cause discomfort or significant clinical consequences for the infant; however, children with chronic gastroesophageal reflux may exhibit poor growth, vomiting, hoarseness, coughing, and chronic sore throat. Management strategies include smaller more frequent meals and thickening the formula or breast milk with 1 to 2 tablespoons of rice cereal per 2 ounces of liquid. Keeping the infant upright for 30 minutes after feeding and raising the head of the crib may also help. If nonpharmacologic therapies fail, therapy with H_2RAs and PPIs may be indicated if the cause of symptoms is confirmed or likely to be GERD. Ranitidine is commonly used, but chronic use may lead to diminished efficacy over time. Overuse of ranitidine has been associated with infections and other adverse effects. PPIs have also been shown to be safe and effective in patients aged 1 to 17 years, although long-term safety is largely unknown.

Geriatric

Elderly patients are at higher risk for GERD due to their decreased ability to produce saliva and decreased gastric motility. Additionally, they are more likely to have comorbidities and medications that can further complicate the presentation of symptoms and treatment availability. Often, elderly patients do not seek medical care because they feel their symptoms are related to normal aging processes or their symptoms present atypically (dental erosions, chest pain, etc.). Even when they do seek pharmacologic management, drug interactions and adverse effects limit their choice in therapy. Due to declining renal function, exercise caution when recommending aluminum-containing antacids. Elderly patients are more vulnerable to the central nervous system side effects of H_2RAs. PPIs are often prescribed in this patient population due to their efficacy, relative tolerability, and once-daily dosing. However, the long-term effects on bone fractures must be considered when using PPI therapy for a prolonged duration.

Women

Heartburn commonly occurs during pregnancy due to increased intra-abdominal pressure. Over-the-counter antacids may be safely used in moderation. Sodium bicarbonate–containing medications must be avoided due to the risk of metabolic alkalosis and fluid overload.

Monitoring Patient Response

Patients should be evaluated for treatment response within the first few weeks of starting therapy. If symptoms decrease, a full course of therapy should continue. If symptoms do not completely resolve after 6 weeks with an H_2RA or after 4 weeks with a PPI, therapy continues for an additional 6 and 4 weeks, respectively. For erosive GERD, if symptoms do not improve by 8 weeks with an H_2RA or by 4 weeks with a PPI, therapy can extend to 12 weeks with an H_2RA and 16 weeks with a PPI. Patients should be monitored periodically for adverse effects accordingly. For patients who have persistent symptoms, consider endoscopy testing or referral to a gastroenterologist.

After remission is achieved, consider discontinuation of therapy. Most patients, however, will experience recurring symptoms and require retreatment. If recurrence is frequent, initiate maintenance therapy at the lowest effective dose after remission is achieved.

Patient Education

Drug Information

Patients should be educated on possible side effects and instructed to notify their health care providers if they become intolerable. Given the many potential drug–drug interactions, medication profiles must be reviewed and proper timing of administration of medications should be relayed to the patient.

Nutritional and Lifestyle Changes

Lifestyle changes should be incorporated into any GERD treatment plan. You should encourage weight loss, elevation of the head of the bed when sleeping, consuming smaller meals and avoiding causative foods, avoiding tight-fitting clothes, smoking cessation, moderation of alcohol, and avoiding recumbency for 3 hours after meals. Instead of making all of these changes simultaneously, gradual approaches to lifestyle changes tend to be less overwhelming and more manageable for patients.

Complementary and Alternative Medicine

Peppermint is commonly used for the self-treatment of GERD. It is reported to accelerate gastric emptying and LES pressure. Patients with PUD, however, should avoid peppermint as it may potentiate ulcer formation. Acupuncture was shown to be effective in controlling regurgitation and heartburn in patients with persistent heartburn despite PPI therapy in one study. Electroacupuncture led to a decreased rate of TLESR in 14 healthy volunteers. Studies with larger sample sizes and longer durations are needed to confirm the benefit of this treatment modality for GERD.

Selecting the Most Appropriate Agent for PUD

Choice in treatment depends on the etiology (*H. pylori* or NSAID induced), resistance patterns, and if complications are present. Because resistance patterns differ geographically, regimens that have been studied and validated in the United States are preferred (Figure 29.2).

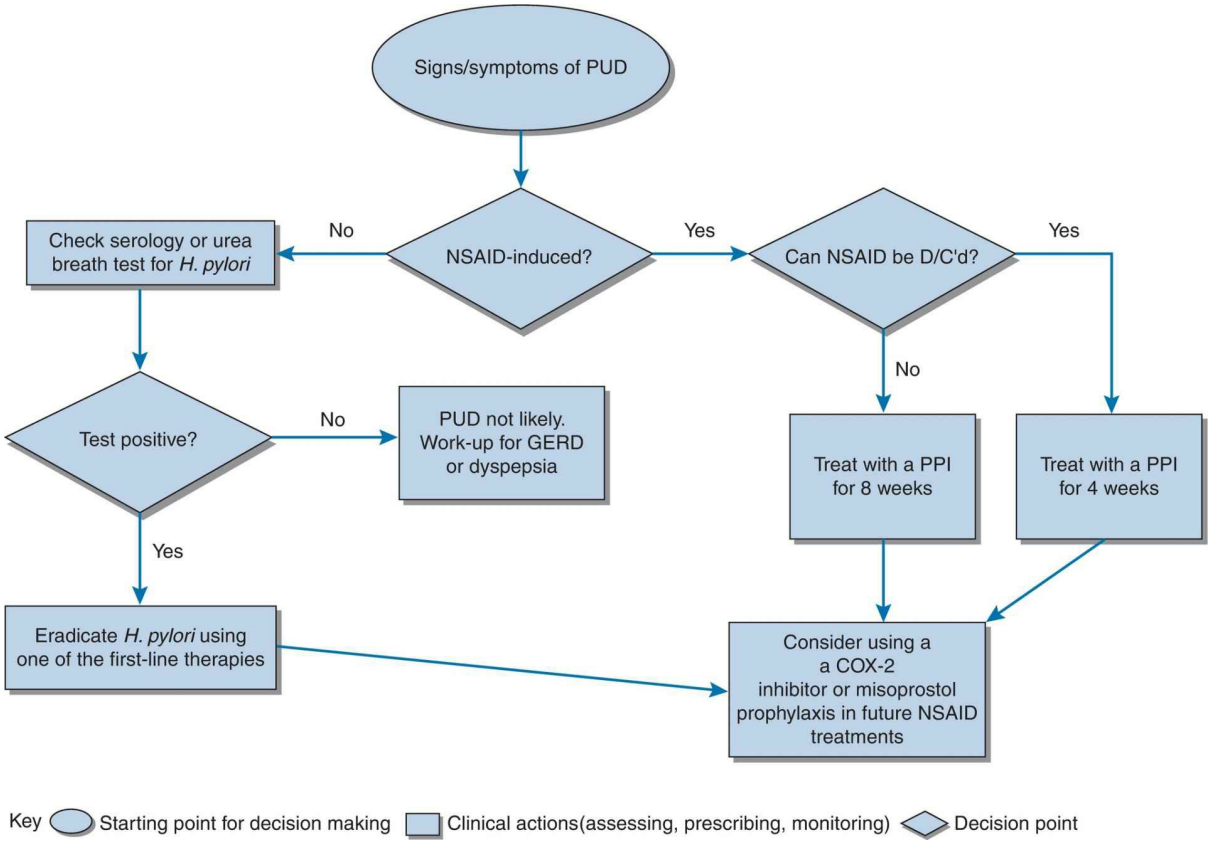

FIGURE 29.2 Treatment algorithm for PUD.

First-Line Therapy

Recommended regimens are listed in Table 29.7. A PPI-based regimen with two antibiotics is commonly used. Amoxicillin is preferred since it is highly effective against *H. pylori* and resistance rates remain low. However, for patients with a penicillin allergy, metronidazole is a viable substitute for amoxicillin. Eradication rates with first-line regimens are between 70% and 85%, but rates have recently been declining due to a rise in clarithromycin resistance. Therefore, these regimens are not recommended where clarithromycin-resistant strains are prevalent. Longer, 14-day durations lead to higher eradication and lower resistance rates.

TABLE 29.7 Treatment for *H. pylori* Eradication

Type	Regimen	Duration	Comments
Triple therapy	1. PPI once or twice daily 2. Amoxicillin 1 g bid 3. Clarithromycin 500 mg bid	7–10 d (up to 14 d)	First line
	Or 1. PPI once or twice daily 2. Metronidazole 500 mg bid 3. Clarithromycin 500 mg bid	10–14 d	Metronidazole can substitute for amoxicillin in penicillin allergy.
Sequential therapy	1. PPI once or twice daily × 5 d 2. Amoxicillin 1 g bid × 5 d Followed by 1. PPI once or twice daily × 5 d 2. Clarithromycin 500 mg bid × 5 d 3. Metronidazole 500 mg bid × 5 d	10 d (5 d for each regimen)	First line, but has not been validated in the United States
Quadruple therapy	1. PPI once or twice daily 2. Amoxicillin 1 g bid 3. Clarithromycin 500 mg bid 4. Metronidazole 500 mg bid	10 d	Second line
Bismuth-based quadruple therapy	1. PPI twice daily 2. Bismuth subsalicylate 525 mg qid 3. Metronidazole 250 mg qid 4. Tetracycline 500 mg qid	10–14 d	Second line or as salvage therapy for persistent infection or penicillin allergy
Levofloxacin-based triple therapy	1. PPI once or twice daily 2. Amoxicillin 1 g bid 3. Levofloxacin 500 mg daily	10 d	Salvage therapy for persistent infection Has not been validated in the United States

Sequential therapy, where the patient takes a PPI and amoxicillin for 5 days and follows that with triple therapy for another 5 days, has been shown to be just as effective as standard triple therapy in eradicating *H. pylori*. Though less costly compared to standard triple therapy, this regimen has not yet been validated in the United States.

In NSAID-induced ulcers, patients should be tested for *H. pylori* and treated with the above regimens if positive for infection. The NSAID should be discontinued, and a PPI, H_2RA, or sucralfate should be initiated (doses in Table 29.8). The NSAID could also be changed to a lower dose, acetaminophen, or a COX-2 inhibitor like celecoxib. If the NSAID must be continued, a PPI or misoprostol should be taken concomitantly with the NSAID to promote healing and prophylaxis of future ulcers. In cases where patients cannot discontinue the NSAID, H_2RAs are significantly less effective at healing ulcers. PPIs also appear to be more effective than misoprostol when NSAID therapy continues.

TABLE 29.8 Dosing regimens for PUD management

Generic (Trade) Name	*H. pylori* Dose	NSAID-Induced Ulcer Prevention Dose	NSAID-Induced Ulcer Treatment Dose	Usual Range	Dose Adjustments
Proton Pump Inhibitor					
dexlansoprazole (Dexilant)	30–60 mg daily	30–60 mg daily	30–60 mg daily	30–60 mg/d	Dose adjustment for hepatic impairment
esomeprazole (Nexium)	40 mg daily or bid	20–40 mg daily	40 mg daily	20–40 mg/d	
omeprazole (Prilosec)	20–40 mg daily or bid	20 mg daily	20–40 mg daily	20–40 mg/d	
omeprazole/bicarbonate (Zegerid)					
pantoprazole (Protonix)	40 mg daily or bid	20 mg daily	40 mg daily	20–40 mg/d	
rabeprazole (AcipHex)	20 mg daily or bid	20 mg daily	20 mg daily	20 mg/d	
Histamine-2 Receptor Antagonists					
cimetidine (Tagamet)	400 mg bid	400 mg daily	300 mg qid or 400 mg bid or 800 mg qhs	800–1,600 mg/d in divided doses	Dose adjustment for renal and hepatic impairment
famotidine (Pepcid)	40 mg daily	20 mg daily	40 mg daily	20–40 mg/d	Dose adjustment for renal impairment
nizatidine (Axid)	150 mg bid	150 mg daily	150 mg bid or 300 mg daily	150–300 mg/d	
ranitidine (Zantac)	150 mg bid	150 mg daily	150 mg bid or 300 mg daily	150–300 mg/d	
Mucosal Protectants					
sucralfate (Carafate)	N/A	N/a	1 g qid	2–4 g/d	None
misoprostol (Cytotec)	N/A	200 mcg qid	200 mcg qid	400–800 mcg/d	None

Successful eradication alone helps to prevent recurrence of *H. pylori*–induced ulcers; however, in patients who failed eradication therapy, have a history of ulcer-related complications, or have repeated recurrence of ulcers, maintenance therapy with a PPI or H_2RA should be considered.

Second-Line Therapy

For those who fail initial eradication therapy, a PPI-based regimen should be initiated using different antibiotics. Bismuth-based quadruple therapy is effective as salvage therapy for treatment failures. It is also preferred if cost is a major barrier to therapy. Emerging data on levofloxacin-based triple therapy support its efficacy and tolerability, but since this regimen has not been validated in the United States, and resistance rates are increasing, it should be reserved for salvage therapy only.

In areas with high rates of clarithromycin resistance, quadruple therapy with a PPI, amoxicillin, clarithromycin, and metronidazole has high eradication rates despite the regimen containing clarithromycin.

H_2RA-based *H. pylori* eradication regimens are less preferred due to lower eradication rates.

Probiotics have a possible role in *H. pylori* infection when taken alongside eradication regimens. Preliminary data show increased eradication rates and decreased adverse effects,

particularly diarrhea.

Third-Line Therapy

In the case of repeated *H. pylori* eradication treatment failures, or persistence of symptoms after 8 to 12 weeks of treatment, referral to a gastroenterologist for endoscopy and biopsy is warranted to establish diagnosis and exclude other causes.

Preventative Therapy in NSAID-Induced PUD

The risks of GI complications and cardiovascular safety must both be weighed when deciding the appropriate approach to prevention of PUD when NSAID therapy must be continued. Consequently, the American College of Gastroenterology provides guidance on choice of therapy when GI and cardiovascular risks are considered (Table 29.9). PPIs and misoprostol have both shown efficacy in preventing NSAID-induced ulcers, most of which are gastric ulcers. While PPIs are more commonly used due to its more tolerable side effect profile compared to misoprostol, large randomized controlled trials of PPI cotherapy are lacking. The trials available to date show promising results in preventing ulcers when taken with NSAIDs and even with COX-2 inhibitors. H_2RAs are not optimal since they are effective in preventing duodenal ulcers, not gastric ulcers. However, if H_2RAs must be used due to cost, high-dose regimens show greater efficacy compared to low doses. Of all NSAIDs, naproxen has the least cardiovascular risk associated and is preferred in patients with high risk for cardiovascular events.

TABLE 29.9 Recommendations for Prevention of NSAID-Related Ulcers

Cardiovascular Risk	Gastrointestinal Risk	Recommendation
Low	Low (no risk factors)	NSAID alone
	Moderate (1–2 risk factors)	NSAID plus PPI or misoprostol
	High (>2 risk factors, history of complicated ulcer)	Alternative therapy, or COX-2 inhibitor plus PPI or misoprostol
High	Low (no risk factors)	Naproxen plus PPI or misoprostol
	Moderate (1–2 risk factors)	Naproxen plus PPI or misoprostol
	High (>2 risk factors, history of complicated ulcer)	Avoid NSAID and COX-2 inhibitor; seek alternative therapy

Celecoxib is the only COX-2 inhibitor available in the United States and originally was thought to have less GI effects compared to nonselective NSAIDs. However, available evidence shows that it may have the same GI adverse effects compared to other NSAIDs, especially in patients taking concomitant aspirin. Additionally, there is a dose-dependent increase in cardiovascular events, particularly with higher doses and longer durations of treatment.

Special Population Considerations

Pediatric

H. pylori is most often contracted during childhood and has higher prevalence in communities with lower socioeconomic status and poorer sanitation conditions. In children with diagnosed *H. pylori*–associated PUD, pharmacologic eradication is recommended due to high relapse rates if left untreated. If *H. pylori* infection is confirmed in the absence of PUD or if an *H. pylori*–positive child has a first-degree relative with gastric cancer, consider treatment in these children. Triple therapy (PPI plus 2 antibiotics), sequential treatment, and bismuth-based therapy for 10 to 14 days are viable treatment options in children. Ideally, obtaining susceptibility data will guide therapy. Avoid tetracycline in children younger than 8 years of age due to risk for reduced bone growth and permanent tooth discoloration.

Geriatric

A number of factors put the elderly population at higher risk for PUD and its complications. Because older patients may not present with typical symptoms of *H. pylori* infection, diagnosis and treatment may be delayed. Comorbidities and concomitant medications, especially with NSAIDs, aspirin, bisphosphonates, and anticoagulants, further increase the risk of PUD. Additionally, mucosal defense mechanisms decline with age. Elderly patients have a higher potential for GI malignancies, and so endoscopy is the preferred method of diagnosis over noninvasive testing. *H. pylori* eradication regimens are similar for the adult population; however, older patients experience more treatment failures due to antibiotic resistance and problems with adherence. They are also more vulnerable to the adverse effects and drug interactions associated with treatment regimens. A treatment plan must be carefully individualized to each patient, and you should counsel patients on the importance of adherence to the entire treatment regimen.

Women

Women who are pregnant or planning to become pregnant should avoid misoprostol due to its abortifacient properties. Consider obtaining a negative pregnancy test in women of child-bearing age before initiating misoprostol.

Monitoring Patient Response

During treatment, patients should be assessed for resolution of symptoms, adverse effects, and adherence. Patients can expect resolution of symptoms within 7 days of antiulcer therapy and within a few days of discontinuing NSAIDs. If symptoms continue or recur after 14 days of treatment, this signifies treatment failure and a retreatment plan is necessary. In the case of treatment failures, patients should be assessed for adherence and proper administration of complex regimens.

Most patients with uncomplicated *H. pylori* infection will not need confirmation of eradication; however, consider confirming eradication with a urea breath test 6 to 8 weeks after the end of treatment in patients who are at risk for complications or have frequent recurrence of disease.

If patients continue NSAID therapy, monitor them closely for complications such as bleeding, obstruction, penetration, or perforation.

Patient Education

Drug Information

Nonadherence to treatment and prevention regimens is a significant cause of treatment failures. These regimens can be complex and costly and come with intolerable side effects. Additionally, since patients often feel better within several days of treatment initiation, they may feel compelled to discontinue their medications midtreatment. Counseling patients on the importance of full adherence to recommended therapies is essential in ensuring proper administration and maximal benefit of these therapies. Patients should also be informed of possible side effects to expect and how to appropriately manage them should they occur.

Nutritional and Lifestyle Changes

Encourage patients to avoid causative behaviors such as cigarette smoking and NSAID use (if possible). While no foods are known to increase the risk of PUD, some foods may exacerbate the symptoms and discomfort associated with PUD. Advise patients to avoid spicy foods, caffeine, and alcohol to aid in symptom relief. Stress reduction is also encouraged, as psychological stress is sometimes associated with worsening of symptoms.

Complementary and Alternative Medicine

Few studies exist examining the effect of licorice and its ability to enhance gastric mucosal protective mechanisms. In a recent study, licorice appeared to be just as effective as bismuth when taken with amoxicillin, metronidazole, and omeprazole in the eradication of *H. pylori*. Given the small sample size and lack of data in the United States, more robust studies are needed to confirm its utility in the treatment and prevention of PUD. Adverse effects of licorice include hypertension and hypokalemia.

Case Study*

J.G. is a 42-year-old white man presenting with a 2-month history of intermittent midepigastric pain. The pain sometimes wakes him up at night and seems to get better after he eats a meal. J.G. informs you that his doctor told him that he had an infection in his stomach 6 months ago. He never followed up and has been taking over-the-counter Zantac 75 for 2 weeks without relief. He takes no other medications. He is concerned because the pain is continuing. He has no other significant history except he is a 20 pack-year smoker and he drinks 5 cups of coffee a day. He eats late at night and goes to bed about 30 minutes after dinner. He is allergic to penicillin.

Diagnosis: Peptic Ulcer Disease

1. List specific goals for treatment for J.G.
2. What drug therapy would you prescribe for J.G.? Why?
3. What are the parameters for monitoring success of the therapy?
4. Discuss specific patient education based on the prescribed therapy.
5. List one or two adverse reactions for the selected agent that would cause you to change therapy.
6. What would be the choice for second-line therapy?
7. What over-the-counter and/or alternative medications would be appropriate for J.G.?
8. What lifestyle changes would you recommend to J.G.?
9. Describe one or two drug–drug or drug–food interaction for the selected agent.

* Answers can be found online.

30 Constipation, Diarrhea, and Irritable Bowel Syndrome

Veronica F. Wilbur

Functional bowel disorders of the lower gastrointestinal (GI) tract can include symptoms of hypogastric cramping, abdominal pain, diarrhea, or constipation. Constipation and diarrhea can be self-limiting or considered symptoms of possibly serious medical problems. Temporary dysfunctions of the bowel can include common GI upsets that can cause short-lived episodes of diarrhea or episodes of constipation. Irritable bowel syndrome (IBS) and chronic idiopathic constipation (CIC) are two of the most common GI complaints globally (Ford et al., 2014). Additionally, the increased prescribing of opiates and opioid narcotics has led to an increase in opioid-induced constipation (OIC) (Camerilli, 2011). IBS typically presents with vague, crampy hypogastric pain and can be accompanied by constipation, diarrhea, and/or alternating patterns, while CIC presents with issues of stool consistency and problems with defecation but without the presence of abdominal pain. Similar pharmacologic agents are used to treat the symptoms of IBS, CIC, OIC, or diarrhea, whether self-limited or chronic.

Constipation

Constipation is a common GI symptom that is defined as infrequent or difficult evacuation of stool. Every individual affected by constipation defines it differently, but normal defecation can vary from daily to three times a day or to every 3 days. Constipation can be a consequence of multiple factors, including diet, lifestyle, medications, and many disease states. In a systematic review of the epidemiology of constipation globally by Suares and Ford (2011), the mean prevalence of constipation in the general population was found to be 14%. Constipation affects 2.2 females to 1 male, and the incidence increases with age, especially in those over age 65. Sommers et al. (2011) report a 41.5% increase of emergency room visits and ambulatory care visits for constipation between 2006 and 2011. The incidence of constipation in children is reported between 0.7% and 29% worldwide with prevalence equal between boys and girls (Rajindrajith & Devanarayana, 2011). Dietary and lifestyle modifications are the preferred therapy for constipation, but many patients use over-the-counter (OTC) laxatives for relief. Americans spend over $290 million billion for OTC and prescription laxatives and over $7.5 billion dollars annually for treatment (Pomeranz et al., 2013). Most of these laxatives are considered safe and effective, but overuse or abuse may have serious consequences.

Causes

Constipation is a diagnosis based on a thorough history and physical examination. If an identifiable cause is present, constipation is then classified as a secondary symptom. However, constipation may be a symptom of an underlying disease state (Box 30.1). The patient's lifestyle (e.g., diet, inactivity) or concomitant medications (Box 30.2) may also contribute to constipation. Chronic idiopathic constipation is usually caused by a reduction in the propulsive capacity of the colon (slow transit constipation) or a functional outlet. Another cause of constipation is from the use of opioid drugs and is classified as OIC. Although constipation is often a benign condition, it can be a symptom of a more serious problem. If left untreated in an elderly patient, constipation may lead to impaction, stercoral ulceration, anal fissures, megacolon, volvulus, and possibly carcinoma of the colon.

BOX 30.1 Disorders Associated with Constipation

- Bowel obstruction
- Colonic tumors
- Depression
- Diabetes
- Diverticulitis
- Hypercalcemia
- Hypothyroidism

- Irritable bowel syndrome
- Megacolon
- Parkinsonism
- Spinal injury
- Stroke
- Uremia

BOX 30.2 Selected Medication Associated with Constipation

- Activated charcoal
- Antacids (aluminum or calcium containing)

- Anticholinergics (sedating)
- Antihistamines

- Antipsychotics
- Bile acid sequestrants
- Calcium supplements
- Clonidine

- Diuretics
- Ferrous salts
- HMG-CoA reductase inhibitors (i.e., statins)
- Narcotic analgesics
- Sodium polystyrene sulfonate
- Sucralfate
- Tricyclic antidepressants
- Verapamil

Pathophysiology

The absorptive capacity and motility of the colon are major factors of bowel function. Approximately 9 L of fluid enters the small intestine daily from ingestion or intestinal secretions. The small intestine absorbs approximately 80% of this fluid load, which is approximately half of its capacity. The colon absorbs the remainder, with the exception of approximately 0.1 L of water that is passed in the stool. If absorption of the small intestine is reduced, the fluid load adds to the burden of the colon, which is capable of absorbing 4 to 5 L of fluid per day. Fluid in excess of this amount results in diarrhea. Likewise, excessive reabsorption of water results in constipation.

The colon can be divided into three distinctive functional areas: (1) the cecum and proximal colon, (2) the transverse colon, and (3) the distal colon and rectum. Each area performs different roles in preparing the chyme for expulsion. The variation in the neurogenic tone of each area affects the capacity of the colon to retain or release the fecal material.

The motility of the bowel is affected by the flow of chyme from the coloileal reflex, and its visceral hypersensitivity can contribute to the sense of urgency and tenesmus of proximal colonic transit. The neurogenic aspects of colon motility are poorly understood and need further study. Some of the stimuli thought to affect colonic activity are awakening from sleep or rest, ingestion of a high-calorie meal, and the sight or smell of food.

With OIC, the opioid receptors in the gut are mediated from the central nervous system (CNS) and reduce GI propulsion, thereby altering the autonomic outflow. Additionally, this reduces bowel tone and contractility, ultimately prolonging transit time of the stool. Other characteristics of OIC include increased anal sphincter tone and decreased response to anal distention resulting in difficulty with evacuation (Camerilli, 2011; Kumar et al., 2014).

Diagnostic Criteria

The definition of constipation varies widely between health care providers and patients. Constipation, as previously noted, can be idiopathic or caused by medications, or in rare cases organic. Therefore, a function definition is the infrequent bowel movements accompanied by straining with hard feces that lead to straining and a feeling of incomplete evacuation of the rectum. An important distinction between CIC and IBS is the absence of abdominal pain associated with the bowel pattern.

The diagnosis of constipation stems primarily from the history. A careful history (Box 30.3) can help the provider decide which diagnostic tests, if any, may be appropriate. Alarm symptoms include a sudden change in bowel habits after the age of 50 years, blood in stools, anemia, weight loss, and a family history of colon cancer (Bharucha et al., 2013) and require further workup.

BOX 30.3 History and Physical Examination for Chronic Constipation

Important history questions:
Onset and duration of symptoms
Patient's definition of constipation
Presence of abdominal cramping relieved by defecation (*if yes, think IBS*)
Presence of blood in the stool
Important aspects of the physical examination:
Evaluation of the perianal area for scars, fistulas, fissures, and external hemorrhoids
Observe the perineum at rest and while the patient is bearing down.
Digital rectal examination—check for fecal impaction, stricture, or rectal masses.

Initiating Drug Therapy

Lifestyle modifications are preferred over pharmacologic therapy for treating constipation. Diet, exercise, and bowel habit training are usually targeted. However, research is inconclusive as to the value of increasing fluid intake and exercise (Leung et al., 2011) and is controversial for the increased use of fiber (Ho et al., 2012). The recommendations for dietary fiber originated in 1971 (Burkett, 1993) and gained widespread acceptance as necessary for a healthy diet and normal bowel movements; however, further study has not substantiated this premise. However, increasing fiber has not proven harmful, and according to the National Health Statistics Report (Clarke et al., 2015), Americans eat 5 to 14 g of fiber daily, far short of the most recent recommendations of 20 to 35 g by the American Dietetic Association (American Dietetic Association, 2008). Increased dietary fiber can be recommended for most patients without fear of colon obstruction. Fiber should be both soluble and insoluble in the form of fruits, vegetables, and whole grains, which cannot be digested by the body. Fiber should be slowly increased to 20 to 25 g/d over a 1- to 2-week period to improve compliance with therapy. Dietary fiber is still postulated to increase stool weight and shorten intestinal transit time. Fiber accelerates right colon transit, but there are few treatments for patients where the transit problem is the left colon. Fiber therapy may not be effective for all patients.

One additional lifestyle modification includes establishing a regular pattern for bathroom visits especially with the elderly. Patients should also be counseled not to ignore the urge to defecate, because this delay increases the time for absorption of fluid from the stool. Biofeedback, a method of retraining the pelvic floor muscles to relax during defecation, may be effective in selected patients.

Measures to treat patients with OIC currently mirror those of acute and chronic constipation; however, there is little research that supports this approach.

Goals of Drug Therapy

An adequate trial of lifestyle modification should be attempted first. If this fails, pharmacologic management with laxatives may be appropriate; however, there is little evidence that laxatives cause dependency and should be withheld from long-term treatment (Müller-Lissner et al., 2005; Wald, 2007).

The goal of therapy for constipation is to increase the water content of the feces and increase motility of the intestines to promote comfortable defecation, using the lowest effective dose of a laxative for the least amount of time possible. Only if a patient fails therapy for 3 to 6 months should the health care provider consider ordering colon transit studies to evaluate the transit time of stool in the intestine (Basson, 2015). Responses to laxatives vary and depend on the patient as well as the preparation. Several classes of laxatives are available for the symptomatic treatment of constipation: bulk-forming agents, saline laxatives, lubricant laxatives, surfactants (emollients), hyperosmotic laxatives, and stimulant laxatives. Proper selection of a laxative should be based on the individual clinical situation (Table 30.1).

TABLE 30.1 Overview of Selected Laxatives and Atypical Agents

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
Bulk-Forming Laxatives			
methylcellulose (Citrucel) 2–6 g/d	Flatulence, stomach upset, fullness	GI obstruction	Take with plenty of water. Avoid in patients with GI ulceration.
psyllium (Metamucil) 3.4–10.2 g/d	Same as above	Same as above	Same as above Sugar-free formulation caution with phenylketonuria
polycarbophil (FiberCon) 1–6 g/d	Same as above	Same as above	Same as above Calcium content may interact with tetracycline or quinolone antibiotics.
malt soup extract (Maltsupex) 12–64 g/d	Same as above	Same as above	Same as above
wheat dextrin (Benefiber) Powder: 1 tbsp daily for age 6 and up chewables: Age 12—adult three tablets three times daily Ages 6–11 1½ tablets three times daily	Same as above	Same as above Not a good choice for those with possible celiac disease	Shelf life of 2 y Store in a cool environment. Less flatulence production than other bulking agents
Lubricants and Surfactants			
mineral oil 5–45 mL/d	Rectal seepage, irritation	Do not use with surfactants.	Impairs absorption of fat-soluble vitamins Caution in elderly and very young due to potential for development of lipid pneumonia
docusate sodium (Colace) 50–500 mg/d	Stomach upset	Do not use with mineral oil.	Most effective at preventing "straining" in high-risk patients (see text)

Generic (Trade) Name and Dosage	Selected Adverse Events	Contraindications	Special Considerations
docusate calcium (Surfak) 50–240 mg	Same as above	Same as above	Same as above
docusate potassium (Dialose) 100–300 mg	Same as above	Same as above	Same as above
Saline Agents			
sodium phosphate enema (Fleet) 118 mL/d Only one enema in 24 h	Alterations in fluid/electrolyte balance, diarrhea	Caution in patients with congestive heart failure, hypertension, edema, and renal dysfunction.	Care should be taken in the elderly and those with existing electrolyte disturbances.
magnesium citrate 240 mL/d	GI upset, diarrhea	Caution in renal dysfunction.	Stagger administration times of tetracycline and quinolone antibiotics.
magnesium hydroxide (Phillips' milk of magnesia) 30–60 mL/d	GI upset, diarrhea	Same as above	Caution in renal dysfunction and the elderly. Stagger administration times of tetracycline and quinolone antibiotics.
magnesium sulfate (Epsom salt) 1–2 tsp in ½ glass water	GI upset, diarrhea	Same as above	Caution in renal dysfunction and the elderly. Stagger administration times of tetracycline and quinolone antibiotics.
Hyperosmotic Agents			
lactulose (Chronulac, Constilac, Duphalac) 15–60 mL	GI upset, diarrhea, flatulence	Caution in diabetic patients.	Use lactulose with caution in patients with diabetes.
sorbitol 130–150 mL	GI upset, diarrhea, flatulence	Same as above	Caution in diabetic patients.
Stimulants			
senna (Senokot) Tabs: 2–8/d Supp: 1 qhs Granules: 1–4 tsp/d	Griping, diarrhea, gas, discoloration of urine	GI obstruction	Caution for laxative abuse, cathartic colon.
bisacodyl (Dulcolax) Tabs: 1–3/d Supp: 1 pr qd	Griping, diarrhea, gas	GI obstruction	Do not crush or chew tablets. Avoid concomitant administration of antacids and pH-lowering agents.
castor oil 15–60 mL/d	Stomach upset, diarrhea, colic	GI obstruction	Too potent for routine use
Secretagogues—Chloride Channel Activators			
lubiprostone (Amitiza) 24-mcg capsule bid	Nausea is most common, diarrhea, abdominal pain, abdominal distention, and flatulence.	Known or suspected GI mechanical obstruction	Approved for both genders only for CIC/OIC Capsules must be taken whole and with food and water.
Guanylate Cyclase-C Agonist linaclotide (Linzess) 145 mg capsule daily	Diarrhea, abdominal pain, flatulence, and abdominal distention	Avoid in known or suspected mechanical obstruction.	Dose is different for IBS-C. Dose is different for IBS-C. Avoid in children <6 years old, but use with caution in 6–17 y.
Peripherally Acting Mu-Opioid Receptor Antagonist (PAMORA)			
naloxegol (Movantik) 12.5–25 mg tablet one daily	Abdominal pain, diarrhea, nausea, flatulence, vomiting headache, and hyperhidrosis	Same as above	Pregnancy Category C: can cause narcotic withdrawal for fetus Can cause narcotic withdrawal especially with methadone

Bulk-Forming Laxatives

Bulk-forming laxatives work by binding to the fecal contents and pulling water into the stool. This ultimately softens and lubricates the stool, eases its passage, and reduces straining. Water is reabsorbed from fecal masses that stay in the colon for extended periods, and the result is dry stools. Bulk-forming agents hold water in the stool or swell and increase stool bulk. The bulk stimulates the movement of the intestines and facilitates the passage of intestinal contents. These types of laxatives are not useful when constipation results from the use of opioid medications.

Bulk-forming laxatives generally consist of psyllium seed husk, methylcellulose, polycarbophil, and wheat dextrin, which are made of polysaccharides, cellulose derivatives, or wheat starch such as methylcellulose (Citrucel) or psyllium (Metamucil). Polycarbophil (FiberCon) and wheat dextrin (Benefiber) have significant water-absorptive properties and also are used as antidiarrheals. All bulk-forming agents used for constipation should be taken with plenty of fluid (8 ounces) to increase efficacy. Malt soup extract (Maltsupex) made from barley malt reduces fecal pH. This may contribute to its laxative effect. Traditionally, these products have been marketed only as powders, which must be dissolved in water. Now, many fiber products are available in powder, wafer, and Caplet forms. Patients may need to try several before finding one that works for them. Brand names include Metamucil, FiberCon, and Citrucel. Metamucil is the preferred agent because it is the safest and most physiologic. Sugar-free methylcellulose and psyllium products are available for patients with diabetes. Patients with celiac disease or gluten intolerance should avoid using wheat dextrin products.

Contraindications to the use of bulking agents are symptoms of an acute surgical abdomen, intestinal obstruction or perforation, or inability to drink an adequate amount of fluid.

Action for all agents may begin in 12 to 24 hours, but a full effect is not usually seen for up to 3 days.

A half-cup to one bowl daily of wheat bran can provide adequate fiber supplementation, but synthetic forms of fiber are often better absorbed than food. Other foods can also add fiber to the diet and should be reviewed with the patient. The patient should be encouraged to drink adequate amounts of fluid throughout the day; if not contraindicated, up to 2,500 mL is preferred. These agents are more likely to be used as preventive measures. However given, they can take effect within 12 to 24 hours, and some acute relief of symptoms is possible.

Adverse Events

Overall, these agents are usually well tolerated, but compliance can be a problem because the most common side effect is increased flatulence, and some bloating can occur. With severe constipation, all agents can cause abdominal fullness and cramping. If these agents

are used excessively, nausea and vomiting may occur.

Contraindications

Because bulk-forming laxatives have the most physiologic effect and are not systemically absorbed, they are the preferred agents for symptomatic treatment of constipation. However, these agents are not completely benign and should be avoided in patients with strictures of the esophagus, GI ulcerations, or stenosis secondary to the possibility of obstruction from increased bulk of intestinal contents. In addition, some bulk-forming agents may contain as much as 20 g of carbohydrates per dose. Sugar-free bulk-forming agents are available and are recommended for diabetic patients.

Interactions

The sugar-free preparations may contain aspartame, which is metabolized to phenylalanine and should be used cautiously with patients who must restrict their phenylalanine intake. Wheat gluten is a by-product of extracting the gluten from wheat; however, complete extraction cannot be guaranteed and should be avoided in patients with gluten intolerance. Concomitant administration of calcium-containing bulk laxatives may reduce the effectiveness of quinolone or tetracycline, so patients should separate the administration time of these agents.

Hyperosmotic Laxatives

Lactulose (Cephulac), sorbitol, polyethylene glycol/electrolyte solution (PEG-ES, Colyte), and polyethylene glycol (PEG, MiraLAX) are examples of hyperosmotic laxatives. These agents serve as or are metabolized to solutes in the intestinal tract. The increased concentration of solutes creates osmotic pressure by drawing fluid from a less concentrated gradient to the more concentrated gradient inside the GI tract. This increase in osmotic pressure stimulates intestinal motility and propulsion of fecal contents. The PEG products do not degrade colonic bacteria and therefore produce less bloating. Glycerin (Colace Suppository, Fleet Glycerin Suppository, and Pedia-Lax Suppository) helps the stool to evacuate by similar mechanisms, but also provides local rectal stimulation.

In addition to its osmotic effect, glycerin also has a local irritant effect in the suppository form. The irritant action adds to the osmotic action to stimulate bowel movement.

Lactulose is a disaccharide analog that is metabolized by bacteria to acids that increase osmotic pressure and acidify the contents of the colon. The result is increased intestinal motility and secretion.

In addition to its use for the symptomatic treatment of constipation, sorbitol is also used to prevent constipation in combination with activated charcoal for poisoning. Sodium polystyrene sulfonate (Kayexalate), a cation exchange resin used for treating hyperkalemia, is often combined with sorbitol to reduce the potential for constipation from the resin.

PEG-ES is a nonabsorbable solution that acts as an osmotic agent. It is usually used to evacuate the bowel before a GI examination such as a flexible sigmoidoscopy or colonoscopy. The solution is reconstituted with 1 gallon of tap water and should be chilled before consumption to increase palatability. The patient should begin drinking the solution at 4 PM the day before the procedure. One glass (8 oz.) of the reconstituted solution should be consumed every 10 minutes over 3 hours until all 4 L are consumed. The patient should fast for 4 hours before ingesting the solution, and only clear liquids are allowed after ingestion.

Contraindications

Lactulose syrup should be used with caution in diabetic patients because it contains lactose and galactose. Lactose is also contraindicated in patients with appendicitis, acute surgical abdomen, fecal impaction, or intestinal obstruction. Caution must be used in diabetic patients because of sugar content.

Other osmotic agents such as magnesium hydroxide (milk of magnesia) or magnesium citrate (Citroma) can be used to promote defecation. Approximately 15% to 30% of the magnesium in these agents may be absorbed systemically; therefore, caution is needed in patients who have renal failure and decreased ability to excrete magnesium.

When taken appropriately, these agents are well tolerated. The most common adverse events are abdominal cramping and nausea. However, the use of these agents may be counterproductive in patients with changes in colonic transit time, IBS, or severe bloating and fullness (Wald, 2007).

In addition, sorbitol as a caloric sweetener has the potential to affect blood glucose levels and should be used with caution in diabetic patients. PEG-ES is not recommended in patients with gastric obstruction, bowel perforation, or colitis.

Adverse Reactions

Glycerin is among the safest laxative preparations available and is often used in infants and children. Rectal irritation is the most common side effect of glycerin suppositories. The most common side effects associated with lactulose and sorbitol include GI upset and diarrhea. PEG-ES rapidly cleanses the bowel and often causes nausea, abdominal fullness, cramps, and bloating.

Interactions

There are few documented interactions with the osmotic laxatives. However, because antacids may neutralize the acids produced from lactulose and interfere with its mechanism of action, concomitant administration of antacids should be avoided with lactulose. No other medications should be given within 1 hour of consumption of PEG-ES because the medication will likely be flushed from the GI tract.

Saline Laxatives

Like hyperosmotic laxatives, saline laxatives draw water into the intestine through osmosis. This creates an increase in intraluminal pressure and a resultant increase in intestinal motility. Magnesium citrate (citrate of magnesia), magnesium hydroxide (Phillips' milk of magnesia), magnesium sulfate (Epsom salt), sodium phosphate, and sodium biphosphate (Fleet enemas) are examples of saline laxatives (see Table 30.1). For treatment of constipation, the dose of sodium phosphate as an enema should not exceed the recommended volume or more than one dose in 24 hours. Magnesium citrate and sodium phosphate and biphosphate are used as bowel evacuants for endoscopic examinations such as flexible sigmoidoscopy or colonoscopy.

Contraindications

Oral sodium phosphate is no longer on the market due to concerns about severe electrolyte imbalances. However, the enema version still exists, but caution in administration should still be exercised. When prescribing sodium phosphate enemas, care should be exercised with individuals who are at higher risk for complications, including young children, individuals over 55 years of age, and those who are dehydrated, have kidney dysfunction or inflammation of the bowel, or are taking medications that can affect the kidneys. In addition, phosphates can accumulate in patients with renal dysfunction, leading to serious complications such as hyperphosphatemia, hypokalemia, hypocalcemia, hypernatremia, metabolic acidosis, and coma.

Magnesium hydroxide and magnesium sulfate are commonly used for the symptomatic treatment of constipation. Because the kidneys eliminate magnesium, magnesium-containing laxatives should be used with caution in the elderly and in patients with decreased renal function. Excessive magnesium levels can result in CNS depression (drowsiness), muscle weakness, decreased blood pressure, and electrocardiographic changes.

Adverse Events

Dehydration is a concern with the use of saline laxatives, and these agents must be used with caution in patients who cannot tolerate excessive fluid loss and dehydration.

Interactions

Because milk of magnesia also has antacid properties and can increase the pH of the intestines, it should not be administered at the same time with agents that require an acidic environment to be absorbed. The most common example of this type of interaction is with the antifungals itraconazole (Sporanox) and ketoconazole (Nizoral). Therefore, administration of any antacid should be separated from administration of ketoconazole or itraconazole by at least 2 hours. In addition, the magnesium found in magnesium hydroxide and magnesium sulfate can bind with tetracycline and quinolone antibiotics to

form a nonabsorbable complex that may reduce the effectiveness of the antibiotics. Administration of quinolones and tetracyclines should be separated from administration of magnesium-containing compounds.

Stimulant Laxatives

These laxatives vary in effects but act by increasing peristalsis through direct effects on the smooth muscle of the intestines and simultaneously promoting fluid accumulation in the colon and small intestine. Because of the irritating effect of the agents on the musculature, these agents should be avoided in long-term treatment. Stimulant laxatives include bisacodyl (Dulcolax) and senna concentrates (Senokot, Senokot S). Previously, long-term use of stimulant laxatives has been speculated to addictive and can create permanent injury to the colonic mucosa; however, the research does not support this premise (Kamm et al., 2011).

Contraindications

As with other laxatives, stimulants are contraindicated in patients with appendicitis, acute surgical abdomen, fecal impaction, or intestinal obstruction. Rectal fissures and hemorrhoids can be exacerbated by stimulation of defecation. Action begins 6 to 10 hours after oral administration and 15 minutes to 2 hours after rectal administration.

Adverse Events

These agents are not as well tolerated as the osmotic laxatives or bulking agents because of their side effects, which include nausea, vomiting, and abdominal cramping. These side effects can be more severe with cases of severe constipation. Long-term or excessive use can lead to laxative dependence.

Surfactant Laxatives

This class of laxatives reduces the surface tension of the liquid contents of the bowel. Ultimately, this promotes incorporation of additional liquid into the stool, forming a softer mass, and promotes easier defecation. However, stool softeners have insufficient data to support their efficacy, and fiber products may be superior to improve stool frequency (Brandt et al., 2005). Examples of this class include docusate sodium (Colace) and docusate calcium (Surfak). For patients who should not strain during defecation, this is the laxative of choice. Emollient laxatives only prevent constipation; they do not treat it. Combining these agents with fiber products helps promote defecation. Administration of emollient laxatives concomitantly with mineral oil is contraindicated because of increased absorption of the mineral oil. Action with these agents usually occurs between 1 and 3 days.

Contraindications

Docusate calcium or docusate potassium may be recommended for patients on sodium-restricted diets (e.g., hypertension, congestive heart failure). The sodium content of Colace (docusate sodium) is quite small (5.2 mg per capsule) and is likely insignificant.

Adverse Events

These agents are extremely well tolerated when used to prevent constipation. The most common side effect is stomach upset; other side effects, such as mild abdominal cramping, diarrhea, and throat irritation, are infrequent. Patients should take surfactants with plenty of water to improve effectiveness.

Interactions

Docusate, as a surfactant emollient laxative, may increase the absorption of mineral oil and potentially increase the risk for liver toxicity; therefore, this combination should be avoided.

Lubricant Laxatives

Mineral oil (liquid paraffin) coats and softens the stool and prevents reabsorption of water from the stool by the colon. Lubricant laxatives are effective at preventing straining in high-risk patients (e.g., rectal surgery, labor and delivery, stroke, hemorrhoids, hernia, myocardial infarction).

Contraindications

Mineral oil may be aspirated and cause lipid pneumonia when administered to young, elderly, or bedridden patients. With the availability of safer laxative preparations, mineral oil should probably be avoided in these populations. If mineral oil is chosen, it should not be administered to patients before bedtime or when they are reclining to prevent aspiration.

Adverse Events

Mineral oil has an unpleasant taste, and because it is not absorbed, large single doses can seep through the anal sphincter and cause irritation. Dividing doses may prevent this.

Interactions

Mineral oil can impair the absorption of fat-soluble vitamins A, D, E, and K. Because warfarin (Coumadin) interferes with the synthesis of vitamin K–dependent clotting factors, a reduction in absorption of vitamin K may increase the effects of the anticoagulant. Although no direct interactions with oral anticoagulants have been reported, prothrombin levels may decrease. The docusates, as surfactant emollient laxatives, may increase the absorption of mineral oil and potentially increase the risk for liver toxicity; therefore, this combination should be avoided.

Secretagogues

Chloride Channel Activators

There is only one drug in this class, lubiprostone (Amitiza), and it is a derivative from prostaglandin. While the entire mechanism is not understood, it appears to work by enhancing chloride-rich intestinal fluid without altering serum sodium and potassium concentrations. The activation of the chloride channel in the intestines pulls water into the lumen of the intestine. The drug is poorly absorbed systemically and appears to act locally on the intestines, improving stool consistency and motility. Lubiprostone is approved for treatment of adults, men and women with chronic constipation or OIC (see Table 30.1).

Contraindications

Lubiprostone is contraindicated in patients with potential mechanical obstruction, severe diarrhea, or hypersensitivity to components of the product. It is contraindicated in pregnant women and children.

Adverse Events

Nausea is the most common side effect of lubiprostone. The rate of nausea is dose dependent and was experienced by approximately 29% of patients. Other common GI side effects include diarrhea, abdominal pain, abdominal distention, and flatulence. The most commonly reported neurologic side effect is headache.

Interactions

No drug–drug interactions have been discovered with lubiprostone. In vitro studies showed the cytochrome P-450 isoenzymes are not inhibited by the drug.

Guanylate Cyclase-C Agonist

Linaclotide (Linzess) is the first of this class for the indications of CIC and IBS. The mechanism of action is topical rather than system, elevating intracellular cGMP, which stimulates secretion of chloride and bicarbonate into the intestinal lumen. Along with the increased fluid, stool transit time is accelerated. Linzess is approved for 18 years and older with CIC. The recommended dosage for CIC is 145 mcg orally once a day, 30 minutes prior to the first meal of the day.

Contraindications

Linaclotide is contraindicated for children less than 6 years old, and while it may be used off-label, the safety and efficacy between 6 and 17 years old has not been established. The drug should not be used if the patient has known or suspected mechanical obstruction.

Adverse Events

The most common side effect for linaclotide is diarrhea, reported by 20% of study participants. Other GI side effects include abdominal pain, flatulence, and abdominal distention. Some (4%) reported headache.

Interactions

Since linaclotide does not interact with the cytochrome P-450 system, no drug–drug interactions have been studied. Administration of recommended clinical doses is encouraged by the prescriber.

Peripherally Acting Mu-opioid Receptor Antagonist (PAMORA)

This class acts as antagonist of opioid binding at the mu-opioid receptors. At the prescribed dose, this agent blocks in tissues such as the GI tract, therefore decreasing the constipating effects of opioids. Naloxegol (Movantik) is the only agent in this class. It is a PEGylated derivative of naloxone and a substrate for the P-glycoprotein transporter. This reduces the passive permeability across the blood–brain barrier and with recommended doses limits potential for interference with centrally mediated opioid analgesia.

The only indication for naloxegol is OIC, and the dose is 25 mg once daily, but if not tolerated can be reduced to 12.5 mg daily.

Contraindications

Naloxegol is contraindicated in patients with known or suspected GI obstruction or potential for GI perforation. Some patients can experience opioid withdrawal especially those who are receiving methadone. Naloxegol is pregnancy category C, and use in pregnancy may cause withdrawal for the unborn fetus.

Adverse Reactions

The most common reactions are related to the GI system and include abdominal pain, diarrhea, nausea, flatulence, vomiting headache, and hyperhidrosis.

Interactions

Avoid concomitant use of moderate CYP3A4 inhibitors (e.g., diltiazem, erythromycin, verapamil) due to potential increased risk of adverse reactions. Use of strong CYP3A4 inducers (e.g., rifampin, carbamazepine, St. John's wort) is not recommended because they may decrease the efficacy of naloxegol. Avoid concomitant use of naloxegol with another opioid antagonist due to the increased risk of opioid withdrawal.

Selecting the Most Appropriate Agent

If lifestyle modification fails to reverse constipation, then selection of an appropriate laxative is necessary. The choice of laxative agent depends on several factors, including the type of constipation (acute, CIC, or OIC), medical history, goal of therapy, concomitant medications, and the potential for side effects, age, and personal preference. Table 30.2 describes first-, second-, and third-line therapies (Figure 30.1).

TABLE 30.2 Recommended Order of Treatment for Constipation

Order	Agents	Comments
First line	Bulk-forming agents (methylcellulose, psyllium, polycarbophil, malt soup extract, wheat dextrin)	Avoid in patients with GI obstruction or ulceration Take with plenty of water
	Docusate derivatives	Most effective at preventing straining at stool in high-risk patients (see text)
	Glycerin	Used most often in infants and small children
	naloxegol (Movantik)	Indication for OIC only
	linaclotide or lubiprostone	Consider for first or second line for CIC or OIC
Second line	Milk of magnesia, magnesium sulfate, lactulose, sorbitol	Caution in renal dysfunction and the elderly Use with caution in diabetic patients Caution: laxative abuse, cathartic colon
	linaclotide or lubiprostone	Add if not used as first line
Third line	Stimulant laxatives (senna, cascara sagrada, casanthranol, bisacodyl)	Impairs absorption of fat-soluble vitamins; use with caution in elderly and very young (lipid pneumonia)
	Mineral oil	Use with caution in congestive heart failure, hypertension, edema, and renal dysfunction
	Sodium biphosphates (only enema available)	Used as a bowel evacuant for endoscopic examinations
	Magnesium citrate	Too potent to be used routinely for constipation
	Castor oil	

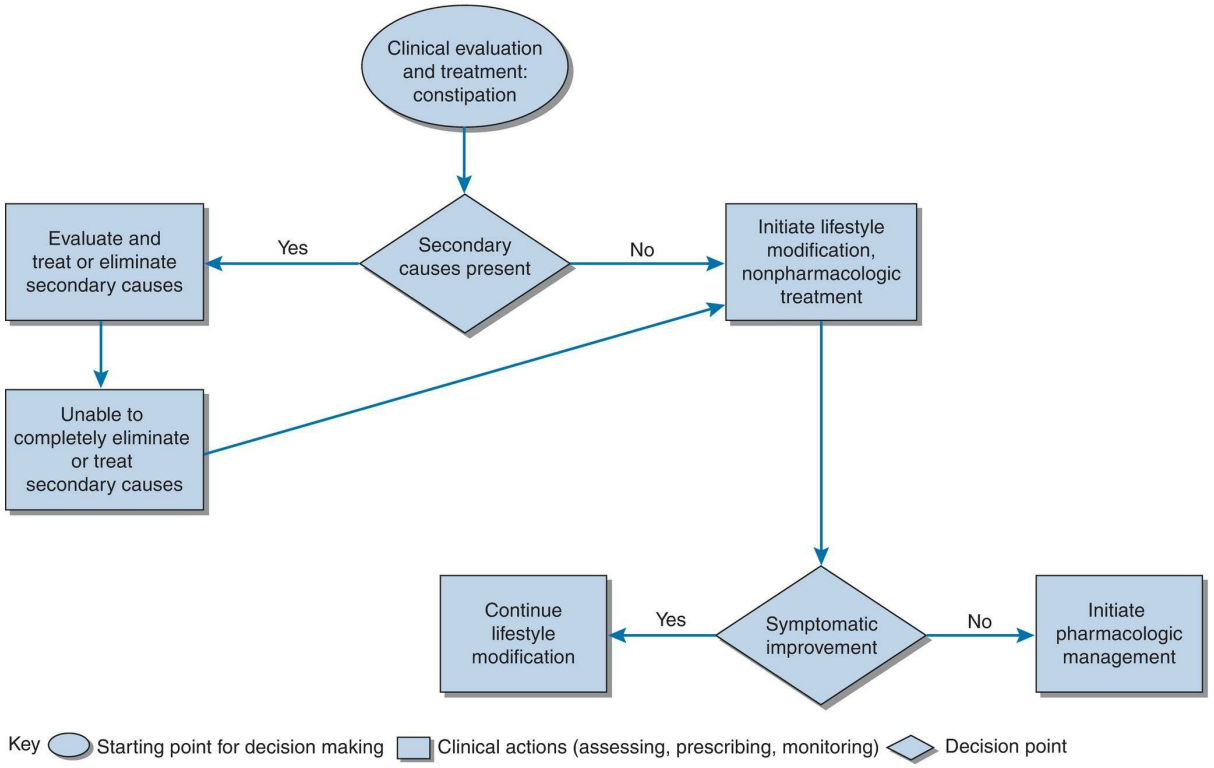

Figure 30.1 Treatment algorithm for constipation.

First-Line Therapy

For all types of constipation, acute, CIC, and OIC, a bulk-forming laxative is recommended provided no contraindications exist. Bulk-forming laxatives are not systemically absorbed. In addition, their pharmacologic effect is the most physiologic, meaning they have an effect similar to that of the natural effect of fiber from food on the GI tract. Their side effects are usually mild, and if necessary, they can be administered safely for longer durations than other classes of laxatives such as the stimulants.

When hard or dry stools are the chief complaint or in situations where straining should be avoided (e.g., hernia, cardiovascular disease), a stool softener such as docusate is considered first-line therapy. Stool softeners also are not systemically absorbed, and their side effects are usually minimal.

Glycerin suppositories have a local irritant effect on the rectum and are probably the safest of all preparations. This is preferred as first-line therapy in infants.

Linaclotide (Linzess) and lubiprostone (Amitiza) can be considered as first-line therapy for constipation, especially if it is CIC. Both drugs can increase the incidence of diarrhea, but overall are very well tolerated and have no reported drug–drug interactions. These drugs have been proven to produce rapid and sustained improvement in bowel habits.

For OIC, naloxegol (Movantik) is considered first-line therapy along with bulk-forming laxatives and dietary approaches. Lubiprostone (Amitiza) also has the indication

for OIC.

Second-Line Therapy

If a more rapid onset of action is desired, magnesium hydroxide may be chosen. Although it has a faster onset of action, dehydration from excessive use is a concern, particularly in patients unable to tolerate excessive fluid loss. In addition, magnesium-containing preparations should be avoided in patients with renal insufficiency or the elderly.

If the bulk-forming agents and magnesium hydroxide are ineffective or contraindicated, an osmotic laxative such as lactulose or sorbitol may be chosen. However, flatulence and the sweet taste limit compliance. In addition, lactulose and sorbitol should be used with caution in patients with diabetes.

If not used as first-line therapy, consider use of linaclotide (Linzess) and lubiprostone (Amitiza).

Third-Line Therapy

If bulk-forming or osmotic diuretics fail to work, a stimulant laxative may be chosen. Stimulant laxatives are very effective. Mineral oil is effective as a lubricant laxative and may be an option in patients who should avoid straining. However, although mineral oil would seem safe, its ability to impair absorption of necessary vitamins and to cause aspiration pneumonitis limits its use. In addition, seepage is an inconvenient side effect that likely limits compliance. If an agent is necessary to soften the stool to prevent straining, docusate is a safer alternative.

Sodium biphosphate as an enema is another option. These agents have the potential to cause fluid and electrolyte abnormalities and exacerbate concomitant disease states such as hypertension and congestive heart failure. Therefore, these agents should be used only after safer agents have failed. Because sodium biphosphate enemas and magnesium citrate solutions have a rapid onset of action, these agents are often preferred and are usually reserved for endoscopic procedures.

Castor oil is a potent cathartic that should not be used routinely for treating constipation.

Special Populations

Pediatric

Constipation can be distressing for children, particularly young children. Most children do not have an underlying pathophysiologic process. Stress over potty training or painful stools secondary to acute constipation can result in avoidance of defecation by the child. This in turn can result in larger, harder, and more painful stools, which eventually leads to soiling. Constipation and encopresis, a condition where soft stool is involuntarily lost, are often combined. Parents usually pay little attention to their child's bowel frequency unless incontinence occurs. The parents may become angry with the child, leading to further stress. To avoid constipation that may result in soiling, parents should be cognizant of their child's bowel habits.

Constipation may also result in urinary incontinence and urinary tract infections in children, particularly girls. Overflow incontinence may occur when the distended rectum presses on the bladder wall, causing bladder outflow obstruction. Fecal soiling in the external urethral opening predisposes constipated girls to infection. Treatment of constipation can reduce infection and incontinence.
